With its rapidly increased cell efficiency to as high as over 25% and incredible suitability to process, equipment and operation, the perovskite is truly a rising star for next generation solar cells. In fact, its cell efficiency has surpassed all other thin film solar cells. We have studied a few different deposition technologies, including dry processing such as vacuum-based alternating precursor deposition, partial co-evaporation of inorganic components; dry atmospheric deposition by using direct contact reactive process; and wet solution processing such as small area spin-coating, large-area blade coating and high-throughput slot-die coating. At present, the wet solution deposition processes are well-advanced with significantly higher efficiencies over 23%. In comparison, the vacuum processes are under development with best cell efficiency still lower than 22%. This article is intended to compare and opt for the best one with most promises for future largescale processing by screening these technologies developed in research laboratories. With mature industrial equipment and engineering processes, we improved the vacuum deposited perovskite cell efficiency to 21.32%, highest for this type to our knowledge. In addition, the films produced using dry deposition seem to show better stability against high humidity, temperature and light-soaking.

Cationic Management for Efficient and Stable $FAPbI_3$-Based Perovskite Solar Cells Sang Il Seok; Ulsan National Institute of Science and Technology (UNIST), Korea (the Republic of)

Highly efficient perovskite solar cells (PSCs) with power conversion efficiencies (PCEs) > 25% are fabricated with formamidinium (FA)-based lead triiodide ($FAPbI_3$) perovskites. In general, mixed cations and anions containing FA, methylammonium (MA), Cs, I and Br ions are used to stabilize the black α-phase against d-phase of the pristine $FAPbI_3$. Disadvantageously, the additives such as MA, Cs and Br to $FAPbI_3$ widen its bandgap and reduce the thermal stability due to the lower thermal decomposition of MA to FA. Therefore, in order to further increase PCE through the enhanced photocurrent density due to the increased light harvesting, stabilizing the a-$FAPbI_3$ without blue-shift of the bandgap is needed. In addition, structural dimensions, distortion, and dielectric properties can vary significantly depending on the ionic radius and type of the A-site cation. In this presentation, I would like to introduce the impact of cationic management on the efficiency and long-term stability of perovskite solar cells.

Defect Related Charge Traps and Doping in Perovskites, Solar Cells and Tandem Devices Jinsong Huang; University of North Carolina-Chapel Hill, United States

In this talk, I will present our recent progress in understanding the fundamental properties of metal halide perovskites and the related device developments. First, the nature of defects induced charge traps and doping in perovskite materials will be discussed, and their chemical origin will be analyzed. A recent development in characterizing the spatial and energetic distributions of defects will be presented, which revealed the significant difference in trap density between single crystals and polycrystalline films, but similarity in distribution of the traps. Second, the healing of defects and tuning the doping in perovskites by multiple processes will be presented that boost the efficiency and stability of perovskite solar cells and modules. TFinally, a new charge recombination layer for all perovskite tandem solar cells will be presented which not only simply the fabrication process, but also significantly enhance tandem solar cell efficiency and stability.

6:00 AM *F.EL08.07.05
Efficient Perovskite Solar Cells with Various Bandgaps Jingbi You; Chinese Academy of Sciences, China

Lead halide perovskite is a new type of semiconductor optoelectronic material, which owns large absorption coefficient, long diffusion length, which make it as an excellent photovoltaic material. Perovskite solar cells with different bandgaps of absorber need to be studied for making efficient single or tandem solar cells. In this talk, we will show: 1) By contact engineering, for the bandgap around 1.5 eV, we have achieved close to 25% efficiency, 2) By the composition engineering, we have pushed the PCE of inorganic perovskite $CsPbI_3$ based solar cells to 20% efficiency, 3) According to the defect engineering, over 20% efficiency of the perovskite solar cells have been demonstrated for the perovskite bandgap around 1.35 eV.

Phase Stable and Less-Defect Perovskite Quantum Dots—Optical Property, Photoexcited Carrier Dynamics and Application to Solar Cells Qing Shen, Feng Liu, Chao Ding and Yaohong Zhang; The University of Electro-

Communications, Japan

Perovskite quantum dots (QDs) as a new type of colloidal nanocrystals have gained significant attention for both fundamental research and commercial applications owing to their appealing optoelectronic properties and excellent chemical processability.[1] For their wide range of potential applications, synthesizing colloidal QDs with high crystal quality is of crucial importance. However, like most common QD systems, those reported perovskite QDs still suffer from a certain density of trapping defects, giving rise to detrimental non-radiative recombination centers and thus low photoluminescence quantum yield (PL QY). Halide vacancy in perovskites has been widely accepted to be the main factor preventing near-unity PL QY by creating uncoordinated Pb octahedra and the subsequent localized deep trap states.[2] Very recently, we have succeeded in synthesis of phase-stable and less-defect perovskite QDs, including $FAPbI_3$ QDs, $CsPbI_3$ QDs and Sn-Pb alloyed QDs.[3-6] We have demonstrated that a high room-temperature PL QY of up to 100% can be obtained in $FAPbI_3$ and $CsPbI_3$ perovskite QDs, signifying the achievement of almost complete elimination of the trapping defects. This is realized by the modulation of halide precursor involved in the synthesis, in which trioctylphosphine (TOP) is used to dissolve halide salts. For Sn-Pb alloyed QDs, although the alloyed QDs possess much improved structural stability than that of the pure Pb- and Sn-based one, they still suffer from an extremely low PL QY of ~0.3%, indicative of the severe charge trapping in these Sn-containing perovskites. Such low PL QY is believed to result from the widely known facile oxidation of Sn^{2+} to Sn^{4+}. To address this issue, we have demonstrated very recently that the deep-level trap states in Sn-based perovskites can be well suppressed by Na^+ doping, which gives rise to a dramatically improved PL QY of ~28% without alerting their favorable electronic structure. X-ray photoelectron spectroscopy (XPS) studies suggest the formation of a stronger chemical interaction between I^- and Sn^{2+} ions upon Na doping. On the other hand, though the reported TOP-based route has demonstrated efficacy in producing $CsSn_xPb_{1-x}I_3$ QDs (x = 0~0.6) with superior structural stability, such synthetic protocol can only find success in making these I-related QDs, preparing those pure Cl- and Br-based analogues remains challenging because of the insufficient solubility of $PbBr_2$ and $PbCl_2$ in TOP. Therefore, by taking advantage of the strong coordinating ability of trioctylphosphine oxide (TOPO), we have recently reported the first synthesis of $ASn_xPb_{1-x}X_3$ QDs (A = Cs, FA, MA) with excellent tunability in both Sn/Pb ratio and a full range of halide covering. The ability to generate all possible, unique combinations has offered great material versatility for the perovskite QD family. Further, by employing ultrafast spectroscopic techniques, we have resolved the fundamental photoexcited charge carrier dynamics in these alloyed QDs, which shall pave the way for future study for enhancing their usefulness in optoelectronic applications.[7-9] We expect the successful synthesis of the "ideal" perovskite QDs will exert profound influence on their applications to both QD-based light-harvesting and -emitting devices in the near future.

Linking Fundamental Properties to Devices by Multiscale Modelling Alison B. Walker, Matthew J. Wolf, Lewis A. Irvine and Thijs J. Smolders; University of Bath, United Kingdom

Solar cells utilising a metal–halide perovskite (MHP) as the active layer boast maximum power conversion efficiencies rivalling those of commercial silicon based cells, despite the low temperature, solution-based processing methods used in their fabrication. However, those fabrication methods lead to structural and stoichiometric heterogeneity on multiple length scales, with high concentrations of mobile ionic defects, which are believed to underlie undesirable device characteristics such as current–voltage hysteresis and performance degradation.
To further development of perovskite based solar cells, an increased understanding of the complex and often intertwined phenomena underlying both their high performance and the degradation of this performance is essential. The insights and predictions provided by the application of multiscale modelling techniques to the study of phenomena occurring at multiple length- and time-scales continue to play a critical role in this effort.
In this talk I will focus on our use of atomic, mesoscale and continuum modelling techniques to explore aspects of electron and ion dynamics in MHPs and devices based on them. Applications include the effects of pressure and grain boundaries on ion motion; polaronic and hot carrier dynamics; and the influence of the electron and hole transporting layers on current–

voltage hysteresis in perovskite based solar cells.

The Perovskite Database Project—Insights Gain from Pooling all the World's Perovskite Device Data Tor J. Jacobsson[1,2] and Eva Unger[1]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Uppsala University, Sweden

Over the last ten years, the halide perovskites have grown from an academic curiosity into one of the hottest topics in renewable energy research, and more than 15000 papers on perovskite solar cell have now been published. The sheer amount of papers makes it increasingly difficult to get a good overview of what has been going on in the field, and we firmly believe that much could be gained if the data in all those papers could be stored in one place where it would be easily accessible by the research community. Such a collection of data would lead to a better overview, better experimental design, as well as new insights that would be hard to get from data scattered over thousands of articles. It thus represents a way to accelerate the pace of development by applying scientific openness. In this project, we have with the help of a large group of volunteers manually extracted all extractable device data found in the over 15000 perovskite papers so far published. Around the time of presentation this data will be made available in the form of a web application together with interactive graphics enabling anyone to explore and learn from the completeness of the published perovskite device data. We will in this presentation describe what we have created, what can be conclude from the accumulated data, as well as the potential future benefits for the perovskite community if this approach to data sharing gets universally implemented.

Perovskite/Si Tandem Cells Enabled by Efficient and Stable Wide Bandgap Perovskite via Anion-Engineered Two-Dimensional Additives Daehan Kim[1], Hee Joon Jung[2], Ik Jae Park[3], Bryon W. Larson[4], Sean P. Dunfield[4], Chuanxiao Xiao[4], Jekyung Kim[1], Jinhui Tong[4], Passarut Boonmongkolras[1], Su Geun Ji[3], Fei Zhang[4], Seong Ryul Pae[1], Min Kyu Kim[1], Vinayak Dravid[2], Joseph J. Berry[4], Jin Young Kim[3], Kai Zhu[4], Dong Hoe Kim[5] and Byungha Shin[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Northwestern University, United States; [3]Seoul National University, Korea (the Republic of); [4]National Renewable Energy Laboratory, United States; [5]Sejong University, Korea (the Republic of)

Perovskite/Si tandem technology has been highlighted as the next technology to achieve ultrahigh efficiency, however progress has been deterred due to difficulties in optimizing the unstable and low-efficiency wide bandgap perovskite (~1.7 electron volts). Here, we have developed a wide bandgap perovskite that simultaneously improves the electrical properties and enhances the passivation effect using a novel strategy that involves tuning the anion of 2D additives ($PEAI_xSCN_{1-x}$).

We have observed the formation of defects in 2D phase via high-resolution TEM analysis and revealed that anion-engineering of 2D-forming additives leads to improved crystallinity and enhanced charge transport properties (higher mobility, longer carrier mobility, and uniform current flow through grains).

Additionally, we demonstrated a 20.7% efficient wide bandgap perovskite solar cell along with excellent long-term stability under continuous light illumination (80% of the initial efficiency was maintained after 1000 hours of illumination). This is the record efficiency among the reported wide bandgap perovskite solar cells. Using this anion-engineered wide bandgap perovskite cell as a top cell, we fabricated a monolithic 2-terminal perovskite/Si tandem cell with 26.7% efficiency (26.2% certified). Notably, the perovskite top cell in our champion tandem device contributes to ~64% of the total open-circuit voltage, which is the largest contribution from any perovskite top cell among the reported perovskite/Si tandem cells that identified relative contributions of each cell.

This work will be essential for future research on perovskite passivation using 2D additives and present a huge impact for the development of perovskite/Si tandem cells with efficiencies over 30%.

7:05 AM F.EL08.07.10
Efficient Flexible Lead-Free Perovskite Solar Cells Enabled by Grain Boundaries Functionalization Min Chen, Zhenghong Dai and Nitin Padture; Brown University, United States

Hybrid perovskites materials have been skyrocketing the field of new generation photovoltaics and immediately expanding into advanced optoelectronics. Among the tremendous efforts in commercialization for perovskite solar cell (PSC) technology, the flexible Lead-free PSCs has drawn a great attention from the public to meet with the increasing demands for portable and wearable electronic devices. However, the fracture behavior in the prepared perovskite thin film will typically occur within the grain boundaries, which will retard the PCE performance and negatively affect the mechanical stability during the bending test. Here, we functionalized the volatile and brittle grain boundaries by incorporating low-dimensional (LD) phase. The LD phase was in-situ grown within the grain boundaries. Such in-situ grown LD phase not only enhanced the stability by passivating the grain boundaries defects, but also avoided the crack within the grain boundaries by linking with the neighbored grains. As a result, the prepared flexible lead-free PSCs showed remarkable endurance to mechanical cyclic-bending fatigue, with a PCE retention of 80% after 2,000 cycles.

7:15 AM F.EL08.07.11
Effects of Pressure on Photoconversion Efficiencies of FAI-Based Perovskite Solar Cells Oluwaseun K. Oyewole[1], Deborah Oyewole[1], Benjamin Agyei-Tuffour[2], Juan Martin Hinostroza Tamayo[1], Richard Koech[1], Reisya Ichwani[1], Jaya Cromwell[1], Nancy Burnham[1] and Winston Soboyejo[1]; [1]Worcester Polytechnic Institute, United States; [2]University of Ghana, Ghana

Power conversion efficiencies (PCEs) of perovskite photovoltaics now exceed 25%. Perovskite solar cells hold great promise because of their potential low cost, tunable optoelectronic properties, and the possibility of improving their stability. For their commercial success, it is important to keep improving both their performance characteristics and stability. In this paper, a combined experimental and theoretical technique is used to study the effects of pressure on efficiencies of formamidinium-based perovskite solar cells. The interfacial surface contacts in the multilayered structures are predicted before fabricating the perovskite solar cells. A range of pressures is then applied to heal both pre-existing cracks within layered films and along the multilayered interfaces. The results show that the PCEs of the perovskite solar cells increased from ~18% to ~ 23% for applied pressures between ~ 0 – 6 MPa. A decrease in the PCEs is observed for pressure applied beyond 6 MPa. The implications of the results are discussed for lamination and roll-to-roll fabrication of perovskite solar cells.

7:25 AM F.EL08.07.13
Inverted Single-Crystal MAPbI3 Solar Cells Efficient with 21.9% Efficiency by Lowering the Crystallization Temperature Bekir Turedi; King Abdullah University of Science and Technology, Saudi Arabia

Single-crystal materials are playing a dominant role in shaping established solar cell technologies such as Silicon and GaAs. With their low concentrations of non-radiative carrier recombination centers, single-crystals have led the way in terms of efficiency and are on of the most promising paths forward to approaching the theoretical Shockley-Queisser (SQ) limit for solar cells. In theory, lead halide perovskite single-crystals, with their orders of magnitude lower defect density, longer carrier diffusion lengths, and superior light absorption compared to their polycrystalline counterparts, should offer a chance for perovskite solar cell (PSC) technology to overcome the limitations of polycrystalline thin films and get as close as practical to the SQ theoretical limit. Unfortunately, due to challenges in crystal growth and device integration conditions, the pace of progress (In comparison to polycrystalline PSCs) has been very slow in single-crystal devices. In a recent study, we demonstrated the potential of SC-PSCs by realizing ~21.1% efficient devices based on ~20 μm-thick methylammonium lead iodide monocrystalline absorber films. The preferred method, thus far, to grow $MAPbI_3$ single-crystal films for PSCs involves solution-processing at temperatures exceeding 120 °C, which adversely affects the film's crystalline quality, especially at the surface, primarily due to the loss of methylammonium iodide. Here, we devised an approach that enables the thin film $MAPbI_3$ crystal growth on a charge carrier transport layer at lower temperatures (<90 °C), and, thereby, limiting the escape of methylammonium iodide (MAI) from the crystal structure. We showed that this strategy extends the radiative charge carrier lifetime due to a significant reduction in non-radiative recombination channels. SC-PSCs fabricated with this method exhibit an enhanced V_{OC} of up to 1.15 V (Control 1.08 V) and a champion PCE of 21.93%. With no grain-boundaries at play, our work indicates the importance of the surface in advancing perovskite photovoltaic technology and provides an approach to grow perovskite single-crystal films under more favorable conditions for better optoelectronic qualities. We believe that our findings will be of wide interest to the perovskite materials and solar cell communities.

SESSION F.EL08.08: Vapor Deposition and Upscaling of Perovskites

Halide Perovskites—Unprecedented Opportunities for Semiconductor Design and Processing David Mitzi; Duke University, United States

Although known for many years, organic-inorganic hybrid and related inorganic halide-based perovskites have received extraordinary attention recently, in part due to the unique physical properties and chemical diversity offered by these structures, which make them outstanding candidates for applications in photovoltaic and other semiconductor devices (especially for systems based on Pb, Sn and Ge). Perovskite structures consist of networks of corner-sharing metal halide octahedra that can extend in three or lower dimensions, providing opportunity to probe how dimensionality of the inorganic framework impacts semiconducting character. Further, incorporation of more complex organic cations within lower-dimensional perovskites enables combining outstanding inorganic-derived semiconducting character with organic-derived properties (e.g., luminescence, chirality), a feature extending well-beyond what is attainable with more established inorganic semiconductors (e.g., Si or GaAs) and underlying the creation of multifunctional organic-inorganic compounds and electronics [1]. This talk will emphasize chemical/structural versatility [2] and implications for semiconductor design (both with regards to properties and processing), as well as new characterization approaches for elucidating materials properties. Examples of topics that may be covered include custom-designed organic cations that template or stabilize the formation of difficult-to-realize lead-free perovskite structures [3], merging computational/experimental approaches to predict/verify optoelectronic character and guide design of complex organic-inorganic hybrids [4] and the use of a new carrier-resolved photo-Hall (CRPH) technique [5] to explore the impact of additive engineering on majority/minority carrier properties in perovskite films. Outstanding functionality and versatile processing provide two pillars for future application and study of this exciting and evolving materials family. References: [1] D. B. Mitzi, K. Chondroudis, C. 5:15 AM F.EL08.08.02
ALD/MLD of 2-D Perovskite Passivation Layers Jacob Vagott and Juan Pablo Correa Baena; Georgia Institute of Technology, United States

Atomic layer deposition (ALD) is a sequential thin film deposition technique with great potential for increasing the performance of high-efficiency perovskite solar cells (PSCs) through advantages such as high uniformity and thickness control. Although ALD is limited to inorganic precursors, molecular layer deposition (MLD) allows for the use of organic precursors and can be used in conjunction with ALD to result in high-quality hybrid organic—inorganic films. Organic—inorganic perovskite materials for PSCs are typically solution processed; this is undesirable when compared to vapor processes due to the use of toxic solvents which require careful control of the atmosphere, making it difficult to manufacture. This research focuses on the design of a process for depositing hybrid organic—inorganic perovskite films through a combined ALD/MLD process. There are currently no processes for depositing perovskite materials by ALD/MLD without some degree of solution processing. Since sequential deposition methods allow for precise thickness control, it would be possible to then deposit both methylammonium lead iodide and 2-D perovskites. 2-D perovskites have shown the potential to be effective surface passivators for perovskite solar cells. As passivation layers, 2-D perovskites improve long-term stability, decrease interfacial defects and charge recombination, and increase efficiency by enhanced charge extraction from the bulk perovskite.

5:25 AM F.EL08.08.03
Triple-Halide Multi-Cation Perovskite Solar Cells via Hybrid Vapor-Solution Technique Amir Zarean Afshord, Wiria Soltanpoor, Ummugulsum Gunes, Zenep Gozukara, Gorkem Gunbas and Selcuk Yerci; Middle East Technical University,

Turkey

Employing scalable deposition techniques adaptable to complex multi-cation halide perovskites is a significant step towards the commercialization of perovskite optoelectronics. The hybrid vapor-solution method has been shown to render uniform and conformal perovskite layers on textured surfaces such as random pyramids of Si substrates [1,2]. During that method, a seed layer containing Cs/Pb iodide is deposited by co-evaporating CsI and PbI_2 in a vacuum chamber followed by transformation into a perovskite layer by spin-coating an isopropanol solution of formamidinium/methylammonium-halide (FA/MA-halide). In this study, the deposition rate of CsI with respect to PbI_2 in terms of crystallinity and device performance was investigated. A CsI:PbI_2 rate ratio of 1:10 was found optimal. Later, the concentrations of FAI, MABr, and MACl were systematically optimized to deposit triple halide multi-cation perovskite solar cells. This is the first time a triple-halide multi-cation perovskite layer is fabricated using the hybrid vapor-solution method. A comparison between perovskites with double and triple halides showed a superior solar cell performance of Br-free triple cation perovskite compared to the other species. This is attributed to the wider absorption range of that perovskite with narrower bandgap. The champion devices showed efficiencies of 18.1% in the n-i-p and 17.6% in the p-i-n structure. The presented analysis exhibits good control on the halide composition during the hybrid vapor-solution method.

Controllable Single-Source Flash Evaporation of Organic-Metal-Halide Perovskite Films with Wafer-Scale Uniformity Jonghoon Lee, Woocheol Lee, Heebeom Ahn, Junwoo Kim, Youngrok Kim, Daekyoung Yoo, Keehoon Kang and Takhee Lee; Seoul National University, Korea (the Republic of)

Organic-inorganic halide perovskites (OHPs) are widely studied due to their excellent optoelectronic properties for solar cell and light-emitting diode applications. Conventional solution-processing techniques such as spin-coating method are commonly used in lab-scale device production but it is essential to explore other deposition techniques compatible for large-scale production. To overcome this, single-source flash evaporation technique, in which a single source of materials of interest is rapidly heated to be deposited in a few seconds, is one of the candidate techniques for large-scale thin film deposition of OHPs. [1.2] In this work, we investigated the reliability and controllability of the single-source flash evaporation technique for methylammonium lead iodide (MAPbI3) perovskite. In-depth statistical analysis was employed to demonstrate that the MAPbI3 films prepared via the flash evaporation have an ultrasmooth surface and uniform thickness throughout the 4-inch wafer scale. We also show that the thickness and grain size of the MAPbI3 film can be controlled by adjusting the amount of the source and number of deposition steps. In addition, we demonstrate that the reliability of the technique has a direct impact on the device characteristics of the fabricated photodetector devices via statistical analysis.

Improving the Performance of Solution-Sheared Perovskite Solar Cell with a Surface-Functionalized Coating Blade Min Kyu Kim, Hyeon Seok Lee, Steve Park and Byungha Shin; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The currently prevailing technique to produce high quality perovskite films is one-step spin-coating with antisolvent dripping. However, this method has disadvantages when considering mass production due to large waste of precursor solution and poor coverage over a large substrate. Solution-shearing, a type of blade coating methods, is better suited for large scale production and has been applied to printing of halide perovskite. However, devices fabricated by spin-coating generally outperforms those by solution-shearing, which suggests that the quality of spin-coated films is better than solution-sheared films. Herein, we report on a simple modification of a shearing blade that enabled us to access a wider property-map

of the coated perovskite films, thereby improving device performance compared to a conventional glass blade. More specifically, the key was functionalization of the blade's surface into non-wetting. The non-wetting blade formed a thicker meniscus because a lower surface energy of the blade applied a weaker shearing force to the precursor solution compared to a wetting blade. The thicker meniscus yielded not only a thicker film but also a larger average domain size because of the reduced nucleation rate. Carrier lifetime, measured by time resolved photoluminescence, of the perovskite film with the non-wetting blade was twice as long as that with the conventional blade, suggesting much improved film quality with the surface modification of the blade. These structural and optoelectronic changes led to an improved power conversion efficiency of 19.0% while that of the reference device was 17.7%. Additionally, we have successfully coated a uniform perovskite film over 70 cm2 using the non-wetting blade demonstrating large-scalability of solution shearing.

5:55 AM F.EL08.08.07
Laser Printed Metal Halide Perovskite Colin Tyznik[1], Zachary A. Lamport[2] and Oana D. Jurchescu[1]; [1]Wake Forest University, United States; [2]Columbia University, United States

The emergence of hybrid organic-inorganic perovskites (HOIPs) has been an exciting development in semiconductor research. Due to their cost-effective processing, high charge carrier mobilities, and band gap tunability, these materials have been incorporated in a wide array of applications such as solar cells, light emitting diodes, and photodetectors. HOIPs have been processed using a wide variety of methods: solution deposition, vacuum deposition, and even from a melt. Here, we report the first example of metal halide perovskite that has been deposited by laser printing on a flexible substrate. Laser printing is a solvent-free manufacturing method that is scalable and high-throughput, and that can be easily adopted and modified for flexible substrates of any shape and size. To formulate the toner, the CH3NH3PbI3 powder was first obtained using standard procedures. This powder was combined with carnauba wax, hexamethyldisilazane (HMDS) treated fumed silica, and a charge control agent, to create a toner that was then printed onto polyethylene terephthalate (PET) using an office laser printer. Scanning electron microscope (SEM) electron dispersive X-ray spectroscopy (EDS) revealed that a vertical phase-separation of the toner components occurred in the printed film, with the perovskite layer segregated in the middle. Atomic force microscope (AFM) measurements were used to evaluate the morphology of the films as a function of processing conditions. Electrical measurements were performed in air and dark and an average resistivity of 1.6*107 ?m was obtained, a value comparable with that of spin-coated films. Space-charge limited current (SCLC) mobilities were estimated to be 20 cm2/Vs. The current-voltage characteristics exhibit no hysteresis and the properties are constant over a large period of time, due to the fact that the non-perovskite toner components encapsulate the perovskite layer. Our work introduces an exciting new avenue for the fabrication of stable perovskite devices that is scalable and devoid of hazardous solvents.

Impurity Control as a Pathway Towards Controllable, Up-Scalable Co-Evaporation of Methylammonium Perovskite Thin-Film Solar Cells Juliane Borchert[1], Ievgen Levchuk[2], Lavina C. Snoek[1], Mathias U. Rothmann[1], Henry Snaith[1], Christoph J. Brabec[2], Laura Herz[1] and Michael Johnston[1]; [1]University of Oxford, United Kingdom; [2]Friedrich-Alexander Universität Erlangen-Nürnberg, Germany

Since their emergence in 2009 perovskites solar cells have reached a remarkable efficiency of 25.2 % [1]. Metal-halide perovskites exhibit low Shockley-Read-Hall recombination rates, high absorption coefficients across much of the solar spectrum as well as high charge-carrier diffusion lengths and mobilities [2]. These properties are ideal for a wide range of applications, including solar cells, transistors, light-emitting devices and lasers. A particularly simple and popular design for perovskite solar cells is the planar architecture, which was first fabricated using co-evaporation of methylammonium lead iodide (MAI) and lead iodide (PbI2) [3]. Co-evaporation makes it possible to deposit perovskite thin-films that are smooth, very planar and pin-hole-free over large areas [4]. This makes evaporated thin-films advantageous for the fabrication of perovskite solar cells and for detailed studies of the optoelectronic properties of the material. Furthermore, no solvents are required which makes this method fully additive and prevents damage to underlying layers. This is important both for the manufacturing of tandem solar cells and the upscaling of perovskite solar cells. While this method was initially mainly used for the deposition of MAPbI3, it has recently been extended to other perovskite materials including formamidinium lead iodide (FAPbI3) [4], triple-cation perovskites [5] and perovskites incorporating tin [6]. Despite this progress, several hurdles remain on the way to large-area co-evaporated perovskite solar cells. One issue are challenges with the evaporation of MAI [7]. Especially the rate control with conventional quartz micro balances (QMBs) does not work reliably for this material. Furthermore, it has been reported that impurities in MAI influence the film morphology and efficiency of solution-processed perovskite solar cells [8]. Therefore it is important to study the evaporation mechanics of MAI and the influence of impurities in-depth, which we set out to do in this contribution [9]. We compared two different MAIs, an impure one, and a highly purified MAI. A wide range of techniques was employed to characterise the precursors and deposited films, including nuclear magnetic resonance (NMR), infra red spectroscopy and mass spectroscopy. We were able to identify impurities in MAI and

track their presence over the course of an evaporation. Furthermore, we characterised the purity of commercially available MAI and found drastic differences between manufacturers. Finally we fabricated solar cells with MAI of different purity and characterised their performance. We found that impurities critically influence the process control during the co-evaporation of perovskite thin-films. Based on this finding we give recommendations to improve the control over the evaporation and therefore the reproducibility of the process. These insights pave the way towards the upscaling of co-evaporated perovskite solar cells. [1] https://www.nrel.gov/pv/cell-efficiency.html [2] MB Johnston, LM Herz (2016) Acc. Chem. Thermal Evaporation for Large-Area Perovskite Solar Cells Andres Felipe Castro Mendez, Vivek Prakash, Carlo Andrea Riccardo Perini and Juan Pablo Correa Baena; Georgia Institute of Technology, United States

Perovskite Solar Cells (PSC) have achieved up to 25.2% efficiency in the lab-scale by solution processing. However, one of the barriers towards their commercialization is scalability. Achieving this is difficult because of the various layers that are commonly deposited through spin coating, a solution process that is undesirable in industry. The use of toxic solvents presents another challenge to fabricate perovskite modules. To overcome the limitations of solution processing, thermal evaporation has been explored as a robust deposition method that can be upscaled. Thermal evaporation provides three main advantages. First, it can provide scalability. Second, it allows better control and homogeneity of the thickness of the films. And third, it allows for the fabrication of graded compositions throughout the thin film. However, thermal evaporation of perovskites has been difficult to achieve due to the challenges associated with measuring accurately the deposition rate of organic cations such as methylammonium iodide. Here, we systematically study different approaches to coevaporate perovskites with various stoichiometries. We correlate film stoichiometry to the deposition temperature/rate of the organic precursors through XRD and XPS measurements, demonstrating good control and reproducibility of the films over a 10 cm2 area. The films with varying stoichiometries were incorporated into solar devices where it was observed an improvement of efficiency in large areas with respect to the conventional deposition techniques.

6:25 AM F.EL08.08.11
2D-on-3D Hybrid Organic-Inorganic Perovskite Heterostructure Thin Films Deposited by RIR-MAPLE Niara E. Wright[1], Steven Harvey[2] and Adrienne Stiff-Roberts[1]; [1]Duke University, United States; [2]National Renewable Energy Laboratory, United States

Despite the exceptional increase in the power conversion efficiency of perovskite solar cells (PSCs) over the past decade, the feasibility of commercial systems depends upon achieving stable device performance over thousands of hours. While the crystalline structure of three-dimensional (3D) metal halide perovskites is responsible for unique semiconductor properties advantageous to photovoltaics, such as strong absorption and a tunable bandgap1, this structure also leads to aggressive degradation by humidity, light, and oxygen that prevent the required stability. Fortunately, two-dimensional (2D) perovskites have been shown to have improved stability due to the hydrophobic nature of these materials.2,3 Thus, work is being done to incorporate 2D perovskites as passivating layers for the photovoltaic active regions in 3D metal halide PSCs. While quasi-2D perovskite structures are widely studied, experimental investigations of 2D-on-3D interfaces have been limited due to processing challenges.4 The purpose of this work is to investigate how resonant infrared, matrix-assisted pulsed laser evaporation (RIR-MAPLE) can overcome these processing challenges to create high-quality 2D-on-3D hybrid organic-inorganic perovskite heterostructures. Eventually, such structures could be used as passivation layers in PSCs. RIR-MAPLE is a vapor deposition technique that uses a low-power, Er:YAG (2.94 ?m) laser to evaporate a matrix solvent in a frozen target, which gently ejects the precursor material onto the substrate without evaporating the precursor itself.5,6 In this work, 2D-on-3D heterostructure thin films of (PEA)2PbBr4 (PEA = phenethylammonium, C8H12N) on MAPbI4 (MA = methylammonium, CH3NH3) are deposited by RIR-MAPLE. Growth conditions and in-situ annealing protocols at the interface of the two materials are investigated to achieve a heterostructure with little to no compositional mixing between the layers. X-ray diffraction spectroscopy and time-of-flight secondary ion mass spectrometry (TOF-SIMS) are performed to confirm that the films are compositionally distinct across the interface. UV-Vis absorbance spectroscopy of the 2D-on-3D heterostructures is conducted to determine the optical properties of the films. Furthermore, efficient charge transport in the

vertical direction is influenced by the quantum well orientation of the 2D perovskite layer. Wells oriented perpendicular to the 3D surface will assist in vertical transport, and wells that are parallel to the 3D surface will impede vertical transport. Spin-coated PEA-based 2D perovskites have been shown to have parallel orientation with respect to the substrate, while preliminary work has demonstrated that these materials have a random orientation of crystalline grains when deposited by RIR-MAPLE. To explore charge transport in the 2D-on-3D heterostructure, current measurements through an anode-heterostructure-cathode configuration are conducted to focus on the transport through the interface itself. In this way, additional variables related to full device architectures are minimized. Separate 2D and 3D hybrid perovskite films, as well as spin-coated heterostructures, are characterized as references for comparison to the RIR-MAPLE-deposited heterostructures. A. D. S.-R. and N. E. W. acknowledge research supported as part of the Center for Hybrid Organic Inorganic Semiconductors for Energy (CHOISE), an Energy Frontier Research Center funded by the U. S. The Importance of Knowing Your Surface in Perovskites—When Methylammonium Iodide Content Alters the Structural, Surface, Electronic and Ionic Properties of CH3NH3PbI3 Thibaut Gallet and Alex Redinger; University of Luxembourg, Luxembourg

Optimizing hybrid perovskite devices has been a central research topic in the last few years. This usually is performed through a thorough band alignment engineering of the hole and electron extraction layers with respect to the absorber. This led to the emergence of an uncountable number of organic, inorganic and hybrid layers, usually suitable for specific absorbers, which makes it hard to repeat their improving effects on slightly different absorbers. This comes from the fact that surfaces and therefore interfaces are complex media that are still not well understood but are the major starting points for the fabrication of efficient working solar cells. Density of surface states, surface workfunction homogeneity, grains and grain boundaries properties, optoelectronic properties at the surface are the most important characteristics to determine in order to boost the power conversion efficiency. Kelvin Probe Force Microscopy (KPFM) is a suitable tool to access most of these properties but the measurements outcomes are delicate to interpret, especially for perovskites, essentially because they are often performed under ambient conditions. In this contribution we present our results obtained on methylammonium lead iodide perovskites (MAPI), grown by co-evaporation, where the methylammonium iodide (MAI) concentration is changed by varying the pressure inside the physical vapor deposition (PVD) chamber. We focus our work on the analysis of the surface of our samples without exposing them to air to minimize their contamination to moisture and oxygen. For that, we used Frequency Modulation KPFM (FM-KPFM) under ultra-high vacuum (UHV), photoluminescence (PL), time resolved-PL (TRPL), structural and compositional techniques to understand the impact of MAI concentration in MAPI on the surface. In a first part, we show the impact of varying the MAI pressure inside the PVD by looking at two different pressures. We compare the surface of these two samples by first using KPFM under UHV, which gives the impression that different compounds are deposited on the surface of the samples. For a better interpretation of our results, we additionally use X-ray diffraction (XRD) and Energy Dispersive Spectroscopy (EDS) which enables us to create a link between I/Pb ratio and the transition from a cubic to tetragonal structure. In a second part, we discuss the effect that annealing the samples under inert gas has on the surface workfunction. We see that depending on the initial MAI concentration, the outcome of annealing at several temperatures is different. We again use EDS and XRD for a better understanding but we also perform PL and TRPL. We start to illuminate our sample to access surface photovoltage values and we see how the difference in MAI concentration initially and through the annealing steps influence the ionic mobility at the surface, where different ionic species migrate depending on the absorber's state. Finally, we introduce PL and TRPL to potentially link minority carrier lifetime, PL bandgap and surface photovoltage and we perform a thickness study with KPFM to define an energy band diagram and summarize the key effects of varying the MAI concentration on the surface and why it is important to clearly identify the state of the surface before optimizing the device via band alignment engineering.

Vapor Deposition Enables Interface Design and Defect Passivation for Highly Efficient Perovskite Solar Cells Carlo Andrea Riccardo Perini, Andres Felipe Castro Mendez, Jake Vargott, Juanita Hidalgo and Juan Pablo Correa Baena; Georgia Institute of Technology, United States

To go beyond the present 25.2 % solar cell efficiency record, halide perovskite point defects should be either reduced or passivated. Device interfaces need to be designed to minimize recombination and boost charge carrier extraction. 2D

perovskites are effective interface passivation layers which, included in solar cell device structures, enabled the highest published efficiencies. However, 2D perovskites are mostly processed via solution, which limits the control over the deposited film resulting in losses that manifest as increased series resistance or recombination. The requirement of solvent orthogonality for the 3D and 2D perovskite deposition limits the choice of possible material compositions, whereas the solution deposition of the 3D perovskite limits the use of the 2D passivation to the top 3D surface. Vapor deposition methods are established in manufacturing and enable us to overcome these limitations. Here, we demonstrate a vapor deposition route for 2D passivation of a 3D perovskite, which enables a down to monolayer control and conformal film uniformity. The quality of the 2D passivation layer is probed combining time resolved photoluminescence with spatially resolved hyperspectral luminescence imaging and X-ray beam induced current. Films are then incorporated in complete solar cell device structures demonstrating enhanced performances with respect to the solution processed counterparts. In addition, benefiting from a full vapor deposition of the 2D-3D perovskite stack, a bottom interface 2D passivation is demonstrated.

Solvent-Free Synthesis of Alternative Inorganic Halide Materials with Application in Optoelectronics Paz Sebastia-Luna, Michele Sessolo, Franciso Palazon and Henk Bolink; University of Valencia, Spain

Lead halide perovskites have shown outstanding properties when applied in optoelectronic devices, such as solar cells and light-emitting diodes.[1,2] Nevertheless, the presence of highly toxic lead together with their low environmental stability might become a bottleneck for their commercialization. Herein we present different inorganic halides based on non-toxic metals with potential application in optoelectronics. Among these, Cu(I)-based fully inorganic ternary metal halides are particularly promising, especially for applications in light-emitting diodes (LEDs). Blue, highly luminescent materials (required for the fabrication of white light-emitting diodes) are commonly more challenging to obtain than red or green emitters, due to the increased probability of non-radiative recombination. We report the synthesis of two different series of inorganic cesium copper halides, with the general formulas Cs3Cu2X5 and CsCu2X3 (X = Cl, Br, I, and mixtures thereof). Cs3Cu2I5 has been identified as the most promising material, as it maintains blue luminescence with photoluminescence quantum yield exceeding 40% even after being exposed to air for several days. Importantly, we employed a dry mechanochemical synthesis which avoids the use of solvents and high temperatures and allows the preparation of phase-pure compounds.[3] Homogeneous Cs3Cu2I5 thin-films were also fabricated by single-source vacuum deposition (SSVD) employing the pre-synthesized luminescent compounds. The emission spectrum and crystallinity is maintained in thin films, even without any further post-deposition treatment.[4] Using similar synthesis and thin-film processing techniques, we investigate several cesium bismuth halides and their potential use in thin-film solar cells. Finally, we present the synthesis and characterization of an unexplored family of materials, called anti-perovskites, which are based on silver chalcogenides compounds. These materials have potential applications in IR photodiodes and tandem solar cells, thanks to their narrow bandgap < 1 eV. References: [1]. Leijtens, T., Bush, K. A., Prasanna, R., y McGehee, M. D. Molecular Engineering of Two-Dimensional Organic-Inorganic Hybrid Perovskites Letian Dou; Purdue University, United States

Two-dimensional halide perovskites are exciting new semiconductors that show great promising in low cost and high-performance optoelectronics devices including solar cells, LEDs, photodetectors, transistors, etc. In the first part of this talk, I will present a molecular approach to the synthesis of high-quality organic-inorganic hybrid perovskite quantum wells through incorporating widely tunable organic semiconducting building blocks as the surface capping ligands. By introducing sterically tailored groups into the molecular motif, the strong self-aggregation of the conjugated organic molecules can be

suppressed, and single crystalline organic-perovskite hybrid quantum wells and superlattices can be easily obtained via one-step solution-processing. Energy transfer and charge transfer between adjacent organic and inorganic layers are extremely fast and efficient, owing to the atomically-flat interface and ultra-small interlayer distance. In the second part, I will present the synthesis and characterization of a stable lead-free Sn (II)-based two-dimensional perovskite featuring a p-conjugated oligothiophene ligand. The conjugated ligands facilitate formation of micrometer-size large grains, improve charge injections, and stabilize the inorganic perovskite layers. Thin film field-effect transistors based on (4Tm)2SnI4 exhibit enhanced hole mobility up to 2.3 cm2V-1s-1, and dramatically improved stability over the previous benchmark material (PEA)2SnI4. Stabilization mechanisms were investigated via single crystal structure analysis as well as density functional theory calculations. It was found that the large conjugated organic layers not only serve as thick and dense barriers for moisture and oxygen, but also increase the crystal formation energy via strong intermolecular interactions.

5:15 AM *F.EL08.09.02
Multiscale Structural Engineering of Luminescent Metal Halides for Thermography and Security Tags Maksym V. Kovalenko; ETH Zurich, Switzerland

Metal halides offer unique structural engineerability of practically useful optical functionalities. In particular, low-dimensional compounds often exhibit broadband emission from highly localized, self-trapped excitions. These compounds exhibit strong temperature dependence of the photoluminescence lifetime. Using a range of tin based halides, [C(NH2)3]2SnBr4 to Cs4SnBr6 and (C4N2H14I)4SnI6, we show the radiative-lifetime-based thermal imaging [1]. The fluorescence lifetimes are governed by the phonon-assisted de-trapping of self-trapped excitons, and their values can be varied over several orders of magnitude by adjusting the temperature (up to 20 ns °C-1). The sensitive range conveniently spans up to 100 °C. The resulting thermometric precision is as high as 0.013 °C, using conventional TSCPC fluorescence lifetime imaging (FLI). We also showcase a great utility of the time-of-flight technology (ToF-FLI) for cost-effective fluorescence lifetime imaging. In our ongoing work, we find that analogous Sb(III) compounds as thermoluminophores are much more environmentally stable than easily oxidizable Sn(II) compounds and can be used to increase spatial resolution [2]. We also present unicolor security tags composed of lifetime-tunable lead-halide perovskite nanocrystals that can be deciphered with both existing time-correlated TCSPC-FLI microscopy and a novel ToF-FLI prototype. In particular, we partially substituted formamidinium for ethylenediammonium {en} to generate “hollow” {en}FAPbBr3 NCs, which exhibit same PL spectrum but 3-fold longer fluorescence lifetimes [3].

Halide Perovskite Nano—Increasing Long Term Stability of Perovskite Nanoparticles and Exploring Synergies with Conventional Quantum Dots Ivan Mora-Sero; Universitat Jaume I, Spain

Halide perovskite have revolutionized not just photovoltaic field but the complete optoelectronic devices spectra for their outstanding properties as low-non radiative recombination, high absorption coefficient, good transport properties, facile material synthesis and huge versatility and tunability. When halide perovskites become nano the properties of their nanoparticles are also exceptional with impressive photoluminescence quantum yields (PLQY) close or even as high as 100%. However, the long term stability of perovskite nanoparticles is the Achilles’ heel of these materials. In this presentation we analyze as with an appropriated synthesis routes, affecting the nanoparticle capping or the perovskite composition, is possible to produce ultra-stable halide perovskite nanoparticles for more than 15 months.
On the other hand the interaction of halide perovskite and colloidal semiconductor quantum dots can produce interesting synergistic interactions. We show that the interaction of PbS quantum dots and nanoplatelets can produce the stabilization of $FAPbI_3$ perovskite black phase and also the increase of the efficiency, stability and reproducibility of the photovoltaic devices prepared with of $FAPbI_3$ with embedded QDs. The use of PbS nanoplatelets also improve the long term stability of $CsFAPbI_3$ perovskite. Incorporation of PbS QDs allows the dramatic decrease of the annealing temperature for the formation of black $FAPbI_3$ phase perovskite thin film, from the 170C required without QDs to 85C when QDs are present. This result points the interest of Perovskite-Quantum Dot Nanocomposites, for further development of advanced optoelectronic devices.

5:45 AM *F.EL08.09.04
Stability Improvement of Perovskite Light-Emitting Diodes Through Composition Engineering and Surface

Passivation Ni Zhao, Yuwei Guo, Nan Li and Yongheng Jia; Chinese University of Hong Kong, Hong Kong

The past few years have seen a significant improvement in the efficiency of organometal halide perovskite-based light emitting diodes (PeLEDs). However, the poor operation stability of the devices still hinders the commercialization of this technology for practical applications. In this talk I will introduce our recent efforts in understanding the degradation mechanisms of PeLEDs and developing material strategies to improve the device stability. Firstly, using time-of-flight secondary ion mass spectrometry we find the degradation of $FAPbI_3$- based PeLEDs during operation is directly associated with ion migration and incorporation of binary alkali cations, i.e., Cs^+ and Rb^+, in $FAPbI_3$ could suppress ion migration and significantly enhance the lifetime of PeLEDs. Combining experimental and theoretical approaches, we further reveal that Cs^+ and Rb^+ ions stabilize the perovskite films by locating at different lattice positions, with Cs^+ ions present relatively uniformly throughout the bulk perovskite while Rb^+ ions preferentially on the surface and grain boundaries, both leading to strong Coulomb interactions between the cations and the inorganic framework and consequently greatly enhanced device stability. Secondly, we introduced electroabsorption spectroscopy (EA) to study the degradation process of PeLEDs during operation and directly evaluate the stability of each functional layer (i.e., charge transporting layers and light-emitting layer) by monitoring their unique optical signatures. The EA measurements unambiguously reveal that the degradation of the PeLEDs occurs predominantly in the perovskite layer. With finite element method-based device modeling, we further point out that the degradation is likely to initiate from the interface between the perovskite and hole transporting layers and that the interface defects could further accelerate the degradation. Inspired by these observations, a surface treatment step is introduced to passivate the perovskite surface with phenylalkylammonium iodide. After molecular optimization, the PeLEDs exhibit an external quantum efficiency of 17.5% and a long T50 lifetime of over125 hours under a high biasing current density of 100 mA cm^2.

6:00 AM F.EL08.09.05
Bright and Effectual Perovskite Light Emitting Electrochemical Cells Leveraging Ionic Additives Masoud Alahbakhshi[1], Aditya Mishra[1], Ross Haroldson[1], Arthur Ishteev[2], Jiyoung Moon[1], Qing Gu[1], Jason D. Slinker[1] and Anvar Zakhidov[1]; [1]The University of Texas at Dallas, United States; [2]ITMO University, Russian Federation

Perovskite light emitting diodes (PeLEDs) have drawn considerable attention for their favorable optoelectronic properties. Perovskite light emitting electrochemical cells (PeLECs) - devices that utilize mobile ions - have recently been reported but have yet to reach the performance of the best PeLEDs. We leveraged a poly(ethylene oxide) electrolyte and a lithium salt in CsPbBr3 thin films to produce PeLECs of improved brightness and efficiency. In particular, we found that a single layer PeLEC from CsPbBr3:PEO:LiPF6 with 0.5% wt. LiPF6 produced bright (~15000 cd/m2) electroluminescence of improved efficiency (3.0 Lm/W). To understand this improved performance among PeLECs, we characterized these perovskite thin films with photoluminescence (PL) spectroscopy, scanning electron microscopy (SEM), atomic force microscopy (AFM), X-ray photoelectron spectroscopy (XPS), and X-ray diffraction (XRD). These studies revealed that this optimal LiPF6 concentration improves electrical double layer formation, reduces the occurrence of voids, charge traps, and pinholes, and increases grain size and packing density.

6:10 AM F.EL08.09.06
Perovskite Light Emitting Electrochemical Cells Jason D. Slinker, Aditya Mishra, Masoud Alahbakhshi, Ross Haroldson and Anvar Zakhidov; The University of Texas at Dallas, United States

Solution processed organic-inorganic metal halide perovskites with the chemical formula ABX_3 have emerged as next generation light emitting materials. Recently, ion migration has been demonstrated to significantly influence the performance of metal halide perovskite devices. The interplay between electronic and ionic currents provides a new pathway to utilize metal halide perovskites as emissive materials in light emitting electrochemical cells (PeLEC). Light emitting electrochemical cells (LECs) utilize ionic motion to generate electrical double layers for high carrier injection and potential doping effects to achieve efficient operation in single layer devices. Recently, our group demonstrated bright and effectual PeLECs with simple single layer architectures, leveraging a polyelectrolyte and a lithium ionic additive ($LiPF_6$) to achieve devices with a high maximum luminance of >10000 cd m^{-2} and operation exceeding 100 hours over 800 cd m^{-2}. To understand this improved performance among PeLECs, we characterized these perovskite thin films with photoluminescence (PL) spectroscopy, scanning electron microscopy (SEM), atomic force microscopy (AFM), X-ray photoelectron spectroscopy (XPS), and X-ray diffraction (XRD). These studies revealed that this optimal $LiPF_6$ concentration improves electrical double layer formation, reduces the occurrence of voids, charge traps, and pinholes, and increases grain size and packing density. Electrochemical impedance spectroscopy with equivalent circuit modeling revealed that electrical double layer widths are minimized with an optimal $LiPF_6$ concentration and inversely correlate with efficient performance. These results demonstrate that an optimal $LiPF_6$ concentration improves stability and efficiency through improved double layer formation and retention

of perovskite structure.

6:20 AM F.EL08.09.07
Modulation of Growth Kinetics and Dimensional Control of Vacuum-Deposited Cs-Pb-Br Perovskite for Efficient Light-Emitting Diodes Mingue Shin[1], Ho Seung Lee[1], Young Chul Sim[1], Yong-Hoon Cho[1], Kyung Cheol Choi[1], Sung-Wook Nam[2], Aditya Sadhanala[3], Ravichandran Shivanna[3], Miguel Anaya[3], Alberto Jimenez-Solano[4], Hyewon Yoon[1], Seokwoo Yeon[1], Samuel D. Stranks[3], Robert Hoye[3] and Byungha Shin[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Kyungpook National University, Korea (the Republic of); [3]University of Cambridge, United States; [4]Max Plank Institute for Solid State Research, Germany

Due to exceptional color purity and good thermal stability, all-inorganic halide perovskite (CsPbBr3) has been attracting interest as the next-generation materials for light-emitting diodes (LEDs). However, its low exciton binding energy is one of the factors limiting luminescence efficiency and spatial confinement of excitons is a promising way to resolve this issue. Here, we present two strategies of spatially confining excitons in vacuum-deposited Cs-Pb-Br light emitters. In the first part, we have modulated growth kinetics unique to thermal evaporation to form fine-grain-structured CsPbBr3 polycrystalline films. By adjust the deposition rate, nucleation rate was controlled, which then influenced the finalgrain structure. With this strategy, we demonstrate a green light-emitting (at 524 nm) LED with a maximum current efficiency of 1.07 cd/A and an extremely narrow electroluminescence spectrum of 18 nm—the results that highlight the potential of vacuum-processed CsPbBr3 films for high efficiency LEDs. In the second part, we have controlled dimensionality of by adjusting the flux ratio of the two source materials, CsPb and PbBr2, to deposit Cs-Pb-Br films. Under the excess flux of CsPb the so-called zero-dimensional Cs4PbBr6 formed, producing strong green emission with high photoluminescence quantum yield close to 90%. The green emission from Cs4PbBr6 is unusual considering its large bandgap of 3.9 eV. Through in-depth transmission electron microscopy study and optical measurement such as photothermal deflection spectroscopy and photoluminescence contour map, we identified the inclusion of trace amount of CsPbBr3 "impurities" as the source of the green emission. We have achieved a 60-fold improvement in external quantum efficiency from an LED with a CsPbBr3-embedded Cs4PbBr6 light emitter compared to the control device with CsPbBr3. Details of the materials characterization and device analysis will be discussed.

Origin of High Piezoelectricity and Energy Harvesting Performance in Inorganic Halide Thin Films Da Bin Kim and Yong Soo Cho; Yonsei University, Korea (the Republic of)

Halide perovskite materials have been actively studied to chase other suitable applications with unveiled characteristics. Piezoelectricity-related applications using the halide perovskites are another area that may be suitable with unique potentials. However, the studies on piezoelectricity of the halide perovskites are very limited probably due to the difficulty in fabricating quality thin films or bulk specimens although the possession of ferroelectricity of the materials has been theoretically estimated with calculated polarization values in literature. Here, we report the high piezoelectricity of representative inorganic halides, CsPbBr3, which was optimized with poling process, and their energy harvesting characteristics in the form of thin film. This is the very first report of revealing effective piezoelectric coefficient for any inorganic halide perovskite and demonstrating piezoelectric energy harvesting performance using inorganic halides. So far, the piezoelectric coefficients of 6-25 pm/V were reported only for the methylammonium lead halides (MAPbX3) or formamidinium lead halides (FAPbX3)-based hybrid perovskite thin films. Our highest value of ~40.3 pm/V for the optimized CsPbBr3 with film thickness and poling field was chased to understand origin of the high piezoelectricity via structural estimation associated with the changes in bonding angles. As expected from the high piezoelectricity, the electromechanical energy-harvesting performance was very competitive, such as 16.4 V output voltage and 604 nA output current for a larger size sample of 5 cm2. The values obtained for the inorganic CsPbBr3 thin films are the highest ones compared to any reported values for inorganic-organic hybrid halide perovskite thin films.

6:40 AM F.EL08.09.10
Charge Transport in Lead Halide Perovskite Field-Effect Transistors Amita Ummadisingu, Youcheng Zhang and Henning Sirringhaus; University of Cambridge, United Kingdom

In recent years, lead halide perovskites have been found to be interesting candidates for various applications such as solar cells and light-emitting diodes, due to their excellent optical and electronic properties(*1, 2*). However, a deeper understanding of the intrinsic charge transport in thin films of these materials is currently lacking and it is essential for the bottom-up design of opto-electronic devices(*2*). Here, we fabricated three-dimensional (3D) perovskite thin film field-effect transistors (FETs), and employed them to investigate the temperature-dependent charge transport. We explored several state-of-the-art 3D

perovskite compositions starting with methylammonium lead iodide, followed by numerous triple cation and Rb-incorporated perovskite compositions(*3*). A significant issue with these materials is the migration of ions and this results in partial screening of the applied gate field which gives a lower field-effect mobility than expected in these FETs(*4*). Initial trials resulted in FETs that did not display any modulation of the drain current with the gate voltage due to ion migration. This problem was suppressed through extensive optimization of both the deposition methods and the compositions using Design of Experiments (DOE) principles. The transfer characteristics of optimized FET devices show that these devices exhibit n-type behavior and low hysteresis even at room temperature. One of the triple cation compositions shows the best performance and it exhibits a good saturation electron field-effect mobility and an on/off ratio of $\sim 10^4$ at room temperature. Our results bring us closer to achieving the high field-effect mobility values predicted for lead halide perovskites and in understanding the charge transport mechanism in thin films of these materials.

High-Quality CuBi2O4 Photoelectrodes with Increased Stability by Rapid Thermal Processing of Bi2O3/CuO Grown by Pulsed Laser Deposition Ronen Gottesman, Angang Song, Igal Levine, Maximilian Krause, Nazmul Islam, Daniel Abou-Ras, Thomas Dittrich, Roel Van de Krol and Abdelkrim Chemseddine; Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

A new approach for fabricating high-quality ternary photoelectrodes such as CuBi2O4 will be presented. Pulsed laser deposition (PLD)1 is used to deposit the binary oxides Bi2O3 and CuO on FTO substrates, and rapid thermal processing (RTP)2 is used to achieve an efficient solid-state reaction between the two oxide films. It is shown that when Bi2O3 is deposited first, the thin film photoelectrodes are comprised of single-phase, compact, crystalline, and well-defined CuBi2O4 particles. A comparative study with conventional furnace heating reveals the significance of radiative heating in the processing of complex metal oxides photoelectrodes. Additionally, the much shorter heating times enable the use of FTO substrates at temperatures up to 650 °C, also resulting in a low thermal budget (the product of process temperature and processing duration at elevated temperatures). In a comparative study with CuBi2O4 photoelectrodes produced by spray-pyrolysis, a benchmark synthesis technique of photoactive materials3 and complex metal-oxide photoelectrodes,4 the CuBi2O4 layer fabricated by PLD + RTP photoelectrodes featured superior electronic properties, which were sustained even in cases of a secondary oxide co-existence in the film by deliberately altering the Bi:Cu stoichiometry ratio during the PLD stage. The photoelectrodes have shown an efficient charge separation, low tail energies, and band-gap energy virtually identical to that of a CuBi2O4 single crystal, shown by modulated surface photovoltage analysis5 and confocal Raman microscopy. Furthermore, bare photoelectrodes, without the addition of electron scavengers, protection layers, or catalysts, exhibited exceptional photoelectrochemical stability, substantially improving the prospects of implementing CuBi2O4 photoelectrodes in photoelectrochemical devices towards high solar-to-hydrogen efficiency. Advances in Material Properties for Perovskite-Perovskite Tandems Giles Eperon[1,2]; [1]Swift Solar, United States; [2]National Renewable Energy Laboratorty, United States

Multijunction all-perovskite solar cells offer a route towards efficiencies of III-V materials at low cost by combining the advantages of low thermalization loss in multijunction architectures with the beneficial properties of perovskites - namely low processing cost, high throughput fabrication, and compatibility with flexible substrates. Here, I will discuss why flexible all-perovskite tandems are a very attractive iteration of the perovskite technology. I will focus on what is needed to make a good perovskite-perovskite tandem on a flexible substrate, and the advances that we have made towards this goal.
I will cover advances including a) the development and understanding of wide bandgap materials that leverage a novel bandgap-tuning strategy (without increasing bromine, hence avoiding significant phase segregation) to reach the ideal bandgaps for all-perovskite tandems, resulting in efficient devices that are stable to the combined stresses of heat and light; b) advances that we have made in interlayer design, working towards more ideal material properties for reducing shunt resistance; and c) the integration of these approaches to develop >23% efficient monolithic all-perovskite tandems on rigid substrates and 21% efficient devices on flexible plastic substrates.

The Many Faces of Characterization in Developing a Commercial Perovskite on Silicon Tandem Solar Cell Laura Miranda; Oxford PV, United Kingdom

Perovskite solar absorbers have the potential to disrupt the photovoltaic industry predominantly with their simultaneous promise of high efficiency and low cost. Whilst these two properties ensure a steady stream of research and development opportunities, commercial scaling requires assuring that the devices are sufficiently characterized to be confident of their long-term performance. Oxford PV has been addressing the challenges associated with commercially scaling its perovskite on silicon tandem solar cell design. Key practices that have been adopted during the development of highly efficient, reliable, and cost-competitive solar cells are the use of rigorous characterization tools and techniques, and the development of necessary models. This talk will highlight some of the challenges and considerations associated with bringing perovskite on silicon tandem solar cells from a laboratory prototype to a commercial product ready for manufacturing and how characterization has shaped and continues to inform that process.

5:30 AM *F.EL08.10/F.EL06.07/F.EN02.08.03
Passivation Strategies and Interlayers for Perovskite-Based Tandem Photovoltaics Ulrich W. Paetzold, Saba Gharibzadeh, Tobias Abzieher, Ihteaz M. Hossain, Hang Hu, Thomas Feeney, Somayeh Moghadamzadeh, Mahdi Malekshahi Byranvand,, Bahram Abdollahi Nejand, Paul Fassl and Bryce Sydney Richards; Karlsruhe Institute of Technology, Germany

Single-junction crystalline silicon solar cells dominate the photovoltaics market today, but their power conversion efficiencies (PCEs) are approaching the practical limit for this technology. The emergence of hybrid organic-inorganic metal halide perovskite semiconductors over the past decade has opened a window of opportunity to advance the performance of the market-dominating photovoltaic technologies through the development of tandem solar cells. These tandem solar cells promise high PCEs (>33%). To reach this landmark, a number of scientific and technological challenges related to high-efficiency perovskite-based tandem solar cell architectures, stable and high-quality perovskite semiconductor materials, and light management concepts need to be addressed. In this presentation, our progress on passivation strategies and novel interlayers to reduce the voltage losses in wide-bandgap and low-bandgap perovskite solar cells (PSCs), and in turn to increase the PCE of perovskite-based tandem photovoltaics, will be presented.
The search for efficient passivation interlayers for wide-bandgap perovskite top solar cells in *n-i-p* architecture directed our research in the past towards solution-processed 2D/3D perovskite heterostructures. Making use of these heterostructures for interface passivation, wide-bandgap PSCs (E_g ~1.72 eV) with record open-circuit voltage for this bandgap and very high PCEs of up to 19.4% were demonstrated [1]. The reduced voltage deficit is a result of the decreased non-radiative recombination losses at the perovskite/hole-transport layer (HTL) interface. The solution-processed 2D/3D perovskite heterostructure is compatible with 3D perovskite absorber layers of a wide range of bandgaps (1.65 eV $\leq E_g \leq$ 1.85 eV) [2]. Using this strategy in 4-terminal perovskite/silicon and perovskite/CIGS tandem solar cells, high PCEs > 27% [3], and > 25% [2] were demonstrated, respectively, thereby significantly exceeding the record PCESs reported for the respective single-junction solar cell technologies.
Beyond these past results, at the MRS fall meeting we will further present our latest work on novel interlayers and

passivation strategies to minimize the voltage loss in wide-bandgap (1.65 eV ≤ E_g ≤ 1.75 eV) as well as low-bandgap (E_g ~ 1.26 eV) perovskite solar cells in *p-i-n* architecture. The *p-i-n* architecture is a key to realize high-performance 2-terminal perovskite/silicon as well as perovskite/perovskite tandem solar cells. Moreover, we will present a novel route to deposit uniform ultra-thin polymer passivation layers onto perovskite thin films by chemical vapor deposition (CVD) [4]. The CVD polymerization promises reliable, scalable, and homogeneous deposition for future large-area processing of perovskite-based tandem solar cells.

Towards Highly Efficient Monolithic 2- and 3-Terminal Perovskite Silicon Tandem Solar Cells Lars Korte, Eike Koehnen, Philipp Wagner, Philipp Tockhorn, Marko Jost, Amran Al-Ashouri, Lukas Kegelmann, Marcel Roß, Bernd Stannowski and Steve Albrecht; Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

Integrating metal halide perovskite top cells with crystalline silicon (c Si) bottom cells into monolithic tandem devices has recently attracted increased attention due to the high efficiency potential of these cell architectures. To further increase the tandem device performance to a level well above the best single junctions, optical and electrical optimizations as well as a detailed device understanding for such architectures need to be developed [1]. Here we present our recent results on such monolithic tandem cells in the common 2-terminal (2T) as well as in a novel 3-terminal (3T) contacting scheme.
In the 2T design, we recently demonstrated a certified power conversion efficiency (PCE) of 29.15% [2,3]. I will discuss some key elements to this result: using a silicon heterojunction cell electron contact on the rear side, enabling the integration of a perovskite top cell in the p-i-n configuration; employing self-assembled monolayers (SAMs) as hole selective contacts for further reduction of non-radiative recombination losses, etc. With the latter, efficiencies of up to ~ 21 % were demonstrated for p-i-n perovskite single junctions [3].
In 3T tandems, one of the three contacts is shared by both subcells, allowing for the individual operation of both subcells in a monolithic device with a single substrate, thus combining the characteristic advantages of 2T and 4-terminal (4T) devices: high combined photogeneration currents as in state-of-the-art 2T tandems, and ideally independent electrical operation similar to 4T tandems, making the cell more robust against varying spectra. I will discuss our recent proof-of-concept study [4], demonstrating a 3T perovskite/silicon tandem cell by manufacturing an n-i-p perovskite top cell on an interdigitated back contact (IBC) silicon heterojunction solar cell. In our proof-of-concept device, the combined PCE of ~ 17% is still limited both optically and electrically, and it will be discussed how optimizations of the cell stack can bring this architecture to a PCE level comparable to 2T tandems. Furthermore, I will demonstrate that the subcells can indeed be operated largely independently at their individual maximum power points, allowing to extract the maximum power output for varying spectral conditions similar to 4T cells. A minimized series resistance at the shared electron contact on the cell's rear side is identified as the crucial parameter for independent operation of the subcells, and I will discuss pathways to approach the simulated efficiency potential by an optimized device design.

Solution Processed Perovskite Subcell in Monolithic Perovskite/Si Tandem Solar Cells and Their Cost and Stability Concerns Qi Chen[1] and Huanping Zhou[2]; [1]Beijing institute of Technology, China; [2]Peking University, China

Among all commercialization routes for perovskite photovoltaics (PV), the perovskite/Si tandem is of particular interest as it capitalizes the mature silicon industry with decades of experience. Here we report low-temperature solution process for efficient two-terminal perovskite/Si tandem solar cells, wherein electrical and optical properties of the tunneling junction are carefully modulated. Moreover, we improve materials stability by introducing Eu^{2+}/Eu^{3+} "redox shuttle" to suppress the Pb^0/I^0 impurities which inevitably occurred during device operation. In addition, we carefully analyze the cost of tandem devices in terms of levelized cost of energy (LCOE) by adopting the "bottom-up cost model". It reveals perovskite PV exhibit low materials cost, which reduces the LCOE substantially in tandem devices. We conclude that further efforts are required to simultaneously improve the efficiency and lifetime of perovskite modules, which ultimately endows the competitiveness of perovskite tandem solar cells.

SESSION F.EL08.11/F.EL06.04: Joint Session: Contacts and Interfaces in Halide Perovskite Devices

Implications of Defects in Defect Tolerant Materials—Understanding Surfaces in Metal Halide Perovskite Solar Materials, Device and Related Systems Joseph J. Berry[1,2]; [1]National Renewable Energy Laboratory, United States; [2]University of Colorado Boulder, United States

Photovoltaic (PV) devices based on metal halide perovskite (MHP) absorbers have reached outstanding performance over the past few years, surpassing power conversion efficiency of over 25% for lab cells and with large area devices in excess of 16%. For the solar application stability, the most demanding requirement to assess for PV, remains the outstanding issue. The problem of stability motivates basic science driven work on MHP based PV at NREL. Material and device insight can enable MHP PV stability along with the associated opportunities to further improve efficiency, scalability and realize unique device architectures. This talk will highlight work at NREL to develop understanding of defects and interfaces in MHPs and what these experiments indicate regarding the requirements to enhance stability of HPSCs. Discussion will focus on efforts to more carefully understand the implications of processing on a range of defects and interfaces to provide a foundation for enabling the technological requirements for PV and other devices. Ongoing efforts make, measure and ultimately control defects via material formation and processing in the context of high-volume manufacturing will also be touched upon. Hypothesized links between device architecture choices, questions regarding materials integration and coupling of formation along with resulting defects to stability will be discussed. More importantly approaches to move from hypothesis to insight using different experimental approaches will be presented. Work at NREL along these lines to provide critical insight regarding interface formation and passivation that appears to have direct implications for performance and its evolution over time in the resulting devices will be presented. New approaches to understanding the critical physical, chemical and electronic properties to provide predictive insight will also be discussed.

5:15 AM *F.EL08.11/F.EL06.04.02
Passivated Interfaces and Surface Recombination Velocities in Mixed Cation Mixed Halide Perovskites David S. Ginger; University of Washington, United States

Surfaces and charge-extracting contacts remain major sources of non-radiative recombination loss; limiting the performance of perovskite PV compared to theoretical limits. We investigate mixed-cation mixed-halide perovskites and demonstrate that, with chemical surface passivation, they can achieve >4 μs minority carrier lifetimes, and >20% external PL quantum yields (PLQY), and nearly single-exponential decay kinetics. This high PLQY observed corresponds to ~97% of the Shockley-Queisser theoretical quasi-fermi level splitting, a first for MA-free mixed-cation mixed-halide compositions. The high PLQY and long PL lifetimes allow us to measure average surface recombination velocities (SRV) <10cm/s, with a champion low of ~1cm/s (a conservative estimate). We show how such improvements in SRV should lead to an absolute improvement in PCE of >4% even with the best of contact alignments. We investigate different MA-free high bandgap compositions, including bandgaps relevant for tandem applications (1.7-1.8eV), and demonstrate performance improvements across all these compositions with our surface passivation strategy. Lastly, using a combination of surface characterization techniques, we show Lewis base interactions of the passivating agent with the perovskite surfaces.

5:30 AM *F.EL08.11/F.EL06.04.03
Vacuum Deposited Perovskite Solar Cells with Multilayer Charge Selective Contacts Michele Sessolo, Sang-Hyun

Chin, Chris Dreessen, Lidón Gil-Escrig, Ana M. Igual-Muñoz, Beom-Soo Kim, Daniel Perez-del-Rey, Isidora Susic, Kassio P. Zanoni and Henk Bolink; Universitat de València, Spain

In solar cells, perovskite films are typically sandwiched in between charge selective layers, either organic or inorganic semiconductors, as well as their combinations. Electron/hole selectivity results from appropriate alignment of the electronic transport levels of these layers with the electronic bands of the perovskite. While transport layers should efficiently extract the photogenerated charge carriers, they should also not quench the perovskite luminescence to avoid a reduction of the quasi-Fermi level splitting and hence the maximum attainable photovoltage. Finally, ohmic charge injection/extraction and a high built-in potential are desirable to maximize fill factor both in single junction and tandem perovskite solar cells. We will review these design rules using fully vacuum deposited solar cells as a platform, as every layer can be fine-tuned or exchanged without substantially alter the device fabrication. The focus will be on wide bandgap, mixed halide perovskite solar cells, which suffer from a higher voltage deficit as compared to narrow bandgap analogous. We will highlight the importance of using non-quenching, energetically-matched hole and electron transport layers in order to reduce non-radiative charge recombination losses. Novel strategies and multilayers structures (including inorganic, organic and ionic compounds) to improve the device functioning will be presented. The implication for the perovskite compositional stability as well as for the device lifetime will also be discussed.

5:45 AM *F.EL08.11/F.EL06.04.04
Approaches to Defect Mitigation in Halide Perovskites Nakita K. Noel; Princeton University, United States

Within a decade, there has been a surge of interest into halide perovskite semiconductors. With tuneable bandgaps, versatile and facile deposition processes and excellent optoelectronic properties, these materials have found applications in photovoltaics (PV), broad-spectrum photodetectors, light-emitting diodes and lasers. While research into using these materials for emission and X-ray detection applications is now beginning to surge; currently, halide perovskites are most well known for their remarkable PV performance, with perovskite solar cells achieving certified power conversion efficiencies exceeding 25% in a remarkably short developmental timescale. Despite the truly impressive device performance, these materials have not yet reached their full potential. The major obstacle to this is an incomplete understanding of crystallisation processes, as well as defects which exist on the surfaces and interfaces of perovskite thin-films. Deficiencies at these interfaces, likely formed during the crystallisation process, are responsible for the major losses in perovskite-based optoelectronic devices; limiting charge extraction, increasing non-radiative recombination, contributing to hysteresis and increasing the voltage-loss of perovskite photovoltaics. Herein, I will present various effective strategies to reduce the defect densities of perovskite films and thus improve the performance of perovskite optoelectronic devices. First, I will discuss how manipulating precursor solutions can have significant impact on the quality of the perovskite films, through enabling reduced defect density. Consequently, this is one approach which can be used to boost device performance. Next, I will focus on a strategy in which we extrinsically modify the bottom interface of perovskite solar cells such that the crystallization of the perovskite yields films with fewer defects. Specifically, we show that ionic liquids can have a dramatic effect on the interfacial trap density in a perovskite solar cell. And finally, I will illustrate an approach in which we manipulate the charge-carrier density in the perovskite thin-film after its fully crystallized. We utilise molecular dopants to significantly alter the interfacial energetics in order to suppress non-radiative recombination losses. As a result, we observe a boost in both performance and stability. Importantly, these interface modification strategies can be used in tandem, resulting in further improvements in device efficiency. The utility of these defect mitigation strategies can readily be applied beyond perovskite PV and is likely to also improve the performance of a range of other perovskite-based optoelectronic devices.

6:00 AM F.EL08.11/F.EL06.04.05
Transparent Conducting Oxides for Upscalable Solar Cells—Assessing Deposition Methods Yury Smirnov[1], Laura Schmengler[1], Riemer Kuik[1], Pierre-Alexis Repecaud[1], Mehrdad Najafi[2], Sjoerd Veenstra[2], Erkan Aydin[3], Stefaan De Wolf[3] and Monica Morales-Masis[1]; [1]University of Twente, Netherlands; [2]TNO-Solliance, Netherlands; [3]King Abdullah University of Science and Technology (KAUST), Saudi Arabia

Transparent electrodes are essential components of several kinds of high-efficiency solar cells. The photovoltaic devices working in the broadband spectra, from the ultraviolet (UV) to the near-infrared (NIR), require minimized parasitic absorption and high conductivity for these electrodes. Transparent conductive oxide (TCO) thin films are widely accepted choices for such applications. Among various successful TCOs, recently, Zr-doped indium oxide (IZrO) has been demonstrated as a broadband transparent and conductive material suitable for silicon heterojunction (SHJ) and silicon/perovskite tandem solar cells.[1,2] The main advantage of IZrO is combining specifications of wide bandgap, high carrier density, and high electron mobility in the same material.
Magnetron sputtering is by far the most established technique to fabricate TCO layers. During sputtering target material is

removed in a ballistic process that sensitively depends on many interconnected processing parameters. This makes a stoichiometric transfer of target material challenging, while high kinetic energies of the arriving species may damage sensitive functional layers beneath. Conversely, in Pulsed Laser Deposition (PLD), the energy source for material ablation is physically decoupled from the vacuum equipment. This favors the stoichiometric transfer of the target material as well as provides a larger choice for deposition pressures and thermalizing the arriving species.
Despite these advantages, PLD is still considered an exotic fabrication method within the photovoltaic community due to the common concerns about the scalability of the technique reasoned by the small sample size for uniform coating and low deposition rates. In fact, significant progress in the upscaling of PLD[3] has already allowed fabrication of high-quality films by on 200 mm circular wafers and fabrication of superconducting tape with deposition rates > 750 nm/min[4], which is considerably high deposition rate.
In our work, we introduce wafer-scale (4") room-temperature fabrication of high-mobility IZrO by PLD with deposition rates on par (>3 nm/min) with lab-scale RF sputtering equipment. We studied the optoelectronic properties and microstructure of the films and made a comparison with IZrO films grown by RF sputtering, both fabricated from an IZrO solid target with the same composition.
X-ray diffraction (XRD) reveals that as-deposited IZrO films are amorphous with small embedded nanocrystals. Their orientation is preserved as the preferred one after solid-phase crystallization at 200 °C. IZrO films exhibit excellent optoelectrical properties combining low absorptance (<10%) in the measured range (300-1500 nm) with high mobility (>60 cm^2/Vs) leading to impressive sheet resistivity (R_{sh}) of <20 Ohm/sq for a 100-nm PLD grown film.
When applied as a front electrode in solar cells, IZrO enables high short circuit currents and the possibility to reduce the amount of indium by reducing the thickness of the films compared to standard ITO, which is critical considering the large scale utilization of such materials. On the other hand, higher deposition pressures during PLD fabrication offer a promising way to mitigate the sputter-induced damage for the deposition of rear transparent electrodes on top of sensitive functional layers as in the perovskite solar cells, which opens new opportunities for the development of high-efficiency tandem solar cells.

Overcoming Redox Reactions at Perovskite/Nickel Oxide Interfaces to Boost Voltages in Perovskite Solar Cells Caleb C. Boyd[1], R. C. Shallcross[2], Neal R. Armstrong[2] and Michael McGehee[3]; [1]Stanford University, United States; [2]The University of Arizona, United States; [3]University of Colorado Boulder, United States

Metal halide perovskite solar cells have largely fulfilled their potential of combining III-V-like optoelectronic properties with low-cost, solution-processing deposition techniques, achieving single-junction power conversion efficiencies (PCEs) >25%. A semiconducting nickel oxide (NiO_x) thin film is a highly desirable wide bandgap hole harvesting contact for perovskite solar cells and organic solar cells because it is low-cost, stable, and readily scalable.(*1*)Perovskite solar cells with NiO_x HTLs have delivered some of the best reported stability results under a variety of stressors, including the 85°C/85% relative humidity damp heat test, temperature cycling from -40°C to 85°C, and extended operational stability at elevated illumination and temperature.(*2*, *3*) However, perovskite solar cells made with NiO_x HTLs typically result in lower open-circuit voltages (V_{OC}) compared to ultra-thin, undoped organic hole transport layers, which are more expensive and present problems for both scalability and stability. Enhancing the V_{OC} and increasing efficiency of NiO_x-based devices will directly result in a decreased photovoltaic module cost ($/W).
Here, we identify a surface-assisted electron transfer-proton transfer (ET-PT) mechanism at the NiO_x/perovskite interface leading to barriers for hole harvesting and device V_{OC} loss. Specifically, under-coordinated metal cation sites ($Ni^{\geq 3+}$) act both as a Lewis acid/oxidant towards dissociated lead halide precursors (i.e. I^-) and as a Brønsted base (proton-acceptor) with protonated amine precursors, forming A-site deficient – and therefore $PbI_{2-x}Br_x$-rich – perovskite at the perovskite/NiO_x interface. This defective perovskite region both increases recombination at the interface and acts as a hole extraction barrier, resulting in device V_{OC} loss.
We demonstrate the elimination of the extraction barrier via a simple, easily scaled approach: titration of surface oxide proton-acceptor sites by incorporating 1-5 mol% excess A-site cation to the perovskite precursor solution. This amount is sufficient to counteract the loss of organic cation, preventing formation of a $PbI_{2-x}Br_x$ layer at the interface, ultimately leading to a V_{OC} increase >200 mV. We demonstrate that this mechanism applies to all forms of NiO_x, including thin films created from sol-gel precursors, nanoparticles, atomic layer deposition (ALD), and radio frequency (RF) sputtering, and is

generalizable across multiple perovskite active layers, including state-of-the-art single junction and tandem relevant compositions. A p-i-n perovskite solar cell with 19.7% PCE at maximum power point (MPP) and V_{OC} up to 1.15 V is achieved. Devices maintain >90% of their initial performance after 2000 hours of thermal stability testing at 85 °C or >80% of their initial performance after 400 hours of accelerated operational stability testing under illumination and 55 °C in nitrogen. Our results extend the generality of acid/base-coupled oxidation-reduction reactions as the driving force for interface equilibration at metal oxide/perovskite interfaces, suggesting that metal halide perovskites have similar reactions with many types of metal oxide layers.

Balancing the Electronic Structure of Flexography-Printed NiO for Rapid Scaling of Perovskite Solar Cells Julia Huddy, Andrew B. Hamlin, Francesco Guarnieri and William J. Scheideler; Dartmouth College, United States

Perovskite solar cells (PSCs) have potential to deliver TW-scale energy via low-cost manufacturing. However, scaling is limited by slow, high temperature annealing of the inorganic transport layers and insufficient understanding of how scalable processing impacts interfacial device physics. This study addresses the NiO, a leading hole transport layer (HTL) for both high-stability single junction architectures and tandem cells. We present a method for scaling ultrathin NiO HTLs by pairing high-speed (60 m/min) flexographic printing with a rapid annealing Cu:NiO sol-gel ink. By engineering precursor rheology for rapid film-leveling, large area (> 50 cm^2) NiO HTLs were flexographically printed with high uniformity and photovoltaic performance matching that of spin coated films. Doping and the combustion precursor design enables 30X faster annealing while reducing intrinsic variability of work function and conductivity originating from NiOH surface species.

Integrating these printed transport layers in planar inverted PSCs allows rapid fabrication of high-efficiency (PCE > 16 %) $Cs_xFA_{1-x}PbI_{1-y}Br_y$ solar cells with low hysteresis and open circuit voltages (V_{OC}) of 1.11 V. XPS studies of the transition from Ni-OH to Ni-O bonding for low-temperature annealed NiO clarify the balance required for both effective carrier collection and high photostability. Paired with variable illumination intensity measurements and detailed transient photovoltage characterization, these measurements provide an improved understanding of the intrinsic defects present at the NiO-perovskite interface and the impact of scalable synthesis of interfacial charge transport layers.

Late News: Interfacial Engineering in High Efficiency Vacuum Deposited Perovskite Solar Cells—From Metal Oxide Extraction Layers to Large Area Devices Daniel Perez-del-Rey[1], Henk Bolink[1] and Pablo P. Boix[2]; [1]University of Valencia, Spain; [2]Institut de ciència del materials, Spain

Vacuum deposition is a key technique in the field of perovskite photovoltaics due to the advantages it presents with respect to the classical deposition methods such as solution processed perovskites. The lack of solvents and the need of annealing makes it a good candidate for industrialization and upscaling as it has already been demonstrated in the OLED field. Despite its advantages, tuning the interfaces is essential to reach the high power conversion efficiencies found in solution processed perovskite solar cells. Metal oxides are an interesting choice for extraction layers due to their improved stability and reduced parasitic absorption. In this work we present our recent advances in using metal oxides as extraction layers optimising the interfaces in order to reach record open circuit voltages in CH3NH3PbI3 perovskite and using MoO3 as extraction layer by molecular passivation in both PiN and NiP structure improving the stability and opening new possibilities for tandem applications. We also show how we implemented this stable pinhole-free bottom layers in large area devices and mini modules, which is very promising for future industrial purposes.

Alloying and Slicing Halide Double Perovskites Adam Slavney[1], Bridget Connor[1], Kurt P. Lindquist[1], Linn Leppert[2], Jeffrey Neaton[3] and Hemamala Karunadasa[1,4]; [1]Stanford University, United States; [2]University of Twente, Netherlands; [3]Lawrence Berkeley National Laboratory, United States; [4]SLAC National Accelerator Laboratory, United States

Halide double perovskites provide a flexible platform for manipulating electronic structure through synthetic design. I will present some recent studies from our group, where we have attempted to increase the compositional and structural complexity of halide perovskites through chemical substitution. In our quest to understand the electronic structure of double perovskites, we developed a simple model that allows us to predict the bandgap symmetry based on chemical composition. Our work constructs an intuitive picture of how the molecular orbitals of metal-hexahalide coordination complexes give rise to electronic bands in the extended perovskite lattice and describes how these molecular orbitals vary across the bands to give rise to the overall band structure. Although the effects of quantum confinement of Pb and Sn perovskites have been well studied, 2D analogs of 3D double perovskites are notably lacking. I will present a series of 2D double perovskites and discuss the optical and electronic consequences of dimensional reduction of the 3D double perovskite lattice to 2D derivatives.

Hot Carriers in Halide Perovskites Tze Chien Sum; Nanyang Technological University, Singapore

Halide Perovskites exhibit outstanding light-harvesting and emissive properties. Presently, record power conversion efficiencies (PCE) >25% in solar cells and external quantum efficiencies (EQE) >20% in light-emitting devices have been demonstrated. The perovskite field has since expanded well beyond photovoltaics and LEDs into other optoelectronic domains of lasers, x-ray detectors, memristors etc. Emerging frontier areas include multiphoton, multi-exciton generation and hot carrier applications. In this talk, I will focus on the hot carrier phenomena in halide perovskites and our recent work in this area.

5:30 AM *F.EL08.13/F.EL02..03
Defects Engineering and Photophysical Processes in 2D Perovskites Annamaria Petrozza; Istituto Italiano di Tecnologia, Italy

Low-dimensional perovskites are rapidly emerging due to their distinctive emission properties. Here, first I will present the fundamental properties of pristine 2D perovskites, such as the nature of the primary photo-excitations, their relaxation through electronic states and their diffusion across thin films. Such properties will be correlated and modulated by the structural characteristics of the 2D perovskites. Then, I will discuss the possibility of perovskite doping by controlled addition of impurity ions which may enable new electronic, magnetic, and optical performances. I will explore new doping strategies based on transition and rare earth metals for tuning of the emission wavelength (from UV to NIR, further extending the typical range covered with perovskites) and luminescent enhancement. The suitability of doping for the realization of 4 level perovskite lasers will be assessed. Doping with heterovalent ions will be tested to selectively increase *p* and *n* type conductivity of the material. The addition of alkaline-earth metals as B-site dopants will be tested to improve the material stability

5:45 AM F.EL08.12/F.EL02.12.01
High-Efficiency Blue Photoluminescence in the $Cs_2NaInCl_6:Sb^{3+}$ Double Perovskite Phosphor Matthew Gray[1], Shruti Hariyani[2], T. Amanda Strom[3], Jackson Majher[1], Jakoah Brgoch[2] and Patrick Woodward[1]; [1]The Ohio State University, United States; [2]University of Houston, United States; [3]University of California, Santa Barbara, United States

In this report, the photoluminescent properties of a lead-free double perovskite $Cs_2NaInCl_6$ doped with Sb^{3+} are explored. The host crystal structure is a cubic double perovskite with Fm-3m symmetry, a = 10.53344(4) Å, and rock salt ordering of Na^+ and In^{3+}. It is a wide bandgap compound (Eg ≈ 5.1 eV), and substitution with Sb^{3+} leads to strong absorption in the UV due to localized $5s^2 \rightarrow 5s^15p^1$ transitions on Sb^{3+} centers. Radiative relaxation back to the $5s^2$ ground state, via a $^3P_1 \rightarrow {}^1S_0$ transition, leads to intense blue luminescence, centered at 445 nm, with a photoluminescent quantum yield of 79%. The Stokes shift of 0.94 eV is roughly 33% smaller than it is in the related vacancy ordered double perovskite Cs_2SnCl_6. The reduction in Stokes shift is likely due to a change in coordination number of Sb^{3+} from 6-coordinate in

$Cs_2NaInCl_6$ to 5-coordinate in Cs_2SnCl_6. In addition to the high quantum yield, $Cs_2NaInCl_6:Sb^{3+}$ exhibits excellent air/moisture stability and can be prepared from solution; characteristics make it a promising blue phosphor for applications involving near-UV excitation.

5:55 AM F.EL08.12/F.EL02.12.04
Tuning the Photophysical Behavior of 2D Perovskites by Engineering the Nature of the Organic Component Ferdinand C. Grozema; Delft University of Technology, Netherlands

Two-dimensional (2D) halide perovskites are a class of emitter materials that are enjoying growing attention recently. The materials are related to 3D halide perovskites but either part or all of the small A-site cations are replaced by large organic molecules with an amonium binding moiety, for example butylamonium or phenyl-ethylamonium. This (generally) leads to the formation of a layered structure where a layer of metal-halide octahedra is formed and the large organic cations separate the layers from each other. Mixing of large and small A-site cations can lead to quasi-2D multi-layer materials where multiple layers of metal halide octahedra are separated by the organic molecules, for instance forming Ruddlesden-Popper or Dion-Jacobson structures. The emissive properties of these materials are intricately linked to the structural dynamics and formation of possible defects in the inorganic layers.

In this work we explore how modifications of the large organic amonium ion can affect the structural dynamics of the inorganic layer, combining molecular dynamics simulations with time-resolved spectroscopy. Using time-resolved fluorescence and ultrafast transient absorption spectroscopy we have studied the photophsyical behavior of 2D perovskites with a range of different organic cations inorder to gain insight in the relation between the structure and the exciyted state dynamics, These measurements indicate marked differences that can not solely be attributed to changes in the average structure of the materials.

To explain these differences we have performed classical molecular dynamics simulations for a variety of structures, for instance aliphatic alkyl chains, amonium ions containing aromatic moieties such as phenyls or perylene, but also di-functional ions containing two binding sites that can connect to an inorganic pervskite layer on both sides. The results indicate that there are marked differences between the different structures in terms of their structural rigidity. Multi-layer Ruddlesden-Popper structures are generally more rigid than single layers, however, the rigidity of the single layer structures can be strongly enhanced by engineering of the interactions between organic cations, for instance by introduction of large conjugated ions. In addition, di-functional ligands resulting in Dion-Jacobson like structures also lead to more rigid structures. Comparison with the experimental results allows us to derive some design rules that indicate how engineering of the organic part of the structure can help in improving the the emissive properties of the materials that is mostly due to the inorganic layer structure.

Atomic Layer Deposition of 2D Perovskite Passivation Layers Jacob Vagott, Carlo Andrea Riccardo Perini and Juan Pablo Correa Baena; Georgia Institute of Technology, United States

In order to further advance perovskite solar cell efficiency from the current record of 25.2%, it is important to minimize perovskite perovskite crystal defects and increase interface performance through passivation layers. 2-D perovskites have shown great potential as passivation layers but are primarily deposited by solution processing. Drawbacks of using solution processing for 2-D perovskite films include toxicity of the solvent, potential insolubility of the precursors, and lack of precise thickness control. Atomic layer deposition (ALD) could be a solution to these problems. ALD allows for the deposition of highly uniform layers of perovskite with great control over the final thickness of the film. Self-limiting in nature, ALD processes may allow for depostion of monolayers of perovskite with more control than solution processing techniques. Although an established deposition technique, ALD processes for perovskites have yet to be developed. Through this work, we consider ALD as a method of depositing 2-D perovskites as passivation layers for perovskite solar cells. These passivation layers are further incorporated into devices and their effect on solar cell efficiency is analyzed.

Understanding the Effects of Sr Chemical Doping on Pb/Sn Based Perovskite Films Hurriyet Yuce Cakir[1,2] and Juan Pablo Correa Baena[2]; [1]Izmir Institute of Technology, Turkey; [2]Georgia Institute of Technology, United States

Organometal halide perovskites have been in the spotlight of semiconductor science over the past decade. Their exceptional electronic-optical properties and easy production from solution give them an edge over the semiconductor applications. The organic-inorganic halide perovskite solar cells (PSCs) have attracted the incredible attention of the researchers working on solar cells owing to a rapid increase in the efficiency of 25.5% since 2009[1,2].
Furthermore, tin/lead (Sn/Pb)-based perovskite offers lower toxicity compared to the lead-based perovskites[3]. Their bandgaps are close to 1.3-1.4 eV which is the ideal bandgap of an absorber layer in a solar cell regarding the Shockley-Queisser model[4].
In this study, we have performed SrI_2 addition (ranging from 0.1% to 5.0% concentrations) to the $(FASnI_3)_{0.8}(MAPbBr_3)_{0.2}$ perovskite to improve their physical properties. Moreover, we have investigated the incorporation of SrI_2 into perovskites impacts on the morphological and optical properties of perovskite films.

F.EL08.13.06

Revealing the Internal Luminescence Quantum Efficiency of Perovskite Films via Accurate Quantification of Photon Recycling Paul Fassl[1], Vincent Lami[2], Ian Howard[1], David Becker-Koch[2], Felix Berger[2], Lukas Falk[2], Raphael Schmager[1], Jana Zaumseil[2], Bryce Sydney Richards[1], Yana Vaynzof[2] and Ulrich W. Paetzold[1]; [1]Karlsruhe Institute of Technology, Germany; [2]Heidelberg University, Germany

The high refractive index of perovskite semiconductors at their emission wavelength (n ~ 2.3-2.6) results in a narrow emission escape cone and a large amount of photoluminescence (PL) to be trapped within perovskite thin films. Due to strong band edge absorption and a very small luminescent stokes shift, this effect leads to considerable photon reabsorption and reemission - an effect known as photon recycling (PR) [1] - as well as a concurrent red-shift of propagating PL due to emission filtering [2]. As recently highlighted, the self-absorption induced redistribution of charge carriers and outcoupling of propagated PL can lead to a significant misinterpretation of measurements of the intrinsic bimolecular recombination and charge carrier diffusion coefficients as well as of asymmetric PL spectral shapes [3, 4]. For perovskite films with low non-radiative recombination and parasitic absorption losses, PR can be of great advantage as it allows higher charge carrier densities at steady-state and thus increased device open-circuit voltage [5]. However, most current models still start from the simplified assumption that all initially trapped PL will be reabsorbed at some point without the possibility of being outcoupled, likely overestimating the effect of PR [6]. In this study, we show that in external photoluminescence quantum efficiency (PLQE) measurements employing an integrating sphere setup, the PL spectra of polycrystalline perovskite films with layer thicknesses typically employed for thin film solar cells (~150-500 nm) exhibit a notable red-shift and broadening. Such asymmetric PL spectra are often ignored or misinterpreted in the literature. We developed an all-optical model that considers both PR and outcoupling of initially trapped filtered PL due to scattering, which can reproduce spectral shapes with varying extents of red-shifts. We determined the true PL spectral shape as well as the absorption spectrum via high resolution confocal PL measurements and photothermal deflection spectroscopy respectively. Our model allows to estimate the total escape probability in addition to the initially generated internal PL intensity and thus to determine the internal PLQE of perovskite thin films. We confirm our assumptions by various control experiments and Monte Carlo simulations, benchmarking the model for perovskite thin films with different grain size, thickness and composition. Our approach serves as a new guideline for estimating these important parameters directly from measurements of the external PLQE and PL spectrum using an integrating sphere setup. [1] L. M. F.EL08.13.07

Energy Level Alignment of Formamidinium Tin Iodide with Organic Contact Materials Jonas Horn, Pascal Schweitzer and Derck Schlettwein; Justus Liebig University Giessen, Germany

The alignment of energy levels at the interface of perovskite absorber and adjacent hole- and electron-transporting material affects the formation of space-charge regions and interfacial recombination. These have consequences for charge transport in the layers and, therefore, for the efficiency of devices. We measured this alignment by the use of Kelvin-probe-force microscopy (KPFM) to gain a detailed understanding of this alignment of energy levels. This study is focused on Formamidinium tin iodide (FASnI3) as perovskite absorber. This material avoids the toxicity problems of lead and is known to yield the highest power conversion efficiencies amongst all lead free perovskite absorbers. The most common solar cell geometry for FASnI3 implements C60 as electron-transporting material, which is prepared on FASnI3 by physical vapor deposition (PVD). Intermittently to PVD, we use KPFM to simultaneously monitor morphology and work function of C60 during its growth on FASnI3. We show that a sufficiently high deposition rate is needed to avoid island formation of C60 and obtain a homogeneously covering film with constant work function. We further show that the width of the space charge layer in C60is larger than the film thickness often implemented in perovskite solar cells (20 nm - 30 nm). A band bending in the range of 300 meV is observed and consequences for prospective device operation are discussed.

F.EL08.13.08

The Underlying Mechanism of Surface Defect Passivation Process for Organohalide-Lead Perovskite Nanocrystals Artavazd Kirakosyan[1], Duc Chinh Nguyen[1], Min-Gi Jeon[1], Jae Hyuck Jang[2], Jihoon Choi[1] and MoonRyul Sihn[1]; [1]Chungnam National University, Korea (the Republic of); [2]Korea Basic Science Institute, Korea (the Republic of)

Organolead halide perovskite nanocrystals (NCs) have emerged as a versatile and promising active material for many optoelectronic applications such as solar energy harvesting, light-emitting device, and photodetectors owing to their size- and composition-dependent optoelectronic properties. Although the extensive studies on their optical and electronic properties have been studied in the last several years, their low stability, structural integrity, and poor luminescence stability associated with the fast attachment-detachment dynamics of surface capping molecules during post-processing limit their practical applications in optoelectronics. Therefore, an in-depth understanding of the surface chemical processes is required. We found that the amine group (-NH3+) immobilizes Br- anion at the corner of undercoordinated PbBr64- octahedron on the MAPbBr3 surface resulting in a charge-balanced Pb-Br framework where Br/Pb ratio is slightly higher than stoichiometry, and thus provides exciton radiative recombination and high photoluminescence quantum yield. In contrast, the oleic acid is not able to coordinate with the surface moieties of the perovskite, but rather carboxyl acid groups (-COO-) etch Pb2+ into solution when only acid was used. Interestingly, a mixture of oleic acid and amine-functionalized surfactants was found to promote amine conversion to ammonium ion (-NH2 + H+ ® -NH3+), which is favorable for their localization on the surface. Our results show that the Br vacancies at the non-passivated surface result in a reduction of Pb2+ to Pb0 by trapping the electrons generated from the exciton dissociation, which provides the main pathway for exciton trapping. Acknowledgment This work is supported by the National Research Foundation of Korea (NRF) grant funded by the Korean government (No. NRF-2019R1I1A2A01060608) and by Nano-Material Technology Development Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Science, ICT and Future Planning. F.EL08.13.11

Impact of Temperature and Humidity on the Stability of the Optical Properties and Structure of Formamidinium Lead Iodide Thin Films and Solar Cells Marie Solange Tumusange, Biwas Subedi, Cong Chen, Maxwell M. Junda, Juan Zuo, Zhaoning Song, Yanfa Yan and Nikolas Podraza; University of Toledo, United States

Organic-inorganic lead halide perovskite polycrystalline thin films used as absorber layers in high efficiency solar cells have direct band gaps, high absorption coefficients, and potentially low-cost solution-based fabrication processing. However, these materials are inclined to degradation with exposure to humidity, oxygen, heat, and ultraviolet light. Formamidinium lead iodide (FAPbI3) is an attractive composition perovskite as it has a more symmetric crystal structure due to a larger cation radius for FA compared to that for methylammonium (MA) as well as an elevated decomposition temperature for improved stability. Even though FAPbI3 is among the more stable perovskite compositions, solar cells incorporating these absorbers still degrade with atmospheric exposure over time. Here we study the behavior of FAPbI3 film structure and complex optical properties under controlled temperature variations and relative humidity (RH) exposure. In situ real time spectroscopic ellipsometry (RTSE) measurements are collected over the near infrared to ultraviolet spectral range (0.75-5.9 eV) for polycrystalline FAPbI3 thin films deposited on glass substrates which are then held at different temperatures, ranging from 7 to 70oC, in a sealed nitrogen chamber with controlled 0, 26, and 85% RH introduced. From RTSE, the optical response in the form of complex dielectric function (e = e1 + ie2) spectra is deduced using a parametric model accounting for above band

gap critical points, the direct band gap, an Urbach tail, and degradation induced sub-gap absorption due to defects. Variations in parameters describing spectra in e are tracked as functions of temperature, controlled RH, and the amount of time films are held under those conditions. Changes in bulk thickness, surface roughness thickness, and surface roughness relative density are also tracked with time under these conditions. For example, RTSE indicates no change in structure and minimal changes in e at 0% RH regardless of temperature. However, when FAPbI3 is exposed to 26% RH at 7oC, RTSE indicates changes in parameters describing e and structure, such as increases in film thickness with time indicative of water intercalation. To the contrary, slight film densification is observed over time when held at 26% RH and 70oC. These RTSE studies show that deviations from near room temperature with controlled relative humidity induces more changes in optical and structural properties with time than when the sample is exposed to only humidity. In all cases of RH exposure sub-gap absorption increases with time, most notably in widening of the Urbach tail obtained from the parametric model for e. To further study how other ambient conditions affect perovskite stability, RTSE is performed for FAPbI3 with exposure to controlled amounts of both oxygen and relative humidity as a function of temperature. RTSE is applied directly to measure a FAPbI3 based solar cell to track changes in the perovskite absorber over time and identify potential correlations with device performance.

F.EL08.13.12

Diagnosis of Optical and Electrical Losses in Organic-Inorganic Lead Halide Perovskite Photovoltaics via External Quantum Efficiency Modelling Biwas Subedi, Chongwen Li, Zhaoning Song, Maxwell M. Junda, Kiran Ghimire, Yanfa Yan and Nikolas Podraza; University of Toledo, United States

Organic-inorganic lead halide perovskite-based photovoltaics (PV) exhibit high initial efficiency, can be processed at potentially low cost, and material bandgaps can be tuned by composition. Solution-processing enables fabrication of a range of different ABX3 (A: methylammonium—MA, formamidinium—FA, Cs; B: Pb, Sn; X: I, Br, Cl) perovskite compositions to meet these needs in single or tandem junction PV. Unfortunately, these perovskites may degrade upon exposure to relative humidity and oxygen in ambient air, during device processing, and overtime during device operation. Like all PV devices, performance depends on the characteristics of each material and interfaces between layers to minimize sources of optical and electronic losses. External quantum efficiency (EQE) simulations of perovskite PV assess sources of parasitic optical losses with input complex optical response of all component materials and known multiple layer device structure. From these simulations, the optical performance of devices with different structures or component materials is predicted. Comparison of simulated EQE with experimental measurement validates the optical model when simulated and experimental EQE match but also more importantly identifies electronic losses such as incomplete carrier collection when experimental EQE is less than the simulation. Obtaining the most accurate input complex optical response of perovskite films and layer thicknesses in devices is necessary to maximize the amount of information gained from EQE and its modeling. Toward this end, spectroscopic ellipsometry (SE) over the near-infrared to the ultraviolet wavelength range (0.73-5.9 eV) is used to characterize the complex optical response of solution-processed perovskite films of different compositions. Photothermal deflection spectroscopy (PDS) and unpolarized transmittance complement SE by enhanced sensitivity to low values of absorption coefficient (?) in the vicinity of the bandgap. Extension to low values of ? enables detection of exponential band tailing and Urbach Energy (EU), with narrower EU indicative of more ordered and higher electronic quality material. A parametric optical property model has been developed which includes contributions from electronic transitions above the bandgap, the direct bandgap, an exponentially decaying Urbach tail, and sub-gap absorption due to defects. Complex optical properties of perovskite films, including wide-bandgap FA1-xCsxPb(I1-yBry)3 and narrow-bandgap (FASnI3)x(MAPbI3)1-x compositions, in both as-prepared and degraded states are determined. SE data is collected for complete perovskite PV to deduce layer thicknesses and perovskite complex optical properties within the device. This information serves as direct input for EQE simulation. Comparison with perovskite PV experimental EQE enables the deduction of optical and electronic device performance losses arising from perovskite composition and device architecture, variations in near bandgap perovskite optical response resulting from complete device processing, and perovskite degradation during solar cell operation. As an example, similar simulated and experimental EQE in (FASnI3)x(MAPbI3)1-x (0.3 ? x ? 0.7) perovskite PV validates the optical model and indicates minimal losses. In another case, for FAPbI3 PV comparisons between simulation and experimental EQE indicate sources of both optical and electronic losses arising from device processing.

Enhanced Charge Extraction Through Double-Layered Electron Transfer Films for Hybrid Perovskite Planar Solar Cells Jihyun Kim, Hye Ri Jung, Yeon Soo Kim and William Jo; Ewha Womans University, Korea (the Republic of)

The electron transfer film (ETF) plays an important role in obstructing recombination of electrons and holes between the perovskite layer and fluorine-doped tin oxide in planar perovskite solar cells (PSCs). In addition, at the compact spin-coated SnO2 ETF, morphological defects, such as pinholes and cracks, due to roughness of the substrate seriously impact on the performance of PSCs. Here, we investigate the variables that can control the charge extraction using spin-coated SnO2,

sputtered TiO2 and double-layered (DL) ETF composed of TiO2 on SnO2 and SnO2 on TiO2. We determined the resistance, mobility, conductivity and carrier concentration of double-layered ETF based on PSCs by a 4-probe method. The electrical properties show that the DL-ETF can effectively reduce the trap density at perovskite/ETF interface, promote the electron transfer, and suppress the interface recombination rather than SnO2 alone. The band structure and the carrier transport mechanism at perovskite/DL-ETF interface were explained by conductive atomic force microscopy, Kelvin probe force microscopy and ultraviolet photoelectron spectroscopy. Complementary composite DL-ETF has been found to eliminate severe current leakage inside the device, reducing interface defects and hysteresis. More importantly, DL-ETF accelerates at electron extraction and transport owing to the excellent mobility. Finally, DL-ETF based PSCs yield higher power conversion efficiency with improved JSC than the device with SnO2 alone. Therefore, these are beneficial for reducing the recombination of carriers in the electron traps, leading to the enhancement of device performance.

Leveraging Electrochemical Techniques to Augment and Accelerate Halide Perovskite Technology Development Moses Kodur[1], Ross Kerner[2], Zachary Dorfman[1], Justin H. Skaggs[1], Taewoo Kim[1], Joseph J. Berry[2] and David P. Fenning[1]; [1]University of California, San Diego, United States; [2]National Renewable Energy Laboratory, United States

Improving the repeatability and operational stability of interfaces in perovskite devices is crucial to extend device lifetime. With each sequential step in perovskite device fabrication comes a risk of a failed device integration or an interaction that leads to longer-term device instability. Here, we present simple electrochemical techniques to evaluate fundamental properties of charge transport layers and limits of stability before completion of a full device stack, with the objective of improving batch yield, deconvoluting the troubleshooting process, and accelerating the development of new perovskite absorbers, their contact layers, and high-efficiency devices.

We focus on two exemplary measurements using easily accessible aqueous electrolytes. First, we show that an outer sphere redox couple such as the ferro/ferricyanide system allows facile evaluation of the semiconducting properties (conduction band minimum position, doping level, etc.) of SnO_x electron transport layers. The anodic and cathodic features in cyclic voltammograms of the SnO_x are correlated to final solar cell efficiency and offer an early screen of quality. Second, we show that ionic permeability/reactivity of SnO_x layers, which can lead to irreversible absorber degradation under bias, can be rapidly evaluated by potentiostatic measurements in the presence of organohalide salts. This technique reveals the influences of processing condition and deposition method on susceptibility to bias-induced degradation reactions.

These process control measurements can be readily adapted to devices of any area and are compatible with industry-scale fabrication techniques to improve process reliability and reproducibility. While our work focuses on the development and characterization of SnO_x layers, the fundamental principles can be adapted for a wide variety of charge transport layers so long as the proper electrochemical set-up is implemented, making this method a powerful tool for halide perovskite development.

Wide-Bandgap Perovskites in the Spotlight—Multimodal Study of Photo-Induced Halide Segregation in Solar Cells Kunal Datta, Bas T. van Gorkom, Matthew J. Dyson, Martijn M. Wienk and Rene A. Janssen; Eindhoven University of Technology, Netherlands

Segregation of illuminated mixed-halide perovskites into iodide- and bromide-rich domains presents a critical bottleneck in the application of wide-bandgap absorbers in single- and multi-junction architectures. And while its occurrence has been well-studied in thin films, the influence on operational solar cells lacks sufficient understanding.
This work employs a multimodal characterization procedure to observe the slow progression of halide segregation in efficient solar cells prepared in the p-i-n architecture using sequentially processed perovskite absorbers. Photoluminescence spectroscopy is used to identify the stages that demixing of halide ions entails while simultaneous tracking of photovoltaic parameters allows correlating performance degradation to the migration of ionic species in each stage. A new stage of the process is thus observed upon prolonged illumination. Characterization of sub-bandgap features reveals the occurrence of photo-induced defect formation whose suppression through cationic substitution provides a strategy for stabilization of wide-bandgap compositions against halide segregation.

F.EL08.13.19
Elucidating the Role of Electrochemical Halide Reactions in Perovskite Optoelectronic Devices Under Prolonged Reverse Bias Jay B. Patel[1,2], Luca Bertoluzzi[3], Kevin A. Bush[3], Caleb C. Boyd[3,1], Ross Kerner[1] and Michael McGehee[2,1]; [1]National Renewable Energy Laboratory, United States; [2]University of Colorado Boulder, United

States; [3]Stanford University, United States

Partial shading of a solar module can bring a set of cells within the module to operate under reverse bias. When a solar cell is shaded in a module, the photogenerated current falls and a negative voltage (reverse bias) builds up as the other illuminated cells in series try to push current through it. Moreover, metal-halide perovskite photodetectors are regularly operated in reverse bias, and therefore it is critical to understand how these devices behave under reverse bias. Previous studies have shown that perovskite solar cells with a wide variety of compositions and contacts exhibit unusual behavior, compared to typical silicon solar cells, in reverse bias that includes both reversible performance loss and non-reversible degradation. [1, 2] Furthermore, we have shown that when a perovskite solar cell is held under reverse bias, the mobile ions move in a way such that there is favorable band energetics to allow for hole injection into the perovskite, yet the consequence of this process was unclear. [1]
Recent investigations have shown that photogenerated holes can induces electrochemical oxidation of halides into halogens. [3, 4] These halogens can leave the perovskite absorber and diffuse into contacts and cause further detrimental reactions with the electrodes. [5] To elucidate and understand the degradation mechanisms that occurs when perovskite solar cells are held under reverse bias, we have developed an advanced drift-diffusion model that incorporates an electrochemical term that can explain the short-circuit, open circuit and fill factor losses we experimentally measure. Our model conclusively shows that the injected holes can trigger the oxidation of halides to form neutral halogen interstitials. The density of halogen interstitials is much higher in reverse bias because there are hardly any electrons available to reduce the halogens back into halides. The resulting halogens act as bulk recombination centers and lead to a sharp decline in all the JV device characteristics. While the interstitial halogen density will decay when the cell is finally operated in forward bias, permanent degradation will occur if the halogen diffuses out of the perovskite layer into the transport layers or electrodes. Finally, we discuss how changing parameters such as the mobile ion density or the permeability of contacts can positively influence device performance and stability.

Anionic Diffusion in Two-Dimensional Halide Perovskite Heterostructures Akriti Akriti[1], Enzheng Shi[1], Stephen B. Shiring[1], Jiaqi Yang[1], Yao Gao[1], Cindy L. Atencio-Martinez[2], Alan J. Pistone[1], Peilin Liao[1], Brett Savoie[1] and Letian Dou[1]; [1]Purdue University, United States; [2]University of Los Andes, Colombia

The soft crystal lattice of hybrid halide perovskites facilitates anionic diffusion which impacts material stability, optoelectronic properties and solid-state device performance. Two-dimensional (2D) halide perovskites with bulky organic barriers have been used for improving the extrinsic stability as well as suppressing intrinsic anionic diffusion. With this strategy, devices with enhanced stability and reduced hysteresis have been achieved. Nevertheless, a fundamental understanding of the role of organic cations in inhibiting anionic diffusion across the perovskite-ligand interface is missing. Through this study, we demonstrate a quantitative investigation of the anionic inter-diffusion in atomically sharp and flat 2D heterojunctions between two arbitrarily determined phase-pure halide perovskite single crystals. Stark differences are observed in anion diffusion across 2D halide perovskite lateral and vertical heterostructures. Halide inter-diffusion in lateral heterostructures is found to be similar to the classical Fickian diffusion featuring continuous concentration profile evolution. However, vertical heterostructures show a "quantized" layer-by-layer diffusion behavior governed by a local free energy minimum and ion-blocking effects of the organic cations. Surprisingly, halide inter-diffusion coefficients for 2D perovskites capped with short aliphatic organic cations (e.g. butylammonium) are only 1~2 order of magnitudes smaller than that of 3D perovskites, suggesting the ineffectiveness of these cations in blocking the anionic migration. Furthermore, we found that bulkier and more rigid π-conjugated organic cations inhibit halide inter-diffusion much more effectively ($D < 10^{-20}$ m^2/s) compared to aliphatic cations. These results offer significant insights into the mechanism of anionic diffusion in 2D perovskites and provide a new materials platform for heterostructure assembly and device integration.

Chemical Diversity in Lead-Free, Layered Double Perovskites—A Combined Experimental and Computational Approach Brenda Vargas[1], Raúl Torres[1], Diana Reyes-Castillo[1], Joelis Rodríguez-Hérnandez[2], Milan Gembicky[3], Eduardo Ménendez-Proupin[4] and Diego Solis-Ibarra[1]; [1]UNAM, Mexico; [2]Centro de Investigaciones en Química Aplicada, Mexico; [3]University of California, United States; [4]Universidad de Chile, Chile

Akin to the expansion in compositional diversity that halide double perovskites provided to three-dimensional perovskites [1-2], layered double perovskites could further expand the diversity of two-dimensional (2D) perovskites, and therefore, they could also enhance the properties or expand the possible applications of such materials [3]. Despite the great promise of halide 2D double perovskites, up to date, there are only four confirmed members of this family of materials [3-6]. Herein, we explore 90 hypothetical new members of this family of materials by a combined theoretical, computational, and experimental method. The combination of these tactics allowed us to predict several new materials, out of which we experimentally synthesized and characterized five new layered double perovskites, some of which show promising properties for their use in photovoltaics and optoelectronics. Further, our work highlights the vast diversity of compositions and therefore of applications that double-layered perovskites have yet to offer. References [1] X. Zhao, D. Yang, J. Ren, Y. Sun, Z. Ion Exchange-Diffusion Mechanisms in Transforming Calcite into Lead (Pb)-Free Perovskite Light Absorbers Jonathan B. Junio, Marlon T. Conato and Candy C. Mercado; University of the Philippines Diliman, Philippines

The synthesis of perovskite materials has gone beyond the traditional wet chemistry routes into other methods such as a sequential ion exchange process that can produce perovskite materials from calcite in either thin film or bulk form. The use of lead (Pb), the most successful element in terms of PSC efficiency performance, was already successfully demonstrated in an ion exchange process. In this work, tin (Sn) is chosen since it has the most potential to replace Pb since they are on the same group and for the similarity in ionic radii of their ions (Pb2+, Sn2+) at 1.19 and 1.02 ?, respectively. Methyl ammonium tin triiodide (MASnI3) has a lower bandgap (1.2 to 1.4 eV) that induces broader absorption spectrum as compared with the benchmark MAPbI3 counterpart (1.55 eV). The second alternative - strontium (Sr) has an ionic radius of 1.18 ? indicating possible ion exchange in the strontianite structure. The band gap for the Sr perovskite was estimated at 3.6 eV, considerably higher than that for the lead perovskite and therefore not suitable for direct solar cell applications but can be used as a top cell in tandem architectures. These ion exchange processes are observed using x-ray absorbance and photoelectron spectroscopies to elucidate the underlying mechanisms of the sequential ion exchange process. These will shed light into the material transformation with shape preservation from the raw shells or single crystal calcite towards the intermediate carbonate material and eventually, the Pb-free perovskite material.

A Comparison of Three Emerging Bi-Based (Oxy)Halide Absorbers Grown from Metallic Precursors Andrea Crovetto, Alireza Hijijafarassar, Ole Hansen, Brian Seger, Ib Chorkendorff and Peter Vesborg; Technical University of Denmark,

Denmark

The bismuth-based (oxy)iodides BiI3, BiOI and AgxBiIx+3 share similar layered crystal structures, optimal band gaps for top absorbers in tandem solar cells, and moderate growth temperatures. Similarly to halide perovskite absorbers, they contain a heavy cation with a lone pair of electrons (Bi3+) which has been proposed as one of the features enabling defect tolerance in perovskites. We have grown and characterized BiI3, BiOI, and Ag3BiI6 absorbers and solar cells in a systematic manner by employing a consistent synthesis method ((oxy)iodization of metallic precursor) and a consistent analysis routine. In this way, the individual strengths and weaknesses of the three absorbers, as well as their common challenges, can be outlined. The radiative efficiency of the three materials is within the same order of magnitude, thus indicating a similar degree of defect tolerance. Control of growth orientation should be a priority for this class of materials in view of their anisotropic properties. P-type bulk doping and selection of hole transport layers with deep valence bands could also improve performance. At the device level, we report an improved open circuit voltage of BiI3 solar cells with respect to the state of the art, and we report a proof-of-concept Ag3BiI6/silicon tandem cell. Beyond photovoltaics, the very low dark diode ideality factor in BiI3 devices and the existence of both electronic and ionic conduction in Ag3BiI6 may open up alternative unexpected applications in other fields.

F.EL08.15.03
Boosting the Self-Trapping Emissions in Zero-Dimensional Perovskite Heterojunctions Jun Yin[1], Jean-Luc Bredas[2], Osman M. Bakr[1] and Omar F. Abdelsaboor[1]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]Georgia Institute of Technology, United States

Zero-dimensional (0D) inorganic and hybrid perovskites have attracted great interest for white-light emitting applications due to their broadband emissions originating from the self-trapping excitonic states. In this work, we study a series of 0D inorganic perovskites, A4PbX6 and A4SnX6 (A = K, Rb, and Cs; X = Cl, Br, and I), under the theoretical framework of one-dimensional configuration coordinate diagram using density functional theory (DFT) calculations. We demonstrate that the formation of self-trapping excitonic states of A4PbX6 and A4SnX6 is attributed to the local structural distortion of individual [PbX6]4- and [SnX6]4- octahedron (i.e., the octahedral shrinking under photoexcitation). We further predict the broadband emissions of a new family of 0D A4PbX6/A4SnX6 heterostructures, and find that among these crystal structures Rb4PbI6/Rb4SnI6 exhibits an increased photoluminescence efficiency with good stability as compared to pristine Rb4SnI6. Our findings provide a new material design strategy for boosting the self-trapping emissions with improved stability using 0D inorganic perovskite heterostructures.

F.EL08.15.05
Single-Source Deposition of Double Perovskites for Optoelectronic Devices Nathan Rodkey[1,2], Stan Kaal[2], Paz Sebastia-Luna[1], Yorick A. Birkhölzer[2], Franciso Palazon[1], Henk Bolink[1] and Monica Morales-Masis[2]; [1]Universidad de Valencia, Spain; [2]University of Twente, Netherlands

As halide perovskites (PVKs) continue to garner scientific interest for their potential to enhance efficiencies of solar cells and LEDs, a push has been made towards lead-free and completely inorganic PVKs with increasingly complex stoichiometries. One example of this is the double PVK $Cs_2AgBiBr_6$and $Sn:Cs_2AgBiBr_6$. Synthesis of thin films with these complex stoichiometries is challenging due to the distinct volatility of the constituent elements, usually requiring multi-step or multi-source processes. Here we explore Pulsed Laser Deposition (PLD) as a route to grow these types of complex materials with a single source. PLD offers the advantage of being a volatility-insensitive thin film synthesis technique which we use to demonstrate single-source deposition of $Cs_2AgBiBr_6$ and $Sn:Cs_2AgBiBr_6$. For this, solid targets are made first by mechanochemical synthesis of powders, followed by a uniaxial and isostatic pressing to form the powders into dense, compact targets. X-ray diffraction (XRD) is used to verify the desired PVK phase is maintained along each step of target fabrication. Laser-ablation of the double PVK targets in vacuum leads to formation of $Cs_2AgBiBr_6$ and $Sn:Cs_2AgBiBr_6$ double PVK films after optimization of the deposition parameters. We discuss the effects of deposition pressure and laser fluence on the formation of stoichiometric and phase-pure films, as well as the critical role of the thermalization of the source elements to achieve stoichiometric transfer. In addition to the structural properties, the optoelectronic properties of the films were studied by UV-Vis-NIR spectrophotometry and time-resolved photoluminescence. Notably, >1 um thick films are deposited and all films present high structural stability over the course of 3 months, without the need for an annealing step. This work represents an important step forward in the development of controlled growth and future scalability of complex halide perovskites for efficient optoelectronic devices.

F.EL08.16.06
Improving Blue Light Emission of CsPbBr3 Nanoplatelets via Post-Synthesis Surface Passivation Jinu Park, Joonyun Kim and Byungha Shin; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Lead halide perovskite is considered as a potential candidate for the next generation light emitting diodes (LEDs) due to its extremely narrow light emission spectrum with a typical full width half maximum (FWHM) < 20 nm. In particular, all-inorganic CsPbBr3 has demonstrated the near unity photoluminescence quantum yield (PLQY) for green light emission. A more challenging, yet technologically important, task is developing a high performance blue light emitter. By partially replacing Br of CsPbBr3 with Cl, the emission wavelength can be adjusted to the blue emission; however, CsPbBr3-xClx , suffers from ion migration and phase segregation which result in low PLQY and poor stability. Here, we present a synthesis method to produce nanostructure CsPbBr3 in the form of nanoplatelets (NPLs) that is capable of emitting blue light without the need for anion-substitution. Nanoplatelets with 2 monolayer (ML) and 3 ML of thickness yielded photoluminescence (PL) peak at 435nm with an extremely narrow FWHM of 14.2 nm and PL peak at 456nm with FWHM of 19.6nm, respectively. The luminescence of these nanoplatelets was further improved by post-synthesis treatment with tetrafluoroborate salts-almost 1150% increase in PL intensity was observed without a noticeable broadening of the PL spectrum. Details of the results and discussion of a possible mechanism behind the improvement with the post-synthesis treatment will be presented.

F.EL08.16.07
Highly Luminescent Vacuum-Evaporated All Inorganic CsPbBr3 Perovskite Light Emitters with a Polymer Auxiliary Layer Nakyung Kim, Mingue Shin and Byungha Shin; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

All inorganic halide perovskite CsPbBr3 has emerged as the next-generation material for light-emitting diodes (LEDs) due to its high color purity with a narrow spectral width (< 20 nm) and tunable band gap by adjusting the composition of halide anions, i.e. substitution of Br with I or Cl. Considering the needs for large-area scalability and fine control of the emitter thickness, vacuum-deposition will be a more commercialization-friendly technique to produce perovskite films for LEDs. Here, we prepare CsPbBr3 light emitters by thermal co-evaporation of CsBr and PbBr2 sources. The luminescence of the vacuum-deposited CsPbBr3 films was greatly improved by introducing a poly-ethylene oxide (PEO) layer underneath the CsPbBr3-almost 300-fold increase in photoluminescence quantum yield (PLQY) with the PEO layer compared to the reference sample (CsPbBr3/glass). It is believed that the interaction between PEO and Pb2+ ions leads to the passivation of non-radiative recombination defects. After the careful optimization of the PEO layer thickness and post-deposition thermal treatments of CsPbBr3, we have demonstrated PLQY of 30% from a peak at 521 nm with full-width-half-maximum of ~17nm. Furthermore, the samples exhibit excellent ambient stability. Details of the results and analysis will be discussed.

F.EL08.16.08
Ultra Sensitive Perovskite Halide Based Room Temperature Ammonia Gas Sensor Using Flexible Paper Electronics Avisek Maity and Barnali Ghosh; S.N. Bose National Centre for Basic Sciences, India

In current days, development and search of new materials for solid state thin film gas sensor to detect toxic gases, particularly using nanomaterial for their enhanced functionality, is growing rapidly as view point of both environmental and clinical application. Particularly, gas sensor with low power consumption, room temperature operation, portability and cost effectiveness is highly demandable. Perovskite halides, namely methyl ammonium lead iodide (CH3NH3PbI3) / MAPI is widely popular as photovoltaic and optoelectronic material. Recently we have found that MAPI can act also as an active material for gas sensing to trace hazards pollutants. Ammonia (NH3) not only is one of harmful pollutants in nature but also treated as a biomarker for kidney disease via exhaled breathe analysis in recent days. Thus a room temperature , cost effective, very high sensitivity NH3 gas sesor could extremely beneficial in view point of both environmental and clinical issues. The sensor using MAPI can trace ammonia gas (NH3) by a visual color change method as well as by electrical read out [1-2]. Here we have shown a MAPI based electrical sensor grown on a cheap paper as a substarte for tracing NH3 gas. The paper sensor has a very high sensitivity (98% for 10 ppm NH3) towards NH3 gas at room temperature and sub ppm (<1 ppm) detection capability (down to 10 ppb) by its noise limited detectibility [2]. This ultra high response down to ppb level

can be extremely suitable for exhaled breathe analysis. Current through the sensor increases nearly by one order on exposure to only 10 ppm NH3 gas with a bias voltage of 1 V DC and hence the sensor consumes extremely low power (~ few nano watts). The paper sensor is also highly selective to NH3 gas and maintains stability over 150 days within decrease of 10% sensitivity. This could open up the possibility of perovskite halide (MAPI) as next generation solid state room temperature gas sensor for rapid and cost effective detection using paper electronics. References: [1] Maity, A; Ghosh,B; Fast Response paper based visual color change gas sensor for efficient ammonia detection at room temperature; Scientific Reports (2018), 8,16851 [2] Maity, A; Raychaudhuri, A.K.; Ghosh,B ; High sensitivity NH3 gas sensor with electrical readout made on paper with perovskite halide as sensor material; Scientific Reports (2019) ,9,7777 I

Suppressing Cation Migration in Triple-Cation Lead Halide Perovskites Ilia M. Pavlovetc[1], Michael Brennan[1], Sergiu Draguta[1], Anthony Ruth[1], Jeffrey A. Christians[2], Taylor Moot[3], Steven Harvey[3], Joseph Luther[3] and Masaru Kuno[1,1]; [1]University of Notre Dame, United States; [2]Hope College, United States; [3]National Renewable Energy Laboratory, United States

Mixed cation and anion $APbX_3$-type lead halide perovskites [A^+=Cs^+, $CH_3NH_3^+$ [MA^+], or $(NH_2)_2CH^+$ [FA^+]; X^-=Br^- or I^-] have received extensive attention for use as low cost, efficient light harvesters in solar cells. Issues regarding long-term active layer stability, however, remain unresolved. Electric field-induced ion migration in perovskite solar cells is of particular concern because it results in current-voltage (J-V) hysteresis, metastable power conversion efficiencies and accelerated active layer degradation. Facile ion migration within the perovskite lattice stems from relatively fragile ionic bonding between heavy, low-valence ions. This results in small activation barriers and correspondingly moderate diffusion coefficients for halide anions and A-site cations. The mobile nature of A^+ cations and X^- anions is thus an instability of all metal halide perovskites. While numerous recent studies have focused on halide migration and segregation, significantly less work has gone into investigating cation migration in metal halide perovskites. This is especially true of double- and triple-cation $FA_xMA_yCs_{1-x-y}PbX_3$ alloys.
Here, we demonstrate that bias-induced cation migration is mitigated in mixed α-phase/δ_{ortho}-$CsPbI_3$ triple-cation $FA_xMA_yCs_{1-x-y}PbI_3$ films (referred as α/δ-$FA_{0.33}MA_{0.33}Cs_{0.33}PbI_3$). We verify this by comparing cation movement in lateral devices and working solar cells made of pure α-phase double-/triple-cation perovskite phase systems ($FA_{0.85}Cs_{0.09}PbI_3$ and $FA_{0.76}MA_{0.15}Cs_{0.09}PbI_3$) as well as α/δ-$FA_{0.33}MA_{0.33}Cs_{0.33}PbI_3$. The effects of bias-induced A^+ migration on perovskite stability and device performance are assessed via infrared photothermal heterodyne imaging (IR-PHI), time-of-flight secondary ion mass spectrometry (ToF-SIMS), and solar cell operational stability testing. Enhanced α/δ-$FA_{0.33}MA_{0.33}Cs_{0.33}PbI_3$ cation stability likely stems from "post-perovskite" δ_{ortho}-$CsPbI_3$ inclusions within parent thin films that act as barriers through which cations cannot easily migrate. This resistance to cation migration translates into improved device operational stability of α/δ-$FA_{0.33}MA_{0.33}Cs_{0.33}PbI_3$ lateral devices and solar cells relative to complementary, triple-cation, α-phase $FA_{0.76}MA_{0.15}Cs_{0.09}PbI_3$ devices. This study therefore provides new insights into cation migration in working devices and outlines a materials design strategy for stabilizing metal halide perovskites against bias-induced cation migration.

F.EL08.17.02
Efficient of Ion Migration in Perovskite Solar Cells with Hexagonal Boron Nitride Yifan Yin, Yuchen Zhou and Miriam H. Rafailovich; Stony Brook University, The State University of New York, United States

Organic-inorganic halide perovskite solar cells (PSCs) have been considered a viable member of next generation photovoltaics, which can address the scalability changes with a low-cost solution process. The energy lose in the hybrid system has been approved to be principally caused by defects/traps at grain boundaries and surfaces as well as point defects such as interstitial defects or vacancies in the perovskite compounds crystal lattice. Because of the presence of these defects, both anions (I) and cations (MA^+) can migrate through the organic layer which provides a degradation pathway for perovskite materials even in those well-encapsulated devices: the halide ions can react with metal electrodes such as Ag, forming insulating components (AgI). In addition to the corrosion of electrode, halide ions migrating into organic hole transport layer （HTL）which is deleterious to transport properties, thus retarding device efficiency, especially under solar cell working

conditions. Inspired by the quasi-2D-perovskite which shows a great stability in photovoltaic performance, here, the hexagonal boron nitride (h-BN) was incorporated into the perovskite absorber as an ionic diffusion barrier. The lamellar structure of h-BN consists of a lattice similar to graphite which can be subjected to exfoliation leading to few-layers nanosheets. The exfoliated 2D-layered materials present high surface area and quantum confinement, and also high chemical stability. The integration of this low-cost, lower dimensional material enables a better device stability as the result from the efficient suppression on the ion-migration induced degradation. With the aid of time-of-flight secondary ion mass spectroscopy (TOF-SIMS) and energy dispersive x-ray spectroscopy (EDX). The h-BN/ perovskites has an initial PCE over 20% that shows no degradation exhibit in over 72 h and retained 80% of the original PCE after 800hr, whereas the PCE of pristine MAPI devices diminishes by more than 30% within the first 24 hr.

F.EL08.17.03

Light-Induced Degradation of Hybrid Organic-Inorganic Perovskites Reveals Autocatalytic Kinetics and Increased Stability with Substitution of Larger Organic Cations Emily C. Smith, Christie Ellis, Hamza Javaid and Dhandapani Venkataraman; University of Massachusetts Amherst, United States

Instability under illumination in hybrid organic-inorganic perovskite solar cells represents a major roadblock to the development and commercialization of this thin-film technology. Recently, it has been shown that varying the nature of the organic cation in the perovskite structure represents a potential pathway to tuning stability of materials under illumination. However, many potential mixed-cation perovskite compositions remain unexplored, and, much is still unknown about the degradation kinetics in mixed-cation thin-films. In this work, we successfully fabricated thin-films of substituted methylammonium lead triiodide (MAPI), where we substituted the methylammonium ion with varying percentages of three larger organic cations: imidazolium, dimethylammonium, and guanidinium. We achieved substitution of these large cations for compositions of up to 20-30% while maintaining the structure and optoelectronic properties of the films. We studied the degradation kinetics of the mixed-cation films under illumination using powder x-ray diffraction. We observed that the degradation is autocatalytic. Furthermore, we calculated rate coefficients for the degradation process and observed that the degradation was slowed in films which contained ≤20% of any of the larger cations compared to pristine MAPI films. A maximum decrease of 62% in the degradation rate coefficient was observed in the case of 5% guanidinium substitution. Ultimately, this work provides key insight into the degradation kinetics of mixed-cation perovskite films under illumination and provides a strategy for further stabilization of perovskite thin-films for improved photovoltaic performance.

Effect of Pyrazine and Guadinium Thiocyanate (GuaSCN) on the Structure and Bandgap of Pb and Pb-Free Halide Perovskites Rubaiya Murshed and Shubhra Bansal; University of Nevada Las Vegas, United States

Perovskite solar cells (PSCs) research has been projected over the past decade due to its promising photovoltaic properties, increasing efficiency and low cost. With a need to eliminate toxic lead from prevailing halide perovskite solar cells, several low-toxicity cations have been proposed, among them Sn(II) is considered as one of the most suitable replacements due to its similar electronic configuration and ionic radius to Pb(II). But the Sn-based perovskites are still plagued with low efficiency, oxidation and phase instability. Here we demonstrate the use of atmospheric solution-processed lead-free all inorganic molecular iodosalt compound cesium tin iodide (Cs_2SnI_6) as the light absorber in PSCs. The presence of excess SnF_2 in precursor solution assists phase separation. Due to the good binding affinity to SnF_2, pyrazine is expected to reduce Sn vacancy thus restricts phase separation. The effect of GuaSCN results in increasing grain size and improving film morphology thus improves the structural and optoelectronic properties of low bandgap perovskites. The present work aims at analyzing the effect of pyrazine and guanidinium thiocyanate (GuaSCN) in oxidation reduction and fabrication of low bandgap (1.3 eV) Cs_2SnI_6 films when used separately as a mediator during film fabrication in GBL. Initial results suggest both pyrazine and guanidinium thiocyanate give absorption onset at higher optical wavelength (>1000 nm) and low bandgap (~1.2-1.3 eV). Films in addition of Pyrazine both with and without SnF_2 (0 mol% and 40 mol%) shows mostly cubic Cs_2SnI_6 diffraction patterns in XRD analysis which implies that the effect of SnF_2 is not considerable in this case. The SCN ions increases grain size and produces cubic Cs_2SnI_6 crystals. Heating at higher temperature leads to samples with lower bandgap. Both the absorption vs. wavelength and tauc plot analyses show bandgap at around 1.25 eV. Most of the samples after dark testing for over 100 hours at 65 °C retain their properties and show similar absorption edge and bandgap patterns. Samples having exposure to light at 65 °C show higher bandgap over 2 eV. In this study, the effect of these additives in $Cs(Pb,Sn)I_3$ perovskite with a Sn-Pb ratio of 60:40 is also included. Primary results show separately use of both pyrazine and GuaSCN in precursor solution in a mixture of GBL and DMF result in low bandgap perovskites. Both $Cs(Pb,Sn)I_3$ and Cs_2SnI_6 without these additives tend to have higher bandgap at around 2.3 eV when deposited on glass substrates. Further analysis of the effect of Pyrazine and GuaSCN additives in the stability, morphology and lifetime of $Cs(Pb,Sn)I_3$ and

Cs_2SnI_6 perovskite films will be continued in this study.

F.EL08.17.05
Enabling High Photoconversion Efficiency in Lead-Free Antimony-Based Perovskite Derivatives by Tuning Crystallographic Dimensionality and Microstructure Vincenzo Pecunia, Yueheng Peng and Fengzhu Li; Soochow University, China

The exploration of lead-free perovskite-inspired semiconductors for optoelectronic applications (e.g., single- and multi-junction solar cells, photocathodes for water splitting, photodetectors) has captured ever-growing attention, driven by their promise to replicate the success of the Pb-based counterparts without the toxicity concerns associated with the latter. In particular, an emerging approach to Pb replacement involves Sb, whose attractiveness resides in its highly-polarizable Sb^{3+} cations with filled 5s orbitals, a stable oxidation state, and an ionic radius comparable to Pb^{2+}. A number of antimony-halide perovskite derivatives with a formula $A_3Sb_2X_9$ (A^+: monovalent cation; X^-: halide anion) have thus been explored. Notwithstanding the rise in their reported performance, A-Sb-X absorbers are yet to deliver photoconversion efficiencies comparable to the Pb-based counterparts. Importantly, this has been linked to the zero-dimensional (0D) structure of most A-Sb-X embodiments, as the more attractive two-dimensional (2D) embodiments have been demonstrated only in very few instances, due to constraints on composition or processing conditions.

With the aim of contributing to the realization of the full potential of antimony-halide perovskite derivatives, we have investigated two such systems featuring a desirable 2D structure, exploring the impact of dimensionality, microstructure, and crystallographic orientation on their photoconversion behavior. Herein, we firstly focus on $Rb_3Sb_2I_9$, the only ternary A-Sb-I with a direct bandgap, and also having the smallest exciton binding energy of all reported A-Sb-I embodiments.[1] In order to assess the role of microstructure on the photoconversion efficiency of $Rb_3Sb_2I_9$, we have developed two strategies for its microstructural enhancement, which involve the control of the supersaturation level during the annealing step, or a high-temperature treatment in SbI_3 vapor. Both strategies deliver a dramatic improvement in the film morphology and microstructure.[2] Within sandwich-type planar devices, the resultant high-quality films enable a substantial improvement in external quantum efficiency (EQE), reaching up to 65.4% at short circuit, i.e., the highest to date for perovskite-inspired antimony-/bismuth-halide $A_3M_2X_9$ (M: Sb^{3+}/Bi^{3+}). Importantly, this is achieved without the aid of a mesoporous architecture for charge extraction, thereby revealing the inherent capability and potential of $Rb_3Sb_2I_9$ for efficient photoconversion.

We additionally discuss the impact of dimensionality on the photoconversion capabilities of the $Cs_3Sb_2X_9$ system. Departing from the dedicated high-temperature (≥ 230 °C) processing protocols pursued in the prior literature, we demonstrate that halide mixing enables the 0D-to-2D structural conversion of the $Cs_3Sb_2X_9$ system at temperatures < 150 °C.[3] The resultant 2D absorbers manifest a considerable photoconversion efficiency boost with respect to the 0D counterpart, attaining a peak EQE of 62.5%, which is at the state-of-the-art for all antimony-/bismuth-halide perovskite derivatives.

Through photocurrent-power characterization and Hall effect measurements, we finally reveal that the EQE boost achieved with both 2D $Rb_3Sb_2I_9$ and $Cs_3Sb_2X_9$ arises from their improved charge carrier transport, which we relate to the microstructural enhancement, dimensionality tuning, and crystallographic orientation. Such performance boost and mechanistic insight constitute an important step in realizing the full potential of lead-free antimony-halide perovskite derivatives and related bismuth-based homologs for their application in optoelectronics and photovoltaics.

F.EL08.17.06
A Critical Assessment of the Use of Excess Lead Iodide in Lead Halide Perovskite Solar Cells Bart Roose, Krishanu Dey, Yu-Hsien Chiang, Richard Friend and Samuel D. Stranks; University of Cambridge, United Kingdom

It is common practice in the lead halide perovskite solar cell field to add a small molar excess of lead iodide (PbI_2) to the precursor solution in order to increase device performance. However, recent reports have shown that an excess of PbI_2 can accelerate performance loss. In addition, PbI_2 is photoactive (bandgap ~2.3 eV), which may lead to parasitic absorption losses in a solar cell.

We use XRD and SEM to show that incorporation of PbI_2 into the perovskite film is not straightforward and can have very different effects, depending on how and where PbI_2 is present. At low concentrations, PbI_2 facilitates charge extraction and improves device performance. For higher concentrations, PbI_2 influences how perovskite crystallises and a thick PbI_2 layer can be formed that impedes charge extraction. We show that devices using an optimized quantity of excess PbI_2 exhibit better device performance as compared to stoichiometric devices, both initially and for the duration of a stability test under operating conditions, primarily by enhancing charge extraction. However, PbI_2 is gradually degraded during device operation, largely negating the beneficial effect on charge extraction and introducing trap states that are detrimental for device performance. We find that although excess PbI2 provides a good template for enhanced performance as compared to stoichiometric devices, it can not meet stability requirements needed for commercialization of perovskite solar cells. The community must continue to seek other additives or synthesis routes that fulfill the same beneficial role as excess PbI_2, but which do not suffer from light induced degradation.

F.EL08.17.07
Understanding the Instability of the Halide Perovskite $CsPbI_3$ Through Temperature-Dependent Structural Analysis Daniel B. Straus[1], Shu Guo[1], AM Milinda Abeykoon[2] and Robert J. Cava[1]; [1]Princeton University, United States; [2]Brookhaven National Laboratory, United States

Despite the tremendous interest in halide perovskite solar cells, the structural reasons that cause the all-inorganic perovskite $CsPbI_3$ to be unstable at room temperature remain mysterious especially since many tolerance factor-based approaches predict $CsPbI_3$ should be stable as a perovskite. Here single-crystal X-ray diffraction and X-ray pair distribution function (PDF) measurements characterize bulk perovskite $CsPbI_3$ from 100 to 295 K to elucidate its thermodynamic instability. While Cs occupies a single site from 100 to 150 K, it splits between two sites from 175 to 295 K with the second site having a lower effective coordination number, which along with other structural parameters suggests that Cs rattles in its coordination polyhedron. PDF measurements reveal that on the length scale of the unit cell, the Pb-I octahedra concurrently become greatly distorted, with one of the I-Pb-I angles approaching 82° compared to the ideal 90°. The rattling of Cs, low number of Cs-I contacts, and high degree of octahedral distortion cause the instability of perovskite-phase $CsPbI_3$. These results reveal the limitations of tolerance factors in predicting perovskite stability and provide detailed structural information that suggests methods to engineer stable $CsPbI_3$-based solar cells.

F.EL08.17.08
Enhanced Bending Fracture Behavior of Flexible Halide Thin Films Processed with *In Situ* Stress Da Bin Kim and Yong Soo Cho; Yonsei University, Korea (the Republic of)

Halide perovskites have emerged as attractive materials for electronic and optoelectronic applications because of their unique properties and low-temperature processing. However, the mechanical aspects of the halide thin films have been very limitedly reported although strong bending fracture behavior is required for the flexible system. Here, we suggest a very promising processing way to enhance the bending fracture behavior of the flexible halide thin films with fundamental definitions of the mechanical parameters of the halide materials that have been also unavailable thus far. The processing is based on the assignments of in-situ compressive or tensile stress during the film deposition with a controllable manner. As a result, a substantial improvement of the fracture resistance against the bending operation was observed for the compressively stressed halide thin films. For example as a result of bending fracture evaluation, cesium lead bromide ($CsPbBr_3$) and methylammonium lead iodide ($MAPbI_3$) thin films prepared on PEDOT:PSS-coated polyethersulfone (PES) substrates demonstrated high fracture mode I toughness of 1.18 and 1.66 MPa $m^{0.5}$ for the in-situ compressive strain of -1.09%, which correspond to the enhancements by ~97 and ~100 %, respectively, compared to those for the reference samples. The structural origins of the mechanical enhancements are elucidated with experimental evidences on the variations in lattice distortion and bonding length.

Structural Evolution of Layered Hybrid Lead Iodide Perovskites—Colloidal Nanocrystals or Ruddlesden-Popper Phases? Clayton J. Dahlman[1], Naveen Venkatesan[1], Patrick Corona[2], Rhys M. Kennard[1], Lingling Mao[1], Noah Smith[2], Jiamin Zhang[2], Ram Seshadri[1,2], Matthew Helgeson[2] and Michael Chabinyc[1]; [1]The University of California, Santa Barbara, United States; [2]University of California, Santa Barbara, United States

Hybrid organic-inorganic perovskites (HOIPs) are promising semiconductors with long carrier lifetimes, synthetic tunability, remarkable defect tolerance and simple processing. Recently, 2D analogues have been made by adding insulating cations (e.g. butylammonium) to separate the perovskite structure into sheets. These 2D materials can be formed either in thin films,

large single crystals or as dispersed nanoplatelets of only a few PbX6 octahedra thick. The number of PbX6 octahedra confined between insulating layers (i.e. the '*n*-value') can be tuned by varying precursor stoichiometry, enabling discrete tunability of the bandgap through dielectric and quantum confinement. Controlling the structure of layered hybrid metal halide perovskites, such as the Ruddlesden-Popper (R-P) phases, is challenging because of their tendency to form mixtures of varying composition. Colloidal growth techniques can form dispersions of particles with properties that match the bulk properties of layered R-P phases, but controlling the composition of these particles remains challenging.

In this talk, we explore the microstructure of particles of R-P phases of methylammonium lead iodide prepared by antisolvent precipitation from ternary mixtures of different alkylammonium cations, where one cation is able to form perovskite phases ($CH_3NH_3^+$) and the other two promote layered structures as spacers (*e.g.* $C_4H_9NH_3^+$ and $C_{12}H_{25}NH_3^+$). We illustrate how competition between cations that act as spacers between layers, or as grain-terminating ligands, determines the colloidal particle size of R-P crystallites that form in solution. Optical measurements reveal that quantum well dimensions can be tuned by engineering the ternary cation composition. Transmission synchrotron wide-angle X-ray scattering and small angle neutron scattering reveal changes in the structure of colloids in solvent and after deposition into thin films. In particular, we find that spacers can alloy between R-P layers if they share common steric arrangements, but tend to segregate into polydisperse R-P phases if they do not mix. This study provides a framework to compare the microstructure of colloidal layered perovskites and suggests clear avenues to control phase and colloidal morphology.

Adhesion and Interfacial Fracture of Perovskite Solar Cells Reisya Ichwani, Vanessa Uzonwanne, Juan Martin Hinostroza Tamayo, Deborah Oyewole, Oluwaseun K. Oyewole, Nancy Burnham and Winston Soboyejo; Worcester Polytechnic Institute, United States

Emerging perovskite solar cells (PSCs) are not only required to be highly efficient, but also durable. The mechanical stability of PSCs also requires good adhesion and contacts across their interfaces. These are studied using atomic force microscopy (AFM) and fracture mechanics approaches. AFM pull-off forces are measured for bi-material interfaces that are present in model perovskite solar cells. These are then incorporated into adhesion models for the estimation of adhesion energies and mode I interfacial fracture energies. The mode mixity dependence of interfacial fracture toughness is also studied for interfaces between the perovskite and electron transport layers in PSCs. This is done using Brazil Disk specimens that are used to study the robustness of the interfaces across a range of mode mixities between pure mode I and pure mode II. The underlying crack/microstructure interactions and fracture modes are used to provide insights into the underlying crack-tip shielding due to crack bridging and microcracking. These are modeled using zone and row models that are used to predict the mode-mixity dependence of fracture toughness. The implications of the results are also discussed for the determination of crack path selection criteria in perovskite solar cells.

F.EL08.17.11
Double Perovskite Nanofibers for Photovoltaic and Optoelectronic Applications Nageh K. Allam; American University in Cairo, Egypt

Organic-inorganic hybrid perovskite compounds are currently the archetypal materials for high performance photovoltaic (PV) and optoelectronic devices. However, the remaining bottlenecks preventing their large scale production are their environmental/thermal instability and lead toxicity. Herein, we demonstrate a novel approach to synthesize single-phase electrospun $Cs_2SnI_xCl_{6-x}$ double perovskites with varying halide content (I, Cl or mixed I/Cl) as active materials for potential application in perovskite solar cells (PSCs). The x-ray photoelectron spectroscopy and Raman spectroscopy analyses indicated the *in-situ* formation of graphene oxide (GO) during the annealing process. The GO layer was found to enhance the optical properties and thermal stability of the fabricated perovskites even at high Cl content. Moreover, the presence of GO as an insulating layer significantly decreases the bandgap energy of the resulting perovskites. The perovskites with a mix of iodide and chloride ions showed significantly improved optical properties with higher photoluminescence (PL) intensity than that of pure chloride or iodide counterparts. Moreover, the compound with low chloride content showed superior thermal stability to those reported in the literature. Therefore, the application of the electrospinning technique is a useful strategy to *in-situ* incorporate GO in a lead-free perovskite matrix for potential photovoltaic and optoelectronic applications.

Organic–Inorganic Hybrid Perovskite Single-Crystal Thin Films—Synthesis and Photoluminescence Xiaobing Tang[1], Zhaojin Wang[2], Kai Wang[2] and Fuqian Yang[1]; [1]University of Kentucky, United States; [2]Southern University of Science and

Technology, China

Metallic halide organic–inorganic hybrid perovskites with excellent optoelectrical properties have potential applications in optoelectronic devices and systems. In this work, we demonstrate the feasibility of preparing $CH_3NH_3PbBr_3$ single crystal thin films on poly-TPD hole transport layer by controlling the heating rates. The crystallinity and trap state density of the $CH_3NH_3PbBr_3$ thin films are characterized by X-ray diffraction and photoluminescence and time-resolved photoluminescence, respectively. The crystallinity with the peak intensity of (100) plane of the $CH_3NH_3PbBr_3$ thin films prepared at 2 °C/h is nine times of that prepared at 10 °C/h. The $CH_3NH_3PbBr_3$ thin films prepared at 2 °C/h exhibit a carrier lifetime of 21 ns, which is much larger than 0.6 ns for the $CH_3NH_3PbBr_3$ thin films prepared at 10 °C/h, and an excellent structural stability. F.EL08.17.13

Hybrid Lead Iodide Perovskites with Aromatic Diammonium Cations Xiaotong Li[1], Weijun Ke[1], Yihui He[1], Peijun Guo[2], Mikaël Kepenekian[3], Boubacar Traore[3], Jacky Even[3], Claudine Katan[3], Constantinos Stoumpos[1], Richard D. Schaller[2] and Mercouri G. Kanatzidis[1]; [1]Northwestern University, United States; [2]Argonne National Laboratory, United States; [3]University of Rennes, France

Aromatic diammonium cation, x-(aminomethyl)pyridinium (AMPY, x = 3 or 4) can form 2D Dion-Jacobson lead iodide perovskite, which adopt the general formula of $(xAMPY)(MA)_{n-1}Pb_nI_{3n+1}$ (MA = methylammonium, n = 1−4). By modifying the position of the $-CH_2NH_3^+$ group from 4AMPY to 3AMPY, the stacking of the inorganic layers changes from exactly eclipsed to slightly offset. The perovskite octahedra tilts are also different between the two series, with the 3AMPY series exhibiting smaller bandgaps than the 4AMPY series. Compared to the aliphatic cation of the same size (AMP = (aminomethyl)piperidinium), the aromatic spacers increase the rigidity of the cation, reduce the interlayer spacing and decrease the dielectric mismatch between inorganic layer and the organic spacer, showing the indirect but powerful influence of the organic cations on the structure and consequently on the optical properties of the perovskite materials. Preliminary solar cell devices based on the n = 4 perovskites as absorbers of both series exhibit promising performances. More interestingly, when using 1:4 ratio of AMPY:PbO as starting materials, totally different structures with 3D connection motif form instead. However, because of the steric requirement of the Goldschmidt tolerance factor rule, it is impossible for $(xAMPY)M_2I_6$ to form proper perovskite structures. Instead, a combination of corner-sharing and edge-sharing connectivity is adopted in these compounds leading to the new 3D structures. Devices of $(3AMPY)Pb_2I_6$ crystals exhibit clear photoresponse under ambient light without applied bias, reflecting a high carrier mobility (μ) and long carrier lifetime (τ) and great potential for photo and X-ray detection applications.

F.EL08.17.14

Exploring the Limit of Layer Thickness in 2D Hybrid Lead Halide Perovskites Eugenia S. Vasileiadou[1], Bin Wang[2], Ioannis Spanopoulos[1], Ido Hadar[1], Alexandra Navrotsky[3,2] and Mercouri G. Kanatzidis[1]; [1]Northwestern University, United States; [2]University of California, Davis, United States; [3]Arizona State University, United States

Two-dimensional (2D) hybrid organic-inorganic halide perovskites are a rapidly emerging class of semiconductors whose structural tunability and optoelectronic properties have led to the successful fabrication of solar cell devices with high power conversion efficiency. The features of the 2D perovskite structure that are tuned are the organic “spacer” cation and the number of the inorganic layers (*n*). There is a significant interest to target higher *n*-member compounds for light harvesting applications, due to their attractive photophysical properties such as low bandgap value and high carrier mobility. Herein, we present a comprehensive study on exploring the limit of layer thickness of bulk 2D lead halide perovskites through structural and thermodynamic study. Phase-pure synthesis of a new *n*=6 perovskite compound is reported with the characterization of the single crystal structure and optical properties of the material. Thorough calorimetry studies examine the thermodynamic stability of 2D lead iodide perovskites with layer thickness *n*=2-6. The favorable enthalpy of formation *n*=6 crystals shows that higher *n*-layer thickness is dependent on specific structural aspects. Additionally, the systematic investigation of the variances on the structural parameters and optical properties between different structure types of 2D perovskites, offers guiding principles for the targeted design and synthesis of 2D perovksites for efficient solar cell fabrication. Lastly, the stability studies of thin films demonstrate consistent observations with the thermochemical findings, further shedding light on the behavior of high *n*-layer perovskite materials.

F.EL08.17.15

Amorphous Halide Perovskite Thin Films Susan Rigter[1,2] and Erik C. Garnett[1,2]; [1]AMOLF, Netherlands; [2]University of

Amsterdam, Netherlands

Lead halide perovskites are one of the most exciting and heavily researched classes of optoelectronic materials due to their unique ability to form high quality crystals with tunable band gaps in the visible and near infrared using simple solution precipitation reactions. This facile crystallization is driven by their ionic nature; just as with other salts, it is challenging to form amorphous halide perovskites, particularly in thin-film form where they can most easily be studied. Herein, we show that rapid desolvation promoted by addition of acetate precursors is a general method for making amorphous lead halide perovskite films with a wide variety of compositions, including those using all the common cations (cesium, methylammonium, formamidinium) and anions (bromide, iodide). We show that by controlling the amount of acetate, it is possible to tune from fully crystalline to fully amorphous films, with an interesting intermediate state consisting of crystalline islands embedded in an amorphous matrix. The amorphous lead halide perovskite has a large and tunable optical band gap and improves the optical properties of incorporated crystalline perovskite, opening up the intriguing possibility of using amorphous perovskite as a passivating window layer, as is currently done in record efficiency silicon solar cells.

F.EL08.17.16
Facile Healing of Cracks in Organic-Inorganic Halide Perovskite Thin Films Srinivas K. Yadavalli, Zhenghong Dai, Min Chen, Mingyu Hu, Yuanyuan Zhou and Nitin Padture; Brown University, United States

Organic-inorganic halide perovskite (OIHP) thin films have attracted a great deal of interest as photoactive materials in various optoelectronic devices due to their unprecedented photophysical properties, but their long-term reliability is likely to be limited by their poor mechanical properties. In this context, we explain different possible modes of fracture in OIHP based devices, and for the first time demonstrate facile healing of through-thickness cracks in OIHP thin films which can otherwise be detrimental to the device properties. This is achieved through application of either a moderate compressive stress at room-temperature or a simple heat treatment at moderate temperatures. Based on the findings from a series of *ex situ* residual stress measurements, crack-healing process is found to be time-dependent, which indicates that facile mass-transport in OIHPs plays a key role in this phenomenon. The mechanisms governing crack-healing process are explained based on the fundamentals of brittle fracture. This discovery has broad implications for the prevention and/or restoration of the overall performance, environmental stability, and mechanical reliability of OIHP based devices like solar cells which are poised for commercialization.

F.EL08.17.17
Understanding the Effects of Moisture and Stoichiometry Variations on Composition and Structure in Halide Perovskite Solar Cells Juanita Hidalgo[1], Carlo Andrea Riccardo Perini[1], Andres Felipe Castro Mendez[1], Barry Lai[2], Ruipeng Li[3], Shijing Sun[4], Antonio Abate[5] and Juan Pablo Correa Baena[1]; [1]Georgia Institute of Technology, United States; [2]Argonne National Laboratory, United States; [3]Brookhaven National Laboratory, United States; [4]Massachusetts Institute of Technology, United States; [5]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

Hybrid halide lead perovskites are promising materials for photovoltaic applications. Nonetheless, these materials are highly sensitive and degrade in various environmental conditions. Among these, moisture is a prime cause of material degradation, representing a threat to the commercialization of perovskite-based materials. Hence, it is essential to study how water interacts with a perovskite thin film, what factors trigger instability in the material, and loss in solar cell performances. In order to understand these degradation mechanisms, we expose $Cs_{0.05}(MA_{0.17}FA_{0.83})_{0.95}Pb(I_{0.83}Br_{0.17})_3$ perovskite thin films with different precursor stoichiometries (organic to inorganic ratios) to a moisture treatment with high relative humidity. We monitor the evolution of perovskite crystalline structure, and we correlate it to changes in performances. Characterization with SEM images show morphological changes in the grain size, and XRD patterns evidence structural features that are furthered explained and understood by grazing incidence wide angle X-ray scattering (GIWAXS). Remarkably, we observe improved photovoltaic efficiency for treated films with an excess organic component, correlated with vertical orientation along the (001) plane. In addition, synchrotron-based X-ray fluorescence and X-ray beam induced current (XRF-XBIC) is used to correlate the elemental distribution with the current output of the devices.

HybriD^3 and MatD^3: Curated Materials Data for Hybrid Organic-Inorganic Perovskites and a General Software Stack for Materials Data Xiaochen Du[1,1], Raul Laasner[1], Xixi Qin[1], Connor Clayton[2], Svenja Janke[1], Becca Lau[1], Chi Liu[1], Sampreeti Bhattacharya[3], Juliana Mendes[4], Jun Hu[3], Dovletgeldi Seyitliyev[4], Ruyi Song[1], Manoj Jana[1], Matti Ropo[5], Franky So[4], Kenan Gundogdu[4], Wei You[3], Yosuke Kanai[3], David Mitzi[1,1] and Volker Blum[1,1]; [1]Duke University, United States; [2]Carnegie Mellon University, United States; [3]University of North Carolina at Chapel Hill, United States; [4]North Carolina State University, United States; [5]University of Turku, Finland

Materials research is generating a wealth of data across a vast community. Specifically, the volume of available data on hybrid organic-inorganic perovskites (HOIPs) and related growth in this area is now immense. Keeping track of data of different origins, sample types or levels of theory, with a diverse set of different relevant observables and discoveries, is a challenging task at best. We here present an open database, "HybriD^3" (Design, discovery and dissemination (D^3) of data related to hybrid materials, https://materials.hybrid3.duke.edu), aiming to collect, curate, and make available materials data related to HOIP. The database is designed to provide a broad set of data, i.e., experimental and computational, related to in principle any materials property of relevance to the community: structure, optical or electronic properties, and more. A key goal is to provide the ability to curate data, that is, identify property information closest to the actual properties of a real material prepared in a specific way (bulk crystalline, powder, thin film, nanocrystalline, ...). Importantly, the database is open to the community and designed to accept community input. While the "HybriD^3" database is focused on a particular materials class, the problem of making materials data of all kinds available in a structured, reproducible way is general. The software underlying the HybriD^3 database is thus available as a separate open-source project "MatD^3" (https://github.com/HybriD3-database/MatD3). We also describe this software stack, which can enable materials data at any scale, from small workgroups via focused projects all the way to large and general, open and reproducible materials data collections.

F.EL08.18.02
***Ab Initio* Characterization of the Cs_2ZrX_6 (X=Cl, Br) Family, 0D Ordered Defect Perovskite Emitters** Christopher Savory[1], Anna Abfalterer[2], Javad Shamsi[2], Samuel D. Stranks[2] and David O. Scanlon[1]; [1]University College London, United Kingdom; [2]University of Cambridge, United Kingdom

As halide perovskites have made their significant impact in the fields of photovoltaics, light emitters and other optical devices, research interest has been reignited in families of lead-free 2D, 1D and 0D perovskite-derived materials that, while poorer photovoltaics, can access some of the strong emissive properties of the halide perovskites, while also demonstrating emergent optoelectronic properties of their own.[1] The layered $Cs_3Pn_2X_9$ (Pn = Sb, Bi; X = Cl, Br, I) family demonstrates structured excitonic emission at room temperature[2,3] while the K_2PtCl_6-structured 'vacancy-ordered double perovskites' such as M_2SnI_6 (M=Rb, Sn) have shown both evidence of defect tolerance similar to that seen in the lead halide perovskites as well as strong exciton-phonon coupling.[4,5] As such, the exploration of perovskite-inspired lower dimensionality compounds represents an exciting direction in the research of optical materials.

In this study, inspired by our experimental collaborators' colloidal synthesis of nanocrystals of Cs_2ZrCl6 and Cs_2ZrBr_6, which also belong to the K_2PtCl_6 structure type and demonstrate broad white photoluminescence when formed into thin films, we perform hybrid Density Functional Theory (DFT) calculations in order to predict and rationalize the observed optical and electronic behavior of the Cs_2ZrX_6 materials family, producing good agreement to experiment. By calculating the thermodynamic and luminescent properties of the intrinsic defects within the system, as well as excitonic properties within the QSGW method and the Bethe-Salpeter equation, we attempt to accurately predict the origin of such promising emissive properties. Finally, we present direct comparisons to the analogous M_2SnX_6 family and draw conclusions on the feasibility of extending the field of lead-free perovskite-inspired emitters, and whether such optimal optical properties are available beyond the post-transition metals.

Exploration of Compositional Space in Methylammonium-Free Lead Halogen Perovskites for High-Performance Solar Cells Yu An[1,2], Xianggao Li[1] and Juan Pablo Correa Baena[2]; [1]Tianjin University, China; [2]Georgia Institute of Technology, United States

The certified power conversion efficiency (PCE) of state-of-the-art organic-inorganic metal halide perovskite solar cells (PSCs) has surpassed 25%, coming after single crystalline silicon solar cells. The most widely studied methylammonium (MA) lead iodide undergoes a structural phase transition and degradation due to the volatile MA cation, detrimental to the long-term stability of the devices. Formamidinium (FA), used as the majority cation in most of PCE >20% PSCs, is thermally more stable and has an optimal red-shifted bandgap. However, FA with the relatively large radius induces titled PbI_6 octahedra in $FAPbI_3$, leading to the photoinactive yellow δ-phase at room temperature. Herein, iodide and FA in $FAPbI_3$ were gradually replaced by bromide and cesium (Cs) with smaller radius to suppress the yellow δ-phase and systematically explore the compositional space via regulating the tolerance factor, revealing the crucial link between the crystal structure and optoelectronic properties of the mixed-cation (FA/Cs) lead mixed-halide (I/Br) perovskite. An empirical expression for FA/Cs-Pb-I/Br bandgap as a function of composition was determined, which contributes to tailored bandgap suitable for tandem solar cells. In addition, the FA/Cs-Pb-I/Br films were probed by advanced synchrotron X-ray characterization to understand halide phase segregation, which has been found to be detrimental for solar cell performance.

Interfacial States, Energetics and Atmospheric Stability of Large-Grain Antifluorite Cesium Titanium Bromide Jocelyn Mendes, Julia Martin, Alexander Carl, Emma J. Pellerin and Ronald L. Grimm; Worcester Polytechnic Institute, United States

Cesium titanium bromide, Cs_2TiBr_6, has attracted research interest due to its ~1.8 eV band gap, which makes it desirable for forming tandem junctions with silicon. However, the instability of large-grain Cs_2TiBr_6 in ambient atmosphere prompts further fundamental understanding of its surface chemistry and oxidation. To ascertain stability of the material in ambient atmosphere and establish band edge positions of the material we conducted controlled air exposure experiments and UHV cleaving of nascent material. X-ray photoelectron spectroscopy (XPS) established correct synthesis, effects of atmospheric exposure, and characterization of UHV cleaved samples. Ultraviolet photoelectron spectroscopy (UPS) established band edge positions of Cs_2TiBr_6 with and without surface metal oxide species present. Powder X-ray diffraction (pXRD) quantified the effects of atmospheric exposure over time. The presence of metal oxides on Cs_2TiBr_6 surfaces shifted band alignments towards TiO_2 while UHV cleaved, oxide-free surfaces demonstrated an intrinsically n-type semiconductor. These results elucidate the effects of surface oxides on Cs_2TiBr_6 surfaces, and future routes through which interfacial reactivity may be used to improve atmospheric stability.

Bandgap-Tailored Perovskite Capping Layer Design for Improving Stability and Passivation Noor Titan Putri Hartono[1], Marie-Hélène Tremblay[2], Armi Tiihonen[1], Janak Thapa[1], Shijing Sun[1], Seth R. Marder[2] and Tonio Buonassisi[1]; [1]Massachusetts Institute of Technology, United States; [2]Georgia Institute of Technology, United States

In recent years, the 3D/low-dimensional (LD) perovskite heterostructure consisting of LD perovskite called 'capping layer', deposited atop of 3D perovskite in a device [1], has emerged as a solution for improving perovskite solar cells' (PSCs') stability and interfacial passivation. However, the capping layer materials and processing conditions have been optimized for single-junction PSCs, and not for multi-junction PSCs. To apply the capping layer in multi-junction PSCs, research efforts are required to understand and optimize the bandgap-tailored capping layer material. We propose a detailed study exploring at least 10 different types of LD perovskite with various halides (I, Br, and Cl) and thicknesses, and $CH_3NH_3Pb(I-Br)_3$ absorber mixtures with increasing bandgap from 1.59 to 2.27 eV [2]. The samples are degraded in a well-controlled environmental chamber, under high humidity (85% RH), high heat (85°C), and low illumination (0.17 sun). The same set of samples are screened using photoconductivity, as a proxy for its interfacial passivation property. We also utilize decision tree-based machine learning models and Shapley values [3] to help determine which molecular properties in the capping layers significantly affect the absorber mixtures' stability and conductivity. Our results indicate that capping layers needs to be tailored based on the perovskite absorbers' composition, bandgap, and organic cation types to achieve high stability.

Furthermore, by comparing the optimum bandgap-tailored capping layers through X-ray photoelectron spectroscopy (XPS), Fourier-transform infrared spectroscopy (FTIR), and ultraviolet photoelectron spectroscopy (UPS), we can understand how the film stability is affected by inorganic and organic bonds on the surface of the capping layers, as well as how interfacial passivation is affected by band alignment. Our study suggests that capping layer tuning is a promising approach to increase the stability of perovskite-based tandem solar cells.

Nonlinear Bandgap Behavior in Lead-Free $Cs_2Ag(Sb_xBi_{1-x})Br_6$ Double Perovskite Alloys Seán Kavanagh[1,2,3], Zewei Li[4], Robert Palgrave[3], Richard Friend[4], David O. Scanlon[3], Aron Walsh[2] and Robert Hoye[2]; [1]Thomas Young Centre, UCL, ICL, KCL, QMUL, United Kingdom; [2]Imperial College London, United Kingdom; [3]University College London, United Kingdom; [4]University of Cambridge, United Kingdom

Double perovskites have emerged as promising candidate materials for high-performance next-generation optoelectronic technologies, owing to the ability to replace the toxic Pb^{2+} cation with a pair of more benign cations (*e.g.* Ag^{+} and Bi^{3+}), while preserving the perovskite crystal structure.[1] However, most double perovskites, including the prototypical $Cs_2AgBiBr_6$, have prohibitively wide bandgaps, limiting photoconversion and photocatalytic efficiencies.[2] Recently, it has been demonstrated that the bandgap of $Cs_2AgBiBr_6$ can be reduced through alloying with Sb^{3+},[3] yet the bandgap of the pure Sb-based double perovskite ($Cs_2AgSbBr_6$) remains excessively wide for photo-voltaic/catalytic applications. In this work, we develop a solution-based route to synthesize phase-pure $Cs_2Ag(Sb_xBi_{1-x})Br_6$ thin films, with the mixing parameter x tunable over the entire composition range. In doing so, we observe this system to disobey Vegard's law, exhibiting significant bandgap bowing, such that the mixed alloy ($x = 0.9$) demonstrates the smallest bandgap (2.08 eV, compared to 2.18 eV and 2.25 eV for the pure Sb- and Bi-based double perovskites, respectively). We investigate the possible mechanisms for this nonlinear bandgap variation through relativistic hybrid Density Functional Theory (DFT) calculations, combined with in-depth measurements of the composition, phase and grain structure to yield detailed understanding of the underlying physical origins. The energetic alignment of electron states within these materials is accurately calculated, including consideration of deformation potentials to adequately account for the spurious supercell effects associated with such calculations.[4,5] Our work reveals pathways to bandgap engineering in double perovskite alloys, such that it is better suited to photovoltaic or photocatalytic applications, which may be generally applicable to other mixed-metal double perovskite systems.

Tin Oxynitride-Based Ferroelectric Semiconductors for Solar Energy Conversion Applications Steven T. Hartman, Arashdeep S. Thind and Rohan Mishra; Washington University in St. Louis, United States

Lead-halide perovskites have emerged as a promising class of semiconductors; however they suffer from issues related to lead-toxicity and instability. We report results of a first-principles-based design of heavy-metal-based oxynitrides as alternatives to lead-halide perovskites. We have used density-functional-theory calculations to search a vast composition space of ABO_2N and $ABON_2$ compounds, where B is a p-block cation, and A is an alkaline, alkali-earth, rare-earth or transition metal cation, and identify 10 new ABO_2N oxynitride semiconductors that we expect to be formable. Specifically, we discover a new family of ferroelectric semiconductors with $ASnO_2N$ stoichiometry (A = Y, Eu, La, In, Sc) in the $LuMnO_3$-type structure, which combine the strong bonding of metal oxides with the low carrier effective mass and small,

tunable band gaps of the lead-halide perovskites. These tin oxynitrides have predicted direct band gaps ranging from 1.6 – 3.3 eV, and a sizeable electric polarization up to 17 μC/cm^2, which is predicted to be switchable by an external electric field through a non-polar phase. With their unique combination of polarization, low carrier effective mass and band gaps spanning the entire visible spectrum, we expect ASnO$_2$N ferroelectric semiconductors will find useful applications as photovoltaics, photocatalysts, and for optoelectronics.

How to Design Defect Tolerant Devices Basita Das[1], Irene Aguilera[1], Uwe Rau[1] and Thomas Kirchartz[1,2]; [1]Forschungszentrum Jülich GmbH, Germany; [2]University of Duisburg-Essen, Germany

Perovskite solar cells have emerged as a key photovoltaic technology given the remarkable rise in their efficiency in the past decade. Long non-radiative lifetimes as a result of slow defect-mediated recombination in perovskite materials are key in achieving high open-circuit voltages necessary for high efficiency solar cells.
The quantitative impact of bulk or interface defects on recombination is often estimated by defect statistics based on the model of Shockley, Read and Hall. However, defect statistics depend on defect capture coefficients to calculate defect occupancy and the recombination rate through the defect. Due to the lack of enough experimental data on capture coefficients of novel materials or, alternatively, models to calculate trap energy dependent capture coefficients it is frequently assumed that capture coefficients are symmetric, i.e, $k_n = k_p$ for all defect levels within the bandgap in a device. However, equal or at least similar values of the capture coefficients are not necessarily a typical or even a likely scenario.
To go beyond the state-of-the-art device simulation in photovoltaics involving constant capture coefficients, we present a generalized microscopic model based on the Harmonic oscillator approximation to calculate defect capture coefficients as a function of the host material and the energetic position of the defects. Then we use this capture coefficients to classify the "deep" defects inside a device not merely based on the energetic position of the device but also as a function of the quantitative impact it has on the device. Furthermore, we discuss certain photovoltaic device design principles that can substantially reduce recombination through the dominant recombination centers.

Enhancing Fundamental Understanding of Structure-Property Relationships in Chalcogenide Perovskite Semiconductors with Theoretical and Experimental Studies of Dielectric Response, X-Ray Absorption and Electronic Transport Stephen Filippone[1], Kevin Ye[1], Boyang Zhao[2], Shanyuan Niu[2], Nathan Koocher[3], Daniel Silevitch[4], Ignasi Fina[5], James Rondinelli[3], Jayakanth Ravichandran[2] and Rafael Jaramillo[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Southern California, United States; [3]Northwestern University, United States; [4]California Institute of Technology, United States; [5]Universitat Autònoma de Barcelona, Spain

Electronic materials in perovskite and related structure types are a rich field of study because they combine characteristics of ionic and covalent bonding in crystal structures that are tolerant of distortions and chemical substitution. Tremendous efforts are now underway to understand the structure-property relationships that underpin the photovoltaic performance of lead halide perovskites (LHPs), expanding on and linking decades of research on photovoltaic absorbers, on the one hand, and complex oxide physics on the other. Now we extend this spirit of interdisciplinary, fundamental inquiry to a much less-studied class of materials, the chalcogenide perovskites. Recent works have shown that chalcogenide perovskites have outstanding properties for optoelectronic applications, including: slow minority carrier recombination, strong light absorption, excellent environmental stability, and dopability. Efforts are just now beginning to develop a fundamental understanding of these phenomena and to exploit these exciting materials for applications.

We present a diverse set of studies of the atomistic origin of structure-property relationships in chalcogenide perovskites. We combine impedance spectroscopy, X-ray absorption spectroscopy (XAS), electronic transport, and first-principles theory to understand how atomic structure and particular chemical bonds support outstanding semiconducting properties. Our impedance spectroscopy measurements on single crystals reveal that chalcogenide perovskites are highly-polarizable semiconductors, with stronger dielectric response than any other family of semiconductors with band gap in the VIS-NIR, exceeding even LHPs. Our theoretical calculations agree quantitatively with our measurements, and illustrate the particular polar phonon modes responsible for the large dielectric response. Our XAS studies combining experiment and theory illustrate the importance of directional bonds in determining the near-band edge electronic structure (including the band gap), especially for layered variants in the Ruddlesden-Popper structure type. This electronic anisotropy is further illustrated by electronic transport measurements made on oriented single crystals.

Our results illustrate, in a fundamental and detailed level, the ways in which chalcogenide perovskites differ from their oxide

and halide cousins. We show that the structure-property relationships follow from covalent metal-chalcogen bonds and strong electron-phonon coupling. We conclude that chalcogenide perovskites are highly promising for optoelectronic and energy-conversion technologies.

Novel $C_6H_5NHNH_3I$ Additive for Efficiency Acceleration in Organic-Inorganic Halide Perovskite Solar Cells Md Ashiqur Rahman Laskar[1,2] and Qiquan (Quinn) Qiao[1]; [1]South Dakota State University, United States; [2]Arizona State University, United States

Different additive materials are widely used to improve the power conversion efficiency (PCE) of organic-inorganic halide perovskite solar cells. In this work, we report a novel organic additive material $C_6H_5NHNH_3I$ (Phenylhydrazinium Iodide) which is very effective to enhance the PCE of single cation-single halide based Methylammonium Lead Iodide perovskite solar cells (MLIPSC). In addition to that, we have found the additive is also effective for other types of perovskite composition such as double cation-double halide perovskite solar cells. $C_6H_5NHNH_3I$ promotes perovskite crystal growth and improves the light absorption capability of the active layer. Furthermore, because of reduced defects and charge traps in the additive treated perovskite film, charge carrier lifetime becomes almost double from 1.4 µs to 2.5 µs which ensures minimum recombination of the photogenerated electrons and holes. Besides, approximately 10% increased external quantum efficiency (EQE) and 14% improved built in potential (V_{bi}) of the perovskite solar cells indicate superior device performance. Eventually, accelerated short circuit current density and open circuit voltage of the $C_6H_5NHNH_3I$ treated perovskite solar cells contribute to nearly 20% increment of PCE in MLIPSC.

F.EL08.19.02
Understanding the Effect of Electrode Spacing on $CsPbI_2Br$ Interdigital Photodetector with Chromium Electrodes Haider B. Salman; University of Arkansas, United States

Significant achievements were made in the past few years with perovskite material in optoelectronic applications. One of the advantages of the halide perovskite in photo detection applications is that the band gap of the material can be tuned to cover a wide range of wavelengths by halide mixing. In this paper, the research is focused on the fabrication and characterization of interdigital photodetectors made with $CsPbI_2Br$. The photodetector consists of two interdigitate chromium electrodes deposited on glass substrates with the perovskite filling the spacing between the electrodes. The interdigital pattern of the device was fabricated using photolithography method to deposit 80 nm of chromium. To study the effect of the electrode spacing on the device performance, four types of photodetectors with four different spacing; 50, 20, 10, and 5µm were fabricated. The perovskite was synthesized using one step deposition method with 0.6 molar concentration of $CsPbI_2Br$ precursor. The material was characterized by obtaining the absorbance, the photoluminescence, and the X-ray diffraction spectra. One single peak in the PL spectrum was observed at 648 nm indicating a band gap 1.91 eV. The current voltage curves of the photodetectors were obtained under dark and light conditions using keithley 4200 semiconductor characterization system and Newport solar simulator. The spectral response of the device was obtained suing Bruker ifs 125hr spectrometer. The device with 10 µm spacing showed ~370 on/off ratio at 5 V bias under 100 mW/cm^2 light intensity. Under the same conditions, the device with 5 µm showed an increase in the on/off ratio to 6800. The detectivities of the 10 and 5 µm devices were calculate to be 4.9×10^9, and 2.46×10^{10} Jones respectively.

F.EL08.19.04
Enhancing Chemical Stability and Suppressing Ion Migration in $CH_3NH_3PbI_3$ Perovskite Solar Cells via Direct Backbone Attachment of Polyester on Grain Boundaries Yuchen Zhou[1], Yifan Yin[1], Xianghao Zuo[1], Likun Wang[1], Chang-Yong Nam[2] and Miriam H. Rafailovich[1]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory,

United States

Grain boundary (GB) passivation by polymer additives has been shown effective in improving the performance of solution processed hybrid perovskite solar cells (PSCs). However, the critical stability issue associated with detrimental ion migration in PSCs remains less explored by polymer additives. Here, we show that a new linear polar polymer, polycaprolactone (PCL), can passivate GBs of methylammonium lead triiodie ($MAPbI_3$) perovskites via direct backbone attachment, enabling significantly enhanced environmental stability of n-i-p type PSC. The champion PSC with optimal PCL concentration shows an improved power conversion efficiency (PCE) of 20.1 %. 90% of initial PCE was preserved after 400 h ambient storage. After 100 h thermal aging (85 °C), 80% of the original PCE has also been preserved. The tested PSCs use less stable Spiro-OMeTAD (2,2′,7,7′-tetrakis[N,N-di(4-emethoxyphenyl)amino]-9,9′-spirobifluorene) as hole transport layer (HTL), and, thus, the improved stability indicates critical roles of PCL in retarding moisture ingression as well as suppressing ion migration. Detailed structures of PCL GB passivation is visualized directly via lateral scanning force and transmission electron microscopies. Secondary ion mass spectrometry and ion conduction measurements confirm the PCL GB passivation significantly retards I^- ion migration in $MAPbI_3$ PSCs, while without PCL, I^- ions are actively accumulating in the organic HTL and at the interface between electrodes and the HTL even without externally applied electric field. We envision this passivation strategy by PCL GB functionalization can help the development of environmentally stable, high-performance PSCs.(*This work was supported by the Morin Foundation Trust and the NSF, Inspire program #1344267*)

F.EL08.19.06
Effects of Annealing Temperature on Interdiffusion of Materials in Layered Perovskite Solar Cells Deborah Oyewole[1,2,1], Juan Martin Hinostroza Tamayo[1,1], Oluwaseun K. Oyewole[1,1], Benjamin Agyei-Tuffour[3], Richard Koech[4,1], Reisya Ichwani[1,1], Jaya Cromwell[1], Nancy Burnham[1,1] and Winston Soboyejo[1,1]; [1]Worcester Polytechnic Institute, United States; [2]Sheda Science and Technology, Km 10 Abuja-Lokoja Road, Nigeria; [3]School of Engineering Sciences, University of Ghana, Ghana; [4]African University of Science and Technology, Nigeria

In order to design more efficient and durable perovskite solar cells (PSCs), the effects of annealing temperature on interdiffusion of the constituent elements in layered formamidinium-based PSCs were studied. First, the PSCs were fabricated by spin-coating lead (II) iodide solution onto the mesoporous electron transporting layer (ETL) followed by a mixture of formamidinium ammonium iodide, with small proportion methylammonium bromide and methylammonium chloride. The effect of varying annealing temperature of the perovskite films is then studied to gain insight into the changes that occur on the perovskite film and the overall effects of interdiffusion of constituent elements on photoconversion efficiencies of the PSCs. The results show there is diffusion of tin from fluorine-doped tin oxide to the mesoporous ETL due to sintering. The level of tin in the mesoporous layer decreases with increased annealing temperatures of the perovskite films. The quality of perovskite films is also improved with better uniformly distributed grain sizes for annealing temperatures between room temperature and 130 °C compared to higher annealing temperatures of 140 °C and 150 °C. The overall effects of the interdiffusion of layer constituents on photoconversion efficiencies are then discussed for the design of PSCs.

F.EL08.19.07
A Hole Transport Bilayer for Highly Efficient and Stable Inverted Perovskite Solar Cells Hamza Javaid, Volodimyr V. Duzhko and Dhandapani Venkataraman; University of Massachusetts Amherst, United States

Highly efficient and stable inverted, *i.e.* p-i-n, perovskite solar cells (PSCs) are fabricated by employing a novel hole transport bilayer. Compared to devices with single PTAA interlayer, which have an average power conversion efficiency (PCE) of 18.9%, an enhanced average PCE of 20.2% and a maximum PCE of 21.16% in the bilayer-based devices are observed. The XRD and AFM studies show an improved crystallinity and larger grain size of perovskite films on the bilayer surface. The ultraviolet photoelectron spectroscopy and Mott-Schottky analysis suggest an increased built-in potential with an enhanced upward band bending at the bilayer/perovskite interface. Compared to devices with single PTAA, CuI and PEDOT:PSS interlayer, the bilayer-based devices show significant suppression of *J-V* hysteresis and stable current output at maximum power point. The bilayer-based devices also demonstrate a remarkable long-term stability, as tested in inert atmosphere.

F.EL08.19.08
Toward Rational Design of Stable and Robust Hybrid Perovskite Devices—The Role of Functionalized Organic Cations and Dimensionality Engineering Arvin Kakekhani[1], Marcos A. Reyes-Martinez[2], Xiaoming Zhao[2], Melissa Ball[2,2], Peng Tan[3,1], Sayan Banerjee[1], Lynn Loo[2,2] and Andrew Rappe[1]; [1]University of Pennsylvania, United States; [2]Princeton University, United States; [3]Harbin Institute of Technology, China

Here, we discuss how density functional theory (DFT)-based methods can help us in designing strategies to mitigate the stability and efficiency challenges for hybrid organic-inorganic perovskite (HOIP) systems. On one front, we use first-principles theory to rationalize the elastic properties of layered hybrid perovskites, correlating such properties with interlayer organic-organic interactions and also the HOIP's structural properties e.g., its dimensionality or intrinsic interlayer defects and voids. [1] On a different but complementary front, we have studied fundamental chemistry behind the water degradation of 3D hybrid perovskites and have related this to the chemical properties of the organic cations. [2] We are now expanding this work to study water interactions in layered quasi-2D systems, unraveling the fundamental role of dimensionality in water stability of perovskites. Beyond the realm of bulk-like perovskites, we also study the determining role of organic cations' chemistry on surface stability and defect formation for HOIP nanoparticles. The role of organic cations goes further than directly influencing the inorganic backbone structure, and for some specific functionalized organic cations and through intricate hydrogen-bonding networks, the organic-organic interactions can become important at dictating the electronic and structural properties of layered perovskites. Having a multipronged approach in which we identify descriptors for elastic and electronic properties of perovskite, as well as their stability, allows us to rationalize and help improve experimentally-relevant pathways to create more robust HOIP-based devices capable of performing in real-world PV or LED applications. Few such possibilities which are discussed here include: surface passivation with mixed short organic cations, supramolecular interactions between long cations, secondary organic functionalities, and dimensionality engineering.

Bilayer Perovskite Solar Cells by Grafted PDMS Transfer Process Anisha Mohapatra[1,2] and Chih-Wei Chu[1]; [1]Academia Sinica, Taiwan; [2]National Tsing Hua University, Taiwan

Organic-Inorganic Perovskite solar cells has a great advantage to reach the radiative limit for PCE enhancement. The single junction devices are restricted to attain the radiative limit because of the energy losses. Multi-structure architectures like tandem, heterostructure are adapted to recover the thermodynamic energy loss. The variable bandgap of perovskite is an advantage, which varies from 1.5eV~1.8eV providing a complete solar spectrum coverage. Stacking of high-bandgap perovskite with low bandgap perovskites is a good approach for encountering the energy losses. The perovskite heterostructure is fabricated by sequential deposition of quantum dots and thermally evaporated p-n junctions. Till now, there is no demonstration of any solution process able method in perovskites for stacking perovskite absorbers because of the dissolution of perovskite precursors by the subsequent layers. Therefore, we demonstrated a PDMS printing technique for stacking perovskite layers inspired by multi-stacked organic solar cells. The printing technique is assisted with modification of surface energy of PDMS by grafting process, which facilitates printing of high crystalline pinhole free perovskite layers. On proving ground, we also stacked perovskite layers to form a perovskite heterostructures. We demonstrated the printing of multi-layer perovskite layers to encounter the thermodynamic losses. To understand the advantage of heterostructure for encountering the energy losses, a constant thickness of single layer and heterostructure was maintained for compared the photovoltaic performance. We achieved a photovoltaic performance of ~5%, ~9% for MaPbI3 and MaPbBrI2 layer and ~10% for MAPbBrI2/MAPbI3 heterostructure. This gave us an indication that the heterostructure was able to suppress some non-radiative recombination to overcome the energy losses, which can be a great application for stacking perovskite layers to use in different optoelectronic applications.

F.EL08.19.11

Fracture Behavior of Halide Perovskite Thin Films for Solar Cells Zhenghong Dai, Srinivas K. Yadavalli, Mingyu Hu, Min Chen, Yuanyuan Zhou and Nitin Padture; Brown University, United States

Organic-inorganic halide perovskites (OIHPs) have emerged as the most promising light-absorber materials in thin-film photovoltaic (PVs). However, the low formation energies of OIHPs render them unstable. While significant progress has been made in improving the stability of OIHPs, perovskite solar cells (PSCs) will also need to be mechanically reliable if they are to service satisfactorily for years. In this context, we have studied the fracture behavior of PSCs by measuring their cohesion energies using double cantilever beam method and report a novel approach to strategically enhance the interfacial adhesion and performance of PSCs by interface modification. This work points to a new route for designing mechanically

robust PSCs with long-term durability.

Amplified Spontaneous Emission from All-Inorganic Quasi-2D Perovskites Lei Lei, Dovletgeldi Seyitliyev, Kasra Darabi, Siliang He, Samual Stuard, Qi Dong, Juliana Mendes, Harald Ade, Aram Amassian, Kenan Gundogdu and Franky So; North Carolina State University, United States

Recently, metal-halide perovskite materials are considered as a promising candidate for lasing applications since perovskites may overcome typical limitations showed in organic gain media and the "green-gap" in inorganic semiconductors. While lasing has been demonstrated based on perovskite materials with both 3D and low-dimensionalities, quasi-2D perovskites are a better gain media due to its unique properties such as large binding energy and self-assembled quantum wells. It has been shown that efficient energy funneling from low-dimensional domains to high-dimensional domains will not only enhance the radiative recombination but also facilitate population inversion. However, the trend of how the dimensionality of quasi-2D perovskites affects amplified spontaneous emission (ASE) threshold is still controversial. Here, we investigate ASE of all-inorganic quasi-2D perovskite thin films with different dimensionalities, and try to understand the role of dimensionality in both materials properties and charge carrier dynamics.
In this work, we formed quasi-2D perovskite thin films based on the all-inorganic 3D cesium lead halide perovskite framework due to the improved thermal and optical stability. The dimensionality of quasi-2D perovskites is tuned by varying the concentration of the organic spacer phenethylamine (PEA). In our work, the large organic cation PEA acts as a nucleation center facilitating the crystallization process of perovskites. Via grazing-incidence wide-angle X-ray scattering (GIWAXS) measurements and scanning electronic microscopy, we found that the addition of PEA also enhances the quality of the thin films by controlling the domain size and morphology. As a result, the PLQY increases with the PEA concentration. However, the ASE threshold is not correlated with the PLQY and it reaches to the lowest value (7 $\mu J/cm^2$) at a moderate PEA concentration of 40%. To study the correlation between PEA concentration and ASE threshold, we used transient photoluminescence and transient absorption spectroscopy to study the photophysics of these films. Our results showed that with increasing PEA concentration to 40%, the non-radiative recombination is significantly reduced due to defect passivation, leading to the increasing PLQY and decreasing of ASE threshold. However, the existing of the low-dimensional domains became significant with a higher PEA concentration (60%), which acted as long-lived trap states for excitons and limited the population inversion process. Finally, by using the optimized PEA ratio, the ASE emission was observed over the broad visible range from red to blue, demonstrating its wide wavelength-tunability.

F.EL08.20.02
Direct Observation of the Ultrafast Dynamics of Trapped Carriers in Organic Metal Halide Perovskite Films Kanishka Kobbekaduwa[1], Shreetu Shrestha[2], Pan Adhikari[1], Hsinhan Tsai[2], Wanyi Nie[2] and Jianbo Gao[1]; [1]Clemson University, United States; [2]Los Alamos National Laboratory, United States

Despite the power conversion efficiency (PCE) of the perovskite solar cells soars more than 25 % in less than ten years, their limited stability remains one of the crucial hurdles on the path to commercialization. To improve the device stability, various trap state passivation strategies targeting the bulk perovskite, perovskite surface, and device interfaces have been employed. However, knowledge of the temporal, spatial, and energetic correlation of the defect/trap states is the foundation for fundamental and technical understanding of the impact of the trap/defect states, manifested by the device stability and PCE optimization.
In this report, we directly observe the ultrafast dynamics of trapped carriers in organic lead halide perovskite $MAPbI_3$ thin film by ultrafast photocurrent spectroscopy (UPCS). Under low carrier density, the trapped carriers undergo a multiple trapping and release (MTR) transportmechanism among the shallow trap states and deep trap state, demonstrated by a time-dependent activation energy. Above the trap filling region, in addition to the MTR transport mechanism, the trap-assist Auger recombination occurs, which is demonstrated by the laser intensity dependent decay time. Our results elucidated the trapped carrier dynamics from sub-25 ps to couple ns in the solution-processed film with mobility of ~ 1 cm^2/Vs.

F.EL08.20.03
Exciton Spin Relaxation in 2D Metal Halide Perovskites Sean A. Bourelle; University of Cambridge, United Kingdom

Optoelectronic properties of 2D metal halide perovskites are dominated by the transitions and interactions between excitons. Here, we present a study on the spin relaxation mechanisms for these excitonic states and demonstrate how these mechanisms can be altered. Our analysis utilizes ultrafast spectroscopy methods including Faraday rotation and circularly polarised transient absorption spectroscopy.

F.EL08.20.04
Optical Studies of Mixed-Dimension Perovskites—Excitonic Effects and Morphological Changes with Alkyl-Ammonium Iodide Doping Mohsin Raza Khan, Shahzad Akhtar Ali, Qurat ul Ain, Ataul Haq and Ammar A. Khan; Lahore University of Management Sciences, Pakistan

Organometal halide perovskites are promising materials for optoelectronic applications due to excellent light absorption, charge transport and emissive properties, coupled with potentially low-cost scalable fabrication [1][2]. Perovskite solar cells (PSCs), as well as other devices, currently suffer from moisture and thermal instability of the perovskite semiconductors [3]. There are several complimentary methodologies of increasing the stability of PSCs, and amongst these the formation of hybrid two/three dimensional Ruddleson Popper perovskites is one of the most promising [4]. Mixed dimension perovskites (MDPs) can be formed by the incorporation of long alkyl-chain cations into the crystal structure leading to the formation of a layered crystal structure [5]. The individual layers are separated by covalently linked cations, with a 3D intra layer geometry. The optical, crystalline, electrical and magnetic properties of 3D perovskites can be readily tuned by varying the stoichiometric concentration and chain length of the dopant, leading to a considerable scope for application dependent material engineering. However, exploring this large yet versatile parameter space of dopants requires an understanding of the underlying excitonic processes and morphological dependencies.

In this work, the formation of 2D/3D mixed alkylammonium lead iodide perovskites using Butylammonium (BAI) and Octylammonium (OAI) iodides as additives in methyl-ammonium lead iodide perovskites is demonstrated. A solvent annealing method is employed to improve film morphology. The effect of incorporating these cations on the optical properties of the films is investigated using micro-photoluminescence and absorption studies, and a left shift in band-gap with increasing 2D character is illustrated, in accordance with literature[6]. BAI and OAI demonstrate very different spectral properties, with much larger spectral shifts in the longer chain derivitive, hinting towards a strong effect of the alkyl chain. We further utilise multi-gaussian fitting to reveal insights into edge-states as well as disorder in MDPs, which can have imporant consequences for photovoltaic and light-emitting device applications.

F.EL08.20.05
Benefits of Disorder—Carrier Localisation in Alloyed Hybrid Perovskites for Efficient Luminescence Sascha Feldmann[1], Stuart Macpherson[1], Richard Friend[1], Henning Sirringhaus[1], David Beljonne[2], Samuel D. Stranks[1] and Felix Deschler[3]; [1]University of Cambridge, United Kingdom; [2]Université de Mons, Belgium; [3]Technische Universität München, Germany

Metal halide perovskites have emerged as promising materials for optoelectronic applications like solar cells or light-emitting diodes (LEDs). Here, we investigate mixed-halide perovskites and control the cation alloying to enhance optoelectronic

performance through alteration of the charge carrier dynamics. In contrast to single-halide perovskites, we find high luminescence yields for photoexcited carrier densities far below solar illumination conditions. We employ time-resolved spectroscopy and show that the charge carrier recombination regime changes from second to effectively first order within the first tens of nanoseconds after excitation. Supported by microscale mapping of the optical bandgap, electrically gated transport measurements and first-principles calculations, we demonstrate that spatially varying energetic disorder in the electronic states causes local charge accumulation, creating p- and n-type photodoped regions, which unearths a strategy for efficient light emission at low charge-injection in solar cells. Performance Limiting Structural Heterogeneities in Metal Halide Perovskites Tiarnan A. Doherty[1], Stuart Macpherson[1], Andrew Winchester[2], Duncan Johnstone[1], Miguel Anaya[1], Aron Walsh[3], Paul Midgley[1], Keshav Dani[2] and Samuel D. Stranks[1]; [1]University of Cambridge, United Kingdom; [2]Okinawa Institute of Science and Technology, Japan; [3]Imperial College London, United Kingdom

Halide perovskite materials have promising performance characteristics for low-cost optoelectronic applications. Photovoltaic devices fabricated from perovskite absorbers have reached power conversion efficiencies above 25 per cent in single-junction devices and 28 per cent in tandem devices. Though widely considered defect tolerant materials, perovskites still exhibit a sizeable density of deep sub-gap non-radiative trap states, which create local variations in photoluminescence (*1*, *2*) that fundamentally limit device performance. These trap states have also been associated with light-induced halide segregation in mixed halide perovskite compositions (*3*) and local strain (*4*), both of which can detrimentally impact device stability (*5*). Understanding the nature of these traps will be critical to ultimately eliminate losses and yield devices operating at their theoretical performance limits with optimal stability. We recently revealed that the majority of these trap states in state-of-the-art $(Cs_{0.05}FA_{0.78}MA_{0.17})Pb(I_{0.83}Br_{0.17})_3$ perovskites form in nanoscale clusters at grain boundaries of compositionally and structurally distinct entities [*Nature*, 2020].

In this talk we detail our low-dose, high-resolution and multimodal approach to link photophysical properties to nanoscale structural and compositional heterogeneities. By combining scanning electron microscopy techniques with spatially resolved photoemission measurements, we compare and contrast observed structural defects in $(Cs_{0.05}FA_{0.78}MA_{0.17})Pb(I_{0.83}Br_{0.17})_3$ and $(Cs_{0.05}FA_{0.78}MA_{0.17})PbI_3$ halide perovskite thin films and discuss how they ultimately limit device performance. In so doing, we reveal the nature and origin of the "inhomogenous" perovskite grains that have been directly linked to non-radiative recombination and were previously unidentified (*1*). Finally, by combining scanning electron diffraction measurements with environmental chambers, we perform *in-situ* experiments to explore the local nanoscale structural modifications that occur in perovskite materials under real world operating conditions and how these structural modfications are linked to device degradation.

F.EL08.20.07

Elucidating the Influence of Compositional Heterogeneity on Charge Carrier Accumulation and Photodoping in Metal Halide Perovskites Stuart Macpherson, Jooyoung Sung, Tiarnan A. Doherty, Kyle Frohna, Elizabeth Tennyson, Miguel Anaya, Yu-Hsien Chiang, Akshay Rao and Samuel D. Stranks; University of Cambridge, United Kingdom

Metal halide perovskites are remarkable thin film semiconductors with numerous favorable properties that are optimal for photovoltaic and light emission applications[1]. These characteristics include high absorption coefficients, long charge carrier lifetimes and a tunable bandgap.

We have previously shown that the luminescence efficiency and charge carrier recombination behavior in mixed halide perovskites is significantly altered by the cation alloy employed during fabrication via facile solution processing[2]. The addition of alkali metal cations provides passivation of sub-bandgap defect states and also stabilizes an energetic landscape that facilitates photodoped carrier accumulation, leading to enhanced optoelectronic performance.

Our current work aims to further unveil the influence of microscopic compositional variations on local photoinduced carrier accumulation in (CsMAFA)PbI_xBr_{3-x} perovskite films. We combine Femtosecond Transient Absorption Microscopy with nanoscale X-ray Fluorescence and Atomic Force Microscopy to track carrier diffusion and recombination across a heterogenous chemical and morphological landscape. We find that the complex interplay of local carrier recombination and diffusion will have important ramifications for solar cell and LED device performance.

Ferroelastic Strain and Defect Behavior upon Repeated Bending of Flexible Methylammonium Lead Iodide Perovskite Films Rhys M. Kennard, Clayton J. Dahlman, Ryan DeCrescent, Jon Schuller, Kunal Mukherjee, Ram Seshadri and Michael Chabinyc; University of California, Santa Barbara, United States

The highest solar cell efficiencies in halide perovskite devices are achieved using compositional derivatives of tetragonal methylammonium lead iodide ($MAPbI_3$). Commercialization of flexible perovskite devices will require a thorough understanding of how applied strain modifies the perovskite structure and defect-related properties. A complication of studying strain behavior in tetragonal $MAPbI_3$ is that it is ferroelastic, meaning that it spontaneously forms multiple domains, also called “twins”. These twins exhibit identical crystal structure but different orientation, are inherently strained, and are separated by domain walls. The relative proportions of different twins can be semi-reversibly changed (“domain switching”) upon application of stress, via a process called ferroelastic hysteresis. Separate studies have shown that applying strain to $MAPbI_3$ films modifies defect-related properties such as the degradation rate, the activation energy of ion migration and the photoluminescence lifetime. However, potential correlations between changes to these properties in films and ferroelasticity have proven difficult to establish, as a detailed structural description of the ferroelastic behavior of $MAPbI_3$ under strain is missing.

In this work, we characterized in detail the ferroelastic hysteresis loop of $MAPbI_3$. Films of $MAPbI_3$ were cast on polymer substrates. We used Grazing Incidence Wide-Angle X-ray Scattering (GIWAXS) to first identify twin type and to assess the impact of the polymer substrate on the twins formed. Changes in the populations of different ferroelastic twins, in the strain magnitudes of different lattice planes, and in minimum domain sizes were then characterized for increasingly large applied strains. We thus identified approximate locations for the coercive stress (onset of domain switching) and saturation (all possible domain switching has occurred) on the stress-strain curve of $MAPbI_3$, as well as transformation strain magnitudes imparted by the hysteresis. Changes in the minimum domain sizes enabled deduction of evolution of the number of domain walls. The concentration of domain walls in films was found to closely correlate with previously-reported changes in the activation energy of ion migration, photoluminescence lifetime and degradation rate of $MAPbI_3$ films upon application of strain. The understanding gained by these results will aid design of more stable $MAPbI_3$ flexible devices with better-controlled ionic and electronic properties.

F.EL08.20.10
Ultrafast Photophysics of Metal Halide Perovskite Multiple Quantum Wells—Device Implications and Reconciling Band Alignment Andrew H. Proppe and Edward H. Sargent; University of Toronto, Canada

Metal halide perovskite quantum wells (QWs) have been used to fabricate efficient optoelectronic devices, and exhibit stability superior to that of their bulk 3D counterparts. The perovskite QWs are tuned in synthesis so that they possess different bandgaps and exciton binding energies owing to variable quantum confinement as a function of QW thickness. Accordingly, the device performance of these materials depends on the efficiency of various interwell carrier dynamical

processes, principally exciton and charge transfer. I will discuss the use of transient absorption and ultrafast two-dimensional electronic spectroscopy to probe interwell exciton transfer on timescales of 100s of femtoseconds, and show that interwell charge transfer occurs on timescales of 10s to 100s of picoseconds. These results, in addition to ultraviolet photoelectron spectroscopy experiments, are used to reconcile conflicting observations of type-I and type-II band alignment amongst perovskite QWs.

F.EL08.20.12
Rashba Band Splitting in Methylammonium Lead Iodide—An Insight from Spin-Polarized Scanning Tunneling Spectroscopy Abhishek Maiti, Salma Khatun and Amlan J. Pal; Indian Association for the Cultivation of Science, India

A low recombination rate of photogenerated carriers in methylammonium lead iodide ($MAPbI_3$) enhancing the carrier lifetime and thereby diffusion length is believed to be occurred due to Rashba band splitting [1] which arises due to a large spin-orbit coupling (SOC) arising out of high-*Z* elements (lead and iodine) in the compound along with a lack of centrosymmetry which appears due to a tilted PbI_6 octahedra and rotating electric dipoles of the organic ions leading to an effective magnetic field and thereby lifting the Kramer's spin-degeneracy of the electrons.[2] Regarding the spin-rotation or spin-texture (χ) of the two split-levels, two schools of thought persist amongst theoreticians: (1) spin-forbidden transition model and (2) spin-allowed transition model. In the spin-forbidden transition model, after spin-split, the CB and VB closer to the Fermi energy possess opposite spin-textures. A recombination between electrons in CB-minimum and holes in VB-maximum is hence a spin-forbidden process leading to a low recombination rate and thereby an enhanced carrier lifetime and a longer diffusion length.[1] On the other hand, such possibility has been overruled in the spin-allowed transition model as CB and VB possess a similar type of spin-texture closer to the Fermi energy where the recombination of photo-excited carriers is apparently possible due to spin-allowed nature of the transition.[3] In this regard, we have reported an experimental observation of Rashba splitting in $MAPbI_3$ through spin-polarized scanning tunneling spectroscopy to probe the split bands.[4] d*I*/d*V* spectra recorded at many different points of the film allowed us to spot both the Rashba split-levels and also to deliberate on their spin-textures. We observe that the bands split in such a manner that the conduction and valence bands closer to the Fermi energy have the same type of spin-textures (a spin-allowed transition model). Still a low recombination rate of photogenerated carriers in $MAPbI_3$ has been analyzed by considering Wannier-type excitons, a molecular nature of spin-domains as observed from the d*I*/d*V* images, and therefore a spin-forbidden nature of inter-domain transition.

Late News: Comparison of Different Functionals for First-Principles Calculations of Defects in Metal Halide Perovskites Haibo Xue[1], Geert Brocks[2,1] and Shuxia Tao[1]; [1]Eindhoven University of Technology, Netherlands; [2]University of Twente, Netherlands

Being one of the most promising photovoltaic materials, the metal halide perovskites have attracted plenty of scientific effort in improving their opotoelectronic properties and long-term stability. Both properties are highly sensitive to the nature and the concentration of the intrinsic defects in the perovskites. The first-principles calculation is very useful to predict the thermodynamics relevant to the formation of the defects and their consequences in the optoelectronic properties and plays an essential role in complementing experiments in understanding the defect chemistry and physics. However, due to the intrinsic complexity of the halide perovskites, i. e. hybrid composition and covalent-ionic bonds, diverse results were reported using

different functionals within the density functional theory framework. Here, using the typical perovskite, $MAPbI_3$, as an example, we show a comprehensive comparison of a wide range of functionals including GGAs, meta-GGA (SCAN), and combination of them with atom-pairwise (DFT-D3) and non-local (rev-vdW-DF2 and rVV10) van der Waals (vdW) correction. Our results indicate meta-GGA (SCAN) predicts consistently more accurate geometries and energies than GGAs and the vdW correction is essential for describing the vdW bonds associated with the organic cations in the hybrid perovskites. Based on the above, we suggest the SCAN+rVV10 is the most promising functional and is expected to improve on the accuracy for other halide perovskites in this large family of materials.

F.EL08.21.02

Late News: Machine Learning Framework for Accelerated Development of Halide Perovskites Meghna Srivastava[1], John Howard[2,2], Tao Gong[1] and Marina S. Leite[1]; [1]University of California, Davis, United States; [2]University of Maryland, United States

Metal halide perovskite solar cells (PSC) are a high-efficiency, low-cost alternative to Si photovoltaics. However, various environmental stressors (light, humidity, temperature, bias, and oxygen) initiate degradation in perovskite devices, which limits device lifetimes and impedes commercialization. Discovering materials and fabrication parameters that provide a stable performance is therefore vital. Machine learning (ML) accelerates design at every level of the PSC development process while offering novel physical insight. We present a framework for applying ML to (A) perovskite compositional screening, (B) material synthesis and stability analysis, and (C) full device development and testing. Key parameters such as crystal lattice parameters, quasi-fermi-level splitting, and power conversion efficiency (PCE) are extracted from experimental data, including X-ray diffraction (XRD), photoluminescence (PL), and current-voltage (I-V) characteristics. Traditionally, these data lead to a time-consuming trial-and-error process that informs optimal perovskite compositions, fabrication processes, and device operating conditions. ML models expedite this process and, once trained, use easily acquired experimental data to immediately predict figures of merit or future material/device performance (including forecasting time-resolved behavior). These predictions then guide further experimental investigation. Our generalized roadmap involves (1) identifying the material question of interest, (2) obtaining data for model training, (3) data pre-processing, (4) feature engineering, and (5) model optimization and testing. We demonstrate this process from start-to-finish using several baseline models trained on currently available data from the perovskite community, noting potentials for fine-tuning and extension. As one example, we use past time-series PL and relative humidity (rH) data to forecast humidity-dependent light emission for methylammonium lead triiodide (MAPI), methylammonium lead tribromide, and triple-cation (formamidinium-methylammonium-cesium) perovskite thin films. For this task, we implement an echo state network (ESN), a type of recurrent neural network (RNN). The optimized model predicts PL output with <15% normalized root mean square error (NRMSE) for all compositions over 12+ hours. We train an additional ESN to forecast power output from a PSC with a triple-cation absorber, using light intensity and temperature data as inputs, and obtain an NRMSE of only 3.1%. In addition to time-series prediction, ML models can extrapolate from ground truth experimental data to novel conditions. This reduces laboratory time drastically and eliminates the need for exhaustive trial-and-error work. For example, we train a long short-term memory (LSTM) model on temperature-dependent aging data from a MAPI PSC. We generate degradation traces at unseen temperatures with <3% NRMSE. Finally, we show image-based machine learning, using a convolutional neural network (CNN) to extract hidden trends from dark-field images of spiro-OMeTAD (a common hole-transport layer in PSC devices) and predict film conductance. Although the images have no visual trends discernable by the human eye, the model achieves an NRMSE of 19%. These examples illustrate the versatility of ML as a tool in PSC research, and our workflow is easily generalizable to other facets of development. We propose integrating projects from all three levels of PSC design (composition, material, and device) into a streamlined ML pipeline that includes materials discovery, fabrication, characterization, and stability testing. This pipeline takes advantage of our current technological capabilities in ML, data science, and autonomous experimentation and presents a rational, accelerated pathway to PSC commercialization.

F.EL08.21.03

Late News: Atomistic and Electronic Origin of Phase Instability of Metal Halide Perovskites Junke Jiang[1], Feng Liu[2], Ionut Tranca[1], Qing Shen[2] and Shuxia Tao[1]; [1]Eindhoven University of Technology, Netherlands; [2]The University of Electro-Communications, Japan

The excellent optoelectronic properties of metal halide perovskites (MHPs) have attracted extensive scientific interests and boosted their application in optoelectronic devices. Despite their attractive optoelectronic properties, their poor stability under ambient conditions remains the major challenge, hindering their large-scale practical applications. In particular, some MHPs undergo spontaneous phase transitions from perovskites to non-perovskites. Compositional engineering via mixing cations or anions has been widely reported to be effective in suppressing such unwanted phase transition. However, the atomistic and electronic origins of the stabilization effect remain unexplored. Here, by combining Density Functional Theory (DFT)

calculations and Crystal Orbital Hamilton Population (COHP) analysis, we provide insights for the undesired phase transition of pristine perovskites ($FAPbI_3$, $CsPbI_3$, and $CsSnI_3$) and reveal the mechanisms of the improved phase stability of the mixed compounds ($Cs_xFA_{1-x}PbI_3$, $CsSn_yPb_{1-y}I_3$, and $CsSn(Br_zI_{1-z})_3$). We identify that the phase transition is correlated with the relative strength of the M-X bonds as well as that of the hydrogen bonds (for hybrid compositions) in perovskite and non-perovskite phases. The phase transition can be suppressed by mixing ions, giving rise to either increased bond strength for the perovskite or decreased bond strength in their non-perovskite counterparts. Our results present a comprehensive understanding of the mechanisms for the phase instability of metal halide perovskites and provide design rules for engineering phase-stable perovskite compositions.

Late News: Atmosphere Affecting Lattice and Degradation Mechanisms of High-Efficiency Perovskite Solar Cells Renjun Guo[1], Dan Han[2], Wei Chen[1], Manuel A. Scheel[1], Lennart K. Reb[1], Nian Li[1], Shambhavi Pratap[1], Tianxiao Xiao[1], Suzhe Liang[1], Christian L. Weindl[1], Shanshan Yin[1], Hubert Ebert[2], Matthias Schwartzkopf[3], Stephan V. Roth[3,4] and Peter Muller-Buschbaum[1,5]; [1]Technische Universität München, Germany; [2]Ludwig-Maximilians-Universität München, Germany; [3]Deutsches Elektronen-Synchrotron, Germany; [4]KTH Royal Institute of Technology, Sweden; [5]Heinz Maier-Leibnitz-Zentrum, Germany

Metal halide perovskites have shown a promising future for application in field-effect transistors, light-emitting diodes, sensors, solar cells, and photodetectors due to their excellent optic-electrical properties. Among the excellent properties of perovskites, for example, strong absorption, the long diffusion length of photo-generated charge carriers and low binding energies make it possible to realize next-generation solar cells with 25.2% power conversion efficiency (PCE) in a decade. At the same time, perovskite solar cells (PSCs) have shown a powerful photovoltaic application for replacing silicon solar cells not only due to high PCE but also because of its low processing costs. Despite such advantages, the application of PSCs is currently limited by combining high performance and operational stability, because the PCE of PSCs can degrade due to the presence of temperature, light, humidity, and oxygen. So far, the degradation research on PSCs is carried out without having an established standard protocol. The microscopic degradation mechanisms are not clear under operating conditions upon suggested inert atmospheres based on the International Summit on Organic Photovoltaic Stability protocols. Therefore, it is necessary to establish an improved standard protocol for the long-term degradation of PSCs.

In this respect, we investigate the degradation processes of PSCs under both, AM 1.5G and different atmosphere conditions (vacuum and nitrogen) with in-operando grazing incidence wide-angle X-ray scattering (GIWAXS) and grazing incidence small-angle X-ray scattering (GISAXS). With these approaches, we find that mixed cations lead mixed halides lattice exhibit the effect of photostriction when being operated in different atmospheres. In addition, the nature of photostriction can help the phase segregation of halide perovskites. Pressure conditions can suppress this photostriction behavior. Theoretical calculations based on density functional theory confirm that lattice photostriction behavior can suppress phase segregation induced by thermodynamic driving forces. A standard protocol is suggested based on our findings.

Late News: Study of the Formation of Different Electron Transport Layer (ETL) Materials and Their Impacts on Perovskite Solar Cell (PSC) Performance Luisa Pan[1], Pranati Patnam[2], Benjamin Roitman[3], Yifan Yin[4], Yuchen Zhou[4], Miriam H. Rafailovich[4] and Chang-Yong Nam[5]; [1]The Harker School, United States; [2]Herricks High School, United States; [3]SAR High School, United States; [4]Stony Brook University, The State University of New York, United States; [5]Brookhaven National Laboratory, United States

Perovskite solar cells (PSC) are believed to be the core of next-generation solar cells due to their rapidly increasing efficiency and popularity as an alternative energy source to fossil fuels. However, the interfacial contact between the electron transport layer (ETL) and the perovskite layer in the cell often results in problems of hysteresis. This research investigates different ETL materials to remedy hysteresis in organic-inorganic CH3NH3PbI3 (MAPbI3) PSCs. Compact TiO2 (c-TiO2), SnO2 (0.1M and 0.2M), and mesoporous TiO2 (m-TiO2) (1:4 and 1:6 w:w) were deposited as the chosen ETL materials via spin-casting and followed by high-temperature annealing. The PSC devices were built using FTO glass, MAPbI3, and gold electrodes (80nm).
Scanning electron microscopy (SEM) was utilized to take cross-sectional images of the solar cell after depositing the perovskite layer. Higher values in the precursor ETL solution concentration correlated with increased ETL thickness. Qualitative analysis of the c-TiO2/m-TiO2 bilayer SEM image demonstrated that the perovskite layer also effectively diffused into the porous m-TiO2, which increased the interfacial contact between the perovskite and the ETL. Although the control c-TiO2 had a power conversion efficiency (PCE) of 14.5%, the sample had a hysteresis index of 0.400. In comparison, the 34mM TiO2 sample had a PCE of 11.9% with a more desired hysteresis index of 0.034. The m-TiO2 bilayer

sample, albeit having a PCE of 6.8%, had a hysteresis index of 0.121, suggesting that the mesoporous layer aided in reducing the hysteresis index of the original c-TiO2 ETL.
We gratefully acknowledge support from the Louis Morin Charitable Trust.

Late News: Ultralong Micro-Belts of Luminescent Lead Halide-Based Perovskites Fnu Parul; Indian Institute of Technology Roorkee, India

Ultralong micro-belts of MAPbI3 show bright and stable fluorescence in solution. Luminescent perovskites have been synthesized through centrifugation of a solution-processed with a ligand-assisted reprecipitation technique (LARP). All electron spectroscopic analysis provided evidence for the stacking of nanocrystals as bundles of self-assembled micro-belts. Under an applied bias, migration of free charge carriers through the long axis is feasible. Thus, long micro-belts are promising channel materials for two-electrode nanodevices for good electrical conductivity.

F.EL08.21.07
Late News: Compositional Effect on Water Adsorption on Metal Halide Perovskites QIihua Li, Zehua Chen, Ionut Tranca, Silvia Gaastra-Nedea, David Smeulders and Shuxia Tao; Eindhoven University of Technology, Netherlands

The moisture-induced instability of metal halide perovskites is one of the major challenges for perovskite devices. Although compositional engineering has been widely employed to improve the overall stability of perovskites, its effect on the moisture-induced instability received little attention. Here, we systematically study the interaction of water with the surfaces of primary perovskites, AMX_3 ($A^+ = MA^+, FA^+, Cs^+$; $M^{2+} = Pb^{2+}, Sn^{2+}$; $X^- = I^-, Br^-$), by using Density Functional Theory (DFT) calculations and comprehensive chemical bonding analysis. We reveal that the hydrophilic group NH_3^+ of MA^+ cation may be the cause for instability issues. We find that the adsorption of water on $FAPbI_3$ and $CsPbI_3$ are much weaker than on $MAPbI_3$ due to the less polarity of FA^+ and Cs^+. When exchanging M^{2+} cations, water adsorption on $MASnI_3$ is also less energetically favorable than on $MAPbI_3$ because of the weaker ionic interaction of H_2O-$MASnI_3$. When exchanging X^- anion, water adsorption on $MAPbBr_3$ is slightly weaker than on $MAPbI_3$ due to the slightly weaker covalent interaction of H_2O-$MAPbBr_3$. Our results present a comprehensive understanding of the compositional effect on the interactions of water with perovskites and provide rational design strategies to improve their stability against moisture via compositional engineering.

F.EL08.21.08
Late News: Unified Thermodynamic Theory for Light-Induced Phase Separation in Mixed Halide Perovskites Zehua Chen[1], Geert Brocks[2], Peter Bobbert[1] and Shuxia Tao[1]; [1]Eindhoven University of Technology, Netherlands; [2]University of Twente, Netherlands

In the dark and at room temperature most mixed halide perovskites are thermodynamically stable. Under illumination, however, funneling of photo-excited carriers to a phase with a lower band gap than the parent phase leads to halide demixing. This is problematic for the application of mixed halide perovskites in solar cells. Here, we present a unified thermodynamic theory for this light-induced phase separation and apply it to five mixed iodine-bromine perovskites. Under illumination, the spinodals separating the metastable and unstable regions in the composition-temperature phase diagrams show an upward shift in temperature, while the binodals separating the stable and metastable regions acquire an additional branch signaling the nucleation of a low-band gap iodine-rich phase. We find that the threshold illumination intensity is mainly governed by the band gap difference of the parent and iodine-rich phase. Partial replacement of organic cations by cesium reduces this difference and therefore has a stabilizing effect.

F.EL08.21.09
Late News: Charge Carrier Dynamics in Two-Dimensional Hybrid Perovskites—Impact of Spacer Cations Dibyajyoti Ghosh; Los Alamos National Laboratory, United States

Two-dimensional (2D) halide perovskites are promising materials for environmentally stable next-generation optoelectronic device applications. However, there is very little atomistic understanding of the charge carrier dynamics at ambient conditions for these materials, limiting the possibilities to tune their optoelectronic performances through compositional engineering routes. *Here, by combining nonadiabatic molecular dynamics with time-domain density functional theory methods at room temperature, we study the dominant non-radiative carrier recombination and dephasing processes in monolayered lead halide perovskites*. Our systematic study demonstrates that performance-limiting nonradiative carrier recombination processes greatly depend on the electron-phonon interactions induced by structural fluctuations and instantaneous charge localization in these materials. *The stiffer interlayer packing in presence of selectively chosen spacer*

cations (benzene ring or cyclic dication based), which separates the lead iodide slabs, reduces the thermal fluctuations in these 2D-perovskites to a greater extent.[1-2] These reduce the inelastic electron-phonon scattering and enhance the photogenerated charge carrier lifetime in layered perovskites making them suitable for various optoelectronic devices. The computational insights gained from these studies allow us to outline a set of robust design principles for 2D halide perovskites to strategically tune their optoelectronic properties.

F.EL08.21.12

Late News: Synthesis, Photocatalytic Properties and Phase Stability Studies of Full Inorganic CsPbBr3 and CsPb2Br5 Perovskites Anna L. Pellegrino[1,2] and Graziella Malandrino[1,2]; [1]Università degli Studi di Catania, Italy; [2]INSTM, Italy

The compounds belonging to the family of perovskites show a great variety of mechanical, magnetic and optical properties, and for these reasons are nowadays key materials for many technologies, including piezoelectrics, photovoltaic solar cells and photocatalytic systems.
Among perovskites, the most studied crystal structure ABX_3 for photocatalysis and photovoltaic applications is composed of an organic/inorganic compounds made of: monovalent cation A = methylammonium (MA: $CH_3NH_3^+$); formamidinium (FA: $CH(NH_2)_2^+$); a divalent metal cation B = Pb^{2+}, Sn^{2+}; and an halide anion X = I^-; Br^-; Cl^-. These hybrid lead-based materials have excellent properties and contain elements that are both cheap and abundant. However, they tend to partially decompose when exposed to air, water, ultra-violet light, or heat. For these reasons, several substitutions have been attempted to improve the properties and performances of these materials. One route to improve the stability of these structures is to explore the all-inorganic perovskite systems and thus finding alternatives to replace organic components. Particularly, our attention is devoted to the all-inorganic perovskites, i.e. $CsPbBr_3$ and $CsPb_2Br_5$, which do not have any labile or expensive components and show remarkable stability. Furthermore, unlike the hybrid structures, the entire fabrication process of all-inorganic analogous materials can be operated in ambient atmosphere without humidity control systems. Additionally, $CsPbX_3$ (X = Cl, Br, and I) perovskite family shows high performances for photocatalytic and photo-electrochemical degradation processes of different organic dye compounds, and are also exceptional candidates as photocatalysts for organic reactions. Among the different strategy developed for their synthesis, the surfactants-based solution route is widely applied, which also allows to control the stability and the growth kinetics according to the surface chemical phenomenon and the solubility equilibrium. Herein we report a novel synthetic strategy, which represents a facile, one-step, low-temperature and surfactant free approach to the synthesis of Cs-Pb-Br microcrystals, using Cs and Pb β-diketonate metallorganic complexes. The present precipitation approach represents an innovative and interesting strategy of synthesis, which avoids the use of surfactant species and toxic solvents, and, taking the advantages of the β-diketonate metalorganic Cs and Pb precursors reactivity, it allows, reproducibly and selectively, the synthesis of $CsPbBr_3$ and $CsPb_2Br_5$ microcrystals. Structural, morphological and compositional analyses of the final products, addressed through X-ray diffraction (XRD), field-emission scanning electron microscopy (FE-SEM) and Energy Dispersive X-ray (EDX) analysis, show the formation of pure and stable $CsPbBr_3$ or $CsPb_2Br_5$ systems characterized by squared microcrystals, with a grain size up to 3μm. The stability of the two different phases has been tested as a function of heating treatment and UV exposure as well. Moreover, as a proof-of-concept, the photocatalytic properties of degradation processes have been tested using organic dye solutions, showing high degradation yield up to 70% under UV lamp (λ=360 nm).

F.EL08.21.13

Late News: Synthesis of Lead-Free All-Inorganic $Cs_3Sb_2Br_9$ Perovskite Microplates by Two-Step Chemical Vapor Deposition for Fast Response Visible Light Photodetector Application Sujit Kumer Shil[1,2], Fei Wang[1], Mohammad Kamal Hossain[1], Cheuk Kai Gary Kwok[1], Kingsley O. Egbo[1], Ying Wang[1] and Kin Man Yu[1,1]; [1]City University of Hong Kong, Hong Kong; [2]Khulna University of Engineering & Technology, Bangladesh

Lead-based halide perovskites ($CsPbX_3$, X=Cl, Br, I) are well-known for their attractive properties which make them suitable materials for many optoelectronic devices. But the toxicity of lead (Pb) undoubtedly hinders the development and commercialization of these devices. Therefore, Pb-free, environmental friendly all-inorganic halide perovskites are now the subject of enormous interest to the scientific community. It has been suggested that antimony (Sb) can be a possible replacement of Pb ($Cs_3Sb_2X_9$) in these inorganic halide perovskites. Until now Sb-based all-inorganic perovskites have been synthesized by solution processes but properties are still inferior to Pb-based materials. However, due to the low melting point of Sb halides, synthesis of high quality $Cs_3Sb_2X_9$ using chemical vapor process is still a challenge. In this work, we present a report on the synthesis and properties of Pb-free all-inorganic $Cs_3Sb_2Br_9$ perovskite microplates by a two-step chemical vapor deposition (CVD) approach. In step-I, CsBr powder was vaporized at 530°C at a pressure of 4.8 Torr under

50 sccm of Ar flow for 10 minutes in a single-zone CVD furnace. In step-II, due to low melting point, $SbBr_3$ powder was vaporized at 90°C under 15 sccm of Ar flow while the pressure and holding time were remained same as step-I. Substrates were placed at 22 cm downstream from the center. Finally $Cs_3Sb_2Br_9$ microplates with average size 20 μm were obtained after annealing the as-grown materials at 140 °C for 25 minutes. XRD analysis of the microplates shows the pure phase crystalline nature of the $Cs_3Sb_2Br_9$ perovskite structure. The optical band gap was measured by spectroscopic ellipsometry to be 2.6 eV. The UV-vis absorption spectrum revealed the exciton absorption peak at around 2.82 eV. Simple photoconductive devices fabricated using these microplates exhibit current on/off ratio of 10^2 upon 450 nm photon irradiation with a fast response of rise and decay time down to 79 ms and 28 ms, respectively. All these results clearly suggest the technological potential of inorganic lead-free $Cs_3Sb_2Br_9$ perovskite microplates for future optoelectronic devices.

Late News: Interfacial Engineering by Double Decked Electron and Hole Extraction Layers for Reproducible and Thermally Stable Perovskite Solar Cells. Shivam Singh and Dinesh Kabra; Indian Institute of Technology Bombay, India

Abstract: We present an interfacial engineering method to fabricate an efficient and thermally stable $MAPbI_3$ based perovskite solar cell with a double decked hole (*H*) and electron (*E*) extraction layers (EL) in an inverted (*p-i-n*) architecture. The double HEL film is fabricated by thermal evaporation of MoO_3 and spin-coating of poly(3,4-ethylene dioxy-thiophene)–poly(styrene sulfonate) (PEDOT:PSS). The double EEL is formed by spin-coating of phenyl-C61-butyric acid methyl ester ($PC_{61}BM$) and bathocuproine (BCP). The role of BCP as a buffer layer is quite established in the community to prevent the formation of metal induced charge state at the perovskite- EEL interface. Despite of presence of BCP interlayer, the thermal stability of *p-i-n* architecture still suffers. We observed that the underneath MoO_3 layer provides an improved morphology for perovskite film and reduces the shunt path. However, the BCP buffer interlayer not only passivates the defects at the perovskite- EEL interface and but also helps to plenaries the thin-films for better contact with Ag. Thus, double EEL and HEL facilitate better charge collection at the interfaces and shows improved power conversion efficiency (PCE) of ~15%. Besides the improved PCE, double EEL and HEL based structures also provide an approach to have better reproducibility and high thermal stability of perovskite solar cells. We also address the issue of area dependent efficiency and explore the reasons behind the increased efficiency of smaller area devices. We believe reproducibility, stability and area dependence are the most important aspects for current perovskite PV research and thus this study will provide an important insight for further development.

Keywords: *$MAPbI_3$, double extraction layer, thermal stability, solar cells, BCP, MoO_3*

F.EL08.21.16
Late News: GFN1-xTB Method for a Fast Calculation of Metal Halide Perovskites Properties for Solar Cells Applications Jose Manuel Vicent-Luna, Sofia Apergi and Shuxia Tao; Eindhoven University of Technology, Netherlands

Metal halide perovskites (MHPs) for perovskite solar cells (PSCs) have gained great attention in just few years due to their rapid increase of photoconversion records of efficiency. In addition, MHPs exhibit a competitive fabrication cost together with a simple route to synthetize. Due to these facts, PSCs are recognized by scientists as a promising technology with enormous potential in the energy market. However, it is well known that many factors cause the degradation of PSCs, thus, industrial applications are critically hampered by instability issues.
Nowadays, experimental and theoretical researchers are investigating many possible alternatives to increase the stability of PSCs. In this context, computational techniques are being extremely useful to understand the properties of MHPs at microscopic level that cause instability of the material. Density functional theory (DFT) calculations are the key method for studying material properties, but the high computational cost limits the study to small systems and short time-scales. Classical simulations seem to be an option to overcome these limitations, but they suffer from other drawbacks such as classical simulations cannot describe electrons and chemical reactions. The study of many applications of MHPs requires the simultaneously modeling of electrons and ions in relatively large systems, sometimes not computationally affordable by the standard techniques. Therefore an intermediate approach between DFT and classical simulations is often desired. In this regard, semi-empirical Quantum Mechanics methods, such as density functional tight binding (DFTB), combine the

functionalities of describing both electrons and ions. Traditional DFTB methods are based on a simplification of the Kohn-Sham DFT total energy, using pre-computed interactions of element pairs, considerably reducing the computational cost. However, this parameterization lacks of transferability and is limited to a number of elements. A new extended tight binding method called GFN1-xTB has been recently developed to cover all the elements of the periodic table. This method was designed for the fast calculation of diverse physicochemical properties of systems of a few thousand atoms and has the advantageous of maintaining high accuracy and a limited number of parameters which can be refined for the study of a given application.
The performance of GFN1-xTB is benchmarked for a set of MHPs and compared with density functional theory calculations. We study organic and inorganic MHPs with formula ABX_3, with A = MA, FA, and Cs; B = Pb and Sn; X = I, Br, and Cl, being a total of 18 MHPs with cubic, tetragonal, and orthorhombic forms. We included the computation of structural, vibrational, and optoelectronic properties of these semiconductors. This work aims to provide a general overview of the performance of GFN1-xTB for the fast computation of the main features of MHPs. Our results indicate that this method can describe the targeted features of the MHPs, but performs worse for geometry relaxation calculations. We also identified the drawbacks of the method for particular compositions of MHPs, which hamper its use for solar cell applications.

F.EL08.21.17
Late News: Lone-Pair Driven Ferroelectric and Piezoelectric Response of Germanium Halide Perovskites CsGeX3 (X = Cl, Br, and I) Jiwoo Lee[1], Young-Kwang Jung[1] and Aron Walsh[1,2]; [1]Yonsei University, Korea (the Republic of); [2]Imperial College London, United Kingdom

While much attention has been paid to halide perovskites based on Pb and Sn cations on the B-site, Ge compounds offer a distinct combination of structure and properties. All three cations feature the same s^2 lone pair configuration; however, the stereochemical activity varies in each case. We performed a computational analysis via density-functional-theory and Berry phase calculations of the $CsGeX_3$ (X = Cl, Br, I) series. Our motivation is to clarify the existence and magnitude of ferroelectricity and piezoelectricity, which has important technological consequences such as polar nanodomains that can reduce the recombination of light-excited electron-hole pairs and extend the carrier lifetime [2]. The explanation for the origin of spontaneous polarization in Ge halide perovskites in terms of an on-site second-order Jahn-Teller effect has not been hitherto investigated [3]. In this work, we investigate the role of halide anions in spontaneous polarization within the modern first-principles theory of polarization. Our calculation results show that interaction between Ge lone-pair electrons and halogen *p*-orbital mainly determines the depth of the ferroelectric double well and the spontaneous polarization strength with Cl > Br > I. Further exploration of lone pair systems offers an exciting pathway to design novel photoelectric devices [4,5].

Late News: A Reactive Force Field for Large Scale Simulations of Metal Halide Perovskites Mike Pols[1,2], Jose Manuel Vicent-Luna[1,2], Ivo Filot[3,2], Adri v. Duin[4] and Shuxia Tao[1,2]; [1]Materials Simulation and Modelling, Department of Applied Physics, Eindhoven University of Technology, Netherlands; [2]Center for Computational Energy Research, Eindhoven University of Technology, Netherlands; [3]Laboratory of Inorganic Materials Chemistry, Schuit Institute of Catalysis, Eindhoven University of Technology, Netherlands; [4]Department of Mechanical Engineering, The Pennsylvania State University, United States

Metal halide perovskites have been the focus of many computational studies over the past few years. The bulk of these investigations were done using methods based on quantum mechanics (QM). However, the computational cost of QM methods is high, severely limiting the length and time scales of the systems that can be investigated. Molecular dynamics (MD) simulations have been successfully applied to simulate larger material systems and at longer time scales by making use of classical force fields (CFF). Nonetheless, the predefined connectivity in CFF makes them unsuited for the simulation of chemical reactions. A reactive force field (ReaxFF) is an extension to CFF by including a dynamic bond order that is calculated from the interatomic distances and allows for the simulation of bond breaking and formation. In this presentation, I will outline our progress in the creation of the first ReaxFF for halide perovskites, $CsPbI_3$.

Atomic Layer Deposition of 2D Perovskite Passivation Layers Jacob Vagott, Carlo Andrea Riccardo Perini and Juan Pablo Correa Baena; Georgia Institute of Technology, United States

In order to further advance perovskite solar cell efficiency from the current record of 25.2%, it is important to minimize perovskite perovskite crystal defects and increase interface performance through passivation layers. 2-D perovskites have shown great potential as passivation layers but are primarily deposited by solution processing. Drawbacks of using solution processing for 2-D perovskite films include toxicity of the solvent, potential insolubility of the precursors, and lack of precise thickness control. Atomic layer deposition (ALD) could be a solution to these problems. ALD allows for the deposition of highly uniform layers of perovskite with great control over the final thickness of the film. Self-limiting in nature, ALD processes may allow for depostion of monolayers of perovskite with more control than solution processing techniques. Although an established deposition technique, ALD processes for perovskites have yet to be developed. Through this work, we consider ALD as a method of depositing 2-D perovskites as passivation layers for perovskite solar cells. These passivation layers are further incorporated into devices and their effect on solar cell efficiency is analyzed.

F.EL08.13.04
Understanding the Effects of Sr Chemical Doping on Pb/Sn Based Perovskite Films Hurriyet Yuce Cakir[1,2] and Juan Pablo Correa Baena[2]; [1]Izmir Institute of Technology, Turkey; [2]Georgia Institute of Technology, United States

Organometal halide perovskites have been in the spotlight of semiconductor science over the past decade. Their exceptional electronic-optical properties and easy production from solution give them an edge over the semiconductor applications. The organic-inorganic halide perovskite solar cells (PSCs) have attracted the incredible attention of the researchers working on solar cells owing to a rapid increase in the efficiency of 25.5% since 2009[1,2].
Furthermore, tin/lead (Sn/Pb)-based perovskite offers lower toxicity compared to the lead-based perovskites[3]. Their bandgaps are close to 1.3-1.4 eV which is the ideal bandgap of an absorber layer in a solar cell regarding the Shockley-Queisser model[4].
In this study, we have performed SrI_2 addition (ranging from 0.1% to 5.0% concentrations) to the $(FASnI_3)_{0.8}(MAPbBr_3)_{0.2}$ perovskite to improve their physical properties. Moreover, we have investigated the incorporation of SrI_2 into perovskites impacts on the morphological and optical properties of perovskite films.

F.EL08.13.06
Revealing the Internal Luminescence Quantum Efficiency of Perovskite Films via Accurate Quantification of Photon Recycling Paul Fassl[1], Vincent Lami[2], Ian Howard[1], David Becker-Koch[2], Felix Berger[2], Lukas Falk[2], Raphael Schmager[1],

Jana Zaumseil[2], Bryce Sydney Richards[1], Yana Vaynzof[2] and Ulrich W. Paetzold[1]; [1]Karlsruhe Institute of Technology, Germany; [2]Heidelberg University, Germany

The high refractive index of perovskite semiconductors at their emission wavelength (n ~ 2.3-2.6) results in a narrow emission escape cone and a large amount of photoluminescence (PL) to be trapped within perovskite thin films. Due to strong band edge absorption and a very small luminescent stokes shift, this effect leads to considerable photon reabsorption and reemission - an effect known as photon recycling (PR) [1] - as well as a concurrent red-shift of propagating PL due to emission filtering [2]. As recently highlighted, the self-absorption induced redistribution of charge carriers and outcoupling of propagated PL can lead to a significant misinterpretation of measurements of the intrinsic bimolecular recombination and charge carrier diffusion coefficients as well as of asymmetric PL spectral shapes [3, 4]. For perovskite films with low non-radiative recombination and parasitic absorption losses, PR can be of great advantage as it allows higher charge carrier densities at steady-state and thus increased device open-circuit voltage [5]. However, most current models still start from the simplified assumption that all initially trapped PL will be reabsorbed at some point without the possibility of being outcoupled, likely overestimating the effect of PR [6]. In this study, we show that in external photoluminescence quantum efficiency (PLQE) measurements employing an integrating sphere setup, the PL spectra of polycrystalline perovskite films with layer thicknesses typically employed for thin film solar cells (~150-500 nm) exhibit a notable red-shift and broadening. Such asymmetric PL spectra are often ignored or misinterpreted in the literature. We developed an all-optical model that considers both PR and outcoupling of initially trapped filtered PL due to scattering, which can reproduce spectral shapes with varying extents of red-shifts. We determined the true PL spectral shape as well as the absorption spectrum via high resolution confocal PL measurements and photothermal deflection spectroscopy respectively. Our model allows to estimate the total escape probability in addition to the initially generated internal PL intensity and thus to determine the internal PLQE of perovskite thin films. We confirm our assumptions by various control experiments and Monte Carlo simulations, benchmarking the model for perovskite thin films with different grain size, thickness and composition. Our approach serves as a new guideline for estimating these important parameters directly from measurements of the external PLQE and PL spectrum using an integrating sphere setup. [1] L. M. Pazos-Outon et al., Photon Recycling in Lead Iodide Perovskite Solar Cells. Science 2016, 351, 1430-1433. [2] B. Energy Level Alignment of Formamidinium Tin Iodide with Organic Contact Materials Jonas Horn, Pascal Schweitzer and Derck Schlettwein; Justus Liebig University Giessen, Germany

The alignment of energy levels at the interface of perovskite absorber and adjacent hole- and electron-transporting material affects the formation of space-charge regions and interfacial recombination. These have consequences for charge transport in the layers and, therefore, for the efficiency of devices. We measured this alignment by the use of Kelvin-probe-force microscopy (KPFM) to gain a detailed understanding of this alignment of energy levels. This study is focused on Formamidinium tin iodide (FASnI3) as perovskite absorber. This material avoids the toxicity problems of lead and is known to yield the highest power conversion efficiencies amongst all lead free perovskite absorbers. The most common solar cell geometry for FASnI3 implements C60 as electron-transporting material, which is prepared on FASnI3 by physical vapor deposition (PVD). Intermittently to PVD, we use KPFM to simultaneously monitor morphology and work function of C60 during its growth on FASnI3. We show that a sufficiently high deposition rate is needed to avoid island formation of C60 and obtain a homogeneously covering film with constant work function. We further show that the width of the space charge layer in C60is larger than the film thickness often implemented in perovskite solar cells (20 nm - 30 nm). A band bending in the range of 300 meV is observed and consequences for prospective device operation are discussed.

The Underlying Mechanism of Surface Defect Passivation Process for Organohalide-Lead Perovskite Nanocrystals Artavazd Kirakosyan[1], Duc Chinh Nguyen[1], Min-Gi Jeon[1], Jae Hyuck Jang[2], Jihoon Choi[1] and MoonRyul Sihn[1]; [1]Chungnam National University, Korea (the Republic of); [2]Korea Basic Science Institute, Korea (the Republic of)

Organolead halide perovskite nanocrystals (NCs) have emerged as a versatile and promising active material for many optoelectronic applications such as solar energy harvesting, light-emitting device, and photodetectors owing to their size- and

composition-dependent optoelectronic properties. Although the extensive studies on their optical and electronic properties have been studied in the last several years, their low stability, structural integrity, and poor luminescence stability associated with the fast attachment-detachment dynamics of surface capping molecules during post-processing limit their practical applications in optoelectronics. Therefore, an in-depth understanding of the surface chemical processes is required. We found that the amine group (-NH3+) immobilizes Br- anion at the corner of undercoordinated PbBr64- octahedron on the MAPbBr3 surface resulting in a charge-balanced Pb-Br framework where Br/Pb ratio is slightly higher than stoichiometry, and thus provides exciton radiative recombination and high photoluminescence quantum yield. In contrast, the oleic acid is not able to coordinate with the surface moieties of the perovskite, but rather carboxyl acid groups (-COO-) etch Pb2+ into solution when only acid was used. Interestingly, a mixture of oleic acid and amine-functionalized surfactants was found to promote amine conversion to ammonium ion (-NH2 + H+ ® -NH3+), which is favorable for their localization on the surface. Our results show that the Br vacancies at the non-passivated surface result in a reduction of Pb2+ to Pb0 by trapping the electrons generated from the exciton dissociation, which provides the main pathway for exciton trapping. Impact of Temperature and Humidity on the Stability of the Optical Properties and Structure of Formamidinium Lead Iodide Thin Films and Solar Cells Marie Solange Tumusange, Biwas Subedi, Cong Chen, Maxwell M. Junda, Juan Zuo, Zhaoning Song, Yanfa Yan and Nikolas Podraza; University of Toledo, United States

Organic-inorganic lead halide perovskite polycrystalline thin films used as absorber layers in high efficiency solar cells have direct band gaps, high absorption coefficients, and potentially low-cost solution-based fabrication processing. However, these materials are inclined to degradation with exposure to humidity, oxygen, heat, and ultraviolet light. Formamidinium lead iodide (FAPbI3) is an attractive composition perovskite as it has a more symmetric crystal structure due to a larger cation radius for FA compared to that for methylammonium (MA) as well as an elevated decomposition temperature for improved stability. Even though FAPbI3 is among the more stable perovskite compositions, solar cells incorporating these absorbers still degrade with atmospheric exposure over time. Here we study the behavior of FAPbI3 film structure and complex optical properties under controlled temperature variations and relative humidity (RH) exposure. In situ real time spectroscopic ellipsometry (RTSE) measurements are collected over the near infrared to ultraviolet spectral range (0.75-5.9 eV) for polycrystalline FAPbI3 thin films deposited on glass substrates which are then held at different temperatures, ranging from 7 to 70oC, in a sealed nitrogen chamber with controlled 0, 26, and 85% RH introduced. From RTSE, the optical response in the form of complex dielectric function (e = e1 + ie2) spectra is deduced using a parametric model accounting for above band gap critical points, the direct band gap, an Urbach tail, and degradation induced sub-gap absorption due to defects. Variations in parameters describing spectra in e are tracked as functions of temperature, controlled RH, and the amount of time films are held under those conditions. Changes in bulk thickness, surface roughness thickness, and surface roughness relative density are also tracked with time under these conditions. For example, RTSE indicates no change in structure and minimal changes in e at 0% RH regardless of temperature. However, when FAPbI3 is exposed to 26% RH at 7oC, RTSE indicates changes in parameters describing e and structure, such as increases in film thickness with time indicative of water intercalation. To the contrary, slight film densification is observed over time when held at 26% RH and 70oC. These RTSE studies show that deviations from near room temperature with controlled relative humidity induces more changes in optical and structural properties with time than when the sample is exposed to only humidity. In all cases of RH exposure sub-gap absorption increases with time, most notably in widening of the Urbach tail obtained from the parametric model for e. To further study how other ambient conditions affect perovskite stability, RTSE is performed for FAPbI3 with exposure to controlled amounts of both oxygen and relative humidity as a function of temperature. RTSE is applied directly to measure a FAPbI3 based solar cell to track changes in the perovskite absorber over time and identify potential correlations with device performance.

F.EL08.13.12

Diagnosis of Optical and Electrical Losses in Organic-Inorganic Lead Halide Perovskite Photovoltaics via External Quantum Efficiency Modelling Biwas Subedi, Chongwen Li, Zhaoning Song, Maxwell M. Junda, Kiran Ghimire, Yanfa Yan and Nikolas Podraza; University of Toledo, United States

Organic-inorganic lead halide perovskite-based photovoltaics (PV) exhibit high initial efficiency, can be processed at potentially low cost, and material bandgaps can be tuned by composition. Solution-processing enables fabrication of a range of different ABX3 (A: methylammonium—MA, formamidinium—FA, Cs; B: Pb, Sn; X: I, Br, Cl) perovskite compositions to meet these needs in single or tandem junction PV. Unfortunately, these perovskites may degrade upon exposure to relative humidity and oxygen in ambient air, during device processing, and overtime during device operation. Like all PV devices,

performance depends on the characteristics of each material and interfaces between layers to minimize sources of optical and electronic losses. External quantum efficiency (EQE) simulations of perovskite PV assess sources of parasitic optical losses with input complex optical response of all component materials and known multiple layer device structure. From these simulations, the optical performance of devices with different structures or component materials is predicted. Comparison of simulated EQE with experimental measurement validates the optical model when simulated and experimental EQE match but also more importantly identifies electronic losses such as incomplete carrier collection when experimental EQE is less than the simulation. Obtaining the most accurate input complex optical response of perovskite films and layer thicknesses in devices is necessary to maximize the amount of information gained from EQE and its modeling. Toward this end, spectroscopic ellipsometry (SE) over the near-infrared to the ultraviolet wavelength range (0.73-5.9 eV) is used to characterize the complex optical response of solution-processed perovskite films of different compositions. Photothermal deflection spectroscopy (PDS) and unpolarized transmittance complement SE by enhanced sensitivity to low values of absorption coefficient (?) in the vicinity of the bandgap. Extension to low values of ? enables detection of exponential band tailing and Urbach Energy (EU), with narrower EU indicative of more ordered and higher electronic quality material. A parametric optical property model has been developed which includes contributions from electronic transitions above the bandgap, the direct bandgap, an exponentially decaying Urbach tail, and sub-gap absorption due to defects. Complex optical properties of perovskite films, including wide-bandgap FA1-xCsxPb(I1-yBry)3 and narrow-bandgap (FASnI3)x(MAPbI3)1-x compositions, in both as-prepared and degraded states are determined. SE data is collected for complete perovskite PV to deduce layer thicknesses and perovskite complex optical properties within the device. This information serves as direct input for EQE simulation. Comparison with perovskite PV experimental EQE enables the deduction of optical and electronic device performance losses arising from perovskite composition and device architecture, variations in near bandgap perovskite optical response resulting from complete device processing, and perovskite degradation during solar cell operation. As an example, similar simulated and experimental EQE in (FASnI3)x(MAPbI3)1-x (0.3 ? x ? 0.7) perovskite PV validates the optical model and indicates minimal losses. In another case, for FAPbI3 PV comparisons between simulation and experimental EQE indicate sources of both optical and electronic losses arising from device processing.

F.EL08.13.13
Enhanced Charge Extraction Through Double-Layered Electron Transfer Films for Hybrid Perovskite Planar Solar Cells Jihyun Kim, Hye Ri Jung, Yeon Soo Kim and William Jo; Ewha Womans University, Korea (the Republic of)

The electron transfer film (ETF) plays an important role in obstructing recombination of electrons and holes between the perovskite layer and fluorine-doped tin oxide in planar perovskite solar cells (PSCs). In addition, at the compact spin-coated SnO2 ETF, morphological defects, such as pinholes and cracks, due to roughness of the substrate seriously impact on the performance of PSCs. Here, we investigate the variables that can control the charge extraction using spin-coated SnO2, sputtered TiO2 and double-layered (DL) ETF composed of TiO2 on SnO2 and SnO2 on TiO2. We determined the resistance, mobility, conductivity and carrier concentration of double-layered ETF based on PSCs by a 4-probe method. The electrical properties show that the DL-ETF can effectively reduce the trap density at perovskite/ETF interface, promote the electron transfer, and suppress the interface recombination rather than SnO2 alone. The band structure and the carrier transport mechanism at perovskite/DL-ETF interface were explained by conductive atomic force microscopy, Kelvin probe force microscopy and ultraviolet photoelectron spectroscopy. Complementary composite DL-ETF has been found to eliminate severe current leakage inside the device, reducing interface defects and hysteresis. More importantly, DL-ETF accelerates at electron extraction and transport owing to the excellent mobility. Finally, DL-ETF based PSCs yield higher power conversion efficiency with improved JSC than the device with SnO2 alone. Therefore, these are beneficial for reducing the recombination of carriers in the electron traps, leading to the enhancement of device performance.

Leveraging Electrochemical Techniques to Augment and Accelerate Halide Perovskite Technology Development Moses Kodur[1], Ross Kerner[2], Zachary Dorfman[1], Justin H. Skaggs[1], Taewoo Kim[1], Joseph J. Berry[2] and David P. Fenning[1]; [1]University of California, San Diego, United States; [2]National Renewable Energy Laboratory, United States

Improving the repeatability and operational stability of interfaces in perovskite devices is crucial to extend device lifetime. With each sequential step in perovskite device fabrication comes a risk of a failed device integration or an interaction that leads to longer-term device instability. Here, we present simple electrochemical techniques to evaluate fundamental properties of charge transport layers and limits of stability before completion of a full device stack, with the objective of improving batch yield, deconvoluting the troubleshooting process, and accelerating the development of new perovskite absorbers, their contact layers, and high-efficiency devices.

We focus on two exemplary measurements using easily accessible aqueous electrolytes. First, we show that an outer sphere

redox couple such as the ferro/ferricyanide system allows facile evaluation of the semiconducting properties (conduction band minimum position, doping level, etc.) of SnO_x electron transport layers. The anodic and cathodic features in cyclic voltammograms of the SnO_x are correlated to final solar cell efficiency and offer an early screen of quality. Second, we show that ionic permeability/reactivity of SnO_x layers, which can lead to irreversible absorber degradation under bias, can be rapidly evaluated by potentiostatic measurements in the presence of organohalide salts. This technique reveals the influences of processing condition and deposition method on susceptibility to bias-induced degradation reactions.

These process control measurements can be readily adapted to devices of any area and are compatible with industry-scale fabrication techniques to improve process reliability and reproducibility. While our work focuses on the development and characterization of SnO_x layers, the fundamental principles can be adapted for a wide variety of charge transport layers so long as the proper electrochemical set-up is implemented, making this method a powerful tool for halide perovskite development.

Wide-Bandgap Perovskites in the Spotlight—Multimodal Study of Photo-Induced Halide Segregation in Solar Cells Kunal Datta, Bas T. van Gorkom, Matthew J. Dyson, Martijn M. Wienk and Rene A. Janssen; Eindhoven University of Technology, Netherlands

Segregation of illuminated mixed-halide perovskites into iodide- and bromide-rich domains presents a critical bottleneck in the application of wide-bandgap absorbers in single- and multi-junction architectures. And while its occurrence has been well-studied in thin films, the influence on operational solar cells lacks sufficient understanding.
This work employs a multimodal characterization procedure to observe the slow progression of halide segregation in efficient solar cells prepared in the p-i-n architecture using sequentially processed perovskite absorbers. Photoluminescence spectroscopy is used to identify the stages that demixing of halide ions entails while simultaneous tracking of photovoltaic parameters allows correlating performance degradation to the migration of ionic species in each stage. A new stage of the process is thus observed upon prolonged illumination. Characterization of sub-bandgap features reveals the occurrence of photo-induced defect formation whose suppression through cationic substitution provides a strategy for stabilization of wide-bandgap compositions against halide segregation.

F.EL08.13.19
Elucidating the Role of Electrochemical Halide Reactions in Perovskite Optoelectronic Devices Under Prolonged Reverse Bias Jay B. Patel[1,2], Luca Bertoluzzi[3], Kevin A. Bush[3], Caleb C. Boyd[3,1], Ross Kerner[1] and Michael McGehee[2,1]; [1]National Renewable Energy Laboratory, United States; [2]University of Colorado Boulder, United States; [3]Stanford University, United States

Partial shading of a solar module can bring a set of cells within the module to operate under reverse bias. When a solar cell is shaded in a module, the photogenerated current falls and a negative voltage (reverse bias) builds up as the other illuminated cells in series try to push current through it. Moreover, metal-halide perovskite photodetectors are regularly operated in reverse bias, and therefore it is critical to understand how these devices behave under reverse bias. Previous studies have shown that perovskite solar cells with a wide variety of compositions and contacts exhibit unusual behavior, compared to typical silicon solar cells, in reverse bias that includes both reversible performance loss and non-reversible degradation. [1, 2] Furthermore, we have shown that when a perovskite solar cell is held under reverse bias, the mobile ions move in a way such that there is favorable band energetics to allow for hole injection into the perovskite, yet the consequence of this process was unclear. [1]
Recent investigations have shown that photogenerated holes can induces electrochemical oxidation of halides into halogens. [3, 4] These halogens can leave the perovskite absorber and diffuse into contacts and cause further detrimental reactions with the electrodes. [5] To elucidate and understand the degradation mechanisms that occurs when perovskite solar cells are held under reverse bias, we have developed an advanced drift-diffusion model that incorporates an electrochemical term that can explain the short-circuit, open circuit and fill factor losses we experimentally measure. Our model conclusively shows that the injected holes can trigger the oxidation of halides to form neutral halogen interstitials. The density of halogen interstitials is much higher in reverse bias because there are hardly any electrons available to reduce the halogens back into halides. The resulting halogens act as bulk recombination centers and lead to a sharp decline in all the JV device characteristics. While the interstitial halogen density will decay when the cell is finally operated in forward bias, permanent degradation will occur if the halogen diffuses out of the perovskite layer into the transport layers or electrodes. Finally, we discuss how changing parameters such as the mobile ion density or the permeability of contacts can positively influence device performance and stability.

F.EL08.13.20
Anionic Diffusion in Two-Dimensional Halide Perovskite Heterostructures Akriti Akriti[1], Enzheng Shi[1], Stephen B. Shiring[1], Jiaqi Yang[1], Yao Gao[1], Cindy L. Atencio-Martinez[2], Alan J. Pistone[1], Peilin Liao[1], Brett Savoie[1] and Letian Dou[1]; [1]Purdue University, United States; [2]University of Los Andes, Colombia

The soft crystal lattice of hybrid halide perovskites facilitates anionic diffusion which impacts material stability, optoelectronic properties and solid-state device performance. Two-dimensional (2D) halide perovskites with bulky organic barriers have been used for improving the extrinsic stability as well as suppressing intrinsic anionic diffusion. With this strategy, devices with enhanced stability and reduced hysteresis have been achieved. Nevertheless, a fundamental understanding of the role of organic cations in inhibiting anionic diffusion across the perovskite-ligand interface is missing. Through this study, we demonstrate a quantitative investigation of the anionic inter-diffusion in atomically sharp and flat 2D heterojunctions between two arbitrarily determined phase-pure halide perovskite single crystals. Stark differences are observed in anion diffusion across 2D halide perovskite lateral and vertical heterostructures. Halide inter-diffusion in lateral heterostructures is found to be similar to the classical Fickian diffusion featuring continuous concentration profile evolution. However, vertical heterostructures show a "quantized" layer-by-layer diffusion behavior governed by a local free energy minimum and ion-blocking effects of the organic cations. Surprisingly, halide inter-diffusion coefficients for 2D perovskites capped with short aliphatic organic cations (e.g. butylammonium) are only 1~2 order of magnitudes smaller than that of 3D perovskites, suggesting the ineffectiveness of these cations in blocking the anionic migration. Furthermore, we found that bulkier and more rigid π-conjugated organic cations inhibit halide inter-diffusion much more effectively ($D < 10^{-20}$ m^2/s) compared to aliphatic cations. These results offer significant insights into the mechanism of anionic diffusion in 2D perovskites and provide a new materials platform for heterostructure assembly and device integration.

F.EL08.14.01
Chemical Diversity in Lead-Free, Layered Double Perovskites—A Combined Experimental and Computational Approach Brenda Vargas[1], Raúl Torres[1], Diana Reyes-Castillo[1], Joelis Rodríguez-Hérnandez[2], Milan Gembicky[3], Eduardo Ménendez-Proupin[4] and Diego Solis-Ibarra[1]; [1]UNAM, Mexico; [2]Centro de Investigaciones en Química Aplicada, Mexico; [3]University of California, United States; [4]Universidad de Chile, Chile

Akin to the expansion in compositional diversity that halide double perovskites provided to three-dimensional perovskites [1-2], layered double perovskites could further expand the diversity of two-dimensional (2D) perovskites, and therefore, they could also enhance the properties or expand the possible applications of such materials [3]. Despite the great promise of halide 2D double perovskites, up to date, there are only four confirmed members of this family of materials [3-6]. Herein, we explore 90 hypothetical new members of this family of materials by a combined theoretical, computational, and experimental method. The combination of these tactics allowed us to predict several new materials, out of which we experimentally synthesized and characterized five new layered double perovskites, some of which show promising properties for their use in photovoltaics and optoelectronics. Further, our work highlights the vast diversity of compositions and therefore of applications that double-layered perovskites have yet to offer. References [1] X. Zhao, D. Yang, J. Ren, Y. Sun, Z. Ion Exchange-Diffusion Mechanisms in Transforming Calcite into Lead (Pb)-Free Perovskite Light Absorbers Jonathan B. Junio, Marlon T. Conato and Candy C. Mercado; University of the Philippines Diliman, Philippines

The synthesis of perovskite materials has gone beyond the traditional wet chemistry routes into other methods such as a sequential ion exchange process that can produce perovskite materials from calcite in either thin film or bulk form. The use of lead (Pb), the most successful element in terms of PSC efficiency performance, was already successfully demonstrated in an ion exchange process. In this work, tin (Sn) is chosen since it has the most potential to replace Pb since they are on the same group and for the similarity in ionic radii of their ions (Pb2+, Sn2+) at 1.19 and 1.02 ?, respectively. Methyl ammonium tin triiodide (MASnI3) has a lower bandgap (1.2 to 1.4 eV) that induces broader absorption spectrum as compared with the benchmark MAPbI3 counterpart (1.55 eV). The second alternative - strontium (Sr) has an ionic radius of 1.18 ? indicating possible ion exchange in the strontianite structure. The band gap for the Sr perovskite was estimated at 3.6 eV, considerably higher than that for the lead perovskite and therefore not suitable for direct solar cell applications but can be used as a top cell in tandem architectures. These ion exchange processes are observed using x-ray absorbance and photoelectron spectroscopies to elucidate the underlying mechanisms of the sequential ion exchange process. These will shed light into the material transformation with shape preservation from the raw shells or single crystal calcite towards the intermediate carbonate material and eventually, the Pb-free perovskite material.

F.EL08.15.01

A Comparison of Three Emerging Bi-Based (Oxy)Halide Absorbers Grown from Metallic Precursors Andrea Crovetto, Alireza Hijijafarassar, Ole Hansen, Brian Seger, Ib Chorkendorff and Peter Vesborg; Technical University of Denmark, Denmark

The bismuth-based (oxy)iodides BiI3, BiOI and AgxBiIx+3 share similar layered crystal structures, optimal band gaps for top absorbers in tandem solar cells, and moderate growth temperatures. Similarly to halide perovskite absorbers, they contain a heavy cation with a lone pair of electrons (Bi3+) which has been proposed as one of the features enabling defect tolerance in perovskites. We have grown and characterized BiI3, BiOI, and Ag3BiI6 absorbers and solar cells in a systematic manner by employing a consistent synthesis method ((oxy)iodization of metallic precursor) and a consistent analysis routine. In this way, the individual strengths and weaknesses of the three absorbers, as well as their common challenges, can be outlined. The radiative efficiency of the three materials is within the same order of magnitude, thus indicating a similar degree of defect tolerance. Control of growth orientation should be a priority for this class of materials in view of their anisotropic properties. P-type bulk doping and selection of hole transport layers with deep valence bands could also improve performance. At the device level, we report an improved open circuit voltage of BiI3 solar cells with respect to the state of the art, and we report a proof-of-concept Ag3BiI6/silicon tandem cell. Beyond photovoltaics, the very low dark diode ideality factor in BiI3 devices and the existence of both electronic and ionic conduction in Ag3BiI6 may open up alternative unexpected applications in other fields.

F.EL08.15.03

Boosting the Self-Trapping Emissions in Zero-Dimensional Perovskite Heterojunctions Jun Yin[1], Jean-Luc Bredas[2], Osman M. Bakr[1] and Omar F. Abdelsaboor[1]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]Georgia Institute of Technology, United States

Zero-dimensional (0D) inorganic and hybrid perovskites have attracted great interest for white-light emitting applications due to their broadband emissions originating from the self-trapping excitonic states. In this work, we study a series of 0D inorganic perovskites, A4PbX6 and A4SnX6 (A = K, Rb, and Cs; X = Cl, Br, and I), under the theoretical framework of one-dimensional configuration coordinate diagram using density functional theory (DFT) calculations. We demonstrate that the formation of self-trapping excitonic states of A4PbX6 and A4SnX6 is attributed to the local structural distortion of individual [PbX6]4- and [SnX6]4- octahedron (i.e., the octahedral shrinking under photoexcitation). We further predict the broadband emissions of a new family of 0D A4PbX6/A4SnX6 heterostructures, and find that among these crystal structures Rb4PbI6/Rb4SnI6 exhibits an increased photoluminescence efficiency with good stability as compared to pristine Rb4SnI6. Our findings provide a new material design strategy for boosting the self-trapping emissions with improved stability using 0D inorganic perovskite heterostructures.

F.EL08.15.05

Single-Source Deposition of Double Perovskites for Optoelectronic Devices Nathan Rodkey[1,2], Stan Kaal[2], Paz Sebastia-Luna[1], Yorick A. Birkhölzer[2], Franciso Palazon[1], Henk Bolink[1] and Monica Morales-Masis[2]; [1]Universidad de Valencia, Spain; [2]University of Twente, Netherlands

As halide perovskites (PVKs) continue to garner scientific interest for their potential to enhance efficiencies of solar cells and LEDs, a push has been made towards lead-free and completely inorganic PVKs with increasingly complex stoichiometries. One example of this is the double PVK $Cs_2AgBiBr_6$and Sn:$Cs_2AgBiBr_6$. Synthesis of thin films with these complex

stoichiometries is challenging due to the distinct volatility of the constituent elements, usually requiring multi-step or multi-source processes. Here we explore Pulsed Laser Deposition (PLD) as a route to grow these types of complex materials with a single source. PLD offers the advantage of being a volatility-insensitive thin film synthesis technique which we use to demonstrate single-source deposition of $Cs_2AgBiBr_6$ and Sn:$Cs_2AgBiBr_6$. For this, solid targets are made first by mechanochemical synthesis of powders, followed by a uniaxial and isostatic pressing to form the powders into dense, compact targets. X-ray diffraction (XRD) is used to verify the desired PVK phase is maintained along each step of target fabrication. Laser-ablation of the double PVK targets in vacuum leads to formation of $Cs_2AgBiBr_6$ and Sn:$Cs_2AgBiBr_6$ double PVK films after optimization of the deposition parameters. We discuss the effects of deposition pressure and laser fluence on the formation of stoichiometric and phase-pure films, as well as the critical role of the thermalization of the source elements to achieve stoichiometric transfer. In addition to the structural properties, the optoelectronic properties of the films were studied by UV-Vis-NIR spectrophotometry and time-resolved photoluminescence. Notably, >1 um thick films are deposited and all films present high structural stability over the course of 3 months, without the need for an annealing step. This work represents an important step forward in the development of controlled growth and future scalability of complex halide perovskites for efficient optoelectronic devices.

F.EL08.16.06
Improving Blue Light Emission of CsPbBr3 Nanoplatelets via Post-Synthesis Surface Passivation Jinu Park, Joonyun Kim and Byungha Shin; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Lead halide perovskite is considered as a potential candidate for the next generation light emitting diodes (LEDs) due to its extremely narrow light emission spectrum with a typical full width half maximum (FWHM) < 20 nm. In particular, all-inorganic CsPbBr3 has demonstrated the near unity photoluminescence quantum yield (PLQY) for green light emission. A more challenging, yet technologically important, task is developing a high performance blue light emitter. By partially replacing Br of CsPbBr3 with Cl, the emission wavelength can be adjusted to the blue emission; however, CsPbBr3-xClx , suffers from ion migration and phase segregation which result in low PLQY and poor stability. Here, we present a synthesis method to produce nanostructure CsPbBr3 in the form of nanoplatelets (NPLs) that is capable of emitting blue light without the need for anion-substitution. Nanoplatelets with 2 monolayer (ML) and 3 ML of thickness yielded photoluminescence (PL) peak at 435nm with an extremely narrow FWHM of 14.2 nm and PL peak at 456nm with FWHM of 19.6nm, respectively. The luminescence of these nanoplatelets was further improved by post-synthesis treatment with tetrafluoroborate salts-almost 1150% increase in PL intensity was observed without a noticeable broadening of the PL spectrum. Details of the results and discussion of a possible mechanism behind the improvement with the post-synthesis treatment will be presented.

Highly Luminescent Vacuum-Evaporated All Inorganic CsPbBr3 Perovskite Light Emitters with a Polymer Auxiliary Layer Nakyung Kim, Mingue Shin and Byungha Shin; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

All inorganic halide perovskite CsPbBr3 has emerged as the next-generation material for light-emitting diodes (LEDs) due to its high color purity with a narrow spectral width (< 20 nm) and tunable band gap by adjusting the composition of halide anions, i.e. substitution of Br with I or Cl. Considering the needs for large-area scalability and fine control of the emitter thickness, vacuum-deposition will be a more commercialization-friendly technique to produce perovskite films for LEDs. Here, we prepare CsPbBr3 light emitters by thermal co-evaporation of CsBr and PbBr2 sources. The luminescence of the vacuum-deposited CsPbBr3 films was greatly improved by introducing a poly-ethylene oxide (PEO) layer underneath the CsPbBr3-almost 300-fold increase in photoluminescence quantum yield (PLQY) with the PEO layer compared to the reference sample (CsPbBr3/glass). It is believed that the interaction between PEO and Pb2+ ions leads to the passivation of non-radiative recombination defects. After the careful optimization of the PEO layer thickness and post-deposition thermal treatments of CsPbBr3, we have demonstrated PLQY of 30% from a peak at 521 nm with full-width-half-maximum of ~17nm. Furthermore, the samples exhibit excellent ambient stability. Details of the results and analysis will be discussed.

Ultra Sensitive Perovskite Halide Based Room Temperature Ammonia Gas Sensor Using Flexible Paper Electronics Avisek Maity and Barnali Ghosh; S.N. Bose National Centre for Basic Sciences, India

In current days, development and search of new materials for solid state thin film gas sensor to detect toxic gases, particularly using nanomaterial for their enhanced functionality, is growing rapidly as view point of both environmental and clinical application. Particularly, gas sensor with low power consumption, room temperature operation, portability and cost

effectiveness is highly demandable. Perovskite halides, namely methyl ammonium lead iodide (CH3NH3PbI3) / MAPI is widely popular as photovoltaic and optoelectronic material. Recently we have found that MAPI can act also as an active material for gas sensing to trace hazards pollutants. Ammonia (NH3) not only is one of harmful pollutants in nature but also treated as a biomarker for kidney disease via exhaled breathe analysis in recent days. Thus a room temperature , cost effective, very high sensitivity NH3 gas sesor could extremely beneficial in view point of both environmental and clinical issues. The sensor using MAPI can trace ammonia gas (NH3) by a visual color change method as well as by electrical read out [1-2]. Here we have shown a MAPI based electrical sensor grown on a cheap paper as a substarte for tracing NH3 gas. The paper sensor has a very high sensitivity (98% for 10 ppm NH3) towards NH3 gas at room temperature and sub ppm (<1 ppm) detection capability (down to 10 ppb) by its noise limited detectibility [2]. This ultra high response down to ppb level can be extremely suitable for exhaled breathe analysis. Current through the sensor increases nearly by one order on exposure to only 10 ppm NH3 gas with a bias voltage of 1 V DC and hence the sensor consumes extremely low power (~ few nano watts). The paper sensor is also highly selective to NH3 gas and maintains stability over 150 days within decrease of 10% sensitivity. This could open up the possibility of perovskite halide (MAPI) as next generation solid state room temperature gas sensor for rapid and cost effective detection using paper electronics. Suppressing Cation Migration in Triple-Cation Lead Halide Perovskites Ilia M. Pavlovetc[1], Michael Brennan[1], Sergiu Draguta[1], Anthony Ruth[1], Jeffrey A. Christians[2], Taylor Moot[3], Steven Harvey[3], Joseph Luther[3] and Masaru Kuno[1,1]; [1]University of Notre Dame, United States; [2]Hope College, United States; [3]National Renewable Energy Laboratory, United States

Mixed cation and anion $APbX_3$-type lead halide perovskites [A^+=Cs^+, $CH_3NH_3^+$ [MA^+], or $(NH_2)_2CH^+$ [FA^+]; X^-=Br^- or I^-] have received extensive attention for use as low cost, efficient light harvesters in solar cells. Issues regarding long-term active layer stability, however, remain unresolved. Electric field-induced ion migration in perovskite solar cells is of particular concern because it results in current-voltage (J-V) hysteresis, metastable power conversion efficiencies and accelerated active layer degradation. Facile ion migration within the perovskite lattice stems from relatively fragile ionic bonding between heavy, low-valence ions. This results in small activation barriers and correspondingly moderate diffusion coefficients for halide anions and A-site cations. The mobile nature of A^+ cations and X^- anions is thus an instability of all metal halide perovskites. While numerous recent studies have focused on halide migration and segregation, significantly less work has gone into investigating cation migration in metal halide perovskites. This is especially true of double- and triple-cation $FA_xMA_yCs_{1-x-y}PbX_3$ alloys.

Here, we demonstrate that bias-induced cation migration is mitigated in mixed α-phase/δ_{ortho}-$CsPbI_3$ triple-cation $FA_xMA_yCs_{1-x-y}PbI_3$ films (referred as α/δ-$FA_{0.33}MA_{0.33}Cs_{0.33}PbI_3$). We verify this by comparing cation movement in lateral devices and working solar cells made of pure α-phase double-/triple-cation perovskite phase systems ($FA_{0.85}Cs_{0.09}PbI_3$ and $FA_{0.76}MA_{0.15}Cs_{0.09}PbI_3$) as well as α/δ-$FA_{0.33}MA_{0.33}Cs_{0.33}PbI_3$. The effects of bias-induced A^+ migration on perovskite stability and device performance are assessed via infrared photothermal heterodyne imaging (IR-PHI), time-of-flight secondary ion mass spectrometry (ToF-SIMS), and solar cell operational stability testing. Enhanced α/δ-$FA_{0.33}MA_{0.33}Cs_{0.33}PbI_3$ cation stability likely stems from "post-perovskite" δ_{ortho}-$CsPbI_3$ inclusions within parent thin films that act as barriers through which cations cannot easily migrate. This resistance to cation migration translates into improved device operational stability of α/δ-$FA_{0.33}MA_{0.33}Cs_{0.33}PbI_3$ lateral devices and solar cells relative to complementary, triple-cation, α-phase $FA_{0.76}MA_{0.15}Cs_{0.09}PbI_3$ devices. This study therefore provides new insights into cation migration in working devices and outlines a materials design strategy for stabilizing metal halide perovskites against bias-induced cation migration.

Efficient of Ion Migration in Perovskite Solar Cells with Hexagonal Boron Nitride Yifan Yin, Yuchen Zhou and Miriam H. Rafailovich; Stony Brook University, The State University of New York, United States

Organic-inorganic halide perovskite solar cells (PSCs) have been considered a viable member of next generation photovoltaics, which can address the scalability changes with a low-cost solution process. The energy lose in the hybrid system has been approved to be principally caused by defects/traps at grain boundaries and surfaces as well as point defects such as interstitial defects or vacancies in the perovskite compounds crystal lattice. Because of the presence of these defects, both anions (I) and cations (MA^+) can migrate through the organic layer which provides a degradation pathway for perovskite materials even in those well-encapsulated devices: the halide ions can react with metal electrodes such as Ag, forming insulating components (AgI). In addition to the corrosion of electrode, halide ions migrating into organic hole transport layer

（HTL）which is deleterious to transport properties, thus retarding device efficiency, especially under solar cell working conditions. Inspired by the quasi-2D-perovskite which shows a great stability in photovoltaic performance, here, the hexagonal boron nitride (h-BN) was incorporated into the perovskite absorber as an ionic diffusion barrier. The lamellar structure of h-BN consists of a lattice similar to graphite which can be subjected to exfoliation leading to few-layers nanosheets. The exfoliated 2D-layered materials present high surface area and quantum confinement, and also high chemical stability. The integration of this low-cost, lower dimensional material enables a better device stability as the result from the efficient suppression on the ion-migration induced degradation. With the aid of time-of-flight secondary ion mass spectroscopy (TOF-SIMS) and energy dispersive x-ray spectroscopy (EDX). The h-BN/ perovskites has an initial PCE over 20% that shows no degradation exhibit in over 72 h and retained 80% of the original PCE after 800hr, whereas the PCE of pristine MAPI devices diminishes by more than 30% within the first 24 hr.

Light-Induced Degradation of Hybrid Organic-Inorganic Perovskites Reveals Autocatalytic Kinetics and Increased Stability with Substitution of Larger Organic Cations Emily C. Smith, Christie Ellis, Hamza Javaid and Dhandapani Venkataraman; University of Massachusetts Amherst, United States

Instability under illumination in hybrid organic-inorganic perovskite solar cells represents a major roadblock to the development and commercialization of this thin-film technology. Recently, it has been shown that varying the nature of the organic cation in the perovskite structure represents a potential pathway to tuning stability of materials under illumination. However, many potential mixed-cation perovskite compositions remain unexplored, and, much is still unknown about the degradation kinetics in mixed-cation thin-films. In this work, we successfully fabricated thin-films of substituted methylammonium lead triiodide (MAPI), where we substituted the methylammonium ion with varying percentages of three larger organic cations: imidazolium, dimethylammonium, and guanidinium. We achieved substitution of these large cations for compositions of up to 20-30% while maintaining the structure and optoelectronic properties of the films. We studied the degradation kinetics of the mixed-cation films under illumination using powder x-ray diffraction. We observed that the degradation is autocatalytic. Furthermore, we calculated rate coefficients for the degradation process and observed that the degradation was slowed in films which contained ≤20% of any of the larger cations compared to pristine MAPI films. A maximum decrease of 62% in the degradation rate coefficient was observed in the case of 5% guanidinium substitution. Ultimately, this work provides key insight into the degradation kinetics of mixed-cation perovskite films under illumination and provides a strategy for further stabilization of perovskite thin-films for improved photovoltaic performance.

Effect of Pyrazine and Guadinium Thiocyanate (GuaSCN) on the Structure and Bandgap of Pb and Pb-Free Halide Perovskites Rubaiya Murshed and Shubhra Bansal; University of Nevada Las Vegas, United States

Perovskite solar cells (PSCs) research has been projected over the past decade due to its promising photovoltaic properties, increasing efficiency and low cost. With a need to eliminate toxic lead from prevailing halide perovskite solar cells, several low-toxicity cations have been proposed, among them Sn(II) is considered as one of the most suitable replacements due to its similar electronic configuration and ionic radius to Pb(II). But the Sn-based perovskites are still plagued with low efficiency, oxidation and phase instability. Here we demonstrate the use of atmospheric solution-processed lead-free all inorganic molecular iodosalt compound cesium tin iodide (Cs_2SnI_6) as the light absorber in PSCs. The presence of excess SnF_2 in precursor solution assists phase separation. Due to the good binding affinity to SnF_2, pyrazine is expected to reduce Sn vacancy thus restricts phase separation. The effect of GuaSCN results in increasing grain size and improving film morphology thus improves the structural and optoelectronic properties of low bandgap perovskites. The present work aims at analyzing the effect of pyrazine and guanidinium thiocyanate (GuaSCN) in oxidation reduction and fabrication of low bandgap (1.3 eV) Cs_2SnI_6 films when used separately as a mediator during film fabrication in GBL. Initial results suggest both pyrazine and guanidinium thiocyanate give absorption onset at higher optical wavelength (>1000 nm) and low bandgap (~1.2-1.3 eV). Films in addition of Pyrazine both with and without SnF_2 (0 mol% and 40 mol%) shows mostly cubic Cs_2SnI_6 diffraction patterns in XRD analysis which implies that the effect of SnF_2 is not considerable in this case. The SCN ions increases grain size and produces cubic Cs_2SnI_6 crystals. Heating at higher temperature leads to samples with lower bandgap. Both the absorption vs. wavelength and tauc plot analyses show bandgap at around 1.25 eV. Most of the samples after dark testing for over 100 hours at 65 °C retain their properties and show similar absorption edge and bandgap patterns. Samples having exposure to light at 65 °C show higher bandgap over 2 eV. In this study, the effect of these additives in $Cs(Pb,Sn)I_3$ perovskite with a Sn-Pb ratio of 60:40 is also included. Primary results show separately use of both pyrazine and GuaSCN in precursor solution in a mixture of GBL and DMF result in low bandgap perovskites. Both $Cs(Pb,Sn)I_3$ and Cs_2SnI_6 without these additives tend to have higher bandgap at around 2.3 eV when deposited on glass substrates. Further

analysis of the effect of Pyrazine and GuaSCN additives in the stability, morphology and lifetime of $Cs(Pb,Sn)I_3$ and Cs_2SnI_6 perovskite films will be continued in this study.

F.EL08.17.05
Enabling High Photoconversion Efficiency in Lead-Free Antimony-Based Perovskite Derivatives by Tuning Crystallographic Dimensionality and Microstructure Vincenzo Pecunia, Yueheng Peng and Fengzhu Li; Soochow University, China

The exploration of lead-free perovskite-inspired semiconductors for optoelectronic applications (e.g., single- and multi-junction solar cells, photocathodes for water splitting, photodetectors) has captured ever-growing attention, driven by their promise to replicate the success of the Pb-based counterparts without the toxicity concerns associated with the latter. In particular, an emerging approach to Pb replacement involves Sb, whose attractiveness resides in its highly-polarizable Sb^{3+} cations with filled 5s orbitals, a stable oxidation state, and an ionic radius comparable to Pb^{2+}. A number of antimony-halide perovskite derivatives with a formula $A_3Sb_2X_9$ (A^+: monovalent cation; X^-: halide anion) have thus been explored. Notwithstanding the rise in their reported performance, A-Sb-X absorbers are yet to deliver photoconversion efficiencies comparable to the Pb-based counterparts. Importantly, this has been linked to the zero-dimensional (0D) structure of most A-Sb-X embodiments, as the more attractive two-dimensional (2D) embodiments have been demonstrated only in very few instances, due to constraints on composition or processing conditions.

With the aim of contributing to the realization of the full potential of antimony-halide perovskite derivatives, we have investigated two such systems featuring a desirable 2D structure, exploring the impact of dimensionality, microstructure, and crystallographic orientation on their photoconversion behavior. Herein, we firstly focus on $Rb_3Sb_2I_9$, the only ternary A-Sb-I with a direct bandgap, and also having the smallest exciton binding energy of all reported A-Sb-I embodiments.[1] In order to assess the role of microstructure on the photoconversion efficiency of $Rb_3Sb_2I_9$, we have developed two strategies for its microstructural enhancement, which involve the control of the supersaturation level during the annealing step, or a high-temperature treatment in SbI_3 vapor. Both strategies deliver a dramatic improvement in the film morphology and microstructure.[2] Within sandwich-type planar devices, the resultant high-quality films enable a substantial improvement in external quantum efficiency (EQE), reaching up to 65.4% at short circuit, i.e., the highest to date for perovskite-inspired antimony-/bismuth-halide $A_3M_2X_9$ (M: Sb^{3+}/Bi^{3+}). Importantly, this is achieved without the aid of a mesoporous architecture for charge extraction, thereby revealing the inherent capability and potential of $Rb_3Sb_2I_9$ for efficient photoconversion.

We additionally discuss the impact of dimensionality on the photoconversion capabilities of the $Cs_3Sb_2X_9$ system. Departing from the dedicated high-temperature (≥ 230 °C) processing protocols pursued in the prior literature, we demonstrate that halide mixing enables the 0D-to-2D structural conversion of the $Cs_3Sb_2X_9$ system at temperatures < 150 °C.[3] The resultant 2D absorbers manifest a considerable photoconversion efficiency boost with respect to the 0D counterpart, attaining a peak EQE of 62.5%, which is at the state-of-the-art for all antimony-/bismuth-halide perovskite derivatives.

Through photocurrent-power characterization and Hall effect measurements, we finally reveal that the EQE boost achieved with both 2D $Rb_3Sb_2I_9$ and $Cs_3Sb_2X_9$ arises from their improved charge carrier transport, which we relate to the microstructural enhancement, dimensionality tuning, and crystallographic orientation. Such performance boost and mechanistic insight constitute an important step in realizing the full potential of lead-free antimony-halide perovskite derivatives and related bismuth-based homologs for their application in optoelectronics and photovoltaics.

F.EL08.17.06
A Critical Assessment of the Use of Excess Lead Iodide in Lead Halide Perovskite Solar Cells Bart Roose, Krishanu Dey, Yu-Hsien Chiang, Richard Friend and Samuel D. Stranks; University of Cambridge, United Kingdom

It is common practice in the lead halide perovskite solar cell field to add a small molar excess of lead iodide (PbI_2) to the precursor solution in order to increase device performance. However, recent reports have shown that an excess of PbI_2 can accelerate performance loss. In addition, PbI_2 is photoactive (bandgap ~2.3 eV), which may lead to parasitic absorption losses

in a solar cell.

We use XRD and SEM to show that incorporation of PbI_2 into the perovskite film is not straightforward and can have very different effects, depending on how and where PbI_2 is present. At low concentrations, PbI_2 facilitates charge extraction and improves device performance. For higher concentrations, PbI_2 influences how perovskite crystallises and a thick PbI_2 layer can be formed that impedes charge extraction. We show that devices using an optimized quantity of excess PbI_2 exhibit better device performance as compared to stoichiometric devices, both initially and for the duration of a stability test under operating conditions, primarily by enhancing charge extraction. However, PbI_2 is gradually degraded during device operation, largely negating the beneficial effect on charge extraction and introducing trap states that are detrimental for device performance. We find that although excess PbI2 provides a good template for enhanced performance as compared to stoichiometric devices, it can not meet stability requirements needed for commercialization of perovskite solar cells. The community must continue to seek other additives or synthesis routes that fulfill the same beneficial role as excess PbI_2, but which do not suffer from light induced degradation.

F.EL08.17.07
Understanding the Instability of the Halide Perovskite $CsPbI_3$ Through Temperature-Dependent Structural Analysis Daniel B. Straus[1], Shu Guo[1], AM Milinda Abeykoon[2] and Robert J. Cava[1]; [1]Princeton University, United States; [2]Brookhaven National Laboratory, United States

Despite the tremendous interest in halide perovskite solar cells, the structural reasons that cause the all-inorganic perovskite $CsPbI_3$ to be unstable at room temperature remain mysterious especially since many tolerance factor-based approaches predict $CsPbI_3$ should be stable as a perovskite. Here single-crystal X-ray diffraction and X-ray pair distribution function (PDF) measurements characterize bulk perovskite $CsPbI_3$ from 100 to 295 K to elucidate its thermodynamic instability. While Cs occupies a single site from 100 to 150 K, it splits between two sites from 175 to 295 K with the second site having a lower effective coordination number, which along with other structural parameters suggests that Cs rattles in its coordination polyhedron. PDF measurements reveal that on the length scale of the unit cell, the Pb-I octahedra concurrently become greatly distorted, with one of the I-Pb-I angles approaching 82° compared to the ideal 90°. The rattling of Cs, low number of Cs-I contacts, and high degree of octahedral distortion cause the instability of perovskite-phase $CsPbI_3$. These results reveal the limitations of tolerance factors in predicting perovskite stability and provide detailed structural information that suggests methods to engineer stable $CsPbI_3$-based solar cells.

F.EL08.17.08
Enhanced Bending Fracture Behavior of Flexible Halide Thin Films Processed with *In Situ* Stress Da Bin Kim and Yong Soo Cho; Yonsei University, Korea (the Republic of)

Halide perovskites have emerged as attractive materials for electronic and optoelectronic applications because of their unique properties and low-temperature processing. However, the mechanical aspects of the halide thin films have been very limitedly reported although strong bending fracture behavior is required for the flexible system. Here, we suggest a very promising processing way to enhance the bending fracture behavior of the flexible halide thin films with fundamental definitions of the mechanical parameters of the halide materials that have been also unavailable thus far. The processing is based on the assignments of in-situ compressive or tensile stress during the film deposition with a controllable manner. As a result, a substantial improvement of the fracture resistance against the bending operation was observed for the compressively stressed halide thin films. For example as a result of bending fracture evaluation, cesium lead bromide ($CsPbBr_3$) and methylammonium lead iodide ($MAPbI_3$) thin films prepared on PEDOT:PSS-coated polyethersulfone (PES) substrates demonstrated high fracture mode I toughness of 1.18 and 1.66 MPa $m^{0.5}$ for the in-situ compressive strain of -1.09%, which correspond to the enhancements by ~97 and ~100 %, respectively, compared to those for the reference samples. The structural origins of the mechanical enhancements are elucidated with experimental evidences on the variations in lattice distortion and bonding length.

F.EL08.17.09
Structural Evolution of Layered Hybrid Lead Iodide Perovskites—Colloidal Nanocrystals or Ruddlesden-Popper Phases? Clayton J. Dahlman[1], Naveen Venkatesan[1], Patrick Corona[2], Rhys M. Kennard[1], Lingling Mao[1], Noah Smith[2], Jiamin Zhang[2], Ram Seshadri[1,2], Matthew Helgeson[2] and Michael Chabinyc[1]; [1]The University of California, Santa Barbara, United States; [2]University of California, Santa Barbara, United States

Hybrid organic-inorganic perovskites (HOIPs) are promising semiconductors with long carrier lifetimes, synthetic tunability, remarkable defect tolerance and simple processing. Recently, 2D analogues have been made by adding insulating cations

(e.g. butylammonium) to separate the perovskite structure into sheets. These 2D materials can be formed either in thin films, large single crystals or as dispersed nanoplatelets of only a few PbX6 octahedra thick. The number of PbX6 octahedra confined between insulating layers (i.e. the '*n*-value') can be tuned by varying precursor stoichiometry, enabling discrete tunability of the bandgap through dielectric and quantum confinement. Controlling the structure of layered hybrid metal halide perovskites, such as the Ruddlesden-Popper (R-P) phases, is challenging because of their tendency to form mixtures of varying composition. Colloidal growth techniques can form dispersions of particles with properties that match the bulk properties of layered R-P phases, but controlling the composition of these particles remains challenging.

In this talk, we explore the microstructure of particles of R-P phases of methylammonium lead iodide prepared by antisolvent precipitation from ternary mixtures of different alkylammonium cations, where one cation is able to form perovskite phases ($CH_3NH_3^+$) and the other two promote layered structures as spacers (*e.g.* $C_4H_9NH_3^+$ and $C_{12}H_{25}NH_3^+$). We illustrate how competition between cations that act as spacers between layers, or as grain-terminating ligands, determines the colloidal particle size of R-P crystallites that form in solution. Optical measurements reveal that quantum well dimensions can be tuned by engineering the ternary cation composition. Transmission synchrotron wide-angle X-ray scattering and small angle neutron scattering reveal changes in the structure of colloids in solvent and after deposition into thin films. In particular, we find that spacers can alloy between R-P layers if they share common steric arrangements, but tend to segregate into polydisperse R-P phases if they do not mix. This study provides a framework to compare the microstructure of colloidal layered perovskites and suggests clear avenues to control phase and colloidal morphology.

F.EL08.17.10
Adhesion and Interfacial Fracture of Perovskite Solar Cells Reisya Ichwani, Vanessa Uzonwanne, Juan Martin Hinostroza Tamayo, Deborah Oyewole, Oluwaseun K. Oyewole, Nancy Burnham and Winston Soboyejo; Worcester Polytechnic Institute, United States

Emerging perovskite solar cells (PSCs) are not only required to be highly efficient, but also durable. The mechanical stability of PSCs also requires good adhesion and contacts across their interfaces. These are studied using atomic force microscopy (AFM) and fracture mechanics approaches. AFM pull-off forces are measured for bi-material interfaces that are present in model perovskite solar cells. These are then incorporated into adhesion models for the estimation of adhesion energies and mode I interfacial fracture energies. The mode mixity dependence of interfacial fracture toughness is also studied for interfaces between the perovskite and electron transport layers in PSCs. This is done using Brazil Disk specimens that are used to study the robustness of the interfaces across a range of mode mixities between pure mode I and pure mode II. The underlying crack/microstructure interactions and fracture modes are used to provide insights into the underlying crack-tip shielding due to crack bridging and microcracking. These are modeled using zone and row models that are used to predict the mode-mixity dependence of fracture toughness. The implications of the results are also discussed for the determination of crack path selection criteria in perovskite solar cells.

Double Perovskite Nanofibers for Photovoltaic and Optoelectronic Applications Nageh K. Allam; American University in Cairo, Egypt

Organic-inorganic hybrid perovskite compounds are currently the archetypal materials for high performance photovoltaic (PV) and optoelectronic devices. However, the remaining bottlenecks preventing their large scale production are their environmental/thermal instability and lead toxicity. Herein, we demonstrate a novel approach to synthesize single-phase electrospun $Cs_2SnI_xCl_{6-x}$ double perovskites with varying halide content (I, Cl or mixed I/Cl) as active materials for potential application in perovskite solar cells (PSCs). The x-ray photoelectron spectroscopy and Raman spectroscopy analyses indicated the *in-situ* formation of graphene oxide (GO) during the annealing process. The GO layer was found to enhance the optical properties and thermal stability of the fabricated perovskites even at high Cl content. Moreover, the presence of GO as an insulating layer significantly decreases the bandgap energy of the resulting perovskites. The perovskites with a mix of iodide and chloride ions showed significantly improved optical properties with higher photoluminescence (PL) intensity than that of pure chloride or iodide counterparts. Moreover, the compound with low chloride content showed superior thermal stability to those reported in the literature. Therefore, the application of the electrospinning technique is a useful strategy to *in-situ* incorporate GO in a lead-free perovskite matrix for potential photovoltaic and optoelectronic applications.

Organic–Inorganic Hybrid Perovskite Single-Crystal Thin Films—Synthesis and Photoluminescence Xiaobing Tang[1],

Zhaojin Wang[2], Kai Wang[2] and Fuqian Yang[1]; [1]University of Kentucky, United States; [2]Southern University of Science and Technology, China

Metallic halide organic–inorganic hybrid perovskites with excellent optoelectrical properties have potential applications in optoelectronic devices and systems. In this work, we demonstrate the feasibility of preparing $CH_3NH_3PbBr_3$ single crystal thin films on poly-TPD hole transport layer by controlling the heating rates. The crystallinity and trap state density of the $CH_3NH_3PbBr_3$ thin films are characterized by X-ray diffraction and photoluminescence and time-resolved photoluminescence, respectively. The crystallinity with the peak intensity of (100) plane of the $CH_3NH_3PbBr_3$ thin films prepared at 2 ^oC/h is nine times of that prepared at 10 ^oC/h. The $CH_3NH_3PbBr_3$ thin films prepared at 2 ^oC/h exhibit a carrier lifetime of 21 ns, which is much larger than 0.6 ns for the $CH_3NH_3PbBr_3$ thin films prepared at 10 ^oC/h, and an excellent structural stability. Acknowledgements: KW is grateful for the support from National Key Research and Development Program (No.2017YFE0120400) and National Natural Science Foundation of China (No.61875082). Hybrid Lead Iodide Perovskites with Aromatic Diammonium Cations Xiaotong Li[1], Weijun Ke[1], Yihui He[1], Peijun Guo[2], Mikaël Kepenekian[3], Boubacar Traore[3], Jacky Even[3], Claudine Katan[3], Constantinos Stoumpos[1], Richard D. Schaller[2] and Mercouri G. Kanatzidis[1]; [1]Northwestern University, United States; [2]Argonne National Laboratory, United States; [3]University of Rennes, France

Aromatic diammonium cation, x-(aminomethyl)pyridinium (AMPY, x = 3 or 4) can form 2D Dion-Jacobson lead iodide perovskite, which adopt the general formula of $(xAMPY)(MA)_{n-1}Pb_nI_{3n+1}$ (MA = methylammonium, n = 1−4). By modifying the position of the $-CH_2NH_3^+$ group from 4AMPY to 3AMPY, the stacking of the inorganic layers changes from exactly eclipsed to slightly offset. The perovskite octahedra tilts are also different between the two series, with the 3AMPY series exhibiting smaller bandgaps than the 4AMPY series. Compared to the aliphatic cation of the same size (AMP = (aminomethyl)piperidinium), the aromatic spacers increase the rigidity of the cation, reduce the interlayer spacing and decrease the dielectric mismatch between inorganic layer and the organic spacer, showing the indirect but powerful influence of the organic cations on the structure and consequently on the optical properties of the perovskite materials. Preliminary solar cell devices based on the n = 4 perovskites as absorbers of both series exhibit promising performances. More interestingly, when using 1:4 ratio of AMPY:PbO as starting materials, totally different structures with 3D connection motif form instead. However, because of the steric requirement of the Goldschmidt tolerance factor rule, it is impossible for $(xAMPY)M_2I_6$ to form proper perovskite structures. Instead, a combination of corner-sharing and edge-sharing connectivity is adopted in these compounds leading to the new 3D structures. Devices of $(3AMPY)Pb_2I_6$ crystals exhibit clear photoresponse under ambient light without applied bias, reflecting a high carrier mobility (μ) and long carrier lifetime (τ) and great potential for photo and X-ray detection applications.

Exploring the Limit of Layer Thickness in 2D Hybrid Lead Halide Perovskites Eugenia S. Vasileiadou[1], Bin Wang[2], Ioannis Spanopoulos[1], Ido Hadar[1], Alexandra Navrotsky[3,2] and Mercouri G. Kanatzidis[1]; [1]Northwestern University, United States; [2]University of California, Davis, United States; [3]Arizona State University, United States

Two-dimensional (2D) hybrid organic-inorganic halide perovskites are a rapidly emerging class of semiconductors whose structural tunability and optoelectronic properties have led to the successful fabrication of solar cell devices with high power conversion efficiency. The features of the 2D perovskite structure that are tuned are the organic “spacer” cation and the number of the inorganic layers (*n*). There is a significant interest to target higher *n*-member compounds for light harvesting applications, due to their attractive photophysical properties such as low bandgap value and high carrier mobility. Herein, we present a comprehensive study on exploring the limit of layer thickness of bulk 2D lead halide perovskites through structural and thermodynamic study. Phase-pure synthesis of a new *n*=6 perovskite compound is reported with the characterization of the single crystal structure and optical properties of the material. Thorough calorimetry studies examine the thermodynamic stability of 2D lead iodide perovskites with layer thickness *n*=2-6. The favorable enthalpy of formation *n*=6 crystals shows that higher *n*-layer thickness is dependent on specific structural aspects. Additionally, the systematic investigation of the variances on the structural parameters and optical properties between different structure types of 2D perovskites, offers guiding principles for the targeted design and synthesis of 2D perovksites for efficient solar cell fabrication. Lastly, the stability studies of thin films demonstrate consistent observations with the thermochemical findings, further shedding light on the behavior of high *n*-layer perovskite materials.

F.EL08.17.15

Amorphous Halide Perovskite Thin Films Susan Rigter[1,2] and Erik C. Garnett[1,2]; [1]AMOLF, Netherlands; [2]University of Amsterdam, Netherlands

Lead halide perovskites are one of the most exciting and heavily researched classes of optoelectronic materials due to their unique ability to form high quality crystals with tunable band gaps in the visible and near infrared using simple solution precipitation reactions. This facile crystallization is driven by their ionic nature; just as with other salts, it is challenging to form amorphous halide perovskites, particularly in thin-film form where they can most easily be studied. Herein, we show that rapid desolvation promoted by addition of acetate precursors is a general method for making amorphous lead halide perovskite films with a wide variety of compositions, including those using all the common cations (cesium, methylammonium, formamidinium) and anions (bromide, iodide). We show that by controlling the amount of acetate, it is possible to tune from fully crystalline to fully amorphous films, with an interesting intermediate state consisting of crystalline islands embedded in an amorphous matrix. The amorphous lead halide perovskite has a large and tunable optical band gap and improves the optical properties of incorporated crystalline perovskite, opening up the intriguing possibility of using amorphous perovskite as a passivating window layer, as is currently done in record efficiency silicon solar cells.

Facile Healing of Cracks in Organic-Inorganic Halide Perovskite Thin Films Srinivas K. Yadavalli, Zhenghong Dai, Min Chen, Mingyu Hu, Yuanyuan Zhou and Nitin Padture; Brown University, United States

Organic-inorganic halide perovskite (OIHP) thin films have attracted a great deal of interest as photoactive materials in various optoelectronic devices due to their unprecedented photophysical properties, but their long-term reliability is likely to be limited by their poor mechanical properties. In this context, we explain different possible modes of fracture in OIHP based devices, and for the first time demonstrate facile healing of through-thickness cracks in OIHP thin films which can otherwise be detrimental to the device properties. This is achieved through application of either a moderate compressive stress at room-temperature or a simple heat treatment at moderate temperatures. Based on the findings from a series of *ex situ* residual stress measurements, crack-healing process is found to be time-dependent, which indicates that facile mass-transport in OIHPs plays a key role in this phenomenon. The mechanisms governing crack-healing process are explained based on the fundamentals of brittle fracture. This discovery has broad implications for the prevention and/or restoration of the overall performance, environmental stability, and mechanical reliability of OIHP based devices like solar cells which are poised for commercialization.

F.EL08.17.17

Understanding the Effects of Moisture and Stoichiometry Variations on Composition and Structure in Halide Perovskite Solar Cells Juanita Hidalgo[1], Carlo Andrea Riccardo Perini[1], Andres Felipe Castro Mendez[1], Barry Lai[2], Ruipeng Li[3], Shijing Sun[4], Antonio Abate[5] and Juan Pablo Correa Baena[1]; [1]Georgia Institute of Technology, United States; [2]Argonne National Laboratory, United States; [3]Brookhaven National Laboratory, United States; [4]Massachusetts Institute of Technology, United States; [5]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

Hybrid halide lead perovskites are promising materials for photovoltaic applications. Nonetheless, these materials are highly sensitive and degrade in various environmental conditions. Among these, moisture is a prime cause of material degradation, representing a threat to the commercialization of perovskite-based materials. Hence, it is essential to study how water interacts with a perovskite thin film, what factors trigger instability in the material, and loss in solar cell performances. In order to understand these degradation mechanisms, we expose $Cs_{0.05}(MA_{0.17}FA_{0.83})_{0.95}Pb(I_{0.83}Br_{0.17})_3$ perovskite thin films with different precursor stoichiometries (organic to inorganic ratios) to a moisture treatment with high relative humidity. We monitor the evolution of perovskite crystalline structure, and we correlate it to changes in performances. Characterization with SEM images show morphological changes in the grain size, and XRD patterns evidence structural features that are furthered explained and understood by grazing incidence wide angle X-ray scattering (GIWAXS). Remarkably, we observe improved photovoltaic efficiency for treated films with an excess organic component, correlated with vertical orientation along the (001) plane. In addition, synchrotron-based X-ray fluorescence and X-ray beam induced current (XRF-XBIC) is used to correlate the elemental distribution with the current output of the devices.

HybriD^3 and MatD^3: Curated Materials Data for Hybrid Organic-Inorganic Perovskites and a General Software Stack for Materials Data Xiaochen Du[1,1], Raul Laasner[1], Xixi Qin[1], Connor Clayton[2], Svenja Janke[1], Becca Lau[1], Chi Liu[1], Sampreeti Bhattacharya[3], Juliana Mendes[4], Jun Hu[3], Dovletgeldi Seyitliyev[4], Ruyi Song[1], Manoj Jana[1], Matti Ropo[5], Franky So[4], Kenan Gundogdu[4], Wei You[3], Yosuke Kanai[3], David Mitzi[1,1] and Volker Blum[1,1]; [1]Duke University, United States; [2]Carnegie Mellon University, United States; [3]University of North Carolina at Chapel Hill, United States; [4]North Carolina State University, United States; [5]University of Turku, Finland

Materials research is generating a wealth of data across a vast community. Specifically, the volume of available data on hybrid organic-inorganic perovskites (HOIPs) and related growth in this area is now immense. Keeping track of data of different origins, sample types or levels of theory, with a diverse set of different relevant observables and discoveries, is a challenging task at best. We here present an open database, "HybriD^3" (Design, discovery and dissemination (D^3) of data related to hybrid materials, https://materials.hybrid3.duke.edu), aiming to collect, curate, and make available materials data related to HOIP. The database is designed to provide a broad set of data, i.e., experimental and computational, related to in principle any materials property of relevance to the community: structure, optical or electronic properties, and more. A key goal is to provide the ability to curate data, that is, identify property information closest to the actual properties of a real material prepared in a specific way (bulk crystalline, powder, thin film, nanocrystalline, ...). Importantly, the database is open to the community and designed to accept community input. While the "HybriD^3" database is focused on a particular materials class, the problem of making materials data of all kinds available in a structured, reproducible way is general. The software underlying the HybriD^3 database is thus available as a separate open-source project "MatD^3" (https://github.com/HybriD3-database/MatD3). We also describe this software stack, which can enable materials data at any scale, from small workgroups via focused projects all the way to large and general, open and reproducible materials data collections.

***Ab Initio* Characterization of the Cs_2ZrX_6 (X=Cl, Br) Family, 0D Ordered Defect Perovskite Emitters** Christopher Savory[1], Anna Abfalterer[2], Javad Shamsi[2], Samuel D. Stranks[2] and David O. Scanlon[1]; [1]University College London, United Kingdom; [2]University of Cambridge, United Kingdom

As halide perovskites have made their significant impact in the fields of photovoltaics, light emitters and other optical devices, research interest has been reignited in families of lead-free 2D, 1D and 0D perovskite-derived materials that, while poorer photovoltaics, can access some of the strong emissive properties of the halide perovskites, while also demonstrating emergent optoelectronic properties of their own.[1] The layered $Cs_3Pn_2X_9$ (Pn = Sb, Bi; X = Cl, Br, I) family demonstrates structured excitonic emission at room temperature[2,3] while the K_2PtCl_6-structured 'vacancy-ordered double perovskites' such as M_2SnI_6 (M=Rb, Sn) have shown both evidence of defect tolerance similar to that seen in the lead halide perovskites as well as strong exciton-phonon coupling.[4,5] As such, the exploration of perovskite-inspired lower dimensionality compounds represents an exciting direction in the research of optical materials.

In this study, inspired by our experimental collaborators' colloidal synthesis of nanocrystals of Cs_2ZrCl6 and Cs_2ZrBr_6, which also belong to the K_2PtCl_6 structure type and demonstrate broad white photoluminescence when formed into thin films, we perform hybrid Density Functional Theory (DFT) calculations in order to predict and rationalize the observed optical and electronic behavior of the Cs_2ZrX_6 materials family, producing good agreement to experiment. By calculating the thermodynamic and luminescent properties of the intrinsic defects within the system, as well as excitonic properties within the QSGW method and the Bethe-Salpeter equation, we attempt to accurately predict the origin of such promising emissive properties. Finally, we present direct comparisons to the analogous M_2SnX_6 family and draw conclusions on the feasibility of extending the field of lead-free perovskite-inspired emitters, and whether such optimal optical properties are available beyond the post-transition metals.

Exploration of Compositional Space in Methylammonium-Free Lead Halogen Perovskites for High-Performance Solar Cells Yu An[1,2], Xianggao Li[1] and Juan Pablo Correa Baena[2]; [1]Tianjin University, China; [2]Georgia Institute of Technology, United States

The certified power conversion efficiency (PCE) of state-of-the-art organic-inorganic metal halide perovskite solar cells (PSCs) has surpassed 25%, coming after single crystalline silicon solar cells. The most widely studied methylammonium (MA) lead iodide undergoes a structural phase transition and degradation due to the volatile MA cation, detrimental to the long-term stability of the devices. Formamidinium (FA), used as the majority cation in most of PCE >20% PSCs, is thermally more stable and has an optimal red-shifted bandgap. However, FA with the relatively large radius induces titled PbI_6 octahedra in $FAPbI_3$, leading to the photoinactive yellow δ-phase at room temperature. Herein, iodide and FA in $FAPbI_3$ were gradually replaced by bromide and cesium (Cs) with smaller radius to suppress the yellow δ-phase and systematically explore the compositional space via regulating the tolerance factor, revealing the crucial link between the crystal structure and optoelectronic properties of the mixed-cation (FA/Cs) lead mixed-halide (I/Br) perovskite. An empirical expression for FA/Cs-Pb-I/Br bandgap as a function of composition was determined, which contributes to tailored bandgap suitable for tandem solar cells. In addition, the FA/Cs-Pb-I/Br films were probed by advanced synchrotron X-ray characterization to understand halide phase segregation, which has been found to be detrimental for solar cell performance.

F.EL08.18.04
Interfacial States, Energetics and Atmospheric Stability of Large-Grain Antifluorite Cesium Titanium Bromide Jocelyn Mendes, Julia Martin, Alexander Carl, Emma J. Pellerin and Ronald L. Grimm; Worcester Polytechnic Institute, United States

Cesium titanium bromide, Cs_2TiBr_6, has attracted research interest due to its ~1.8 eV band gap, which makes it desirable for forming tandem junctions with silicon. However, the instability of large-grain Cs_2TiBr_6 in ambient atmosphere prompts further fundamental understanding of its surface chemistry and oxidation. To ascertain stability of the material in ambient atmosphere and establish band edge positions of the material we conducted controlled air exposure experiments and UHV cleaving of nascent material. X-ray photoelectron spectroscopy (XPS) established correct synthesis, effects of atmospheric exposure, and characterization of UHV cleaved samples. Ultraviolet photoelectron spectroscopy (UPS) established band edge positions of Cs_2TiBr_6 with and without surface metal oxide species present. Powder X-ray diffraction (pXRD) quantified the effects of atmospheric exposure over time. The presence of metal oxides on Cs_2TiBr_6 surfaces shifted band alignments towards TiO_2 while UHV cleaved, oxide-free surfaces demonstrated an intrinsically n-type semiconductor. These results elucidate the effects of surface oxides on Cs_2TiBr_6 surfaces, and future routes through which interfacial reactivity may be used to improve atmospheric stability.

Bandgap-Tailored Perovskite Capping Layer Design for Improving Stability and Passivation Noor Titan Putri Hartono[1], Marie-Hélène Tremblay[2], Armi Tiihonen[1], Janak Thapa[1], Shijing Sun[1], Seth R. Marder[2] and Tonio Buonassisi[1]; [1]Massachusetts Institute of Technology, United States; [2]Georgia Institute of Technology, United States

In recent years, the 3D/low-dimensional (LD) perovskite heterostructure consisting of LD perovskite called ‘capping layer’, deposited atop of 3D perovskite in a device [1], has emerged as a solution for improving perovskite solar cells’ (PSCs’) stability and interfacial passivation. However, the capping layer materials and processing conditions have been optimized for single-junction PSCs, and not for multi-junction PSCs. To apply the capping layer in multi-junction PSCs, research efforts are required to understand and optimize the bandgap-tailored capping layer material. We propose a detailed study exploring at least 10 different types of LD perovskite with various halides (I, Br, and Cl) and thicknesses, and $CH_3NH_3Pb(I-Br)_3$ absorber mixtures with increasing bandgap from 1.59 to 2.27 eV [2]. The samples are degraded in a well-controlled environmental chamber, under high humidity (85% RH), high heat (85°C), and low illumination (0.17 sun). The same set of samples are screened using photoconductivity, as a proxy for its interfacial passivation property. We also utilize decision tree-based machine learning models and Shapley values [3] to help determine which molecular properties in the capping layers significantly affect the absorber mixtures’ stability and conductivity. Our results indicate that capping layers needs to

be tailored based on the perovskite absorbers' composition, bandgap, and organic cation types to achieve high stability. Furthermore, by comparing the optimum bandgap-tailored capping layers through X-ray photoelectron spectroscopy (XPS), Fourier-transform infrared spectroscopy (FTIR), and ultraviolet photoelectron spectroscopy (UPS), we can understand how the film stability is affected by inorganic and organic bonds on the surface of the capping layers, as well as how interfacial passivation is affected by band alignment. Our study suggests that capping layer tuning is a promising approach to increase the stability of perovskite-based tandem solar cells.

Nonlinear Bandgap Behavior in Lead-Free $Cs_2Ag(Sb_xBi_{1-x})Br_6$ Double Perovskite Alloys Seán Kavanagh[1,2,3], Zewei Li[4], Robert Palgrave[3], Richard Friend[4], David O. Scanlon[3], Aron Walsh[2] and Robert Hoye[2]; [1]Thomas Young Centre, UCL, ICL, KCL, QMUL, United Kingdom; [2]Imperial College London, United Kingdom; [3]University College London, United Kingdom; [4]University of Cambridge, United Kingdom

Double perovskites have emerged as promising candidate materials for high-performance next-generation optoelectronic technologies, owing to the ability to replace the toxic Pb^{2+} cation with a pair of more benign cations (*e.g.* Ag^{+} and Bi^{3+}), while preserving the perovskite crystal structure.[1] However, most double perovskites, including the prototypical $Cs_2AgBiBr_6$, have prohibitively wide bandgaps, limiting photoconversion and photocatalytic efficiencies.[2] Recently, it has been demonstrated that the bandgap of $Cs_2AgBiBr_6$ can be reduced through alloying with Sb^{3+},[3] yet the bandgap of the pure Sb-based double perovskite ($Cs_2AgSbBr_6$) remains excessively wide for photo-voltaic/catalytic applications. In this work, we develop a solution-based route to synthesize phase-pure $Cs_2Ag(Sb_xBi_{1-x})Br_6$ thin films, with the mixing parameter x tunable over the entire composition range. In doing so, we observe this system to disobey Vegard's law, exhibiting significant bandgap bowing, such that the mixed alloy ($x = 0.9$) demonstrates the smallest bandgap (2.08 eV, compared to 2.18 eV and 2.25 eV for the pure Sb- and Bi-based double perovskites, respectively). We investigate the possible mechanisms for this nonlinear bandgap variation through relativistic hybrid Density Functional Theory (DFT) calculations, combined with in-depth measurements of the composition, phase and grain structure to yield detailed understanding of the underlying physical origins. The energetic alignment of electron states within these materials is accurately calculated, including consideration of deformation potentials to adequately account for the spurious supercell effects associated with such calculations.[4,5] Our work reveals pathways to bandgap engineering in double perovskite alloys, such that it is better suited to photovoltaic or photocatalytic applications, which may be generally applicable to other mixed-metal double perovskite systems.

Tin Oxynitride-Based Ferroelectric Semiconductors for Solar Energy Conversion Applications Steven T. Hartman, Arashdeep S. Thind and Rohan Mishra; Washington University in St. Louis, United States

Lead-halide perovskites have emerged as a promising class of semiconductors; however they suffer from issues related to lead-toxicity and instability. We report results of a first-principles-based design of heavy-metal-based oxynitrides as alternatives to lead-halide perovskites. We have used density-functional-theory calculations to search a vast composition space of ABO_2N and $ABON_2$ compounds, where B is a p-block cation, and A is an alkaline, alkali-earth, rare-earth or transition metal cation, and identify 10 new ABO_2N oxynitride semiconductors that we expect to be formable. Specifically, we discover a new family of ferroelectric semiconductors with $ASnO_2N$ stoichiometry (A = Y, Eu, La, In, Sc) in the

$LuMnO_3$-type structure, which combine the strong bonding of metal oxides with the low carrier effective mass and small, tunable band gaps of the lead-halide perovskites. These tin oxynitrides have predicted direct band gaps ranging from 1.6 – 3.3 eV, and a sizeable electric polarization up to 17 μC/cm^2, which is predicted to be switchable by an external electric field through a non-polar phase. With their unique combination of polarization, low carrier effective mass and band gaps spanning the entire visible spectrum, we expect $A$$SnO_2N$ ferroelectric semiconductors will find useful applications as photovoltaics, photocatalysts, and for optoelectronics.
Acknowledgments: This work was supported by the National Science Foundation through grant number DMR-1806147.

How to Design Defect Tolerant Devices Basita Das[1], Irene Aguilera[1], Uwe Rau[1] and Thomas Kirchartz[1,2]; [1]Forschungszentrum Jülich GmbH, Germany; [2]University of Duisburg-Essen, Germany

Perovskite solar cells have emerged as a key photovoltaic technology given the remarkable rise in their efficiency in the past decade. Long non-radiative lifetimes as a result of slow defect-mediated recombination in perovskite materials are key in achieving high open-circuit voltages necessary for high efficiency solar cells.
The quantitative impact of bulk or interface defects on recombination is often estimated by defect statistics based on the model of Shockley, Read and Hall. However, defect statistics depend on defect capture coefficients to calculate defect occupancy and the recombination rate through the defect. Due to the lack of enough experimental data on capture coefficients of novel materials or, alternatively, models to calculate trap energy dependent capture coefficients it is frequently assumed that capture coefficients are symmetric, i.e, $k_n = k_p$ for all defect levels within the bandgap in a device. However, equal or at least similar values of the capture coefficients are not necessarily a typical or even a likely scenario.
To go beyond the state-of-the-art device simulation in photovoltaics involving constant capture coefficients, we present a generalized microscopic model based on the Harmonic oscillator approximation to calculate defect capture coefficients as a function of the host material and the energetic position of the defects. Then we use this capture coefficients to classify the "deep" defects inside a device not merely based on the energetic position of the device but also as a function of the quantitative impact it has on the device. Furthermore, we discuss certain photovoltaic device design principles that can substantially reduce recombination through the dominant recombination centers.

F.EL08.18.10
Enhancing Fundamental Understanding of Structure-Property Relationships in Chalcogenide Perovskite Semiconductors with Theoretical and Experimental Studies of Dielectric Response, X-Ray Absorption and Electronic Transport Stephen Filippone[1], Kevin Ye[1], Boyang Zhao[2], Shanyuan Niu[2], Nathan Koocher[3], Daniel Silevitch[4], Ignasi Fina[5], James Rondinelli[3], Jayakanth Ravichandran[2] and Rafael Jaramillo[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Southern California, United States; [3]Northwestern University, United States; [4]California Institute of Technology, United States; [5]Universitat Autònoma de Barcelona, Spain

Electronic materials in perovskite and related structure types are a rich field of study because they combine characteristics of ionic and covalent bonding in crystal structures that are tolerant of distortions and chemical substitution. Tremendous efforts are now underway to understand the structure-property relationships that underpin the photovoltaic performance of lead halide perovskites (LHPs), expanding on and linking decades of research on photovoltaic absorbers, on the one hand, and complex oxide physics on the other. Now we extend this spirit of interdisciplinary, fundamental inquiry to a much less-studied class of materials, the chalcogenide perovskites. Recent works have shown that chalcogenide perovskites have outstanding properties for optoelectronic applications, including: slow minority carrier recombination, strong light absorption, excellent environmental stability, and dopability. Efforts are just now beginning to develop a fundamental understanding of these phenomena and to exploit these exciting materials for applications.

We present a diverse set of studies of the atomistic origin of structure-property relationships in chalcogenide perovskites. We combine impedance spectroscopy, X-ray absorption spectroscopy (XAS), electronic transport, and first-principles theory to understand how atomic structure and particular chemical bonds support outstanding semiconducting properties. Our impedance spectroscopy measurements on single crystals reveal that chalcogenide perovskites are highly-polarizable semiconductors, with stronger dielectric response than any other family of semiconductors with band gap in the VIS-NIR, exceeding even LHPs. Our theoretical calculations agree quantitatively with our measurements, and illustrate the particular polar phonon modes responsible for the large dielectric response. Our XAS studies combining experiment and theory illustrate the importance of directional bonds in determining the near-band edge electronic structure (including the band gap), especially for layered variants in the Ruddlesden-Popper structure type. This electronic anisotropy is further illustrated by electronic transport measurements made on oriented single crystals.

Our results illustrate, in a fundamental and detailed level, the ways in which chalcogenide perovskites differ from their oxide and halide cousins. We show that the structure-property relationships follow from covalent metal-chalcogen bonds and strong electron-phonon coupling. We conclude that chalcogenide perovskites are highly promising for optoelectronic and energy-conversion technologies.

F.EL08.19.01
Novel $C_6H_5NHNH_3I$ Additive for Efficiency Acceleration in Organic-Inorganic Halide Perovskite Solar Cells Md Ashiqur Rahman Laskar[1,2] and Qiquan (Quinn) Qiao[1]; [1]South Dakota State University, United States; [2]Arizona State University, United States

Different additive materials are widely used to improve the power conversion efficiency (PCE) of organic-inorganic halide perovskite solar cells. In this work, we report a novel organic additive material $C_6H_5NHNH_3I$ (Phenylhydrazinium Iodide) which is very effective to enhance the PCE of single cation-single halide based Methylammonium Lead Iodide perovskite solar cells (MLIPSC). In addition to that, we have found the additive is also effective for other types of perovskite composition such as double cation-double halide perovskite solar cells. $C_6H_5NHNH_3I$ promotes perovskite crystal growth and improves the light absorption capability of the active layer. Furthermore, because of reduced defects and charge traps in the additive treated perovskite film, charge carrier lifetime becomes almost double from 1.4 µs to 2.5 µs which ensures minimum recombination of the photogenerated electrons and holes. Besides, approximately 10% increased external quantum efficiency (EQE) and 14% improved built in potential (V_{bi}) of the perovskite solar cells indicate superior device performance. Eventually, accelerated short circuit current density and open circuit voltage of the $C_6H_5NHNH_3I$ treated perovskite solar cells contribute to nearly 20% increment of PCE in MLIPSC.

F.EL08.19.02
Understanding the Effect of Electrode Spacing on $CsPbI_2Br$ Interdigital Photodetector with Chromium Electrodes Haider B. Salman; University of Arkansas, United States

Significant achievements were made in the past few years with perovskite material in optoelectronic applications. One of the advantages of the halide perovskite in photo detection applications is that the band gap of the material can be tuned to cover a wide range of wavelengths by halide mixing. In this paper, the research is focused on the fabrication and characterization of interdigital photodetectors made with $CsPbI_2Br$. The photodetector consists of two interdigitate chromium electrodes deposited on glass substrates with the perovskite filling the spacing between the electrodes. The interdigital pattern of the device was fabricated using photolithography method to deposit 80 nm of chromium. To study the effect of the electrode spacing on the device performance, four types of photodetectors with four different spacing; 50, 20, 10, and 5µm were fabricated. The perovskite was synthesized using one step deposition method with 0.6 molar concentration of $CsPbI_2Br$ precursor. The material was characterized by obtaining the absorbance, the photoluminescence, and the X-ray diffraction spectra. One single peak in the PL spectrum was observed at 648 nm indicating a band gap 1.91 eV. The current voltage curves of the photodetectors were obtained under dark and light conditions using keithley 4200 semiconductor characterization system and Newport solar simulator. The spectral response of the device was obtained suing Bruker ifs 125hr spectrometer. The device with 10 µm spacing showed ~370 on/off ratio at 5 V bias under 100 mW/cm^2 light intensity. Under the same conditions, the device with 5 µm showed an increase in the on/off ratio to 6800. The detectivities of the 10 and 5 µm devices were calculate to be 4.9×10^9, and 2.46×10^{10} Jones respectively.

Enhancing Chemical Stability and Suppressing Ion Migration in $CH_3NH_3PbI_3$ Perovskite Solar Cells via Direct Backbone Attachment of Polyester on Grain Boundaries Yuchen Zhou[1], Yifan Yin[1], Xianghao Zuo[1], Likun Wang[1], Chang-Yong Nam[2] and Miriam H. Rafailovich[1]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

Grain boundary (GB) passivation by polymer additives has been shown effective in improving the performance of solution processed hybrid perovskite solar cells (PSCs). However, the critical stability issue associated with detrimental ion migration in PSCs remains less explored by polymer additives. Here, we show that a new linear polar polymer, polycaprolactone (PCL), can passivate GBs of methylammonium lead triiodie ($MAPbI_3$) perovskites via direct backbone attachment, enabling significantly enhanced environmental stability of n-i-p type PSC. The champion PSC with optimal PCL concentration shows

an improved power conversion efficiency (PCE) of 20.1 %. 90% of initial PCE was preserved after 400 h ambient storage. After 100 h thermal aging (85 °C), 80% of the original PCE has also been preserved. The tested PSCs use less stable Spiro-OMeTAD (2,2′,7,7′-tetrakis[N,N-di(4-emethoxyphenyl)amino]-9,9′-spirobifluorene) as hole transport layer (HTL), and, thus, the improved stability indicates critical roles of PCL in retarding moisture ingression as well as suppressing ion migration. Detailed structures of PCL GB passivation is visualized directly via lateral scanning force and transmission electron microscopies. Secondary ion mass spectrometry and ion conduction measurements confirm the PCL GB passivation significantly retards I^- ion migration in $MAPbI_3$ PSCs, while without PCL, I^- ions are actively accumulating in the organic HTL and at the interface between electrodes and the HTL even without externally applied electric field. We envision this passivation strategy by PCL GB functionalization can help the development of environmentally stable, high-performance PSCs.(*This work was supported by the Morin Foundation Trust and the NSF, Inspire program #1344267*)

Effects of Annealing Temperature on Interdiffusion of Materials in Layered Perovskite Solar Cells Deborah Oyewole[1,2,1], Juan Martin Hinostroza Tamayo[1,1], Oluwaseun K. Oyewole[1,1], Benjamin Agyei-Tuffour[3], Richard Koech[4,1], Reisya Ichwani[1,1], Jaya Cromwell[1], Nancy Burnham[1,1] and Winston Soboyejo[1,1]; [1]Worcester Polytechnic Institute, United States; [2]Sheda Science and Technology, Km 10 Abuja-Lokoja Road, Nigeria; [3]School of Engineering Sciences, University of Ghana, Ghana; [4]African University of Science and Technology, Nigeria

In order to design more efficient and durable perovskite solar cells (PSCs), the effects of annealing temperature on interdiffusion of the constituent elements in layered formamidinium-based PSCs were studied. First, the PSCs were fabricated by spin-coating lead (II) iodide solution onto the mesoporous electron transporting layer (ETL) followed by a mixture of formamidinium ammonium iodide, with small proportion methylammonium bromide and methylammonium chloride. The effect of varying annealing temperature of the perovskite films is then studied to gain insight into the changes that occur on the perovskite film and the overall effects of interdiffusion of constituent elements on photoconversion efficiencies of the PSCs. The results show there is diffusion of tin from fluorine-doped tin oxide to the mesoporous ETL due to sintering. The level of tin in the mesoporous layer decreases with increased annealing temperatures of the perovskite films. The quality of perovskite films is also improved with better uniformly distributed grain sizes for annealing temperatures between room temperature and 130 ºC compared to higher annealing temperatures of 140 ºC and 150 ºC. The overall effects of the interdiffusion of layer constituents on photoconversion efficiencies are then discussed for the design of PSCs.

F.EL08.19.07

A Hole Transport Bilayer for Highly Efficient and Stable Inverted Perovskite Solar Cells Hamza Javaid, Volodimyr V. Duzhko and Dhandapani Venkataraman; University of Massachusetts Amherst, United States

Highly efficient and stable inverted, *i.e.* p-i-n, perovskite solar cells (PSCs) are fabricated by employing a novel hole transport bilayer. Compared to devices with single PTAA interlayer, which have an average power conversion efficiency (PCE) of 18.9%, an enhanced average PCE of 20.2% and a maximum PCE of 21.16% in the bilayer-based devices are observed. The XRD and AFM studies show an improved crystallinity and larger grain size of perovskite films on the bilayer surface. The ultraviolet photoelectron spectroscopy and Mott-Schottky analysis suggest an increased built-in potential with an enhanced upward band bending at the bilayer/perovskite interface. Compared to devices with single PTAA, CuI and PEDOT:PSS interlayer, the bilayer-based devices show significant suppression of *J-V* hysteresis and stable current output at maximum power point. The bilayer-based devices also demonstrate a remarkable long-term stability, as tested in inert atmosphere.

Toward Rational Design of Stable and Robust Hybrid Perovskite Devices—The Role of Functionalized Organic Cations and Dimensionality Engineering Arvin Kakekhani[1], Marcos A. Reyes-Martinez[2], Xiaoming Zhao[2], Melissa Ball[2,2], Peng Tan[3,1], Sayan Banerjee[1], Lynn Loo[2,2] and Andrew Rappe[1]; [1]University of Pennsylvania, United States; [2]Princeton University, United States; [3]Harbin Institute of Technology, China

Here, we discuss how density functional theory (DFT)-based methods can help us in designing strategies to mitigate the stability and efficiency challenges for hybrid organic-inorganic perovskite (HOIP) systems. On one front, we use first-principles theory to rationalize the elastic properties of layered hybrid perovskites, correlating such properties with interlayer organic-organic interactions and also the HOIP's structural properties e.g., its dimensionality or intrinsic interlayer defects and voids. [1] On a different but complementary front, we have studied fundamental chemistry behind the water degradation of 3D hybrid perovskites and have related this to the chemical properties of the organic cations. [2] We are now expanding this work to study water interactions in layered quasi-2D systems, unraveling the fundamental role of dimensionality in water

stability of perovskites. Beyond the realm of bulk-like perovskites, we also study the determining role of organic cations' chemistry on surface stability and defect formation for HOIP nanoparticles. The role of organic cations goes further than directly influencing the inorganic backbone structure, and for some specific functionalized organic cations and through intricate hydrogen-bonding networks, the organic-organic interactions can become important at dictating the electronic and structural properties of layered perovskites. Having a multipronged approach in which we identify descriptors for elastic and electronic properties of perovskite, as well as their stability, allows us to rationalize and help improve experimentally-relevant pathways to create more robust HOIP-based devices capable of performing in real-world PV or LED applications. Few such possibilities which are discussed here include: surface passivation with mixed short organic cations, supramolecular interactions between long cations, secondary organic functionalities, and dimensionality engineering.

Bilayer Perovskite Solar Cells by Grafted PDMS Transfer Process Anisha Mohapatra[1,2] and Chih-Wei Chu[1]; [1]Academia Sinica, Taiwan; [2]National Tsing Hua University, Taiwan

Organic-Inorganic Perovskite solar cells has a great advantage to reach the radiative limit for PCE enhancement. The single junction devices are restricted to attain the radiative limit because of the energy losses. Multi-structure architectures like tandem, heterostructure are adapted to recover the thermodynamic energy loss. The variable bandgap of perovskite is an advantage, which varies from 1.5eV~1.8eV providing a complete solar spectrum coverage. Stacking of high-bandgap perovskite with low bandgap perovskites is a good approach for encountering the energy losses. The perovskite heterostructure is fabricated by sequential deposition of quantum dots and thermally evaporated p-n junctions. Till now, there is no demonstration of any solution process able method in perovskites for stacking perovskite absorbers because of the dissolution of perovskite precursors by the subsequent layers. Therefore, we demonstrated a PDMS printing technique for stacking perovskite layers inspired by multi-stacked organic solar cells. The printing technique is assisted with modification of surface energy of PDMS by grafting process, which facilitates printing of high crystalline pinhole free perovskite layers. On proving ground, we also stacked perovskite layers to form a perovskite heterostructures. We demonstrated the printing of multi-layer perovskite layers to encounter the thermodynamic losses. To understand the advantage of heterostructure for encountering the energy losses, a constant thickness of single layer and heterostructure was maintained for compared the photovoltaic performance. We achieved a photovoltaic performance of ~5%, ~9% for MaPbI3 and MaPbBrI2 layer and ~10% for MAPbBrI2/MAPbI3 heterostructure. This gave us an indication that the heterostructure was able to suppress some non-radiative recombination to overcome the energy losses, which can be a great application for stacking perovskite layers to use in different optoelectronic applications.

Fracture Behavior of Halide Perovskite Thin Films for Solar Cells Zhenghong Dai, Srinivas K. Yadavalli, Mingyu Hu, Min Chen, Yuanyuan Zhou and Nitin Padture; Brown University, United States

Organic-inorganic halide perovskites (OIHPs) have emerged as the most promising light-absorber materials in thin-film photovoltaic (PVs). However, the low formation energies of OIHPs render them unstable. While significant progress has been made in improving the stability of OIHPs, perovskite solar cells (PSCs) will also need to be mechanically reliable if they are to service satisfactorily for years. In this context, we have studied the fracture behavior of PSCs by measuring their cohesion energies using double cantilever beam method and report a novel approach to strategically enhance the interfacial adhesion and performance of PSCs by interface modification. This work points to a new route for designing mechanically robust PSCs with long-term durability.

Amplified Spontaneous Emission from All-Inorganic Quasi-2D Perovskites Lei Lei, Dovletgeldi Seyitliyev, Kasra Darabi, Siliang He, Samual Stuard, Qi Dong, Juliana Mendes, Harald Ade, Aram Amassian, Kenan Gundogdu and Franky So; North Carolina State University, United States

Recently, metal-halide perovskite materials are considered as a promising candidate for lasing applications since perovskites may overcome typical limitations showed in organic gain media and the “green-gap” in inorganic semiconductors. While lasing has been demonstrated based on perovskite materials with both 3D and low-dimensionalities, quasi-2D perovskites are a better gain media due to its unique properties such as large binding energy and self-assembled quantum wells. It has been shown that efficient energy funneling from low-dimensional domains to high-dimensional domains will not only enhance the radiative recombination but also facilitate population inversion. However, the trend of how the dimensionality of quasi-2D perovskites affects amplified spontaneous emission (ASE) threshold is still controversial. Here, we investigate ASE of all-inorganic quasi-2D perovskite thin films with different dimensionalities, and try to understand the role of dimensionality in both materials properties and charge carrier dynamics.
In this work, we formed quasi-2D perovskite thin films based on the all-inorganic 3D cesium lead halide perovskite framework due to the improved thermal and optical stability. The dimensionality of quasi-2D perovskites is tuned by varying the concentration of the organic spacer phenethylamine (PEA). In our work, the large organic cation PEA acts as a nucleation center facilitating the crystallization process of perovskites. Via grazing-incidence wide-angle X-ray scattering (GIWAXS) measurements and scanning electronic microscopy, we found that the addition of PEA also enhances the quality of the thin films by controlling the domain size and morphology. As a result, the PLQY increases with the PEA concentration. However, the ASE threshold is not correlated with the PLQY and it reaches to the lowest value (7 $\mu J/cm^2$) at a moderate PEA concentration of 40%. To study the correlation between PEA concentration and ASE threshold, we used transient photoluminescence and transient absorption spectroscopy to study the photophysics of these films. Our results showed that with increasing PEA concentration to 40%, the non-radiative recombination is significantly reduced due to defect passivation, leading to the increasing PLQY and decreasing of ASE threshold. However, the existing of the low-dimensional domains became significant with a higher PEA concentration (60%), which acted as long-lived trap states for excitons and limited the population inversion process. Finally, by using the optimized PEA ratio, the ASE emission was observed over the broad visible range from red to blue, demonstrating its wide wavelength-tunability.

Direct Observation of the Ultrafast Dynamics of Trapped Carriers in Organic Metal Halide Perovskite Films Kanishka Kobbekaduwa[1], Shreetu Shrestha[2], Pan Adhikari[1], Hsinhan Tsai[2], Wanyi Nie[2] and Jianbo Gao[1]; [1]Clemson University, United States; [2]Los Alamos National Laboratory, United States

Despite the power conversion efficiency (PCE) of the perovskite solar cells soars more than 25 % in less than ten years, their limited stability remains one of the crucial hurdles on the path to commercialization. To improve the device stability, various trap state passivation strategies targeting the bulk perovskite, perovskite surface, and device interfaces have been employed. However, knowledge of the temporal, spatial, and energetic correlation of the defect/trap states is the foundation for fundamental and technical understanding of the impact of the trap/defect states, manifested by the device stability and PCE optimization.
In this report, we directly observe the ultrafast dynamics of trapped carriers in organic lead halide perovskite $MAPbI_3$ thin film by ultrafast photocurrent spectroscopy (UPCS). Under low carrier density, the trapped carriers undergo a multiple trapping and release (MTR) transportmechanism among the shallow trap states and deep trap state, demonstrated by a time-dependent activation energy. Above the trap filling region, in addition to the MTR transport mechanism, the trap-assist Auger recombination occurs, which is demonstrated by the laser intensity dependent decay time. Our results elucidated the trapped carrier dynamics from sub-25 ps to couple ns in the solution-processed film with mobility of ~ 1 cm^2/Vs.

Exciton Spin Relaxation in 2D Metal Halide Perovskites Sean A. Bourelle; University of Cambridge, United Kingdom

Optoelectronic properties of 2D metal halide perovskites are dominated by the transitions and interactions between excitons. Here, we present a study on the spin relaxation mechanisms for these excitonic states and demonstrate how these mechanisms can be altered. Our analysis utilizes ultrafast spectroscopy methods including Faraday rotation and circularly polarised transient absorption spectroscopy.

Optical Studies of Mixed-Dimension Perovskites—Excitonic Effects and Morphological Changes with Alkyl-Ammonium Iodide Doping Mohsin Raza Khan, Shahzad Akhtar Ali, Qurat ul Ain, Ataul Haq and Ammar A. Khan; Lahore University of Management Sciences, Pakistan

Organometal halide perovskites are promising materials for optoelectronic applications due to excellent light absorption,

charge transport and emissive properties, coupled with potentially low-cost scalable fabrication [1][2]. Perovskite solar cells (PSCs), as well as other devices, currently suffer from moisture and thermal instability of the perovskite semiconductors [3]. There are several complimentary methodologies of increasing the stability of PSCs, and amongst these the formation of hybrid two/three dimensional Ruddleson Popper perovskites is one of the most promising [4]. Mixed dimension perovskites (MDPs) can be formed by the incorporation of long alkyl-chain cations into the crystal structure leading to the formation of a layered crystal structure [5]. The individual layers are separated by covalently linked cations, with a 3D intra layer geometry. The optical, crystalline, electrical and magnetic properties of 3D perovskites can be readily tuned by varying the stoichiometric concentration and chain length of the dopant, leading to a considerable scope for application dependent material engineering. However, exploring this large yet versatile parameter space of dopants requires an understanding of the underlying excitonic processes and morphological dependencies.

In this work, the formation of 2D/3D mixed alkylammonium lead iodide perovskites using Butylammonium (BAI) and Octylammonium (OAI) iodides as additives in methyl-ammonium lead iodide perovskites is demonstrated. A solvent annealing method is employed to improve film morphology. The effect of incorporating these cations on the optical properties of the films is investigated using micro-photoluminescence and absorption studies, and a left shift in band-gap with increasing 2D character is illustrated, in accordance with literature[6]. BAI and OAI demonstrate very different spectral properties, with much larger spectral shifts in the longer chain derivitive, hinting towards a strong effect of the alkyl chain. We further utilise multi-gaussian fitting to reveal insights into edge-states as well as disorder in MDPs, which can have imporant consequences for photovoltaic and light-emitting device applications.

Benefits of Disorder—Carrier Localisation in Alloyed Hybrid Perovskites for Efficient Luminescence Sascha Feldmann[1], Stuart Macpherson[1], Richard Friend[1], Henning Sirringhaus[1], David Beljonne[2], Samuel D. Stranks[1] and Felix Deschler[3]; [1]University of Cambridge, United Kingdom; [2]Université de Mons, Belgium; [3]Technische Universität München, Germany

Metal halide perovskites have emerged as promising materials for optoelectronic applications like solar cells or light-emitting diodes (LEDs). Here, we investigate mixed-halide perovskites and control the cation alloying to enhance optoelectronic performance through alteration of the charge carrier dynamics. In contrast to single-halide perovskites, we find high luminescence yields for photoexcited carrier densities far below solar illumination conditions. We employ time-resolved spectroscopy and show that the charge carrier recombination regime changes from second to effectively first order within the first tens of nanoseconds after excitation. Supported by microscale mapping of the optical bandgap, electrically gated transport measurements and first-principles calculations, we demonstrate that spatially varying energetic disorder in the electronic states causes local charge accumulation, creating p- and n-type photodoped regions, which unearths a strategy for efficient light emission at low charge-injection in solar cells. [1]

F.EL08.20.06
Performance Limiting Structural Heterogeneities in Metal Halide Perovskites Tiarnan A. Doherty[1], Stuart Macpherson[1], Andrew Winchester[2], Duncan Johnstone[1], Miguel Anaya[1], Aron Walsh[3], Paul Midgley[1], Keshav Dani[2] and Samuel D. Stranks[1]; [1]University of Cambridge, United Kingdom; [2]Okinawa Institute of Science and Technology, Japan; [3]Imperial College London, United Kingdom

Halide perovskite materials have promising performance characteristics for low-cost optoelectronic applications. Photovoltaic devices fabricated from perovskite absorbers have reached power conversion efficiencies above 25 per cent in single-junction devices and 28 per cent in tandem devices. Though widely considered defect tolerant materials, perovskites still exhibit a sizeable density of deep sub-gap non-radiative trap states, which create local variations in photoluminescence (*1*, *2*) that fundamentally limit device performance. These trap states have also been associated with light-induced halide segregation in mixed halide perovskite compositions (*3*) and local strain (*4*), both of which can detrimentally impact device stability (*5*). Understanding the nature of these traps will be critical to ultimately eliminate losses and yield devices operating at their theoretical performance limits with optimal stability. We recently revealed that the majority of these trap states in state-of-the-art $(Cs_{0.05}FA_{0.78}MA_{0.17})Pb(I_{0.83}Br_{0.17})_3$ perovskites form in nanoscale clusters at grain boundaries of compositionally and structurally distinct entities [*Nature*, 2020].

In this talk we detail our low-dose, high-resolution and multimodal approach to link photophysical properties to nanoscale structural and compositional heterogeneities. By combining scanning electron microscopy techniques with spatially resolved photoemission measurements, we compare and contrast observed structural defects in $(Cs_{0.05}FA_{0.78}MA_{0.17})Pb(I_{0.83}Br_{0.17})_3$ and $(Cs_{0.05}FA_{0.78}MA_{0.17})PbI_3$ halide perovskite thin films and discuss how they ultimately limit device performance. In so doing, we reveal the nature and origin of the "inhomogenous" perovskite grains that have been directly linked to non-radiative recombination and were previously unidentified (*1*). Finally, by combining scanning electron diffraction measurements with environmental chambers, we perform *in-situ* experiments to explore the local nanoscale structural modifications that occur in perovskite materials under real world operating conditions and how these structural modfications are linked to device degradation.

Elucidating the Influence of Compositional Heterogeneity on Charge Carrier Accumulation and Photodoping in Metal Halide Perovskites Stuart Macpherson, Jooyoung Sung, Tiarnan A. Doherty, Kyle Frohna, Elizabeth Tennyson, Miguel Anaya, Yu-Hsien Chiang, Akshay Rao and Samuel D. Stranks; University of Cambridge, United Kingdom

Metal halide perovskites are remarkable thin film semiconductors with numerous favorable properties that are optimal for photovoltaic and light emission applications[1]. These characteristics include high absorption coefficients, long charge carrier lifetimes and a tunable bandgap.

We have previously shown that the luminescence efficiency and charge carrier recombination behavior in mixed halide perovskites is significantly altered by the cation alloy employed during fabrication via facile solution processing[2]. The addition of alkali metal cations provides passivation of sub-bandgap defect states and also stabilizes an energetic landscape that facilitates photodoped carrier accumulation, leading to enhanced optoelectronic performance.

Our current work aims to further unveil the influence of microscopic compositional variations on local photoinduced carrier accumulation in $(CsMAFA)PbI_xBr_{3-x}$ perovskite films. We combine Femtosecond Transient Absorption Microscopy with nanoscale X-ray Fluorescence and Atomic Force Microscopy to track carrier diffusion and recombination across a heterogenous chemical and morphological landscape. We find that the complex interplay of local carrier recombination and diffusion will have important ramifications for solar cell and LED device performance.

Ferroelastic Strain and Defect Behavior upon Repeated Bending of Flexible Methylammonium Lead Iodide Perovskite Films Rhys M. Kennard, Clayton J. Dahlman, Ryan DeCrescent, Jon Schuller, Kunal Mukherjee, Ram Seshadri and Michael Chabinyc; University of California, Santa Barbara, United States

The highest solar cell efficiencies in halide perovskite devices are achieved using compositional derivatives of tetragonal methylammonium lead iodide ($MAPbI_3$). Commercialization of flexible perovskite devices will require a thorough understanding of how applied strain modifies the perovskite structure and defect-related properties. A complication of studying strain behavior in tetragonal $MAPbI_3$ is that it is ferroelastic, meaning that it spontaneously forms multiple domains, also called "twins". These twins exhibit identical crystal structure but different orientation, are inherently strained, and are separated by domain walls. The relative proportions of different twins can be semi-reversibly changed ("domain switching") upon application of stress, via a process called ferroelastic hysteresis. Separate studies have shown that applying strain to $MAPbI_3$ films modifies defect-related properties such as the degradation rate, the activation energy of ion migration and the photoluminescence lifetime. However, potential correlations between changes to these properties in films and ferroelasticity have proven difficult to establish, as a detailed structural description of the ferroelastic behavior of $MAPbI_3$ under strain is missing.

In this work, we characterized in detail the ferroelastic hysteresis loop of $MAPbI_3$. Films of $MAPbI_3$ were cast on polymer substrates. We used Grazing Incidence Wide-Angle X-ray Scattering (GIWAXS) to first identify twin type and to assess the impact of the polymer substrate on the twins formed. Changes in the populations of different ferroelastic twins, in the strain magnitudes of different lattice planes, and in minimum domain sizes were then characterized for increasingly large applied strains. We thus identified approximate locations for the coercive stress (onset of domain switching) and saturation (all possible domain switching has occurred) on the stress-strain curve of $MAPbI_3$, as well as transformation strain magnitudes imparted by the hysteresis. Changes in the minimum domain sizes enabled deduction of evolution of the number of domain walls. The concentration of domain walls in films was found to closely correlate with previously-reported changes in the activation energy of ion migration, photoluminescence lifetime and degradation rate of $MAPbI_3$ films upon application of strain. The understanding gained by these results will aid design of more stable $MAPbI_3$ flexible devices with better-controlled ionic and electronic properties.

Ultrafast Photophysics of Metal Halide Perovskite Multiple Quantum Wells—Device Implications and Reconciling Band Alignment Andrew H. Proppe and Edward H. Sargent; University of Toronto, Canada

Metal halide perovskite quantum wells (QWs) have been used to fabricate efficient optoelectronic devices, and exhibit stability superior to that of their bulk 3D counterparts. The perovskite QWs are tuned in synthesis so that they possess different bandgaps and exciton binding energies owing to variable quantum confinement as a function of QW thickness. Accordingly, the device performance of these materials depends on the efficiency of various interwell carrier dynamical processes, principally exciton and charge transfer. I will discuss the use of transient absorption and ultrafast two-dimensional electronic spectroscopy to probe interwell exciton transfer on timescales of 100s of femtoseconds, and show that interwell charge transfer occurs on timescales of 10s to 100s of picoseconds. These results, in addition to ultraviolet photoelectron spectroscopy experiments, are used to reconcile conflicting observations of type-I and type-II band alignment amongst perovskite QWs.

F.EL08.20.12
Rashba Band Splitting in Methylammonium Lead Iodide—An Insight from Spin-Polarized Scanning Tunneling Spectroscopy Abhishek Maiti, Salma Khatun and Amlan J. Pal; Indian Association for the Cultivation of Science, India

A low recombination rate of photogenerated carriers in methylammonium lead iodide ($MAPbI_3$) enhancing the carrier lifetime and thereby diffusion length is believed to be occurred due to Rashba band splitting [1] which arises due to a large spin-orbit coupling (SOC) arising out of high-*Z* elements (lead and iodine) in the compound along with a lack of centrosymmetry which appears due to a tilted PbI_6 octahedra and rotating electric dipoles of the organic ions leading to an effective magnetic field and thereby lifting the Kramer's spin-degeneracy of the electrons.[2] Regarding the spin-rotation or

spin-texture (χ) of the two split-levels, two schools of thought persist amongst theoreticians: (1) spin-forbidden transition model and (2) spin-allowed transition model. In the spin-forbidden transition model, after spin-split, the CB and VB closer to the Fermi energy possess opposite spin-textures. A recombination between electrons in CB-minimum and holes in VB-maximum is hence a spin-forbidden process leading to a low recombination rate and thereby an enhanced carrier lifetime and a longer diffusion length.[1] On the other hand, such possibility has been overruled in the spin-allowed transition model as CB and VB possess a similar type of spin-texture closer to the Fermi energy where the recombination of photo-excited carriers is apparently possible due to spin-allowed nature of the transition.[3] In this regard, we have reported an experimental observation of Rashba splitting in $MAPbI_3$ through spin-polarized scanning tunneling spectroscopy to probe the split bands.[4] dI/dV spectra recorded at many different points of the film allowed us to spot both the Rashba split-levels and also to deliberate on their spin-textures. We observe that the bands split in such a manner that the conduction and valence bands closer to the Fermi energy have the same type of spin-textures (a spin-allowed transition model). Still a low recombination rate of photogenerated carriers in $MAPbI_3$ has been analyzed by considering Wannier-type excitons, a molecular nature of spin-domains as observed from the dI/dV images, and therefore a spin-forbidden nature of inter-domain transition.

Late News: Comparison of Different Functionals for First-Principles Calculations of Defects in Metal Halide Perovskites Haibo Xue[1], Geert Brocks[2,1] and Shuxia Tao[1]; [1]Eindhoven University of Technology, Netherlands; [2]University of Twente, Netherlands

Being one of the most promising photovoltaic materials, the metal halide perovskites have attracted plenty of scientific effort in improving their opotoelectronic properties and long-term stability. Both properties are highly sensitive to the nature and the concentration of the intrinsic defects in the perovskites. The first-principles calculation is very useful to predict the thermodynamics relevant to the formation of the defects and their consequences in the optoelectronic properties and plays an essential role in complementing experiments in understanding the defect chemistry and physics. However, due to the intrinsic complexity of the halide perovskites, i. e. hybrid composition and covalent-ionic bonds, diverse results were reported using different functionals within the density functional theory framework. Here, using the typical perovskite, $MAPbI_3$, as an example, we show a comprehensive comparison of a wide range of functionals including GGAs, meta-GGA (SCAN), and combination of them with atom-pairwise (DFT-D3) and non-local (rev-vdW-DF2 and rVV10) van der Waals (vdW) correction. Our results indicate meta-GGA (SCAN) predicts consistently more accurate geometries and energies than GGAs and the vdW correction is essential for describing the vdW bonds associated with the organic cations in the hybrid perovskites. Based on the above, we suggest the SCAN+rVV10 is the most promising functional and is expected to improve on the accuracy for other halide perovskites in this large family of materials.

Late News: Machine Learning Framework for Accelerated Development of Halide Perovskites Meghna Srivastava[1], John Howard[2,2], Tao Gong[1] and Marina S. Leite[1]; [1]University of California, Davis, United States; [2]University of Maryland, United States

Metal halide perovskite solar cells (PSC) are a high-efficiency, low-cost alternative to Si photovoltaics. However, various environmental stressors (light, humidity, temperature, bias, and oxygen) initiate degradation in perovskite devices, which limits device lifetimes and impedes commercialization. Discovering materials and fabrication parameters that provide a stable performance is therefore vital. Machine learning (ML) accelerates design at every level of the PSC development process while offering novel physical insight. We present a framework for applying ML to (A) perovskite compositional screening, (B) material synthesis and stability analysis, and (C) full device development and testing. Key parameters such as crystal lattice parameters, quasi-fermi-level splitting, and power conversion efficiency (PCE) are extracted from experimental data, including X-ray diffraction (XRD), photoluminescence (PL), and current-voltage (I-V) characteristics. Traditionally, these data lead to a time-consuming trial-and-error process that informs optimal perovskite compositions, fabrication processes, and device operating conditions. ML models expedite this process and, once trained, use easily acquired experimental data to

immediately predict figures of merit or future material/device performance (including forecasting time-resolved behavior). These predictions then guide further experimental investigation. Our generalized roadmap involves (1) identifying the material question of interest, (2) obtaining data for model training, (3) data pre-processing, (4) feature engineering, and (5) model optimization and testing. We demonstrate this process from start-to-finish using several baseline models trained on currently available data from the perovskite community, noting potentials for fine-tuning and extension. As one example, we use past time-series PL and relative humidity (rH) data to forecast humidity-dependent light emission for methylammonium lead triiodide (MAPI), methylammonium lead tribromide, and triple-cation (formamidinium-methylammonium-cesium) perovskite thin films. For this task, we implement an echo state network (ESN), a type of recurrent neural network (RNN). The optimized model predicts PL output with <15% normalized root mean square error (NRMSE) for all compositions over 12+ hours. We train an additional ESN to forecast power output from a PSC with a triple-cation absorber, using light intensity and temperature data as inputs, and obtain an NRMSE of only 3.1%. In addition to time-series prediction, ML models can extrapolate from ground truth experimental data to novel conditions. This reduces laboratory time drastically and eliminates the need for exhaustive trial-and-error work. For example, we train a long short-term memory (LSTM) model on temperature-dependent aging data from a MAPI PSC. We generate degradation traces at unseen temperatures with <3% NRMSE. Finally, we show image-based machine learning, using a convolutional neural network (CNN) to extract hidden trends from dark-field images of spiro-OMeTAD (a common hole-transport layer in PSC devices) and predict film conductance. Although the images have no visual trends discernable by the human eye, the model achieves an NRMSE of 19%. These examples illustrate the versatility of ML as a tool in PSC research, and our workflow is easily generalizable to other facets of development. We propose integrating projects from all three levels of PSC design (composition, material, and device) into a streamlined ML pipeline that includes materials discovery, fabrication, characterization, and stability testing. This pipeline takes advantage of our current technological capabilities in ML, data science, and autonomous experimentation and presents a rational, accelerated pathway to PSC commercialization.

Late News: Atomistic and Electronic Origin of Phase Instability of Metal Halide Perovskites Junke Jiang[1], Feng Liu[2], Ionut Tranca[1], Qing Shen[2] and Shuxia Tao[1]; [1]Eindhoven University of Technology, Netherlands; [2]The University of Electro-Communications, Japan

The excellent optoelectronic properties of metal halide perovskites (MHPs) have attracted extensive scientific interests and boosted their application in optoelectronic devices. Despite their attractive optoelectronic properties, their poor stability under ambient conditions remains the major challenge, hindering their large-scale practical applications. In particular, some MHPs undergo spontaneous phase transitions from perovskites to non-perovskites. Compositional engineering via mixing cations or anions has been widely reported to be effective in suppressing such unwanted phase transition. However, the atomistic and electronic origins of the stabilization effect remain unexplored. Here, by combining Density Functional Theory (DFT) calculations and Crystal Orbital Hamilton Population (COHP) analysis, we provide insights for the undesired phase transition of pristine perovskites ($FAPbI_3$, $CsPbI_3$, and $CsSnI_3$) and reveal the mechanisms of the improved phase stability of the mixed compounds ($Cs_xFA_{1-x}PbI_3$, $CsSn_yPb_{1-y}I_3$, and $CsSn(Br_zI_{1-z})_3$). We identify that the phase transition is correlated with the relative strength of the M-X bonds as well as that of the hydrogen bonds (for hybrid compositions) in perovskite and non-perovskite phases. The phase transition can be suppressed by mixing ions, giving rise to either increased bond strength for the perovskite or decreased bond strength in their non-perovskite counterparts. Our results present a comprehensive understanding of the mechanisms for the phase instability of metal halide perovskites and provide design rules for engineering phase-stable perovskite compositions.

Late News: Atmosphere Affecting Lattice and Degradation Mechanisms of High-Efficiency Perovskite Solar Cells Renjun Guo[1], Dan Han[2], Wei Chen[1], Manuel A. Scheel[1], Lennart K. Reb[1], Nian Li[1], Shambhavi Pratap[1], Tianxiao Xiao[1], Suzhe Liang[1], Christian L. Weindl[1], Shanshan Yin[1], Hubert Ebert[2], Matthias Schwartzkopf[3], Stephan V. Roth[3,4] and Peter Muller-Buschbaum[1,5]; [1]Technische Universität München, Germany; [2]Ludwig-Maximilians-Universität München, Germany; [3]Deutsches Elektronen-Synchrotron, Germany; [4]KTH Royal Institute of Technology, Sweden; [5]Heinz Maier-Leibnitz-Zentrum, Germany

Metal halide perovskites have shown a promising future for application in field-effect transistors, light-emitting diodes, sensors, solar cells, and photodetectors due to their excellent optic-electrical properties. Among the excellent properties of perovskites, for example, strong absorption, the long diffusion length of photo-generated charge carriers and low binding energies make it possible to realize next-generation solar cells with 25.2% power conversion efficiency (PCE) in a decade. At the same time, perovskite solar cells (PSCs) have shown a powerful photovoltaic application for replacing silicon solar cells not only due to high PCE but also because of its low processing costs. Despite such advantages, the application of PSCs is

currently limited by combining high performance and operational stability, because the PCE of PSCs can degrade due to the presence of temperature, light, humidity, and oxygen. So far, the degradation research on PSCs is carried out without having an established standard protocol. The microscopic degradation mechanisms are not clear under operating conditions upon suggested inert atmospheres based on the International Summit on Organic Photovoltaic Stability protocols. Therefore, it is necessary to establish an improved standard protocol for the long-term degradation of PSCs.

In this respect, we investigate the degradation processes of PSCs under both, AM 1.5G and different atmosphere conditions (vacuum and nitrogen) with in-operando grazing incidence wide-angle X-ray scattering (GIWAXS) and grazing incidence small-angle X-ray scattering (GISAXS). With these approaches, we find that mixed cations lead mixed halides lattice exhibit the effect of photostriction when being operated in different atmospheres. In addition, the nature of photostriction can help the phase segregation of halide perovskites. Pressure conditions can suppress this photostriction behavior. Theoretical calculations based on density functional theory confirm that lattice photostriction behavior can suppress phase segregation induced by thermodynamic driving forces. A standard protocol is suggested based on our findings.

Late News: Study of the Formation of Different Electron Transport Layer (ETL) Materials and Their Impacts on Perovskite Solar Cell (PSC) Performance Luisa Pan[1], Pranati Patnam[2], Benjamin Roitman[3], Yifan Yin[4], Yuchen Zhou[4], Miriam H. Rafailovich[4] and Chang-Yong Nam[5]; [1]The Harker School, United States; [2]Herricks High School, United States; [3]SAR High School, United States; [4]Stony Brook University, The State University of New York, United States; [5]Brookhaven National Laboratory, United States

Perovskite solar cells (PSC) are believed to be the core of next-generation solar cells due to their rapidly increasing efficiency and popularity as an alternative energy source to fossil fuels. However, the interfacial contact between the electron transport layer (ETL) and the perovskite layer in the cell often results in problems of hysteresis. This research investigates different ETL materials to remedy hysteresis in organic-inorganic CH3NH3PbI3 (MAPbI3) PSCs. Compact TiO2 (c-TiO2), SnO2 (0.1M and 0.2M), and mesoporous TiO2 (m-TiO2) (1:4 and 1:6 w:w) were deposited as the chosen ETL materials via spin-casting and followed by high-temperature annealing. The PSC devices were built using FTO glass, MAPbI3, and gold electrodes (80nm).
Scanning electron microscopy (SEM) was utilized to take cross-sectional images of the solar cell after depositing the perovskite layer. Higher values in the precursor ETL solution concentration correlated with increased ETL thickness. Qualitative analysis of the c-TiO2/m-TiO2 bilayer SEM image demonstrated that the perovskite layer also effectively diffused into the porous m-TiO2, which increased the interfacial contact between the perovskite and the ETL. Although the control c-TiO2 had a power conversion efficiency (PCE) of 14.5%, the sample had a hysteresis index of 0.400. In comparison, the 34mM TiO2 sample had a PCE of 11.9% with a more desired hysteresis index of 0.034. The m-TiO2 bilayer sample, albeit having a PCE of 6.8%, had a hysteresis index of 0.121, suggesting that the mesoporous layer aided in reducing the hysteresis index of the original c-TiO2 ETL.
We gratefully acknowledge support from the Louis Morin Charitable Trust.

Late News: Ultralong Micro-Belts of Luminescent Lead Halide-Based Perovskites Fnu Parul; Indian Institute of Technology Roorkee, India

Ultralong micro-belts of MAPbI3 show bright and stable fluorescence in solution. Luminescent perovskites have been synthesized through centrifugation of a solution-processed with a ligand-assisted reprecipitation technique (LARP). All electron spectroscopic analysis provided evidence for the stacking of nanocrystals as bundles of self-assembled micro-belts. Under an applied bias, migration of free charge carriers through the long axis is feasible. Thus, long micro-belts are promising channel materials for two-electrode nanodevices for good electrical conductivity.

Late News: Compositional Effect on Water Adsorption on Metal Halide Perovskites QIihua Li, Zehua Chen, Ionut Tranca, Silvia Gaastra-Nedea, David Smeulders and Shuxia Tao; Eindhoven University of Technology, Netherlands

The moisture-induced instability of metal halide perovskites is one of the major challenges for perovskite devices. Although compositional engineering has been widely employed to improve the overall stability of perovskites, its effect on the moisture-induced instability received little attention. Here, we systematically study the interaction of water with the surfaces of primary perovskites, AMX_3 ($A^+ = MA^+$, FA^+, Cs^+; $M^{2+} = Pb^{2+}$, Sn^{2+}; $X^- = I^-$, Br^-), by using Density Functional Theory (DFT) calculations and comprehensive chemical bonding analysis. We reveal that the hydrophilic group NH_3^+ of MA^+ cation

may be the cause for instability issues. We find that the adsorption of water on $FAPbI_3$ and $CsPbI_3$ are much weaker than on $MAPbI_3$ due to the less polarity of FA^+ and Cs^+. When exchanging M^{2+} cations, water adsorption on $MASnI_3$ is also less energetically favorable than on $MAPbI_3$ because of the weaker ionic interaction of H_2O-$MASnI_3$. When exchanging X^- anion, water adsorption on $MAPbBr_3$ is slightly weaker than on $MAPbI_3$ due to the slightly weaker covalent interaction of H_2O-$MAPbBr_3$. Our results present a comprehensive understanding of the compositional effect on the interactions of water with perovskites and provide rational design strategies to improve their stability against moisture via compositional engineering.

F.EL08.21.08
Late News: Unified Thermodynamic Theory for Light-Induced Phase Separation in Mixed Halide Perovskites Zehua Chen[1], Geert Brocks[2], Peter Bobbert[1] and Shuxia Tao[1]; [1]Eindhoven University of Technology, Netherlands; [2]University of Twente, Netherlands

In the dark and at room temperature most mixed halide perovskites are thermodynamically stable. Under illumination, however, funneling of photo-excited carriers to a phase with a lower band gap than the parent phase leads to halide demixing. This is problematic for the application of mixed halide perovskites in solar cells. Here, we present a unified thermodynamic theory for this light-induced phase separation and apply it to five mixed iodine-bromine perovskites. Under illumination, the spinodals separating the metastable and unstable regions in the composition-temperature phase diagrams show an upward shift in temperature, while the binodals separating the stable and metastable regions acquire an additional branch signaling the nucleation of a low-band gap iodine-rich phase. We find that the threshold illumination intensity is mainly governed by the band gap difference of the parent and iodine-rich phase. Partial replacement of organic cations by cesium reduces this difference and therefore has a stabilizing effect.

Late News: Charge Carrier Dynamics in Two-Dimensional Hybrid Perovskites—Impact of Spacer Cations Dibyajyoti Ghosh; Los Alamos National Laboratory, United States

Two-dimensional (2D) halide perovskites are promising materials for environmentally stable next-generation optoelectronic device applications. However, there is very little atomistic understanding of the charge carrier dynamics at ambient conditions for these materials, limiting the possibilities to tune their optoelectronic performances through compositional engineering routes. *Here, by combining nonadiabatic molecular dynamics with time-domain density functional theory methods at room temperature, we study the dominant non-radiative carrier recombination and dephasing processes in monolayered lead halide perovskites*. Our systematic study demonstrates that performance-limiting nonradiative carrier recombination processes greatly depend on the electron-phonon interactions induced by structural fluctuations and instantaneous charge localization in these materials. *The stiffer interlayer packing in presence of selectively chosen spacer cations (benzene ring or cyclic dication based), which separates the lead iodide slabs, reduces the thermal fluctuations in these 2D-perovskites to a greater extent.*[1-2] These reduce the inelastic electron-phonon scattering and enhance the photogenerated charge carrier lifetime in layered perovskites making them suitable for various optoelectronic devices. The computational insights gained from these studies allow us to outline a set of robust design principles for 2D halide perovskites to strategically tune their optoelectronic properties.

F.EL08.21.12
Late News: Synthesis, Photocatalytic Properties and Phase Stability Studies of Full Inorganic CsPbBr3 and CsPb2Br5 Perovskites Anna L. Pellegrino[1,2] and Graziella Malandrino[1,2]; [1]Università degli Studi di Catania, Italy; [2]INSTM, Italy

The compounds belonging to the family of perovskites show a great variety of mechanical, magnetic and optical properties, and for these reasons are nowadays key materials for many technologies, including piezoelectrics, photovoltaic solar cells and photocatalytic systems.
Among perovskites, the most studied crystal structure ABX_3 for photocatalysis and photovoltaic applications is composed of an organic/inorganic compounds made of: monovalent cation A = methylammonium (MA: $CH_3NH_3^+$); formamidinium (FA: $CH(NH_2)_2^+$); a divalent metal cation B = Pb^{2+}, Sn^{2+}; and an halide anion X = I^-; Br^-; Cl^-. These hybrid lead-based materials have excellent properties and contain elements that are both cheap and abundant. However, they tend to partially decompose when exposed to air, water, ultra-violet light, or heat. For these reasons, several substitutions have been attempted to improve the properties and performances of these materials. One route to improve the stability of these structures is to explore the all-inorganic perovskite systems and thus finding alternatives to replace organic components. Particularly, our attention is

devoted to the all-inorganic perovskites, i.e. $CsPbBr_3$ and $CsPb_2Br_5$, which do not have any labile or expensive components and show remarkable stability. Furthermore, unlike the hybrid structures, the entire fabrication process of all-inorganic analogous materials can be operated in ambient atmosphere without humidity control systems. Additionally, $CsPbX_3$ (X = Cl, Br, and I) perovskite family shows high performances for photocatalytic and photo-electrochemical degradation processes of different organic dye compounds, and are also exceptional candidates as photocatalysts for organic reactions. Among the different strategy developed for their synthesis, the surfactants-based solution route is widely applied, which also allows to control the stability and the growth kinetics according to the surface chemical phenomenon and the solubility equilibrium. Herein we report a novel synthetic strategy, which represents a facile, one-step, low-temperature and surfactant free approach to the synthesis of Cs-Pb-Br microcrystals, using Cs and Pb β-diketonate metallorganic complexes. The present precipitation approach represents an innovative and interesting strategy of synthesis, which avoids the use of surfactant species and toxic solvents, and, taking the advantages of the β-diketonate metalorganic Cs and Pb precursors reactivity, it allows, reproducibly and selectively, the synthesis of $CsPbBr_3$ and $CsPb_2Br_5$ microcrystals. Structural, morphological and compositional analyses of the final products, addressed through X-ray diffraction (XRD), field-emission scanning electron microscopy (FE-SEM) and Energy Dispersive X-ray (EDX) analysis, show the formation of pure and stable $CsPbBr_3$ or $CsPb_2Br_5$ systems characterized by squared microcrystals, with a grain size up to 3μm. The stability of the two different phases has been tested as a function of heating treatment and UV exposure as well. Moreover, as a proof-of-concept, the photocatalytic properties of degradation processes have been tested using organic dye solutions, showing high degradation yield up to 70% under UV lamp (λ=360 nm).

F.EL08.21.13

Late News: Synthesis of Lead-Free All-Inorganic $Cs_3Sb_2Br_9$ Perovskite Microplates by Two-Step Chemical Vapor Deposition for Fast Response Visible Light Photodetector Application Sujit Kumer Shil[1,2], Fei Wang[1], Mohammad Kamal Hossain[1], Cheuk Kai Gary Kwok[1], Kingsley O. Egbo[1], Ying Wang[1] and Kin Man Yu[1,1]; [1]City University of Hong Kong, Hong Kong; [2]Khulna University of Engineering & Technology, Bangladesh

Lead-based halide perovskites ($CsPbX_3$, X=Cl, Br, I) are well-known for their attractive properties which make them suitable materials for many optoelectronic devices. But the toxicity of lead (Pb) undoubtedly hinders the development and commercialization of these devices. Therefore, Pb-free, environmental friendly all-inorganic halide perovskites are now the subject of enormous interest to the scientific community. It has been suggested that antimony (Sb) can be a possible replacement of Pb ($Cs_3Sb_2X_9$) in these inorganic halide perovskites. Until now Sb-based all-inorganic perovskites have been synthesized by solution processes but properties are still inferior to Pb-based materials. However, due to the low melting point of Sb halides, synthesis of high quality $Cs_3Sb_2X_9$ using chemical vapor process is still a challenge. In this work, we present a report on the synthesis and properties of Pb-free all-inorganic $Cs_3Sb_2Br_9$ perovskite microplates by a two-step chemical vapor deposition (CVD) approach. In step-I, CsBr powder was vaporized at 530°C at a pressure of 4.8 Torr under 50 sccm of Ar flow for 10 minutes in a single-zone CVD furnace. In step-II, due to low melting point, $SbBr_3$ powder was vaporized at 90°C under 15 sccm of Ar flow while the pressure and holding time were remained same as step-I. Substrates were placed at 22 cm downstream from the center. Finally $Cs_3Sb_2Br_9$ microplates with average size 20 μm were obtained after annealing the as-grown materials at 140 °C for 25 minutes. XRD analysis of the microplates shows the pure phase crystalline nature of the $Cs_3Sb_2Br_9$ perovskite structure. The optical band gap was measured by spectroscopic ellipsometry to be 2.6 eV. The UV-vis absorption spectrum revealed the exciton absorption peak at around 2.82 eV. Simple photoconductive devices fabricated using these microplates exhibit current on/off ratio of 10^2 upon 450 nm photon irradiation with a fast response of rise and decay time down to 79 ms and 28 ms, respectively. All these results clearly suggest the technological potential of inorganic lead-free $Cs_3Sb_2Br_9$ perovskite microplates for future optoelectronic devices.

F.EL08.21.15

Late News: Interfacial Engineering by Double Decked Electron and Hole Extraction Layers for Reproducible and Thermally Stable Perovskite Solar Cells. Shivam Singh and Dinesh Kabra; Indian Institute of Technology Bombay, India

Abstract: We present an interfacial engineering method to fabricate an efficient and thermally stable $MAPbI_3$ based perovskite solar cell with a double decked hole (*H*) and electron (*E*) extraction layers (EL) in an inverted (*p-i-n*) architecture. The double HEL film is fabricated by thermal evaporation of MoO_3 and spin-coating of poly(3,4-ethylene dioxy-thiophene)–poly(styrene sulfonate) (PEDOT:PSS). The double EEL is formed by spin-coating of phenyl-C61-butyric acid methyl ester ($PC_{61}BM$) and bathocuproine (BCP). The role of BCP as a buffer layer is quite established in the community to prevent the formation of metal induced charge state at the perovskite- EEL interface. Despite of presence of BCP interlayer, the thermal stability of *p-i-n* architecture still suffers. We observed that the underneath MoO_3 layer provides an improved morphology for perovskite film and reduces the shunt path. However, the BCP buffer interlayer not only passivates the defects at the perovskite- EEL interface and but also helps to plenaries the thin-films for better contact with Ag. Thus, double EEL and

HEL facilitate better charge collection at the interfaces and shows improved power conversion efficiency (PCE) of ~15%. Besides the improved PCE, double EEL and HEL based structures also provide an approach to have better reproducibility and high thermal stability of perovskite solar cells. We also address the issue of area dependent efficiency and explore the reasons behind the increased efficiency of smaller area devices. We believe reproducibility, stability and area dependence are the most important aspects for current perovskite PV research and thus this study will provide an important insight for further development.

Keywords: *$MAPbI_3$, double extraction layer, thermal stability, solar cells, BCP, MoO_3*

Late News: GFN1-xTB Method for a Fast Calculation of Metal Halide Perovskites Properties for Solar Cells Applications Jose Manuel Vicent-Luna, Sofia Apergi and Shuxia Tao; Eindhoven University of Technology, Netherlands

Metal halide perovskites (MHPs) for perovskite solar cells (PSCs) have gained great attention in just few years due to their rapid increase of photoconversion records of efficiency. In addition, MHPs exhibit a competitive fabrication cost together with a simple route to synthetize. Due to these facts, PSCs are recognized by scientists as a promising technology with enormous potential in the energy market. However, it is well known that many factors cause the degradation of PSCs, thus, industrial applications are critically hampered by instability issues.
Nowadays, experimental and theoretical researchers are investigating many possible alternatives to increase the stability of PSCs. In this context, computational techniques are being extremely useful to understand the properties of MHPs at microscopic level that cause instability of the material. Density functional theory (DFT) calculations are the key method for studying material properties, but the high computational cost limits the study to small systems and short time-scales. Classical simulations seem to be an option to overcome these limitations, but they suffer from other drawbacks such as classical simulations cannot describe electrons and chemical reactions. The study of many applications of MHPs requires the simultaneously modeling of electrons and ions in relatively large systems, sometimes not computationally affordable by the standard techniques. Therefore an intermediate approach between DFT and classical simulations is often desired. In this regard, semi-empirical Quantum Mechanics methods, such as density functional tight binding (DFTB), combine the functionalities of describing both electrons and ions. Traditional DFTB methods are based on a simplification of the Kohn-Sham DFT total energy, using pre-computed interactions of element pairs, considerably reducing the computational cost. However, this parameterization lacks of transferability and is limited to a number of elements. A new extended tight binding method called GFN1-xTB has been recently developed to cover all the elements of the periodic table. This method was designed for the fast calculation of diverse physicochemical properties of systems of a few thousand atoms and has the advantageous of maintaining high accuracy and a limited number of parameters which can be refined for the study of a given application.
The performance of GFN1-xTB is benchmarked for a set of MHPs and compared with density functional theory calculations. We study organic and inorganic MHPs with formula ABX_3, with A = MA, FA, and Cs; B = Pb and Sn; X = I, Br, and Cl, being a total of 18 MHPs with cubic, tetragonal, and orthorhombic forms. We included the computation of structural, vibrational, and optoelectronic properties of these semiconductors. This work aims to provide a general overview of the performance of GFN1-xTB for the fast computation of the main features of MHPs. Our results indicate that this method can describe the targeted features of the MHPs, but performs worse for geometry relaxation calculations. We also identified the drawbacks of the method for particular compositions of MHPs, which hamper its use for solar cell applications.

F.EL08.21.17
Late News: Lone-Pair Driven Ferroelectric and Piezoelectric Response of Germanium Halide Perovskites CsGeX3 (X = Cl, Br, and I) Jiwoo Lee[1], Young-Kwang Jung[1] and Aron Walsh[1,2]; [1]Yonsei University, Korea (the Republic of); [2]Imperial College London, United Kingdom

While much attention has been paid to halide perovskites based on Pb and Sn cations on the B-site, Ge compounds offer a distinct combination of structure and properties. All three cations feature the same s^2 lone pair configuration; however, the stereochemical activity varies in each case. We performed a computational analysis via density-functional-theory and Berry

phase calculations of the $CsGeX_3$ (X = Cl, Br, I) series. Our motivation is to clarify the existence and magnitude of ferroelectricity and piezoelectricity, which has important technological consequences such as polar nanodomains that can reduce the recombination of light-excited electron-hole pairs and extend the carrier lifetime [2]. The explanation for the origin of spontaneous polarization in Ge halide perovskites in terms of an on-site second-order Jahn-Teller effect has not been hitherto investigated [3]. In this work, we investigate the role of halide anions in spontaneous polarization within the modern first-principles theory of polarization. Our calculation results show that interaction between Ge lone-pair electrons and halogen *p*-orbital mainly determines the depth of the ferroelectric double well and the spontaneous polarization strength with Cl > Br > I. Further exploration of lone pair systems offers an exciting pathway to design novel photoelectric devices [4,5].

Late News: A Reactive Force Field for Large Scale Simulations of Metal Halide Perovskites Mike Pols[1,2], Jose Manuel Vicent-Luna[1,2], Ivo Filot[3,2], Adri v. Duin[4] and Shuxia Tao[1,2]; [1]Materials Simulation and Modelling, Department of Applied Physics, Eindhoven University of Technology, Netherlands; [2]Center for Computational Energy Research, Eindhoven University of Technology, Netherlands; [3]Laboratory of Inorganic Materials Chemistry, Schuit Institute of Catalysis, Eindhoven University of Technology, Netherlands; [4]Department of Mechanical Engineering, The Pennsylvania State University, United States

Metal halide perovskites have been the focus of many computational studies over the past few years. The bulk of these investigations were done using methods based on quantum mechanics (QM). However, the computational cost of QM methods is high, severely limiting the length and time scales of the systems that can be investigated. Molecular dynamics (MD) simulations have been successfully applied to simulate larger material systems and at longer time scales by making use of classical force fields (CFF). Nonetheless, the predefined connectivity in CFF makes them unsuited for the simulation of chemical reactions. A reactive force field (ReaxFF) is an extension to CFF by including a dynamic bond order that is calculated from the interatomic distances and allows for the simulation of bond breaking and formation. In this presentation, I will outline our progress in the creation of the first ReaxFF for halide perovskites, $CsPbI_3$.

High Energy Density and High Temperature Multilayer Polymer Films for Electric Vehicle Applications Lei Zhu and Eric Baer; Case Western Reserve University, United States

Current state-of-the-art biaxially oriented polypropylene (BOPP) film capacitors suffer from low temperature rating (<85 °C) and low energy density. At Case Western Reserve University, we have developed a novel multilayer film technology to meet the stringent requirements for next-generation dielectric film capacitors for electric vehicles. By multilayering a high breakdown strength polymer such as polycarbonate (PC) with a high dielectric constant polymer such as poly(vinylidene fluoride) (PVDF), we have achieved high breakdown strength (>600 MV/m), high energy density at breakdown (16 J/cm^3), and relatively low dielectric dissipation factor (tanδ <0.005) and hysteresis loss (15% loop area). In this presentation, we will identify and discuss fundamental issues for these multilayer dielectric films, which include polarization of amorphous and crystalline dipoles, polarization of impurity ions, and interfacial polarization to achieve enhanced breakdown strength and lifetime at high temperatures.

8:20 AM *F.EN01.01.05
Stabilization of High Energy Density Over a Wide Temperature Range by Blend Structure in Ferroelectric Polymers Yongbin Liu and Jinghui Gao; Xi'an Jiaotong University, China

Achieving stable energy density at elevated temperature remains a great challenge for ferroelectric polymer-based capacitors. It seems that the emerging ferroelectric polymers (e.g. poly (vinylidene fluoride) (PVDF) and its copolymers), which possess spontaneous polarization and large permittivity, provide a promising solution to meet the ever-increasing requirement for high energy density. Nevertheless, the state-of-the-art PVDF-based ferroelectric polymer usually exhibits mediocre temperature stability in energy storage performance, which cannot fully satisfy the applications at elevated temperature caused by the energy consumption or nearby heat sources.
In this work, we report a strategy for stabilizing high energy density of ferroelectric polymer (PVDF) over a wide temperature range by blending with a miscible high-T_g polymer (polymethyl methacrylate (PMMA)). The blending material forms an alternating lamellar structure consisting of high-polarization crystalline regions and strengthened amorphous regions. It is found that this special morphology is able to confine the constructional change of stacked lamellar structure at elevated temperatures. Accordingly, the associated energy storage performances, including energy density, energy storage efficiency and breakdown strength, are remarkably enhanced in a wide temperature range (30 to 70ºC). At 70ºC, the energy density and efficiency of PVDF/PMMA(80/20) is 9.8J cm^{-3} and 67.8%, which surpasses most neat ferroelectric polymers at such an elevated temperature. This work reveals the relationship between lamellar confinement of polymer blend and electric properties under temperature variation, and might provide a valid approach to attain high energy density and temperature stability in ferroelectric polymers.

8:40 AM *F.EN01.01.06
Strategies of Enhancing Electric Breakdown Strength of Nanocomposites by Designing Fillers with Special Microstructure Structure Shuhui Yu, Junyi Yu and Rong Sun; Shenzhen Institutes of Advanced Technology, Chinese Academy of Sciences, China

As one of the most important renewable energy storage technologies, film capacitors have been used in modern electronics and power industries such as wearable electronics, hybrid vehicles, and other fields due to their high power density, long working hours, and environmental friendliness. With the development of electronic devices toward miniaturization and high

performance, there is an urgent need for dielectric materials with high energy storage density. A high breakdown strength (E_b) is crucial for dielectric materials to ensure reliability of electric circuits and to improve electrostatic energy storage density.***E*$_b$ is the result** of space charge movement in the dielectrics under the applied electric field. Effectively reducing the density of charge carriers in the dielectrics is one of the keys to enhancing E_b. In this study, hybrid nanoparticles with special physical microstructure were designed and fabricated. When they were used as fillers,these particles possessing isoelectronic traps or heterojunction have proved efficient in confining space charge carriers generated under applied electric field and meanwhile suppressing their movement through the whole polymer system. As a result, electrical conductivity was reduced and $E_b$was enhanced significantly, leading to improved energy storage density.

9:00 AM *F.EN01.07.01
Triboelectric Charging Mechanisms of Polymers Andris Sutka; Riga Technical University, Latvia

Knowing the polymer triboelectrification mechanisms is the key to provide high-performance triboelectric nanogenerators for mechanical energy harvesting from movement or, vice versa, to eliminate charge accumulation on the surface for safety. Moreover, the triboelectric surface charge has attracted significant interest among scientists recently for particle separation and liquid droplet transport, as well as nanoparticle deposition and surface patterning.
The three main mechanisms considered for polymer electrification are (i) electron transfer [1], (ii) heterolytic covalent bond break and material transfer [2], and (iii) ion transfer [3]. The ion transfer, where ions are separated between water adsorbate layers on contacted polymers, seems not the dominating mechanism as the polymer triboelectrification has been observed in the complete absence of water and between identical materials which should exhibit the same affinity between cationic and ionic species in water. In the past few years, the debate has concentrated on electron transfer and covalent bond breaking as possible dominating polymer triboelectrification mechanisms.
Recently a vast number of triboelectrification experiments has been performed and reported for various polymers with the different structural state, surface adhesion, and morphology. The experimental results indicate that the triboelectrification mechanism for polymer insulators is heterolytic covalent bond cleavage (heterolysis or heterolytic fission) alongside material transfer [4-6]. The surface charge increases with decreasing cohesion energy [4] or increasing surface adhesion [5]. A dramatic three orders of magnitude increase in surface charge when passing the transition temperature from a glassy to a rubbery state also has been observed due to the adhesion, softness, and deformation increases, thus enhance the covalent bond cleavage, material transfer, and surface charge formation [6].
Herein we are highlighting these aspects and illuminating the pathways to enhance the triboelectrification avoiding expensive and complicated nanostructuring approaches.

9:20 AM *F.EN01.05.05
The Preparation and Dielectric Properties of 2D Nano-Sheets Materials and Composites Based on Electrospinning Hua Deng; Sichuan University, China

Two dimensional dielectric fillers have been considered to serve as high performance fillers to enhance both the dielectric constant and breakdown strenght of various dielectric polymer composites. Nevertheless, the fabrication of these 2D fillers is quite often complicated, and usually rely on the nature availability of these materials. Herein, we demonstrate systematic study on the fabrication of 2D TiO2 nanofillers through tunning various processing condition of electrospinning. This research work was carried out to investigate the effects of different solution formulas and electrospinning conditions on the

morphology of the spinning fibers. The influence of calcination temperature on the preparation of dielectric fillers was studied, and it was applied to the preparation of dielectric composite materials based on PVDF and PI. The energy density of two-dimensional nano-sheets dielectric fillers was investigated, and shows high dielectric constant, high Effects, high breakdown strength and low dielectric loss. The extended application of 2D lamellar fillers in polyimade system under high temperature conditions is further discussed achieving an energy density of 3 J/cm3 at 150 degree C; 3.5 J/cm3 at 100 degree C; a charge-dischange efficiency of around 90%. This could provides a theoretical and technical guidelines for the practical application.

9:40 AM *F.EN01.02.08
Rational Design of Dielectric Materials for Flexible Capacitive Pressure Sensing Coatings Jianing Wu, Tianyu Shao and Zhuo Li; Fudan University, China

Flexible pressure sensors are the basic components for many different applications, such as electronic skins, robotics, health-monitoring devices, and human-machine interfaces. Among different working mechanisms, capacitive pressure sensors are widely-used owning to their low energy consumption, simple structure, and high reliability. Pressure sensors in the form of coatings have the advantages of facile applications on various complex surfaces because of the flowability before solidification, capability for large scale production, and low cost. But how to prepare pressure sensing coatings to meet the requirements for different applications remains to be addressed. This talk covers our recent work to enhance the performances of pressure sensing coatings through the rational design of dielectric materials.
Firstly, I will discuss a highly sensitive capacitive pressure sensing coating using thermally expandable microspheres/ polydimethylsiloxane (PDMS) composite as the dielectric layer. The microspheres can expand during the thermal curing process of PDMS, which greatly enhance the compressibility and thus increase the sensitivity of the pressure sensors. At the same time, it achieves a broad pressure sensing range from 10 Pa to 4.5 MPa and also features low hysteresis and good stability against repeated compression.
Secondly, I will discuss a strategy to achieve linear response of capacitive pressure sensor over a broad sensing range. Conventional capacitive pressure sensors usually exhibit a highly non-linear response as the sensitivity drops dramatically towards high pressure. Our strategy employs a percolative composite as the dielectric layer. The fast increase in dielectric constant during compression can compensate the sensitivity drop from the decreased compressibility, leading to a linear response. Owning to the nature of polymer composite, its dispersion not only can be conformally coated on surfaces with various complex shapes, but also can be molded into films with surface microstructures to achieve a unique combination of high sensitivity and linear response over a wide pressure sensing range.

F.EN01

3:00 PM *F.EN01.04.02
Electrical and Electromechanical Reliability of Lead Zirconate Titanate Piezoelectric Films Betul Akkopru-Akgun[1], Kathleen Coleman[1], Wanlin Zhu[1], Raul Bermejo[2] and Susan E. Trolier-McKinstry[1]; [1]The Pennsylvania State University, United States; [2]Montanuniversitaet Leoben, Austria

Use of dielectric materials such as lead zirconate titanate films for dielectric energy storage or for piezoelectric applications necessitates that they be able to sustain high DC electric fields. This paper will describe the coupled failure mechanisms that control these lifetimes for donor-doped, acceptor-doped, and films with graded doping. Curiously, the median failure time of PZT films can be increased on doping with either donors or Mn as an acceptor. It is found that lifetimes under DC fields are dominated by a combination of oxygen vacancy migration, coupled with changes in the interface barrier heights for conduction in thin films. This was assessed through a combination of highly accelerated lifetime testing, thermally stimulated depolarization currents, impedance spectroscopy, deep level transient spectroscopy, and electron energy loss spectroscopy. The relic defect chemistry of the film, including variations in this defect chemistry at interfaces strongly influences both the failure and the asymmetry of the failure as a function of the electrical polarity. As film thickness and/or the piezoelectric coefficients rise, the critical stress required for crack initiation decreases, and the failure modes can shift to electro-

mechanically induced failure. Ball-on-three ball mechanical testing demonstrates that the critical flaw size in the failure of the stack becomes the thickness of the piezoelectric layer itself.

3:20 PM *F.EN01.03.06
Low Temperature and High-Speed Processing of Oxide Dielectric Thin Films Julia W. Hsu; The University of Texas at Dallas, United States

Thin film oxide dielectrics boast high breakdown voltages, low leakage current densities, and high dielectric constants making them ideal for use as gate dielectrics in thin film electronics. However, to fully realize the benefit of thin film electronics, low-cost high-throughput production is necessary. This means reducing not only processing time, but also processing temperature to allow for production on plastic substrates. In this work, we discuss the effects of low temperature UV-assisted processing and high-speed photonic curing on the properties of solution-deposited oxide dielectric films. First, we show the results from exposing sol gel precursor films to UV-ozone (UVO) through a shadow mask. This process accomplishes both lowering the conversion temperature to 250 °C and direct patterning the precursor film with exposed areas converted to oxide after final annealing. We find drastically different capacitance-frequency behavior between Al_2O_3 and ZrO_2 dielectrics, which in turn affects the In_2O_3 transistors' behavior. The origins of this finding are studied through Fourier transform infrared analysis and time dependent drain current measurements. Next, we adapt photonic curing, the use short but high intensity pulses of broadband light, to selectively heat and convert ZrO_2 precursor films on flexible polyethylene naphthalate (PEN) substrates. Photonic curing is typically used to sinter metal nanoparticle inks into conductive metal traces on plastic substrates, but it has not previously been used to fabricate oxide thin film dielectrics on plastic substrates. We demonstrate that the conversion time is reduced from 10s minutes to < 1s and patterning using a shadow mask during photonic curing does not need subsequent thermal annealing, unlike in the UVO processing. Furthermore, by adjusting the photonic curing conditions, the oxide film can be selectively converted on top of Al electrodes, which act as selective area heat absorbers, but not on the bare PEN substrate, resulting in a self-aligned oxide pattern. We achieve a ZrO_2 dielectric with breakdown field of 8 MV/cm and areal capacitance of 200 nF/cm^2 with little frequency dispersion. Finally, we show a pathway to converting ZrO_2 dielectric at a roll-to-roll web speed of up to 50 m/min.

3:40 PM *F.EN01.04.07
Solid-State Cooling Devices Based on Electrocaloric Polymers Qibing Pei; University of California, Los Angeles, United States

Electrocaloric cooling is a solid-state cooling technology, offering several advantages over traditional cooling systems, but few EC devices have been reported with high specific cooling power and high coefficient of performance (COP). We have developed solution processes to fabricate poly(vinylidene fluoride-trifluoroethylene-chlorofluoroethylene) terpolymer thin films. Various material treatment and characterizations were conducted to study and optimize the performance of the terpolymer thin films. We present several EC cooling device designs with compact and desired form factors to transfer heat between a heat source and heat sink, with the ultimate objective to pave the way for new applications that cannot be obtained using existing technologies.

4:00 PM *F.EN01.04.04
Flexible Dielectric Nanocomposites—From Power Energy Storage to Mechanical Energy Harvesting Jinkai Yuan; Ctrde Recherch Paul Pascal, France

Our research activities on the energy-related dielectric polymer nanocomposites will be reviewed. Micro-energy storage devices are highly demanded for diverse miniaturized electronic devices. [1,2] However, making high-energy microcapacitors with currently available printing technologies remains challenging. Based on a composite material of latex polyvinylidene fluoride and polyvinyl alcohol, we created high-energy microcapacitors with inkjet printing technique. A discharged energy density of 12 Jcm^{-3} is achieved at 550 MVm^{-1}.[3] The printed microcapacitors demonstrate mechanical robustness and dielectric stability over time. on the other hand, it is well known that all dielectric materials have electrostriction. They have capability of changing their dielectric properties upon an external mechanical deformation. Based on this effect, we have developed giant electrostriction soft nanocomposites which can serve as an active dielectric layers in a variable capacitor to convert the vibrational mechanical energy into electricity. To make such energy harvester, we prepare an electrostrictive nanocomposite composed of reduced graphene oxide in soft polydimethylsiloxane matrix.[4] The near percolated composite exhibits a large permittivity variation in response to small strain deformation, giving rise to a giant electrostrictive coefficient -4.3×10^{-14} m^2/V^2,[5] indicating that our materials are particularly promising for harvesting mechanical energy applications. Their implementation in actual MEMS generator devices has been also investigated. [6]

Dielectric Materials in Semiconductor Packages Enis Tuncer; Texas Instruments, United States

It is important to determine the dielectric characteristics of semiconductor encapsulation materials based on epoxy resins. There are several such material systems employed to protect the active silicon circuitry. Some of the important properties of the materials are their glass transition temperature, filler content and the level of water absorption which leads to reliability challenges with respect to performance and lifetime. We study changes in the propeties by investigating dielectric relaxation using broadband impedance spectroscopy techniques. It is known that the dielectric relaxation in polymeric systems influenced by the presence of water, which demands special attention in sensitive applications. We will present measurement and analysis methods based on time and frequency domain techniques. It would be appreciated within the materials science community to improve material selection and performance evaluation efforts. We will also share information on the glass transition temperature estimates for a number of composites employed in semiconductor packaging.

4:40 PM *F.EN01.02.01
Atomic Scale Simulation of Charge Transport Properties of Dielectric Polymers Mikael Unge; NKT HV Cables AB, Technology Consulting, Sweden

Sustainable energy sources – such as wind, wave and solar – are attractive for reducing CO_2 emissions and tackling climate change. Often these energy sources are placed at large distances from where the energy is actually needed; off-shore wind farms and desert solar parks. To transfer the electrical power from such remote locations high voltage direct current (HVDC) is the preferred technology due to lower transmission losses. In the design of high voltage component the dielectric properties of the materials used are of significant importance. The conductivity of the leakage current in and the electrical breakdown field of the dielectric material impact and limits the design. To understand how these properties are affected by the materials chemical composition and morphology, material simulation is one approach to understand these phenomena in more detail.

Material simulation methods such as density functional theory (DFT) and molecular dynamics (MD) has an increased usage in literature to study dielectric properties of materials relevant for HV components. Basic properties such as band gaps and trap states, to more challenging properties to calculate such as mobility and electrical breakdown fields are reported. An additional important area is to include material simulation methods in multiscale simulation models to incorporate phenomena on longer time and length scales possible.

In this talk we will present result from several different studies of dielectric polymers using DFT, MD and kinetic Monte Carlo (KMC). Primarily the material of interest in these studies is polyethylene (PE) which is used as insulation in HVDC cables. PE is a semi crystalline material and have a complex structure at micrometer scale. Using linear scaling DFT (LSDFT) we have investigated the electronic structure of different parts of PE morphology. Band gaps and electron localization are calculated and used to determine electronic charge transport properties. A combination of DFT, MD and KMC are used to calculate mobility in PE. A coarse grained model for hopping transport in PE is also being developed. Recently we also applied LSDFT to investigate electronic structure of another dielectric polymer, poly(ethylene oxide), which may be used as polymer electrolyte in solid state batteries. Coupling to models at longer time and length scales are discussed.

5:00 AM F.EN01.01.01
Enhancing the Dielectric Breakdown Strength of Solid-State Polymer Capacitors by Chain End Manipulations Maninderjeet Singh[1], Wenjie wu[1], Mei Dong[2], David Tran[2], Karen Wooley[2], Nihar Pradhan[3], Dharmaraj Raghavan[4] and Alamgir Karim[1]; [1]University of Houston, United States; [2]Texas A&M University, United States; [3]Jackson State University, United States; [4]Howard University, United States

The need for high power density, flexible, pulsed power and lightweight energy storage devices requires the use of polymer film-based dielectric capacitors. The maximum energy storage density of a dielectric capacitor is directly proportional to the square of the maximum voltage that can be applied to the dielectric without causing the electrical breakdown. Theoretically, it has been shown that chain ends contribute adversely to the electrical breakdown of polymer dielectrics at high electric fields, resulting in low energy density in polymer capacitors. In this work, we enhanced the dielectric breakdown voltage and hence the energy density of the polymer capacitor by using well-ordered high molecular weight block copolymers (BCP), in which the chain ends are segregated to narrow zones. The well-ordered and easily processable amorphous BCP based capacitors exhibit an energy density more than 5 J/cm^3, which is higher than that of industrially used crystalline biaxially oriented polypropylene. Cyclic homopolymers (no chain ends) and linear homopolymers having chemistry-controlled chain ends also show enhanced dielectric breakdown strength, resulting in higher energy density as compared to their linear counterparts. These novel insights into manipulating chain end distribution such as in BCPs and with molecular topology to increase the energy density of polymers will help fulfill next-generation energy demands.

5:10 AM F.EN01.01.02
Gamma-Radiated Biochar Carbon for Improved Supercapacitor Performance Ezaldeen Adhamash; South Dakota State University, United States

Biochar carbon YP-50 exposed to gamma radiation at 50 kGy, 100 KGy, and 150 kGy was used as an electrode for an electric double-layer capacitor. The gamma radiation affected the pore structure and pore volume of the biochar electrodes. The optimized surface morphology, pore structure, and pore volume of the biochar with an irradiation dose of 100 kGy showed outstanding specific capacitance of 246.2 F g^{-1} compared to the untreated biochar (115.3 F g^{-1}). The irradiation dose of 100 kGy exhibited higher specific power and specific energy of 0.1 kW kg^{-1} and 34.2 W h kg^{-1} respectively, with a capacity retention of above 96% after 10,000 cycles at a current density of 2 A g^{-1}. This improvement can be attributed to the decrease in average particle size, an increase in the porosity of biochar carbon. Besides, the charge transfer resistance of supercapacitor is significantly reduced from 21.7 Ω to 7.4 Ω after treating the biochar carbon with 100 kGy gamma radiation, which implies an increase in conductivity. This gamma radiation strategy to pretreat the carbon material for improving the properties of carbon materials can be promising for the development of high-performance supercapacitors for large-scale applications.

Late News: Layered Polymer Nanocomposites Reinforced by 2D Interfaces for Electrostatic Energy Storage and Conversion Yifei Wang and Yang Cao; University of Connecticut, United States

Carbon dioxide emissions and ever-growing environmental issues have stimulated the exploration of new energy sources that are required to be renewable and environmentally friendly. Most of the energy in nature is intermittent, such as solar, wind, and tidal energy, which puts forward critical requirements for energy conversion systems with ultrahigh power densities. Among all energy conversion technologies, the electrostatic capacitor has the fastest charge-discharge speed, which has been utilized as the invertors/convertor in hybrid electric vehicles. However, polymers, as the main functional part in electrostatic capacitors, are severely limited by unsatisfied energy densities due to their low dielectric constants, compared with ceramic counterparts.
Although much research work has been done to improve the dielectric polarization, e.g., introducing ceramic nanoparticles with high dielectric constant to construct nanocomposites, the increase in energy storage density is still restricted due to the

compromise in electrical insulation capabilities. These ceramic nanoparticles generally have high electrical conductivity. When a large amount of the nanoparticles is introduced into polymers, conductive paths will be formed in the nanocomposites. As a result, charge migration will become easier, which will lead to not only a high energy loss but also a suppressed breakdown strength.
Here, to address this issue, layered nanocomposites reinforced by 2D interfaces are designed, which possess high dielectric polarization and insulation capabilities simultaneously. MMT nanosheets with anisotropic conductivities (surface conductivity > bulk conductivity) are adopted as the interface materials. It is demonstrated that this 2D interface plays different roles when it is interposed at different positions. In detail, it can block the charge injection when it locates between the electrodes and the surface of the polymers, while it tends to dissipate charges along the in-plane direction when they are inside of the polymers. The above two functions can simultaneously serve the purpose of preventing carriers from penetrating the polymer films. It causes a suppressed leakage current and energy loss, thus leading to an enhanced charge-discharge efficiency and energy density. This proposed method is applicable to a wide range of polymers. Favorable energy storage performance can be achieved in a harsh environment, e.g., high temperature (as high as 250°C), when high-temperature resistant polymers are selected as the matrix. For example, a high energy density of 4.3 J/cm^3 is found in an interface-enhanced barium titanate/polyamideimide nanocomposite at 150°C, which can still be 2.2 J/cm^3 even when the temperature is elevated to 250°C. This work systematically illustrates the impact of the interface reinforcement on the electrostatic energy storage performance and provides guidance for the exploration of high-performance dielectric nanocomposites for renewable energy storage and conversion.

Atomic Scale Simulation of Charge Transport Properties of Dielectric Polymers Mikael Unge; NKT HV Cables AB, Technology Consulting, Sweden

Sustainable energy sources – such as wind, wave and solar – are attractive for reducing CO_2 emissions and tackling climate change. Often these energy sources are placed at large distances from where the energy is actually needed; off-shore wind farms and desert solar parks. To transfer the electrical power from such remote locations high voltage direct current (HVDC) is the preferred technology due to lower transmission losses. In the design of high voltage component the dielectric properties of the materials used are of significant importance. The conductivity of the leakage current in and the electrical breakdown field of the dielectric material impact and limits the design. To understand how these properties are affected by the materials chemical composition and morphology, material simulation is one approach to understand these phenomena in more detail.

Material simulation methods such as density functional theory (DFT) and molecular dynamics (MD) has an increased usage in literature to study dielectric properties of materials relevant for HV components. Basic properties such as band gaps and trap states, to more challenging properties to calculate such as mobility and electrical breakdown fields are reported. An additional important area is to include material simulation methods in multiscale simulation models to incorporate phenomena on longer time and length scales possible.

In this talk we will present result from several different studies of dielectric polymers using DFT, MD and kinetic Monte Carlo (KMC). Primarily the material of interest in these studies is polyethylene (PE) which is used as insulation in HVDC cables. PE is a semi crystalline material and have a complex structure at micrometer scale. Using linear scaling DFT (LSDFT) we have investigated the electronic structure of different parts of PE morphology. Band gaps and electron localization are calculated and used to determine electronic charge transport properties. A combination of DFT, MD and KMC are used to calculate mobility in PE. A coarse grained model for hopping transport in PE is also being developed. Recently we also applied LSDFT to investigate electronic structure of another dielectric polymer, poly(ethylene oxide), which may be used as polymer electrolyte in solid state batteries. Coupling to models at longer time and length scales are discussed.

Designing Polymers Resistant to Electric Field Extremes with Materials Modeling and Machine Learning Deepak Kamal[1], Yifei Wang[2], Huan Tran[1], Lihua Chen[1], Rishi Gurnani[1], Zongze Li[2], Chao Wu[2], Yang Cao[2] and Rampi

Ramprasad[1]; [1]Georgia Institute of Technology, United States; [2]University of Connecticut, United States

Breakdown strength (Ebd), the maximum electric field that can be applied on a dielectric polymer without destroying its insulating characteristics, sets an upper limit on the maximum energy that can be stored in this material. Despite its significance, the breakdown phenomena in polymers remain poorly understood owing to the complex nature of the phenomena. This is a major challenge in the development of new high-energy polymer dielectrics. In this work, we present a multi-step strategy to develop novel high breakdown polymers, sidestepping this challenge - by finding and improving properties that are correlated to Ebd (and easy to estimate) rather than directly attempting to improve Ebd. Specifically the steps involved include - (i) Identification of potential proxy properties correlated to Ebd utilizing available experimental data. (ii) Development and utilization of Density Functional Theory (DFT) based computational models to better understand the proxy properties and to create a dataset which can be used to build machine learning based prediction models of the proxy properties. (iii) Development of machine learning (ML) based prediction models capable of predicting the proxy properties of any given polymer. These models are used as screening tools to downselect potential high breakdown polymers from a candidate set which is much larger than what DFT can handle. (iv) Generation of novel potential high Ebd polymers utilizing optimization strategies (Genetic Algorithm, Graph to Graph translations etc.) and ML models. Finally, the obtained novel polymers are further down selected and suggested for synthesis.

5:25 AM F.EN01.02.03
Fast Simulations of Thermal Transport in Imperfect Dielectrics using Machine Learning and Bayesian Force Fields Anders Johansson, Andrea Cepellotti and Boris Kozinsky; Harvard University, United States

Controlling thermal conductivities of materials is important for a wide range of applications, from thermoelectrics for clean energy generation to electronic devices and thermal barrier coatings. The thermal conductivity is commonly estimated using molecular dynamics simulations within the Green-Kubo formulation. This requires a force field that is both 1) an accurate estimate of the interatomic interactions and 2) fast enough to allow simulations with sufficiently large length and time scales. Traditionally, only empirical force fields have fulfilled both of these requirements, which severely limits the applicability of the method.

In this work, we employ the Gaussian Process-based FLARE force field, which automatically learns the interactions of more complex materials than empirical force fields. The resulting model can then be mapped to a low-dimensional, computationally efficient model. Through GPU-acceleration with LAMMPS and the Kokkos library, we achieve excellent performance and obtain well-converged estimates for the thermal conductivity. Furthermore, we investigate state-of-the-art sampling and spectral denoising methods for further acceleration of the simulations. We apply this machinery to dielectrics with high thermal conductivity and study the effect of impurities.

5:35 AM F.EN01.02.04
First-Principles Method for Temperature-Dependent Dielectric Permittivity and Curie Temperatures of Ferroelectric Materials Woon ih Choi[1], Dae Jin Yang[2] and Doh Won Jung[2]; [1]Samsung Electronics, Korea (the Republic of); [2]Samsung Advanced Institute of Technology, Korea (the Republic of)

High fidelity prediction of dielectric permittivity is of critical importance for the design of better performing devices. However, conventional calculations that are based on quasi-harmonic approximation, are known to incur huge error in particular for ultrahigh-k material such as $SrTiO_3$. This is attributed to the missing of key physics i.e. lattice anharmonicity in the theory. To overcome this, we developed computational workflow that account for anharmonic contribution by performing self-consistent phonon (SCP) theory calculations using Alamode. Preceding preparation of higher order interatomic force constants are determined based on Hellmann-Feynman forces of standard DFT calculations. It turns out that efficient structure sampling is critical to reduce computational cost and maintaining errors in harmonic force constants as small as possible are very important for the accuracy of following SCP calculations. Resultant temperature dependency of transverse optical phonon frequency agrees well with experimentally measured ones. In addition, dielectric permittivity of $SrTiO_3$ calculated from phonon band structure is in good accord with values reported in literatures. We also confirmed that this workflow is able to predict para- to ferro-electric phase transition temperature of ferroelectric materials such as $BaTiO_3$ and $PbTiO_3$.

5:45 AM F.EN01.02.05
High-Throughput Phase-Field Simulations and Machine Learning of Resistive Switching in Resistive Random-Access Memory Kena Zhang[1], Jianjun Wang[2], Yuhui Huang[3], Long-Qing Chen[2], Panchapakesan Ganesh[4] and Ye Cao[1]; [1]The

University of Texas at Arlington, United States; [2]The Pennsylvania State University, United States; [3]Zhejiang University, China; [4]Oak Ridge National Laboratory, United States

Metal oxide-based Resistive Random-Access Memory (RRAM) exhibits multiple resistance states, arising from the activation/deactivation of a conductive filament (CF) inside a switching layer. Understanding CF formation kinetics is critical to achieving optimal functionality of RRAM. Here a phase-field model is developed, based on materials properties determined by *ab initio* calculations, to investigate the role of electrical bias, heat transport and defect-induced Vegard strain in the resistive switching behavior, using MO_{2-x} systems such as HfO_{2-x} as a prototypical model system. It successfully captures the CF formation and resultant bipolar resistive switching characteristics. High-throughput simulations are performed for RRAMs with different material parameters to establish a dataset, based on which a compressed-sensing machine learning is conducted to derive interpretable analytical models for device performance (current on/off ratio and switching time) metrics in terms of key material parameters (electrical and thermal conductivities, Vegard strain coefficients). These analytical models reveal that optimal performance (i.e. high current on/off ratio and low switching time) can be achieved in materials with a low Lorenz number. This work provides a fundamental understanding to the resistive switching in RRAM and demonstrates a computational data-driven methodology of materials selection for improved RRAM performance, which can also be applied to other electro-thermo-mechanical systems.

5:55 AM F.EN01.02.06
Mechanisms of Dielectric Breakdown at Metal Polymer Interfaces Using Reactive Molecular Dynamics Simulations Ankit Mishra[1], Deepak Kamal[2], Aravind Krishnamoorthy[1], Subodh C. Tiwari[1], Ruru Ma[1], Liqiu Yang[1], Ken-ichi Nomura[1], Rampi Ramprasad[2], Rajiv Kalia[1], Aiichiro Nakano[1] and Priya Vashishta[1]; [1]University of Southern California, United States; [2]Georgia Institute of Technology, United States

The performance and reliability of organic dielectric devices depends critically on the chemistry and morphology of metal-organic semiconductor interfaces. Conjugated polymers represents a promising class of organic dielectrics due to their excellent electronic properties which can be tuned over 10 orders of magnitude through reversible doping processes. Aluminium (Al) is popular candidate for device electrodes on account of its low work function and capability to get thermally deposited on top these dielectric polymers to enable desired device architectures. The reliability and efficiency of these devices is dependent upon the stability of these Al-dielectric polymer interfaces since the charge injected from Al layer is a key contributor to polymer degradation and dielectric breakdown. Here, we perform a hybrid reactive molecular dynamics and density functional theory based study to understand how various interfacial features affect charge injection barriers. We utilize first-principles data on Al-polymer interfaces to design efficient ReaxFF force fields capable of simulating realistic interfaces. We demonstrate this approach on various dielectric polymers such as Polypropylene (PP), Polystyrene (PS), Polyethylene (PE) and Polyethylene terephthalate (PET) by carefully examining the effect of deposition rate and size of Al clusters, surface and bulk diffusion of Al clusters on polymer substrate and defects in polymer substrate.

Modelling Dielectric Energy Materials with Lone-Pair Cations Using a Novel Hybrid Approach—From One-Centre Quantum Mechanics to Interatomic Potentials Woongkyu Jee, Scott Woodley and Alexey Sokol; University College London, United Kingdom

A wide range of dielectric energy materials exhibit unusual properties that are due to soft, or highly polarisable constituent cations, e.g., Sn(II), Pb(II) or Bi(III). An accurate account of their behaviour may cause in modern first-principles calculations both methodological and technical difficulties, and, in general, requires high computational costs. Results of such calculations in turn are often difficult to analyse and interpret using chemical or physical intuition that is, however, essential in applied research. The oxides of these heavy main-group elements typically have a medium to wide band gap, and their materials show potential applications in many energy applications including solar/fuel cells and batteries. Examples include: SnO in both bulk and nanoparticle form have been studied as a photoelectric material and rechargeable batteries; whereas PbO and Bi_2O_3 have potential applications in thermoelectric materials and fuel cells, respectively; and $SnTiO_3$ and $PbTiO_3$ perovskites have ferro- and piezo-electric properties. Related compounds including transitions metals show exciting multiferroic properties.

Modelling the effect of the local environment on the Sn(II), Pb(II) and Bi(III) cations at the quantum-mechnical level of theory requires an accurate representation of, at the very least, their valence *s* and *p* orbitals; that can hybridise and occupied by the valence electrons form an *sp*-lone pair in the environment of closed-packed oxides, which avoids forming any direct chemical bonding and makes the cations relatively more polarisable than other cations with closed valence electron configuration. As a result, the formation of an *sp*-lone pair typically induces a local structural distortion about such a cation, i.e., a reduction of the symmetry of the crystal structure, that may have a significant effect on the desired material property and is, therefore, crucial to model correctly. Alkaline earth metal oxides, for example, adopt the NaCl rock salt structure with the space group symmetry of *Fm3m* where each cation is at the centre of a regular octahedron composed of six oxygen anions at the vertices, whereas SnO and PbO have the space group symmetry of *P4*/*nmm* with the six nearest neighbour oxygen anions showing a breakdown of the octahedral symmetry.
Atomistic simulations, based on semi-empirical interatomic potentials – a useful conventional tool for the study of simple ionic materials – are many orders of magnitude cheaper to conduct than a full electronic structure approach, but, alas, cannot successfully reproduce the atomic structure and dielectric properties of materials containing Sn(II), Pb(II) or Bi(III). To resolve this difficulty and model the effect of the *sp*-lone pair electron density we introduce a simple quantum mechanical treatment to the lone pair cations based on a one-centre Hamiltonian approach with an *s* and *p* atomic basis set. Polarisation effects of the other species are captured using a well-known Shell Model. The new approach has been implemented in our in-house software *Sp-Lone pair involved Atomistic Model* (SLAM) code and could easily be implemented in popular molecular-mechanical codes such as GULP and LAMMPS. During this presentation we will demonstrate the accuracy and efficiency of our model by comparison of our results with those from first principles calculations using Density Functional Theory (DFT) and previous interatomic-potential models for bulk materials doped with Sn(II) and nanosized molecular SnO clusters.

6:15 AM *F.EN01.02.08
Rational Design of Dielectric Materials for Flexible Capacitive Pressure Sensing Coatings Jianing Wu, Tianyu Shao and Zhuo Li; Fudan University, China

Flexible pressure sensors are the basic components for many different applications, such as electronic skins, robotics, health-monitoring devices, and human-machine interfaces. Among different working mechanisms, capacitive pressure sensors are widely-used owning to their low energy consumption, simple structure, and high reliability. Pressure sensors in the form of coatings have the advantages of facile applications on various complex surfaces because of the flowability before solidification, capability for large scale production, and low cost. But how to prepare pressure sensing coatings to meet the requirements for different applications remains to be addressed. This talk covers our recent work to enhance the performances of pressure sensing coatings through the rational design of dielectric materials.
Firstly, I will discuss a highly sensitive capacitive pressure sensing coating using thermally expandable microspheres/ polydimethylsiloxane (PDMS) composite as the dielectric layer. The microspheres can expand during the thermal curing process of PDMS, which greatly enhance the compressibility and thus increase the sensitivity of the pressure sensors. At the same time, it achieves a broad pressure sensing range from 10 Pa to 4.5 MPa and also features low hysteresis and good stability against repeated compression.
Secondly, I will discuss a strategy to achieve linear response of capacitive pressure sensor over a broad sensing range. Conventional capacitive pressure sensors usually exhibit a highly non-linear response as the sensitivity drops dramatically towards high pressure. Our strategy employs a percolative composite as the dielectric layer. The fast increase in dielectric constant during compression can compensate the sensitivity drop from the decreased compressibility, leading to a linear response. Owning to the nature of polymer composite, its dispersion not only can be conformally coated on surfaces with various complex shapes, but also can be molded into films with surface microstructures to achieve a unique combination of high sensitivity and linear response over a wide pressure sensing range.

6:30 AM F.EN01.02.09
Stochastic Computational Search of Capacitance Variance Mechanisms in Particle-Based Heterogeneous Dielectrics Venkatesh Meenakshisundaram[1,2], David Yoo[1,2], Andrew Gillman[1], Nicholas Glavin[1] and Phil Buskohl[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States

Dielectric particles are often added to 3D printing inks to tailor the macro level permittivity of printed dielectric substrates and coatings. In these inks, the combined role of particle morphology, discrete spatial arrangement and material properties on variance is difficult to distinguish experimentally and hence poorly understood. This is primarily due to the large parameter space of processing variables as well as electrical sensitivity to local heterogeneities. We address this challenge by combining a finite element capacitor model with a neural network biased genetic algorithm (NBGA) to optimize the volume fraction, particle size and permittivity distributions of dielectric particles to identify systems with high capacitance variance. Analysis

of the database generated from the optimization process provided insights on effect of polydisperse particles on the variance of the system. Design rules/strategies were also identified for achieving target variance. Unsupervised machine learning techniques were applied to the NBGA-created database to extract correlations between the spatial/material distributions of the dielectric particles and the capacitance variance. Collectively, this study provides a useful framework to correlate electrical performance with both macro- and microstructural variation sources, which is key to accelerating the development of 3D printing materials.

Highly Thermally Conductive and Electrically Insulating Polymer Composites Based on Functionalized Boron Nitride Nanosheets Takuya Morishita; Toyota Central R&D Labs., Inc., Japan

Highly thermally conductive and electrically insulating polymer composites are strongly demanded for thermal management applications including next-generation electronics and electric power systems. Anisotropic nanocarbons such as carbon nanotubes (CNTs) and graphenes are excellent nanofillers for improving thermal conductivity (TC) of polymers. However, nanocarbons exhibit high electrical conductivity and the addition of even small amounts of them into polymer matrices leads to decreased electrical insulation. Therefore, morphologically controlled CNT/polymer composites having highly electrical insulation were designed and fabricated [1,2]. However, these composites have not actually been applied towards highly electrically insulating materials requiring much higher TC (>10 W m^{-1} K^{-1}). Meanwhile, boron nitride nanosheet (BNNS) is analogous to graphene and has an increasing interest for the abovementioned applications because of its extremely high TC and highly electrical insulation. BNNSs were easily prepared by direct exfoliation of h-BNs using carefully selected solvents such as ionic liquids (ILs) [3,4] and superacids [5]. ILs and superacids showed strong physical adsorption on h-BN surfaces, giving exfoliated, noncovalently functionalized BNNSs (NF-BNNSs) in high yields. The obtained NF-BNNSs showed high solubility in various solvents and maintained perfect crystallinity of h-BN structure. Therefore, NF-BNNSs acted as excellent nanofillers for dramatically improving TC of polymers. Highly thermally conductive and electrically insulating NF-BNNS/thermoplastic (TP) polymer composite films were produced through a simple wet-process using NF-BNNS solutions. NF-BNNSs were uniformly dispersed in the TP polymers, enhancing both the in- and through-plane TCs. Noncovalent functionalization of BNNSs with ILs or superacids gave high affinity between BNNSs and TP polymer matrices in the composites, leading to extremely high TC (≥15 W m^{-1} K^{-1}) and improved volume resistivity compared with those of previously reported BNNS/TP polymer composites. Moreover, the composites exhibited high flexibility. The proposed approach is very promising for preparation of electrically insulating materials for various thermal management applications.

5:15 AM *F.EN01.03.02
Dielectric Materials in Semiconductor Packages Enis Tuncer; Texas Instruments, United States

It is important to determine the dielectric characteristics of semiconductor encapsulation materials based on epoxy resins. There are several such material systems employed to protect the active silicon circuitry. Some of the important properties of the materials are their glass transition temperature, filler content and the level of water absorption which leads to reliability challenges with respect to performance and lifetime. We study changes in the propeties by investigating dielectric relaxation using broadband impedance spectroscopy techniques. It is known that the dielectric relaxation in polymeric systems influenced by the presence of water, which demands special attention in sensitive applications. We will present measurement and analysis methods based on time and frequency domain techniques. It would be appreciated within the materials science community to improve material selection and performance evaluation efforts. We will also share information on the glass transition temperature estimates for a number of composites employed in semiconductor packaging.

5:30 AM F.EN01.03.03
Ultra-Thin Doped HfO_2 Gate Dielectric for Ultra-Low Power Ubiquitous Electronics Ahmad Zubair[1], Winston Chern[1], Nitul Rajput[2], Kevin Limanta[1] and Tomas Palacios[1]; [1]Massachusetts Institute of Technology, United States; [2]Khalifa University of Science and Technology, United Arab Emirates

Ferroelectric materials are promising candidate for both conventional (e.g. low power, scalable and non-volatile memory) and emerging (e.g. in-memory computing, analog synapses, coupled oscillator networks, spiking neurons and quantum computing) nanoelectronics applications. Conventional ferroelectric materials suffer from lack of thickness scaling and compatibility with CMOS processing. Ultra-thin doped HfO_2 based ferroelectric thin-films have emerged as an attractive option for non-volatile memory and ultra-low power computing due to CMOS compatibility and precise thickness control through atomic layer deposition. In this work, we systematically investigate the scaling properties of ferroelectric $Hf_{0.5}Zr_{0.5}O_2$ in a metal/ferroelectric/insulator/semiconductor (MFIS) capacitors to identify the design space for logic and memory applications.
MFIS capacitors are fabricated on p-Si wafers using standard CMOS processing with different ferroelectric thickness. The ferroelectricity in the doped HfO_2 thin film is introduced by rapid thermal annealing. This high temperature annealing steps leads to structural phase change (monoclinic to orthorhombic) and non-centrosymmetric crystal structure in the doped HfO_2. The dielectric constant, k, of the orthorhombic $Hf_{0.5}Zr_{0.5}O_2$ film is higher than those of HfO_2 and ZrO_2(k = 25) for all thicknesses as observed from the small signal capacitance-voltage (C-V) characteristics. At low gate biases, the $Hf_{0.5}Zr_{0.5}O_2$ film is hysteresis-free and shows negligible frequency dispersion indicating a high-quality interface. This observation indicates that orthorhombic $Hf_{0.5}Zr_{0.5}O_2$ can be a promising way to achieve high- k gate dielectric. At high gate bias, the thinner $Hf_{0.5}Zr_{0.5}O_2$ films shows polarization switching when the effective electric field across the ferroelectric film exceeds the coercive field. However, in the thicker $Hf_{0.5}Zr_{0.5}O_2$ film required gate bias for polarization switching is higher the critical field for dielectric breakdown.
Our results indicate that orthorhombic $Hf_{0.5}Zr_{0.5}O_2$ can be an attractive option for gate dielectric for ubiquitous electronics. The high dielectric constant and relatively lower effective charge of the ferroelectric thin film can enable the polarization switching of the thinner dielectrics. However, to enable non-volatile memory with lower switching voltage additional materials and device engineering would be required as the switching voltage weakly scales with ferroelectric thickness.

5:40 AM F.EN01.03.04
Superionic Charge Accumulation in the In-Plane Direction of Pt Nanoparticle Films Fabricated by Atomic Layer Deposition Munekazu Motoyama[1] and An Jihwan[2]; [1]Nagoya University, Japan; [2]Seoul National University of Science and Technology, Korea (the Republic of)

Here we report the charge accumulation phenomena in Pt nanoparticle (NP) films deposited by the atomic layer deposition (ALD) on borosilicate glass (Pyrex®) substrates. The in-plane capacitance of Pt NP films was measured by AC impedance spectroscopy using Au electrodes patterned with an interval of 6.0 μm on Pyrex substrates. The experimental results show that annealed Pt NP films exhibit very high capacitance on Pyrex substrates. This phenomenon was observed in neither electron-beam-evaporation-deposited-Pt-NP films on Pyrex nor ALD-Pt-NP films on quartz. Although the mechanism of this charge accumulation phenomenon was not fully elucidated, it is considered that protons conduct in the in-plane direction of a Pt NP film via adsorbed water and behave like a supercapacitor to enhance the in-plane capacity. It is found that if the effective volume contributing to the charge accumulation is only the Pt NP film, quite large volume power and volume energy densities (6.3×10^6 W L^{-1}, 7.0×10^2 Wh L^{-1}) are achieved.

5:50 AM *F.EN01.03.06
Low Temperature and High-Speed Processing of Oxide Dielectric Thin Films Julia W. Hsu; The University of Texas at Dallas, United States

Thin film oxide dielectrics boast high breakdown voltages, low leakage current densities, and high dielectric constants making them ideal for use as gate dielectrics in thin film electronics. However, to fully realize the benefit of thin film electronics, low-cost high-throughput production is necessary. This means reducing not only processing time, but also processing temperature to allow for production on plastic substrates. In this work, we discuss the effects of low temperature UV-assisted processing and high-speed photonic curing on the properties of solution-deposited oxide dielectric films. First, we show the results from exposing sol gel precursor films to UV-ozone (UVO) through a shadow mask. This process accomplishes both lowering the conversion temperature to 250 °C and direct patterning the precursor film with exposed areas converted to oxide after final annealing. We find drastically different capacitance-frequency behavior between Al_2O_3 and ZrO_2 dielectrics, which in turn affects the In_2O_3 transistors' behavior. The origins of this finding are studied through Fourier transform infrared analysis and time dependent drain current measurements. Next, we adapt photonic curing, the use short but

high intensity pulses of broadband light, to selectively heat and convert ZrO_2 precursor films on flexible polyethylene naphthalate (PEN) substrates. Photonic curing is typically used to sinter metal nanoparticle inks into conductive metal traces on plastic substrates, but it has not previously been used to fabricate oxide thin film dielectrics on plastic substrates. We demonstrate that the conversion time is reduced from 10s minutes to < 1s and patterning using a shadow mask during photonic curing does not need subsequent thermal annealing, unlike in the UVO processing. Furthermore, by adjusting the photonic curing conditions, the oxide film can be selectively converted on top of Al electrodes, which act as selective area heat absorbers, but not on the bare PEN substrate, resulting in a self-aligned oxide pattern. We achieve a ZrO_2 dielectric with breakdown field of 8 MV/cm and areal capacitance of 200 nF/cm^2 with little frequency dispersion. Finally, we show a pathway to converting ZrO_2 dielectric at a roll-to-roll web speed of up to 50 m/min.

6:05 AM F.EN01.03.07
***Ab Initio* Electronic Transport in Disordered Semiconductors** Andrea Cepellotti and Boris Kozinsky; Harvard University, United States

The field of disordered materials is experiencing a meteoritic rise within materials engineering. In particular, several computational and experimental efforts are aimed at synthesizing novel alloy and highly doped materials, and predictive modeling is a powerful tool to guide the materials space exploration. However, the modeling of charge transport in disordered materials presents a number of challenges. In fact, charge transport in disordered materials is often not well described by common semiclassical methods, such as the Boltzmann transport equation, which have instead been developed for simple dielectric crystals such as silicon. In this work, we present some of our recent efforts aimed at bridging this gap in the modeling of charge transport in disordered materials. In an alloy, in the regime of weak electron localization, the electronic band structure consists of several overlapping flat bands. Here, the prevalent conduction mechanism is due to vertical electronic transitions, rather than diffusion due to electron group velocity. We introduce an ab-initio formalism based on the Wigner distribution that corrects predictions of electronic conductivity by including the effect of these vertical transitions. We exemplify the method with an application to a narrow gap topological semiconductor, Bi_2Se_3, showing that bulk transport is dominated by vertical electronic transitions between the valence and the conduction bands, a phenomenon also known as Zener tunneling effect. Our approach is general, applies to any system and provides a step forward for the modeling of charge transport in disordered materials.

6:15 AM F.EN01.03.08
The Search for Enhanced Dielectric Strength of Polymer-Based Dielectrics Daniel Tan; Guangdong Technion Israel Institute of Technology, China

Remarkable progress has occurred over the past 15 years through nanodielectric engineering involving inorganic nanofillers, coatings, and polymer matrices. The challenges of dielectric polymers remain primarily toward breakdown strength in thin polymer films for capacitor applications. There reported several major technical approaches to enhance the dielectric strength of polymers and nanocomposites, including nanoparticle incorporation in polymers, filler polymer interface engineering, and film surface coating. This work will direct the attention to interface contributions, including the rational design of core-shell structures, the use of low-dimensional fillers and thermally conducting fillers, and the inorganic surface coating of polymer films. These efforts demonstrated the enhancement in dielectric strength by 40–160% when controlling the fillers below 5 wt% in polyvinylidenedifluoride composites. This work will also discuss the possible dielectric mechanisms and the positive role of interfaces against charge transport traps for attaining higher breakdown strength. The investigation of low-dimensional filler/coating materials of high thermal conductivity is considered to be a key scientific subject for future research.

6:25 AM F.EN01.03.09
The Impact of Chemical Modification on Charge Injection at Metal/Polyolefin Interfaces Yiyuan Wang[1], Mikael Unge[2], Sari Laihonen[3] and Arash Mostofi[1]; [1]Imperial College London, United Kingdom; [2]NKT HV Cables AB, Sweden; [3]ABB Power Grids Sweden AB, Sweden

The process of charge injection at metal/polymer interfaces is crucial to many areas of research and technology, such as organic light emitting and harvesting devices, high-voltage capacitors and cables. In this work, we study charge injection at metal/polymer interfaces for two polymers commonly used in high-voltage applications, namely polyethylene (PE) and polypropylene (PP). Using first-principles electronic structure methods, we compute charge injection barriers at model aluminium/PE and aluminium/PP interfaces. We show that the introduction of polar chemical groups (e.g., -COOH, -CH_2Cl, and -CHO) in the polymer chains at the interface can tune the intrinsic charge injection barrier significantly. We take into account of thermal disorder by averaging over a large ensemble of interface structures obtained from first-principles

molecular dynamics trajectories. Our results suggest the possibility of rational design of metal/polymer interfaces via localised chemical modification.

Use of Ultrathin Atomic Layer Deposited Capping Layers to Increase Stability in Thermally Processed Metalcone Thin Films Vamseedhara Vemuri and Nick C. Strandwitz; Lehigh University, United States

Molecular layer deposition (MLD) and atomic layer deposition (ALD) are sequential, self limiting thin film deposition techniques, used to fabricate organic, inorganic, and inorganic-organic hybrid thin films. The hybrid organic-inorganic films deposited using MLD are usually metal alkoxides that are also termed as metalcones. Metalcone films can be subjected to thermal processing to selectively remove the organic parts of the film and induce porosity to form porous dielectric materials. However the as deposited and thermally processed metalcone films are unstable in ambient atmosphere due to the moisture absorption and permeation, which alters the chemical properties of these films. Since the dielectric constant of the water is very high (70-80), the net dielectric constant of these films increases after moisture absorption thus affecting the electrical properties. To preserve the chemical stability and electrical properties of metalcones, this work examines the use of an ultra thin ALD film grown over the as deposited and thermally processed films.
We report the growth of alucone thin films using trimethylaluminum and ethylene glycol as precursors for MLD and water (H_2O) as an oxygen source for ALD reactions. The as deposited MLD films are subjected to thermal processing from 150-350 C in inert atmosphere and under UV light to remove the organic components and induce porosity to form in-organic dielectric films. We examined the thermally induced changes in film‘s chemistry, thickness, density, etch rate and dielectric constant.
Incorporation of the organic components, formation of M-O-C bonding and water absorption is confirmed using FTIR in the as deposited MLD films. By subjecting MLD films to thermal processing the decrease in intensity of hydrocarbon bonds and changes in thickness, density compared to pure MLD films can be observed by FTIR and x-ray reflectivity respectively. The dielectric constant of these films is measured using capacitance-voltage measurements. The dielectric constant of the thermally processed films with a thin ALD layer decreases compared to only thermally processed films indicating that the thin ALD layer thus preserves electrical properties of the film. The as deposited and thermally processed films with and without the ultrathin ALD layer are subjected to CF_4/O_2 plasma etch and the MLD films without an ALD layer shows more than double the etch rate compared to the MLD films with an ALD layer. Both the decreased dielectric contant and etch rates show that the ALD layer acts as a barrier to prevent moisture absorption and preserve the chemical stability and electrical properties of the film.

Dynamic Tuning of Near-Field Radiative Thermal Rectification Fangqi Chen, Xiaojie Liu, Yanpei Tian and Yi Zheng; Northeastern University, United States

Taking advantage of phase transition and reconfigurable metamaterials, dynamic control of nanoscale thermal modulation can be achieved through the near-field radiative thermal rectification devices. An active-tuning near-field thermal rectifier using reconfigurable phase-transition metamaterials is explored. The rectifier has two terminals separated by vacuum, working under a controllable operational temperature around the critical temperature of the phase-transition material VO_2. One of the terminals is a stretchable structure made of PDMS thin film and grating consisting of various types of phase-transition material. The effects of various inclusion forms and all the related geometric parameters are well analyzed. The controllable nanoscale thermal modulation can be achieved and the ultrahigh rectification ratios of 23.7 and 19.8, the highest values ever predicted, can be obtained for two deformation scenarios, respectively. It will shed light on the dynamic tuning of small-scale thermal transport and light manipulation.

Electrical and Electromechanical Reliability of Lead Zirconate Titanate Piezoelectric Films Betul Akkopru-Akgun[1], Kathleen Coleman[1], Wanlin Zhu[1], Raul Bermejo[2] and Susan E. Trolier-McKinstry[1]; [1]The Pennsylvania State University, United States; [2]Montanuniversitaet Leoben, Austria

Use of dielectric materials such as lead zirconate titanate films for dielectric energy storage or for piezoelectric applications necessitates that they be able to sustain high DC electric fields. This paper will describe the coupled failure mechanisms that control these lifetimes for donor-doped, acceptor-doped, and films with graded doping. Curiously, the median failure time of PZT films can be increased on doping with either donors or Mn as an acceptor. It is found that lifetimes under DC fields are dominated by a combination of oxygen vacancy migration, coupled with changes in the interface barrier heights for conduction in thin films. This was assessed through a combination of highly accelerated lifetime testing, thermally stimulated depolarization currents, impedance spectroscopy, deep level transient spectroscopy, and electron energy loss spectroscopy. The relic defect chemistry of the film, including variations in this defect chemistry at interfaces strongly influences both the failure and the asymmetry of the failure as a function of the electrical polarity. As film thickness and/or the piezoelectric coefficients rise, the critical stress required for crack initiation decreases, and the failure modes can shift to electro-mechanically induced failure. Ball-on-three ball mechanical testing demonstrates that the critical flaw size in the failure of the stack becomes the thickness of the piezoelectric layer itself.

Enhancement of Thermoelectric Power Factor Due to Electron-Phonon Interaction at High Carrier Concentrations Natalya Fedorova, Andrea Cepellotti and Boris Kozinsky; Harvard University, United States

Thermoelectric materials directly convert waste heat to electricity and thus hold great potential for power generation with low environmental impact. To be able to compete with established technology and find broad applications, thermoelectric power generators must have high energy conversion efficiency, which is determined by their figure of merit ZT. This, in turn, is proportional to the material's power factor σS^2, where σ is the electrical conductivity and S is Seebeck coefficient. Optimization of PF is a challenging task, since σ and S have conflicting dependencies on different tuning parameters such as carrier concentration and their effective masses.

In this work we employ *ab initio* calculations to investigate the effects of the electron-phonon interaction on the transport properties of thermoelectric materials, focusing on the example of half-Heusler semiconductors. We calculate electron-phonon scattering rates using Wannier-Fourier interpolation of electron-phonon matrix elements and the recently developed electron-phonon averaged approximation. We find that the electron-phonon scattering can lead to anomalous behavior of the transport coefficients, namely the conductivity decreases with increasing number of charge carriers, and Seebeck coefficient changes sign, leading to an unusual peak in the PF at high carrier concentrations. We discuss the origin and magnitude of this enhancement effect starting from the electronic band structure and identify design rules to maximize the material's performance.

Flexible Dielectric Nanocomposites—From Power Energy Storage to Mechanical Energy Harvesting Jinkai Yuan; Ctrde Recherch Paul Pascal, France

Our research activities on the energy-related dielectric polymer nanocomposites will be reviewed. Micro-energy storage devices are highly demanded for diverse miniaturized electronic devices. [1,2] However, making high-energy microcapacitors with currently available printing technologies remains challenging. Based on a composite material of latex polyvinylidene fluoride and polyvinyl alcohol, we created high-energy microcapacitors with inkjet printing technique. A discharged energy density of 12 Jcm^{-3} is achieved at 550 MVm^{-1}.[3] The printed microcapacitors demonstrate mechanical robustness and dielectric stability over time. on the other hand, it is well known that all dielectric materials have electrostriction. They have capability of changing their dielectric properties upon an external mechanical deformation. Based on this effect, we have developed giant electrostriction soft nanocomposites which can serve as an active dielectric layers in a variable capacitor to convert the vibrational mechanical energy into electricity. To make such energy harvester, we prepare an electrostrictive nanocomposite composed of reduced graphene oxide in soft polydimethylsiloxane matrix.[4] The near percolated composite exhibits a large permittivity variation in response to small strain deformation, giving rise to a giant electrostrictive coefficient -4.3×10^{-14} m^2/V^2,[5] indicating that our materials are particularly promising for harvesting mechanical energy applications. Their implementation in actual MEMS generator devices has been also investigated. [6]

Lead-Free Relaxor-Ferroelectric Superlattice for Pyroelectric Energy Harvesting Amrit Sharma, Sangram K. Pradhan, Carl E. Bonner, Jr. and Messaoud Bahoura; Norfolk State University, United States

To overcome the energy crisis and its efficient utilization, there is a great need to harvest clean and green energy from waste-heat, which is abundant, ubiquitous, and free. Energy harvesting, using waste-heat, is one of the most encouraging methods to capture freely accessible heat and converting it to electrical energy. Ferroelectric materials are the most suitable candidates to harvest energy for low power electronic devices, as they exhibit switchable polarization, excellent piezoelectric and pyroelectric coefficients. The most important characteristic of ferroelectric materials is their ability to generate electric power via the pyroelectric effect. In this work, we have grown superlattice of $BaZr_{0.2}Ti_{0.8}O_3$ (barium zirconium titanate, BZT)/ $Ba_{0.7}Ca_{0.3}TiO_3$ (barium calcium titanate, BCT) on $SrRuO_3$ (strontium ruthenate, SRO) deposited on $SrTiO_3$ (strontium titanate, STO) single crystalline substrate via optimized pulsed laser deposition. We observed only the substrate peaks without any secondary peaks in the x-ray diffraction patterns, which confirms the epitaxial nature and phase purity of the grown material. Interface and domain engineering are integrated on these BZT / BCT structures for slim and well-saturated polarization-electric field (P-E) loops with improved saturation polarization.
Solid-state thin-film devices are demonstrated by the conversion of waste-heat into electrical energy by measuring P-E loops at various temperatures using pyroelectric Ericsson cycles and measured an energy conversion density ~ 10.97 MJ/m^3 per cycle. These devices exhibit a large pyroelectric current of ~ 600 nA with a temperature fluctuation of ~ 11°C. Our findings suggest that these lead-free relaxor-ferroelectric superlattices might be superior to the well-known thermoelectric materials for thermal energy harvesting.

6:00 AM *F.EN01.04.07
Solid-State Cooling Devices Based on Electrocaloric Polymers Qibing Pei; University of California, Los Angeles, United States

Electrocaloric cooling is a solid-state cooling technology, offering several advantages over traditional cooling systems, but few EC devices have been reported with high specific cooling power and high coefficient of performance (COP). We have developed solution processes to fabricate poly(vinylidene fluoride-trifluoroethylene-chlorofluoroethylene) terpolymer thin films. Various material treatment and characterizations were conducted to study and optimize the performance of the terpolymer thin films. We present several EC cooling device designs with compact and desired form factors to transfer heat between a heat source and heat sink, with the ultimate objective to pave the way for new applications that cannot be obtained using existing technologies.

6:15 AM F.EN01.04.08
Ultra-High Current Mechanical Energy Harvester Based on Lithium Cobalt Oxide Xiujun Yue[1], Alissa C. Johnson[1], Zhimin Jiang[1], Ryan R. Kohlmeyer[2], Chadd T. Kiggins[2], John Cook[2] and James H. Pikul[1]; [1]University of Pennsylvania, United States; [2]Xerion Advanced Battery Corporation, United States

Mechanical energy harvesters are important for powering wearable devices and microelectronics. Most mechanical energy harvesters supply high voltages (10^0-10^2 V), low currents (10^{-4}-10^{-2} mA/cm^2), and operate at high frequencies (~20-100 Hz). The high voltage and low current outputs, however, do not interface well with many microelectronics (which use low voltage and high current supplied from a battery). Additionally, the high operation frequency of mechanical energy harvesters does not match the low frequency of most mechanical energy sources in daily life.

Here, we report lithium cobalt oxide (LCO) based mechanical energy harvesters that deliver ultra-high current from low-frequency mechanical energy input. LCO is widely used as a cathode material for lithium ion batteries, where its crystal volume changes as lithium ions intercalate/deintercalate during battery cycling. We utilize the reverse process, where a change in volume in the crystal due to external stress causes a change in potential that drives a large current. LCO is conductive (9.25×10^{-4} S/cm) and exhibits a piezoelectrochemical effect, like many dielectrics, that converts mechanical to chemical or electrical energy. Our energy harvester consists of a pair of LCO electrodes with identical composition and different thicknesses. When an external load is applied to the device, the corresponding stress is concentrated on the thick electrode. As the thick electrode volume changes, the free energy of LCO bonds is modified and results in a shift in the electrochemical voltage. When the unloaded LCO is electrically connected to the loaded LCO, the potential difference drives

a current through an external circuit while lithium ions migrate between electrodes through an electrolyte. The current continues until there is 0 V between the electrodes. When the pressure is removed, an opposite potential difference is generated between electrodes. The device can be cycled between low displacements (<100 μm) loads at a wide range of frequencies (10^{-4}-10^{-1} Hz) to convert mechanical energy in into ultra-high currents (0.87 mA/cm^2) and low voltage (~10 mV) power.

Molten salt electrodeposition allowed the synthesis of up to 98% dense and hundreds of micrometer thick monolithic LCO electrodes with no additives, which improved the performance over slurry cast electrodes with binders found in battery electrodes. By reducing mechanical loses that occur in the polymer binders, the high density and single component electrodes enabled a high voltage output close to the theoretical value. Furthermore, the laser-based fabrication process enabled small electrode gaps which contribute to low internal resistance and high output current. The design can be scaled to form array of harvesters connected in series or parallel to generate higher current or voltage to meet the demands of different applications. The usage of aqueous electrolyte in our energy harvester decreases the potential toxic and combustion hazards of organic solvent based electrolytes and avoids the hermetic requirements for battery device packaging. Our work demonstrated an energy harvester with high current capabilities that will create new opportunities for powering wearables and microelectronics with increased functionality.

6:25 AM F.EN01.04.09
Unveiling the Origin of Relaxor Behavior in Ferroelectric Polymers Yang Liu[1], Bing Zhang[2], Wenhan Xu[1], Aziguli Haibibu[1], Zhubing Han[1], Wenchang Lu[2], J Bernholc[2] and Qing Wang[1]; [1]The Pennsylvania State University, United States; [2]North Carolina State University, United States

Relaxor ferroelectric exhibits striking physical properties including ultrahigh piezoelectric coefficients, large dielectric permittivity over a broad temperature range, and strong frequency dependence in dielectric response, which enables a wide range of applications in acoustic sensors, transducers and actuators. Understanding of the origin of unusual properties in relaxor ferroelectrics, however, remains one of the central challenges in ferroelectric materials despite more than 50 years of investigations. Here we reveal that the relaxor behavior of ferroelectric polymers originates from conformational disorder (Y. Liu et al, Nature Materials, in press), which is completely different from classic perovskite relaxors typically characterized by the existence of chemical disorder. We show that chain chirality is essential to the formation of disordered helix conformation arising from local distortions of gauche torsional angles, which consequently give rise to relaxor ferroelectric properties in polymers. Our insights into the origin of relaxor ferroelectric properties in polymers shed new light on fundamental theory of relaxor ferroelectric materials and enable the investigation of the mechanisms of ferroelectric relaxor from a new perspective. The structural model established in this work provides unprecedented guidance for the design of new organic relaxor materials for flexible electronics and energy applications.

6:35 AM F.EN01.04.10
Late News: Nanomaterial-Induced Polarization Templating in Polymer Piezoelectric Generators Nick A. Shepelin[1,2], Peter C. Sherrell[1,2], Eirini Goudeli[1], Emmanuel N. Skountzos[3,4], Joseph G. Shapter[5], Joselito M. Razal[6] and Amanda V. Ellis[1,2]; [1]The University of Melbourne, Australia; [2]St Vincent's Hospital Melbourne, Australia; [3]University of Patras, Greece; [4]FORTH/ICE-HT, Greece; [5]The University of Queensland, Australia; [6]Deakin University, Australia

For the purposes of powering always-on, self-powered sensors and portable/wearable electronics, new reliable and sustainable energy harvesting technologies are required. Piezoelectric generators show exceptional promise to fill this gap, owing to their ability to convert mechanical energy from external sources to electricity, with energy conversion efficiencies >35%.[1] Recent advances in piezoelectric fluoropolymers (e.g., poly(vinylidene floride), PVDF) further enable the use of flexible polymer-based piezoelectric generators with tailored optical transmittance for wearable or implantable energy harvesting from the movements of the human body.

Despite the promising nature of piezoelectric polymers, the extraordinary energy input required during the manufacture steps limits the commercial applicability for energy harvesting. Namely, the electrical energy (>200 MV m^{-1}) and thermal energy (>100 °C), applied to the fluoropolymer in order to align the dipole moments and induce polarization, negates the energy harvested over the device lifetime.[2] Hence, the elimination of this so-called electrical poling step will enable the commercial and environmental viability of flexible piezoelectric generators.

Here, we demonstrate for the first time the dipole templating and polarization locking of a copolymer of PVDF, poly(vinylidene fluoride-*co*-trifluoroethylene) (PVDF-TrFE), in the presence of 1D (carbon nanotube) and 2D (MXene) nanomaterials. The alignment of polarization at the interface, predicted by molecular dynamics models, improves energy

harvesting performance and decreases the energy input for the manufacture of flexible piezoelectric energy harvesters. The presence of single-walled carbon nanotubes (0.02 wt%) exhibits a generated power density of 70.6 μW cm^{-3}, whereas the incorporation of $Ti_3C_2T_x$ MXenes (0.50 wt%) results in a piezoelectric charge coefficient of 52.0 pC N^{-1}, without the use of electrical poling. The composites produced through this method are fully recyclable in acetone and can be reprinted into various form factors without loss of performance, enabling future use for designer energy harvesting systems.

Oleylamine Modified Boron Nitride Nanosheets as Efficient Nanofillers for Electrospun PVDF Nanofibers Madeshwaran Sekkarapatti Ramasamy and Byungki Kim; Korea University of Technology and Education, Korea (the Republic of)

Poly(vinylidene fluoride) (PVDF) have received applications in piezoelectric sensors, actuators and nanogenerators due to their flexibility and electroactive properties. In general, PVDF exhibit five crystalline polymorphs namely, α, δ, β, γ and ε, among them, β (TTTT conformation) and γ (TTTGTTTG' conformation) phases are the electrically active phases. Moreover, γ-phase offers higher breakdown strength and discharge energy density as compared to β-phase, therefore, receiving greater attention as a ferroelectric material. Until now, various approaches such as, high electric field poling, mechanical stretching, electrospinning and incorporation of nanofillers have been established for fabricating PVDF with high content of electroactive phases. In comparison, incorporation of nanofillers can simultaneously enhance the mechanical properties of polymer matrix and can also promote the formation of preferred electroactive phases owing to the interaction between the surface of the fillers and dipoles of the PVDF chains. Recently, mono or few-layered two-dimensional (2D) boron nitride nanosheets (BNNS) have been actively applied as nanofillers for polymer composites because of their extraordinary properties such as, high thermal conductivity, bandgap, thermal stability, Young's modulus and piezoelectric properties. However, their main drawback is related with their poor dispersion in polymer matrix due to their Van der Waals forces. Herein, we report the fabrication of high performance PVDF nanofibers (PVDFNFs) based composites using oleylamine functionalized boron nitride nanosheets (OLABN) as nanofillers. First, PVDFNFs-OLABN composite nanofiber membranes were prepared by liquid-phase exfoliation (LPE) and electrospinning process, and then, the effect of OLABN on the crystalline phases, mechanical and piezoelectric properties of PVDFNFs were systematically investigated. FTIR results revealed that the OLABN promote the formation of polar γ-phase in PVDFNFs. Impressive 343% and 823% enhancements in tensile strength and Young's modulus can be achieved even with addition of only 0.1 wt% OLABN, respectively. The composites exhibited enhanced piezoelectric outputs as compared to reference PVDFNFs. Furthermore, rapid and sharp piezoelectric outputs can be achieved upon force applied by finger tapping/releasing on the PVDFNFs-OLABN (4 wt%) composite based piezo sensors. The output power density of the composites with 4 wt% OLABN was 133% higher than that of reference PVDFNFs. The findings of this study hold a great potential in high performance polymer based piezoelectric sensors/actuators and nanogenerators applications.

Orientation Effects on Antiferroelectric Switching of PbZrO3 Polycrystalline Films Cosme Milesi-Brault[1,2], Stéphanie Girod[1], Sebastjan Glinsek[1], Emmanuel Defay[1] and Mael Guennou[2]; [1]Luxembourg Institute of Science and Technology, Luxembourg; [2]University of Luxembourg, Luxembourg

The interest for antiferroelectric materials has been increasing over the last years, largely because of their potential for energy storage and electrocaloric applications, but also because they still are insufficiently known compared to ferroelectrics. Their key distinctive signature is the antiferroelectric switching revealed by a double hysteresis loop. However, this switching is not often demonstrated, largely due to the large electric fields involved. In particular, the details of the switching behavior of the model antiferroelectric perovskite PbZrO3 are still unclear.

Here, we synthesize and characterize polycrystalline films of PbZrO3, with thicknesses ranging from 85 nm to 850 nm. The samples have been processed via chemical solution deposition on Pt/TiOx/SiO2/Si and fused silica substrates. For the films processed on platinized silicon, platinum top electrodes have been sputtered to apply the field out-of-plane in a metal/insulator/metal (MIM) geometry. For the samples deposited on fused silica substrates, interdigitated platinum electrodes (IDE) have been deposited to apply the field in-plane.

In both geometries, we could observe the double hysteresis loop, signature of antiferroelectric switching. We compare the switching characteristics in the two types of sample, with adequate corrections in order to take into account the differences in geometry in the calculation of the applied field. A saturation polarization of up to 36 μC/cm2 was reached in the IDE geometry. The switching peaks in the current vs. voltage characteristic are generally broader in the IDE geometry as compared to the MIM geometry. Orientation effects alone decrease the switching fields in MIM geometry from 495 kV/cm to 286 kV/cm in the IDE geometry. We discuss these differences with a simple switching model. Additionally, in both geometries, the films display a “ferroelectric-like” contribution at lower fields. This works paves the way for possible applications based on antiferroelectric switching of polycrystalline PbZrO3 thin films.

5:20 AM F.EN01.05.04
Synthesis of Doped Hafnia by Metal-Organic Decomposition (MOD) of Low-Toxicity Chemical Solutions for Energy Harvesting Applications Miguel A. Badillo-Avila, Beatriz Noheda and Mónica Acuautla; University of Groningen, Netherlands

Since the discovery of ferroelectricity in doped-HfO_2 by Böscke et. al in 2011, doped-HfO_2 has been regarded as an eventual replacement of lead zirconate titanate (PZT), and as a highly promising functional oxide for information storage devices, electromechanical systems, energy storage, and piezoelectric-power generation. Highly ordered, highly piezoelectric orthorhombic and rhombohedral doped-HfO_2 film structures have been obtained by physical deposition techniques such as ALD, PLD and sputtering deposition. Such methods have produced groundbreaking results and astonishing conceptual devices. Unfortunately, they require high-vacuum and expensive high-precision equipment. Chemical solution deposition methods have also yielded decent results, albeit less surprising. Yet, they are more suitable for large scale production, particularly for applications where large areas are needed. Nevertheless, current chemical approaches make use of highly unstable or toxic compounds, which require restrictive inert-atmosphere processing conditions. In our work, we have focused on the sustainable synthesis of piezoelectric doped-HfO_2 good-quality films by employing much less or non-toxic chemical precursors, and short/lower thermal treatments. Besides, no special synthesis conditions are required, which makes the processing cheaper.

We have employed Zr and Ca as dopants of HfO_2 because such elements are relatively abundant and, like Hf, they do not present risks for human health or for the environment. Chemical precursor solutions of each corresponding metal oxide are prepared in normal air atmosphere from simple and low toxicity compounds dissolved in alcoholic solvents. Solvation-enhancing agents are used to suspend the precursor metal salts. Combustion-boosting compounds are also added to produce an increased annealing temperature, which promotes crystallization. The solutions are mixed in calculated ratios. Thin films of doped-HfO_2 are deposited in normal conditions via spin-coating on platinized silicon substrates. Each layer is dried at 200 to 400 °C for 5 minutes. The process is repeated several times for increased thickness. The films are later annealed in Ar or air ambience at temperatures between 500 and 800 °C. Top Pt electrodes are deposited by e-beam evaporation.

Uniform and dense doped-HfO_2 layers are deposited from the evaporation and Metal-Organic Decomposition (MOD) of the precursor solution components. The solution can be prepared and safely managed in normal ambient because it does not contain sol-gel-type precursors. The most stable crystalline phase of HfO_2, monoclinic, is obtained for drying temperatures of 200-300 °C after sintering at 500-800 °C under conventional annealing in Ar and air. However, cubic and/or tetragonal phases mixed with monoclinic phase can be obtained for drying temperature of 400 °C and annealing at 500 °C in Ar and air.

Interestingly, pure cubic or tetragonal phase is obtained at a drying temperature of 400 °C and Rapid Thermal Annealing (RTA) at 500 – 700 °C for 5 minutes. Cubic and/or tetragonal phase is required because it has been demonstrated each can undergo phase-transition to ferroelectric orthorhombic phase during wake-up polarization cycling. The cubic, tetragonal and

orthorhombic phases are stabilized by a small crystallite size. On the contrary, bigger crystals lead to the irreversible formation of the monoclinic phase. The use of a relatively high drying temperature of 400 °C promotes the nucleation of small HfO_2 crystals rather than growth. Besides, annealing in RTA does not allow enough time for such crystals to increase in size, thus stabilizing the higher symmetry phases of HfO_2.

The fabrication method developed can be used to make films with piezoelectric response, of easy scalability, and with low-toxicity precursor materials.

The Preparation and Dielectric Properties of 2D Nano-Sheets Materials and Composites Based on Electrospinning Hua Deng; Sichuan University, China

Two dimensional dielectric fillers have been considered to serve as high performance fillers to enhance both the dielectric constant and breakdown strenght of various dielectric polymer composites. Nevertheless, the fabrication of these 2D fillers is quite often complicated, and usually rely on the nature availability of these materials. Herein, we demonstrate systematic study on the fabrication of 2D TiO2 nanofillers through tunning various processing condition of electrospinning. This research work was carried out to investigate the effects of different solution formulas and electrospinning conditions on the morphology of the spinning fibers. The influence of calcination temperature on the preparation of dielectric fillers was studied, and it was applied to the preparation of dielectric composite materials based on PVDF and PI. The energy density of two-dimensional nano-sheets dielectric fillers was investigated, and shows high dielectric constant, high Effects, high breakdown strength and low dielectric loss. The extended application of 2D lamellar fillers in polyimade system under high temperature conditions is further discussed achieving an energy density of 3 J/cm3 at 150 degree C; 3.5 J/cm3 at 100 degree C; a charge-dischange efficiency of around 90%. This could provides a theoretical and technical guidelines for the practical application.

5:45 AM F.EN01.05.06
Ultrathin-Enhanced Ferroelectricity in Doped-HfO_2 Films Directly on Silicon Suraj Cheema[1], Daewoong Kwon[1], Nirmaan Shanker[1,1], Roberto dos Reis[2], Shang-Lin Hsu[2,2], Jun Xiao[1], Cheng-Hsiang Hsu[1], Haigang Zhang[3], Ryan Wagner[3], Ajay Yadav[1], Claudy Serrao[1], Golnaz Karbasian[1], Margaret McCarter[1], Apurva Mehta[4], Evguenia Karapetrova[5], Rajesh Chopdekar[2], Padraic Shafer[2], Elke Arenholz[2,6], Xiang Zhang[2,1], Chenming Hu[1], Roger Proksch[3], Ramamoorthy Ramesh[1,1], Jim Ciston[2] and Sayeef Salahuddin[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Oxford Instruments, United States; [4]SLAC National Accelerator Laboratory, United States; [5]Argonne National Laboratory, United States; [6]Cornell University, United States

The critical size limit of ferroelectric order has extensive implications for the future scaling of energy-efficient electronics, particularly due to the intrinsic ability to control electric polarization with an applied voltage. As ferroelectric materials are made thinner however, polarization is typically suppressed, as size effects in ferroelectrics have been thoroughly investigated in the prototypical perovskite oxides. Furthermore, perovskites suffer from various chemical, thermal, electrical, and interfacial incompatibilities with silicon and modern semiconductor processes. Recently, fluorite-structure binary oxides have attracted considerable interest as they overcome many of the silicon compatibility issues afflicting its perovskite ferroelectric counterparts. Here we report ferroelectricity in ultrathin Zr-doped HfO_2 (HZO) [1], a fluorite-structure oxide grown by atomic layer deposition (ALD) on silicon. We demonstrate the persistence of inversion symmetry breaking and spontaneous, switchable polarization down to a thickness of one nanometer, equivalent to just two fluorite-structure unit cells. Second harmonic generation (SHG) and advanced scanning probe techniques – microwave-frequency scanning capacitance microscopy (SCM) and piezoresponse force microscopy (PFM) coupled with an interferometric displacement sensor (IDS) – establish the presence of inversion symmetry breaking and switchable electric polarization in one nanometer HZO films, respectively. Synchrotron X-ray characterization indicate that polar distortions increase in the ultrathin limit; diffraction markers (structural aspect ratio, interplanar lattice spacing) and spectroscopic signatures (orbital polarization, crystal field splitting) of polarization all demonstrate ultrathin enhancement.

These results indicate not only the absence of a ferroelectric critical thickness, but also ultrathin-enhanced ferroelectricity in HZO thin films on silicon. Notably, such ‘reverse’ size effects oppose conventional perovskite ferroelectric trends, which can be understood from the crystal symmetries involved in the competing fluorite-structure polymorphs. Therefore, this work shifts the search for the fundamental limits of ferroelectricity to simpler transition-metal oxide systems – that is, from perovskite-derived complex oxides to fluorite-structure binary oxides – in which ‘reverse’ size effects can counterintuitively stabilize polar symmetry in the ultrathin regime. From a synthesis perspective, these results suggest that harnessing confinement strain – required to crystallize ultrathin HZO into the metastable ferroelectric orthorhombic phase – offers a new

mechanism to control electric polarization at the atomic-scale beyond epitaxial strain. Furthermore, this approach to integrate nanoscale ferroelectricity in doped-HfO_2 thin films directly on silicon via ALD provides a route towards realizing emerging hyper-scaled energy-efficient nanoelectronics [2]. In particular, we have recently demonstrated ferroelectric tunnel junctions [1] and negative capacitance ferroelectric field-effect transistors [3,4] exploiting ultrathin ferroelectric HZO films on silicon, critical steps towards realistic polarization-driven resistive switching memories and ultralow-power advanced transistors, respectively.

van der Waals Epitaxy of Highly (111)-Oriented $BaTiO_3$ on MXene Andrew Bennett-Jackson[1], Matthias Falmbigl[1], Kanit Hantanasirisakul[1,2], Gu Zongquan[1,1], Dominic Imbrenda[1,1], Aleksandr Plokhikh[1], Alexandria Will-Cole[1], Christine Hatter[1,2], Liyan Wu[3], Babak Anasori[1,2], Yury Gogotsi[1,2] and Jonathan Spanier[1,1,1]; [1]Drexel University, United States; [2]A.J. Drexel Nanomaterials Institute, United States; [3]University of Pennsylvania, United States

We report on the high temperature thin film growth of $BaTiO_3$ on $Ti_3C_2T_x$ (where T_x represents surface terminations, such as O and F) MXene flakes using van der Waals epitaxy on a degradable template layer. MXene was deposited on amorphous and crystalline substrates by spray- and dip-coating techniques, while the growth of $BaTiO_3$ at 700 °C was accomplished using pulsed laser deposition in an oxygen rich environment. We demonstrate that the MXene flakes act as a temporary seed layer, which promotes highly oriented $BaTiO_3$ growth along <111> independent of the underlying substrate. The lattice parameters of the $BaTiO_3$ films are close to the bulk value suggesting that the $BaTiO_3$ films remains unstrained, as expected for van der Waals epitaxy. The initial size of the MXene flakes has an impact on the orientation of the $BaTiO_3$ films with larger flake sizes promoting a higher fraction of the polycrystalline film to grow along the <111>. The deposited $BaTiO_3$ film adopts the same morphology as the original flakes and piezoresponse force microscopy shows a robust ferroelectric behavior for individual grains. Transmission electron microscopy results indicate that the $Ti_3C_2T_x$ MXene fully decomposes during the $BaTiO_3$ deposition and the surplus Ti atoms are readily incorporated into the $BaTiO_3$ film. Electrical measurements show a similar dielectric constant as a $BaTiO_3$ film grown without the MXene seed layer. The demonstrated process has the potential to overcome the longstanding issue of integrating highly oriented complex oxide thin films directly on any desired substrate.

Novel Bi-Based Photocatalysts with Unprecedented Visible-Light-Driven Hydrogen Production Rate: Experimental and DFT Insights Nageh K. Allam; American University in Cairo, Egypt

Green and efficient energy technologies are a key point where nanoscience could make a difference in the paradigm shift from fossil fuels to renewable sources. One attractive possibility is the utilization of solar energy to obtain electricity or chemical fuel based on the ability of semiconductor nanomaterials to function as photocatalysts promoting various oxidation and reduction reactions under sunlight. We report on a novel class of Bi-based photocatalysts for hydrogen production via water splitting. A screening DFT investigation was performed on the $Bi_2(MO_4)_3$ (M= Cr, Mo, and W) systems. The $Bi_2(CrO_4)_3$ system exhibits the smallest bandgap energy, the highest dielectric constant, and the highest absorption in the

visible region among the other counterpart materials. Consequently, $Bi_2(CrO_4)_3$ nanoparticles were synthesized via a simple one-pot method at room temperature and characterized by XRD, XPS, DRS, FE-SEM, HR-TEM, and Raman spectroscopy. The as-prepared yellow $Bi_2(CrO_4)_3$ nanoparticles exhibited direct bandgap energy of 2.45 eV. The photoactivity of the as-prepared $Bi_2(CrO_4)_3$ nanoparticles was tested toward the photocatalytic hydrogen production, where reasonable rates of 522.44, 174.15, and 88.24 μmol/g/h were achieved under UV, AM 1.5, and visible irradiations, respectively in the absence of any hole scavengers. Those rates are higher than those reported for Bi-based photocatalysts.

Thermal–Stimulated Evolution of Structural and Optical Properties of Hafnia Films Co-Doped with Si, N and Nd Grown by Magnetron Sputtering Larysa Khomenkova[1,2], Tetyana V. Torchynska[3], Nadiia Korsunska[1], Leonardo G. Vega Macotela[4], Oleksandr Melnichuk[5] and Fabrice Gourbilleau[6]; [1]V. Lashkaryov Institute of Semiconductor Physics at NASU, Ukraine; [2]National University "Kyiv-Mohyla Academy, Ukraine; [3]Instituto Politécnico Nacional, Mexico; [4]Instituto Politecnico Nacional, Mexico; [5]Mykola Gogol State University, Ukraine; [6]CIMAP, UMR CNRS/CEA/ENSICAEN/UNICAEN, France

Hafnium oxide and its silicates are considered mainly as gate dielectrics owing to their high dielectric constant. Recently, their ferroelectric properties were discovered, whereas optical application of these materials was rarely addressed in spite of promised optical parameters and mechanical and thermal stability. Usually, CVD or ALD approaches are used for the fabrication of hafnia-based films. At the same time magnetron sputtering was considered only by some research groups. In this work, we report on the utility of reactive magnetron sputtering for the fabrication of composite thin films based on HfO_2 co-doped with Si, N, and Nd ions simultaneously.

The evolution of structural and optical properties of such films with annealing temperature was investigated by means of the scanning electron microscopy, energy-dispersive X-ray spectroscopy, X-ray diffraction, Raman scattering, and photoluminescence techniques. It is observed that sputtering of HfO_2-Si-Nd composed target in argon-nitrogen plasma allowed producing homogeneous, dense and smooth films. The analysis of film properties with annealing temperature revealed the stability of film structure up to 950°C.

The light emission in the visible and IR spectral range was detected. It was found that bright Nd^{3+}-related emission can be achieved at lower temperatures (about 950°C) contrary to that reported for Nd-doped Si-SiO_2 or Si-Si_3N_4 materials. The Nd^{3+} PL intensity correlates with the evolution of HfO_2 monoclinic phase. It is shown that the excitation channel of $Nd3_+$ ions under non-resonant excitation involves host defects contained nitrogen ions. The desorption of nitrogen at high annealing temperature (1100°C) via the formation of volatile NO, as well as the formation of the Nd silicate phase results in the quenching of Nd^{3+} photoluminescence. This complex approach used for investigation of our films allowed demonstrating the utility of reactive magnetron sputtering for the fabrication of thin films with stable chemical composition and structure (up to 950°C). These results can be attractive for future applications of the hafnium silicate films (un-doped and doped with rare-earth ions) as emitting elements or waveguides.

Strategy to Choose Best Building Blocks for Efficient Triboelectric Generator Devices Linards Lapčinskis, Kaspars Malnieks, Artis Linarts, Māris Knite and Andris Sutka; Riga Technical University, Latvia

TEG devices have potential to satisfy growing energy needs in portable electronics and sensors providing a clean alternative to conventional batteries.[1] TEG devices are produced from cheap, lightweight, flexible, widely used polymer materials and offer promise to capture neglected and unutilized forms of mechanical energy. TEG device consists from two conductive electrodes from which at least one is covered with polymer insulator film.[1] The two electrodes in TEG are connected by outer circuit and upon electrode oscillation surface charge on polymer layers and electric potential is created that drive electrons to flow between two electrodes in order to balance this electric potential difference. TEG devices can be operated in different modes – vertical separation, sliding, rotating, single electrode etc.[2] but the key feature for high TEG efficiency is surface charge from contact electrification.[3]

Different mechanisms are responsible for contact electrification and depend on material used. It is well demonstrated, that on metal-metal, metal-semiconductor or semiconductor-semiconductor contact the electron transfer occurs,[4,5] but this is not so obvious for polymer insulators.[6] The three mechanisms for polymer insulator contact electrification are considered – electron transfer,[7] ionic transfer,[6] and covalent bond cleavage.[8] Electron transfer between polymers is doubtful, because there are no available free electrons in insulators. Usage of the term "effective work function" in connection to the driving force for charge exchange between polymer insulators is also questionable even if the polymer is contacted with metal.[6] Ion exchange between contacted polymer insulators has been considered, because water under ambient conditions is adsorbed even on hydrophobic polymers.[9] The water layers on contacted surfaces fuse together upon contacting and as different polymer materials may have different affinity towards cations and anions in water, the imbalance between ions form during

separation, thus creating surface charge.[6] However, it has been proven, that contact electrification of polymer insulators also occurs in complete absence of water.[10]
In our work we show that polymer contact-electrification can be predicted using their cohesive energy density. This allows us to select the most suitable materials as the building blocks for efficient TEG devices.

Characterization of Various High k Gate Dielectric Thin Films for TFT Applications Kelsea Yarbrough, Sangram K. Pradhan and Messaoud Bahoura; Norfolk State University, United States

Traditional dielectric materials such as silicon dioxide (SiO_2) is the first choice and mostly used in many electronic devices including Metal Oxide Semiconductor Field Effect Transistors, Thin Film Transistors, and VLSI technology. However, SiO_2 has several disadvantages that researchers are currently looking for alternatives. Scaling down electronics are the most popular device approach where SiO_2 will not be able to fit in these ultralow dimensional adjustments. One approach to scaling down electronics, while sustaining adequate dielectric properties is incorporating high k dielectrics. High k dielectrics refer to materials with a high dielectric constant, which denotes the material ability to store an electrical charge. SiO_2 generally has a dielectric constant value of 4, while high k dielectrics have a dielectric constant greater than approximately 10. Noteworthy high k dielectrics include Hafnium Oxide (HfO_2), Zirconium Oxide (ZrO_2), and Aluminum Oxide (Al_2O_3). In this study, we perform important characterization techniques to analyze HfO_2, ZrO_2, and Al_2O_3 for the possible replacement of SiO_2. These high k dielectric thin films exhibited leakage currents lower than 9.45×10^{-11} and with a thin film roughness of less than .5 nm. These high-quality high k dielectrics thin films were grown by Atomic Layer Deposition on n-type silicon at a different temperature and constant thickness for premise characterization. The effect of temperature on surface morphology, crystalline orientation, and dielectric properties were analyzed through Atomic Force Microscopy (AFM), X-ray Diffraction (XRD), Keithley 4200 SCS, and Four Point Probe measurement system. AFM provided thin film roughness, grain size, and surface morphology for thin films. XRD provided the crystalline orientation of these high k dielectrics with the effect of temperature. Keithley 4200 was used to show and calculate the dielectric properties including; dielectric constant, I-V plots (leakage current), and C-V plots. Lastly, Four Point probe measurement system provided electrical properties for these high k dielectrics. The present work will provide valuable scientific input dielectric performance for the improvement of TFT devices.

Mechanically Robust PVDF/Isocyanate-Treated Graphene Oxide Composite Nanofiber and Its Piezoelectric Sensor Applications Madeshwaran Sekkarapatti Ramasamy and Byungki Kim; Korea University of Technology and Education, Korea (the Republic of)

Graphene, the two dimensional material with sp^2-hybridized carbon atoms arranged in honeycomb-like structure has attracted greatest research interests because of their excellent mechanical and electrical properties. In particular, graphene have been considered as one of the most promising reinforcing nanofillers for developing cost-effective, high performance polymer composites. However, their main drawback is associated with their poor solution processability in organic solvents and agglomeration in polymer matrix due to their Van der Waals forces. Graphene oxide (GO), derived from acidic oxidation of natural graphite possesses abundant oxygen containing functionalities exhibit good solution processability, and therefore, receiving attention as precursor to the graphene-based nanofillers. On the other hand, poly(vinylidene fluoride) (PVDF) have been actively applied in piezoelectric sensors and nanogenerators because of their electroactive properties and flexibility. Generally, PVDF present five crystalline phases such as, α, δ, β, γ and ε, among them, β-phase PVDF with TTTT

conformation shows the best piezoelectric properties, because all the dipoles are arranged parallel which resulted in highest dipole moment per unit cells. Incorporating GO into PVDF matrix can promote the formation of preferred β-phases owing to the interaction between the oxygen functionalities of GO and dipoles of the PVDF chains. In addition, the intrinsic high mechanical properties of GO can also enhance the mechanical properties of PVDF matrix. However, in most of the polymer composite systems, the strength and stiffness increased with the addition of nanofillers, meanwhile, the toughness decreased due to reduction in strain at break, which often restricts their applications in stretchable and flexible electronics. Herein, we report a method for fabricating PVDF/GO composite nanofibers with significantly enhanced mechanical strength and modulus without losing its toughness/stretchability. Isocyanate treated GO (i-GO) nanosheets were incorporated as nanofillers into PVDF nanofibers (PVDFNFs) using solution blending and electrospinning techniques. i-GO exhibit strong interfacial interaction with PVDF due to its reduced hydrophilicity and excellent dispersibilty in organic solvents. FTIR results revealed that the addition of i-GO induce the formation of PVDFNFs with high content of electroactive phases. Interestingly, the tensile strength, modulus and as well as strain-at-break increased with the addition i-GO. Furthermore, the composites displayed enhanced piezoelectric outputs than that of reference PVDFNFs during the static load analysis. The enhanced performance of the composites can be attributed to the strong interaction between i-GO and PVDF achieved through incorporation of chemically modified GO. The reported composites in this study hold a great potential in the field of flexible and stretchable piezoelectric sensors and nanogenerators.

Dramatic Increase in Polymer Triboelectrification by Transition from a Glassy to Rubbery State Artis Linarts, Andris Sutka, Kaspars Malnieks and Linards Lapčinskis; Riga Technical University, Latvia

Triboelectric nanogenerators (TENG) are intriguing energy harvesting devices that convert mechanical energy into electricity and could power small portable devices or charge batteries [1]. Here we report contact electrification of glassy polymers at different temperatures and observing a dramatic three orders of magnitude increase in surface charge when passing the transition temperature to a rubbery state. Transition is accompanied by a larger force required for separation due to material softening and increased stickiness. This enhances material transfer during contact/separation cycles and indicates covalent bond breaking as the mechanism for increased polymer triboelectrification. Undeniably, surface roughness plays a great role in contact electrification, however in our study its impact is overrated when compared to the influence of physical properties.

Matching the Directions of Electric Fields from Triboelectric and Ferroelectric Charges in Nanogenerator Devices for Boosted Performance Kaspars Malnieks, Andris Sutka, Linards Lapčinskis and Artis Linarts; Riga Technical University, Latvia

The field related to triboelectricnanogenerator (TENG) devices is emerging rapidly. Many original and creative TENG concepts have been presented in the literature for harvesting mechanical energy and converting it into electricity (Lee et al., 2019). The working principle of TENG devices is straightforward. Due to electrode oscillation or movement, a potential difference is created, which causes a current flow in the external electric circuit. TENG devices can be integrated into fabrics, wearables, interior objects, membranes (to harvest energy from sound), and even implantable devices.
To enhance the performance of TENG, different approaches have been used. The most obvious way is to increase the specific contact area via nanostructuring (Zhang et al.). Another possibility is the modification of surface or physicochemical properties of the triboelectric material (Sutka et al., 2019). The performance can be also enhanced by using ferroelectric polymer or composite films as the contacting surfaces (Bai et al.). State-of-the-art performance of ferroelectric material-based TENG devices can be expected when the ferroelectric material layers on contacting sides of the device are inversely polarized (Sutka et al). However, previous works related to TENG devices based on ferroelectric materials overlook the dipole that forms between the triboelectric surface charges on contacting surfaces. As soon as we consider this additional factor, it follows that the electric field direction from ferroelectric dipoles should match the direction of the electric field from triboelectric surface charge to achieve maximum electric field strength and electrostatic induction.

Polydimethylsiloxane (PDMS), ethylene-vinyl acetate copolymer (EVA), poly(vinyl acetate) (PVAc), and poly(methyl methacrylate) (PMMA) were used in our studies to prepare TENG devices. The polymer films were spin coated on indium tin oxide (ITO) conductive electrode and contacted against another ITO. The polymer films were given ferroelectric properties by adding 7.5 vol% $BaTiO_3$ nanoparticles. The sign of triboelectric surface charges formed on pure polymers after contacting against ITO was determined by measuring the current between the underlying electrode and the ground in Faraday cup mode. Polymers PDMS, PVAc, and EVA obtain a negative charge on their surface whereas for PMMA a positive charge is observed when contacted ITO. The sign of the net triboelectric charge did not change when $BaTiO_3$ nanoparticles were incorporated into the polymers. All poled $BaTiO_3$/polymer composites exhibit piezoelectric properties. The piezoelectric charges of 2.9 pC/cm^2 , 10.9 pC/cm^2 , 3.7 pC/cm^2 , and 2.4 pC/cm^2 were measured for BaTiO3/EVA, BaTiO3/PDMS, BaTiO3/PVAc, and BaTiO3/ PMMA composites, respectively. The higher piezoelectric response of $BaTiO_3$/PDMS could be attributed to its larger deformability under the constant loading force. Composite layer in each of these TENG devices was tested as non-poled and also positively and negatively poled, so that ferroelectric dipole is matched and mismatched with the previously determined surface charge.
As example $BaTiO_3$/PDMS TENG device performed excellently, and the output was superior to any other presented in this study. The peak open-circuit voltage (V_{OC}) of device with matched dipoles reached 460 V, instant energy and power densities of this TENG device reached 9.7 mJ/m^2 and 143.2 mW/m^2 , respectively. For comparison, a TENG device from the same polymers without $BaTiO_3$ NPs shows V_{OC} as small as 16 V and three orders of magnitude smaller energy and power densities of 0.012 mJ/m^2 and 0.104 mW/m^2. Also, the TENG device from the same inversely polarized composite films but with mismatched dipoles exhibited significantly lower output—V_{OC} of 300 V and instant energy and power densities of 4.0 mJ/m^2 and 91.6 mW/m^2 from the same contacting area.

F.EN01.06.10
Towards Engineering Mixed Oxide Thin Films Using a Genomic Approach—A Case Study of Ta_2O_5-Based Coatings Mariana A. Fazio, Le Yang and Carmen Menoni; Colorado State University, United States

Mixed oxide thin films have found their way into numerous applications ranging from high-k dielectrics to gas sensors to optical coatings with tunable properties. The field is vast and most research conducted on mixed oxide coatings has been approached from the experimental side, leading to an arduous and time-consuming trial-and-error process. In the last decade, emerging computational methods have been conductive to accelerated materials discovery. In particular, the genomics approach behind open access initiatives such as the Materials Project aims to provide materials scientists with a new set of tools: large databases of computational calculations of known and predicted materials. This web-based database leads the way for *in silico* material design that can guide experimentation.

In this work, we carried out an extensive study of tantala (Ta_2O_5) amorphous thin films doped with Al, Si, Sc, Ti, Zn, Y, Zr, Nb and Hf grown by reactive sputtering. The influence of the dopant and post-deposition annealing on the film properties and structure was characterized by grazing-incidence x-ray diffraction, x-ray photoelectron spectroscopy and spectroscopic ellipsometry. Using the Materials Project database, compositional phase diagrams based on density functional theory calculations were constructed for all mixed oxide systems and the annealing process was evaluated via grand potential phase diagrams with varying oxygen chemical potential. The computational calculations agree well with experimental results, predicting formation of ternary compounds after annealing in some systems. When no ternary phase can be stabilized, the dopant acts as an amorphizer agent increasing the crystallization temperature of tantala. In the case where the dopant forms an oxide with similar formation enthalpy to tantala we experimentally observed effects of oxygen competition that lead to formation of phases that are predicted be unstable. Overall, the predictions based on the Materials Project database provide valuable information for tailoring dopant type and concentration in mixed oxide thin films towards specific applications that might require increased thermal stability or to adjust processing conditions for ternary oxide production.

F.EN01.06.11
Characterization of MnO_2-MWCNT Nanocomposite Morphology for Supercapacitor Applications Rian Tucci[1,2], Thomas Sadowski[1,2], Rahul Singhal[3,2] and Christine Broadbridge[1,2]; [1]Southern Connecticut State University, United States; [2]Connecticut State Colleges and Universities (CSCU) Center for Nanotechnology, United States; [3]Central Connecticut State University, United States

Supercapacitors, with long cycle lives and long-term efficiency, have potential to become an appealing alternative to lithium-ion batteries; however, the specific energy of these devices lags well behind current state-of-the-art lithium-ion batteries. Nevertheless, numerous opportunities exist to optimize supercapacitors through the manipulation of the structure and morphology of novel materials. The implementation of hybrid supercapacitors, a device which combines a pseudo-capacitor

with an electrical double layer capacitor, are of interest because material composites have greater charge storage capabilities than their components alone. The most effective hybrid capacitors for charge storage are ones possessing high specific capacitance (capacitance per unit mass). The optimization of a composite for high specific capacitance requires changes to intrinsic material properties, either by changing chemical or physical structures. The current study was aimed at the manipulation of the nanostructure of a manganese dioxide (MnO_2) – multi walled carbon nanotube (MWCNT) composite material via modulation of MWCNT composite concentration. The composite nanostructure was characterized using transmission electron microscopy (TEM), x-ray diffraction (XRD), charge-discharge tests, and cyclic voltammetry. Ten composites, each with different initial MWCNT concentrations, were synthesized via hydrothermal method. All ten concentrations were imaged via TEM. Of those ten, three were chosen to be characterized with electrochemical methods and XRD: 4.8%, 16.9%, and 33.7% mass MWCNT. TEM imaging reveals a nanostructure of polycrystalline MnO_2 adsorbed onto MWCNT. Results indicated that, on average, the thickness of MnO_2 coating decreased as percent mass MWCNT increased. At 33.7% MWCNT mass, MWCNT agglomeration became hard to mitigate and dominated MnO_2 adsorption structure. This is supported by XRD of 33.7% sample showing emergence of (002) plane of CNT, indicating widespread non-coating of MnO_2 in composite. Charge-discharge tests were conducted in with a 1 V window at 0.5, 1, and 2 A/g. Charge-discharge tests with 1 A/g indicate highest specific capacitance for 16.9% mass MWCNT at 150 F/g, compared to 70 and 45 F/g with 4.8% and 33.7% mass MWCNT, respectively. Preliminary results indicate that as MWCNT concentration increases, there is a decline in the average MnO_2 aggregation thickness, with this thickness potentially impacting the specific capacitance of the resulting device.

F.EN01.06.12

Emergent Polar Vortex and Light Switching Behavior in Nanolayered $SrTiO_3/PbTiO_3$ Crystal Ken-ichi Nomura[1], Thomas Linker[1], Rajiv Kalia[1], Aravind Krishnamoorthy[1], Aiichiro Nakano[1], Kohei Shimamura[2], Fuyuki Shimojo[2], Subodh C. Tiwari[1] and Priya Vashishta[1]; [1]University of Southern California, United States; [2]Kumamoto University, Japan

Oxide perovskite is an excellent platform for energy, sensing, and electronics applications, and their dielectric property has been extensively studied to date. Recently, superlattices of dielectric (*e.g.* $SrTiO_3$) and ferroelectric (*e.g.* $PbTiO_3$) materials have been shown to exhibit various emergent properties. An example is a newly discovered materials state of which could overcome fundamental limitations on the power consumption of field-effect transistors. Another emergent property is novel topological states of polarization such as vortex-antivortex arrays and with quantized skyrmion number. The formation of the polarization structures involves nanometric domains with opposite polarization orientation separated by domain walls (DWs). Highly complex DW characteristics as well as DW interactions dictates the design and control of functional ferroelectric devices. Furthermore, these topological phases can be switched on and off by ultrafast light pulses, opening up a fascinating opportunity for light-activated pathways to thermally-inaccessible and emergent metastable states. The scientific challenge here is to understand the intricate interplay between lattice polarization, strains in complex superlattice and polarization-vortex geometries, and excited electrons which triggers the light-induced structural transitions from first principles.
In this talk, I will discuss non-adiabatic quantum molecular dynamics (NAQMD) simulations of light switching behavior of topological states in a $SrTiO_3/PbTiO_3$ superlattice, as well as artificial neural network (ANN) MD simulations to study the structure and dynamics of polar vortex arrays encompassing sufficient length scales to represent realistic supercrystalline dimensions.
This work was supported as part of the Computational Materials Sciences Program funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, under Award Number The simulations were performed at the Argonne Leadership Computing Facility under the DOE INCITE and Aurora Early Science programs and at the Center for High Performance Computing of the University of Southern California.

F.EN01.06.13

Lattice Dynamics and Raman Spectrum of $BaZrO_3$ Constance Toulouse and Mael Guennou; Université du Luxembourg, Luxembourg

$BaZrO_3$ is one of the end-members of remarkable perovskite systems: the binary $Ba(Zr,Ti)O_3$, studied for its relaxor-to-ferroelectric crossover, and the pseudo-ternary $(Ba,Ca)(Ti,Zr)O_3$, identified as promising for lead-free piezoelectrics. Pure $BaZrO_3$ exhibits the simple cubic structure down to 2 K, but theoretical DFT studies show that the cubic phase is slightly unstable, with an unstable phonon mode that should give rise to an antiferrodistortive transition driven by octahedral tilts. It has been also suggested that such distortions exist as distorted nano-domains. Experimentally, because of its very high melting point, investigations of $BaZrO_3$ have been mostly limited to polycrystalline samples. Here, we revisit its structure and properties using recently grown single crystals. In particular, we studied the unstable phonon mode by neutron scattering, and performed Raman measurements in a wide range of temperatures and pressures (up to 20 GPa). With the support of detailed

calculations of the lattice dynamics, we show that the Raman spectrum does not confirm the hypothesis of distorted nano-domains, but instead can be explained by second-order scattering.

F.EN01.06.16
Cellulose Nanoparticles in Energy Storage Applications Prathima P. Tumkur and Govindarajan Ramesh; Norfolk State University, United States

In recent years, environmentally friendly supercapacitors are gaining importance amongst researchers due to environmental concerns. Cellulose is one of the environmentally friendly biomaterials having properties such as renewability, degradability, biocompatibility, and costeffectiveness that has drawn a considerable amount of attention in the energy applications. In the present work, chemically synthesized cellulose nanoparticles were used in the energy storage applications to develop a supercapacitor. A mixture of carbon and cellulose nanoparticles was used as the electrode materials which were coated on a stainless-steel disk and assembled in a coin cell to develop a supercapacitor. Various electrolytes were used in the assembly to determine the best suitable one to obtain improved specific capacitance with large cyclic stability.

F.EN01.06.17
Late News: Controlled Synthesis, Piezoelectric, Magnetic and Dielectric Characterization of Novel Europium Titanate Nanoscale Structures—Implications for Energy Storage and Transfer Benard Kavey and Gabriel Caruntu; Central Michigan University, United States

Europium titanate is known to crystalize in the pyrochlore crystal structure with the general formula $A_2B_2O_7$. Within the crystal structure, the A-site cations are occupied by Eu^{n+} ions whereas the B-sites are occupied by Ti^{n+} ions in which the spins of the atoms are arranged on the vertices of tetrahedrons linked together at their corners. The high degree of freedom of rotation and vibration in the three-dimensional framework of tetrahedrons allows for a stronger spin interaction in the crystal lattice. The result of this interaction brings about a variety of magnetic properties that largely depends on the A-site cations, in this case, Eu^{n+} ions. In this work, novel piezoelectric europium titanate nanorods have been synthesized by using a simple solvothermal route in the temperature range 160-180 ºC. TEM micrographs of the as-prepared samples show nanorods with lengths ranging from 0.3 to 1.2 µm and an average diameter of 40±5 nm. The nanorods become more elongated but rather thinner (length range = 0.5 – 1.6 µm, and diameter = 10±5 nm) when the as-synthesized powder was annealed at 800 ºC. Powder X-ray diffraction pattern of the nanorods showed pure and highly crystalline pattern consistent with the diffraction patterns seen in $Eu_2Ti_2O_7$ nanocrystals. Dielectric spectroscopy of the pelletized $Eu_2Ti_2O_7$ revealed high-k dielectric constant up to e = 4000 at room temperature. In this study, scanning probe microscope was used to measure the magnetic interactions in the solution-processed $Eu_2Ti_2O_7$ nanorods thin-film. AFM topography images showed that the fabricated nanocrystals thin-film have an average thickness of 180 nm on a silicon substrate. The corresponding magnetic force microscope (MFM) images, were obtained my raising the magnetized MFM probe by 25 nm (delta height) above the sample surface in the tapping/lift mode. Since the probe tip uniformly scans at a height of 25 nm above the sample surface, the topography signal of the sample surface was drastically minimized allowing for the magnetic interactions to be mapped. This method allowed for the detection of the nanoscopic magnetic domains by measuring the interaction between the cantilever tip and sample surface. The widespread magnetic interactions can be visibly seen as a change in contrast (phase shift) in the amplitude and phase images.

Late News: MOCVD of Functional Dy-Doped BiFeO3 Film Grown on Single Crystal Quentin Micard[1], Giacomo Clementi[2], Ausrine Bartasyte[2], Paul Muralt[3], Guigliemo G. Condorelli[1] and Graziella Malandrino[1]; [1]University of Catania - INSTM, Italy; [2]FEMTO-ST Institute, University of Bourgogne Franche-Comté, France; [3]EPFL, Switzerland

The deposition of $BiFeO_3$ has been widely investigated in the recent years. Among multiferroic materials $BiFeO_3$ is of a special interest since its ferroelectric and magnetic transition temperatures are well above the room temperature ($T_C \approx 1100$ K and $T_N \approx 650$ K) [1]. Depositions of $BiFeO_3$ films by chemical routes: sol-gel, chemical solution deposition (CSD) and physical methods: sputtering, pulsed laser deposition (PLD) on single crystals such as $SrTiO_3$ or $LaAlO_3$ are well established. Despite its major role in industry MOCVD process is not as much investigated as other deposition techniques, but it has the major advantage to be easily scaled up. Recent works have been focused on A-site doping with rare-earth ions [2].

This work reports a simple MOCVD process for Dy-doped $BiFeO_3$ thin films on conductive Nb-doped $SrTiO_3$ (100) substrates. A multicomponent mixture composed of $Bi(phenyl)_3$, $Dy(hfa)_3$diglyme and $Fe(tmhd)_3$ (phenyl = $–C_6H_5$, H-hfa = 1,1,1,5,5,5-hexafluoro-2,4-pentanedione, diglyme = 1-methoxy-2-(2-methoxyethoxy)ethane, H-tmhd = 2,2,6,6-tetramethyl-3,5-heptandione), has been used as precursor source. Nb:$SrTiO_3$ is acting simultaneously as a substrate and a bottom

electrode, top gold electrodes have been sputtered after film deposition.

The piezoelectric, pyroelectric, and ferroelectric properties strongly depend on the structural and compositional properties of the deposited film with attention to the Dy doping. This correlation has been done using X-ray diffraction (XRD), for the structural characterization, field-emission scanning electron microscopy (FE-SEM), atomic force microscopy (AFM), and energy dispersive X-ray (EDX), X-ray photoelectron spectroscopy (XPX) analyses for the morphologic and chemical characterizations, respectively. For the functional study, the permittivity, piezo-, pyro- and ferro-electric response of deposited films have been investigated by impedance spectroscopy, Piezoelectric Force Microscopy (PFM), pyroelectric measurement and P-V loop, respectively. Significant correlation between Dy doping and film properties have been observed and promising pyro-electric coefficients were measured.

Late News: Synthesis of Novel Lithium Adducts as Precursors for Lithium Niobate Films by DLI-MOCVD Nishant Peddagopu[1], Patrizia Rossi[2], Paola Paoli[2], Ausrine Bartasyte[3] and Graziella Malandrino[1]; [1]INSTM, University of Catania, Italy; [2]University of Florence, Italy; [3]University of Franche-Comté, France

Lithium niobate ($LiNbO_3$) nanomaterials have recently attracted considerable attention due to their wide range of applications in the fields of ferroelectrics, piezoelectrics, and nonlinear optics. This material has been referred to as the "silicon of photonics" due to its exceptional optical properties. Applications for quantum photonics, surface acoustic wave devices, ferroelectric based devices, etc. require the availability of $LiNbO_3$ in thin-film form. To this aim, various techniques have been applied such as capillary liquid epitaxial technique [1], RF- magnetron sputtering [2], spin-coating [3], and metalorganic chemical vapor deposition (MOCVD) [4]. MOCVD represents one of the most appealing processes in view of its easy scalability, but its application requires the use of precursors with appropriate mass transport properties. Despite these promising advantages, industrial applications of an MOCVD process are still limited, likely because the commercial availability of starting molecular compounds is insufficient. Very few lithium precursors are known for vapor phase processes, either MOCVD or atomic layer deposition.
In this work, we report on the syntheses, through a single-step reaction, of novel adducts of lithium hexafluoroacetylacetonato {Li(hfa)} with polyethers (monoglyme = $\{CH_3OCH_2CH_2OCH_3\}$, diglyme = $\{CH_3O(CH_2CH_2O)_2CH_3\}$, triglyme = $\{CH_3O(CH_2CH_2O)_3CH_3\}$ and tetraglyme $\{CH_3O(CH_2CH_2O)_4CH_3\}$ [5]. They have been characterized by elemental analyses, FT-IR spectroscopy, ^1H, and ^{13}C NMR. Single crystal X-ray diffraction studies provide evidence of interesting coordination moieties [7]. Lithium niobate films have been deposited on sapphire and Si using direct liquid injection (DLI-) MOCVD reactor. X-ray diffraction and scanning electron microscopy characterizations have allowed assessing the film quality.
The mass transport properties of these adducts have been investigated through thermogravimetric (TG) analysis. The TG curve of the "Li(hfa)monoglyme" shows a step mass loss with a residue of 6% at 338 ^oC. Thermal analysis data revealed a discrete behavior, when precursors are used in a suited temperature range, regarding conventional MOCVD applications, while its solubility and clean decomposition make these complexes interesting precursors for liquid assisted processes such as liquid-delivery and aerosol-assisted MOCVD or sol-gel applications.
The depositions have been carried in a pulsed liquid injection MOCVD reactor using the different lithium precursors and a correlation between the precursor nature and film properties have been derived.

Novel Bi-Based Photocatalysts with Unprecedented Visible-Light-Driven Hydrogen Production Rate: Experimental and DFT Insights Nageh K. Allam; American University in Cairo, Egypt

Green and efficient energy technologies are a key point where nanoscience could make a difference in the paradigm shift from fossil fuels to renewable sources. One attractive possibility is the utilization of solar energy to obtain electricity or chemical fuel based on the ability of semiconductor nanomaterials to function as photocatalysts promoting various oxidation and reduction reactions under sunlight. We report on a novel class of Bi-based photocatalysts for hydrogen production via water splitting. A screening DFT investigation was performed on the $Bi_2(MO_4)_3$ (M= Cr, Mo, and W) systems. The $Bi_2(CrO_4)_3$ system exhibits the smallest bandgap energy, the highest dielectric constant, and the highest absorption in the visible region among the other counterpart materials. Consequently, $Bi_2(CrO_4)_3$ nanoparticles were synthesized via a simple one-pot method at room temperature and characterized by XRD, XPS, DRS, FE-SEM, HR-TEM, and Raman spectroscopy. The as-prepared yellow $Bi_2(CrO_4)_3$ nanoparticles exhibited direct bandgap energy of 2.45 eV. The photoactivity of the as-prepared $Bi_2(CrO_4)_3$ nanoparticles was tested toward the photocatalytic hydrogen production, where reasonable rates of 522.44, 174.15, and 88.24 µmol/g/h were achieved under UV, AM 1.5, and visible irradiations, respectively in the absence of any hole scavengers. Those rates are higher than those reported for Bi-based photocatalysts.

Thermal–Stimulated Evolution of Structural and Optical Properties of Hafnia Films Co-Doped with Si, N and Nd Grown by Magnetron Sputtering Larysa Khomenkova[1,2], Tetyana V. Torchynska[3], Nadiia Korsunska[1], Leonardo G. Vega Macotela[4], Oleksandr Melnichuk[5] and Fabrice Gourbilleau[6]; [1]V. Lashkaryov Institute of Semiconductor Physics at NASU, Ukraine; [2]National University "Kyiv-Mohyla Academy, Ukraine; [3]Instituto Politécnico Nacional, Mexico; [4]Instituto Politecnico Nacional, Mexico; [5]Mykola Gogol State University, Ukraine; [6]CIMAP, UMR CNRS/CEA/ENSICAEN/UNICAEN, France

Hafnium oxide and its silicates are considered mainly as gate dielectrics owing to their high dielectric constant. Recently, their ferroelectric properties were discovered, whereas optical application of these materials was rarely addressed in spite of promised optical parameters and mechanical and thermal stability. Usually, CVD or ALD approaches are used for the fabrication of hafnia-based films. At the same time magnetron sputtering was considered only by some research groups. In this work, we report on the utility of reactive magnetron sputtering for the fabrication of composite thin films based on HfO_2 co-doped with Si, N, and Nd ions simultaneously.
The evolution of structural and optical properties of such films with annealing temperature was investigated by means of the scanning electron microscopy, energy-dispersive X-ray spectroscopy, X-ray diffraction, Raman scattering, and photoluminescence techniques. It is observed that sputtering of HfO_2-Si-Nd composed target in argon-nitrogen plasma allowed producing homogeneous, dense and smooth films. The analysis of film properties with annealing temperature revealed the stability of film structure up to 950°C.
The light emission in the visible and IR spectral range was detected. It was found that bright Nd^{3+}-related emission can be achieved at lower temperatures (about 950°C) contrary to that reported for Nd-doped Si-SiO_2 or Si-Si_3N_4 materials. The Nd^{3+} PL intensity correlates with the evolution of HfO_2 monoclinic phase. It is shown that the excitation channel of $Nd3_+$ ions under non-resonant excitation involves host defects contained nitrogen ions. The desorption of nitrogen at high annealing temperature (1100°C) via the formation of volatile NO, as well as the formation of the Nd silicate phase results in the quenching of Nd^{3+} photoluminescence. This complex approach used for investigation of our films allowed demonstrating the utility of reactive magnetron sputtering for the fabrication of thin films with stable chemical composition and structure (up to 950°C). These results can be attractive for future applications of the hafnium silicate films (un-doped and doped with rare-

earth ions) as emitting elements or waveguides.

Strategy to Choose Best Building Blocks for Efficient Triboelectric Generator Devices Linards Lapčinskis, Kaspars Malnieks, Artis Linarts, Māris Knite and Andris Sutka; Riga Technical University, Latvia

TEG devices have potential to satisfy growing energy needs in portable electronics and sensors providing a clean alternative to conventional batteries.[1] TEG devices are produced from cheap, lightweight, flexible, widely used polymer materials and offer promise to capture neglected and unutilized forms of mechanical energy. TEG device consists from two conductive electrodes from which at least one is covered with polymer insulator film.[1] The two electrodes in TEG are connected by outer circuit and upon electrode oscillation surface charge on polymer layers and electric potential is created that drive electrons to flow between two electrodes in order to balance this electric potential difference. TEG devices can be operated in different modes – vertical separation, sliding, rotating, single electrode etc.[2] but the key feature for high TEG efficiency is surface charge from contact electrification.[3]
Different mechanisms are responsible for contact electrification and depend on material used. It is well demonstrated, that on metal-metal, metal-semiconductor or semiconductor-semiconductor contact the electron transfer occurs,[4,5] but this is not so obvious for polymer insulators.[6] The three mechanisms for polymer insulator contact electrification are considered – electron transfer,[7] ionic transfer,[6] and covalent bond cleavage.[8] Electron transfer between polymers is doubtful, because there are no available free electrons in insulators. Usage of the term "effective work function" in connection to the driving force for charge exchange between polymer insulators is also questionable even if the polymer is contacted with metal.[6] Ion exchange between contacted polymer insulators has been considered, because water under ambient conditions is adsorbed even on hydrophobic polymers.[9] The water layers on contacted surfaces fuse together upon contacting and as different polymer materials may have different affinity towards cations and anions in water, the imbalance between ions form during separation, thus creating surface charge.[6] However, it has been proven, that contact electrification of polymer insulators also occurs in complete absence of water.[10]
In our work we show that polymer contact-electrification can be predicted using their cohesive energy density. This allows us to select the most suitable materials as the building blocks for efficient TEG devices.

Characterization of Various High k Gate Dielectric Thin Films for TFT Applications Kelsea Yarbrough, Sangram K. Pradhan and Messaoud Bahoura; Norfolk State University, United States

Traditional dielectric materials such as silicon dioxide (SiO_2) is the first choice and mostly used in many electronic devices including Metal Oxide Semiconductor Field Effect Transistors, Thin Film Transistors, and VLSI technology. However, SiO_2 has several disadvantages that researchers are currently looking for alternatives. Scaling down electronics are the most popular device approach where SiO_2 will not be able to fit in these ultralow dimensional adjustments. One approach to scaling down electronics, while sustaining adequate dielectric properties is incorporating high k dielectrics. High k dielectrics refer to materials with a high dielectric constant, which denotes the material ability to store an electrical charge.
SiO_2 generally has a dielectric constant value of 4, while high k dielectrics have a dielectric constant greater than approximately 10. Noteworthy high k dielectrics include Hafnium Oxide (HfO_2), Zirconium Oxide (ZrO_2), and Aluminum Oxide (Al_2O_3). In this study, we perform important characterization techniques to analyze HfO_2, ZrO_2, and Al_2O_3 for the possible replacement of SiO_2. These high k dielectric thin films exhibited leakage currents lower than 9.45×10^{-11} and with a thin film roughness of less than .5 nm. These high-quality high k dielectrics thin films were grown by Atomic Layer

Deposition on n-type silicon at a different temperature and constant thickness for premise characterization. The effect of temperature on surface morphology, crystalline orientation, and dielectric properties were analyzed through Atomic Force Microscopy (AFM), X-ray Diffraction (XRD), Keithley 4200 SCS, and Four Point Probe measurement system. AFM provided thin film roughness, grain size, and surface morphology for thin films. XRD provided the crystalline orientation of these high k dielectrics with the effect of temperature. Keithley 4200 was used to show and calculate the dielectric properties including; dielectric constant, I-V plots (leakage current), and C-V plots. Lastly, Four Point probe measurement system provided electrical properties for these high k dielectrics. The present work will provide valuable scientific input dielectric performance for the improvement of TFT devices.

Mechanically Robust PVDF/Isocyanate-Treated Graphene Oxide Composite Nanofiber and Its Piezoelectric Sensor Applications Madeshwaran Sekkarapatti Ramasamy and Byungki Kim; Korea University of Technology and Education, Korea (the Republic of)

Graphene, the two dimensional material with sp^2-hybridized carbon atoms arranged in honeycomb-like structure has attracted greatest research interests because of their excellent mechanical and electrical properties. In particular, graphene have been considered as one of the most promising reinforcing nanofillers for developing cost-effective, high performance polymer composites. However, their main drawback is associated with their poor solution processability in organic solvents and agglomeration in polymer matrix due to their Van der Waals forces. Graphene oxide (GO), derived from acidic oxidation of natural graphite possesses abundant oxygen containing functionalities exhibit good solution processability, and therefore, receiving attention as precursor to the graphene-based nanofillers. On the other hand, poly(vinylidene fluoride) (PVDF) have been actively applied in piezoelectric sensors and nanogenerators because of their electroactive properties and flexibility. Generally, PVDF present five crystalline phases such as, α, δ, β, γ and ε, among them, β-phase PVDF with TTTT conformation shows the best piezoelectric properties, because all the dipoles are arranged parallel which resulted in highest dipole moment per unit cells. Incorporating GO into PVDF matrix can promote the formation of preferred β-phases owing to the interaction between the oxygen functionalities of GO and dipoles of the PVDF chains. In addition, the intrinsic high mechanical properties of GO can also enhance the mechanical properties of PVDF matrix. However, in most of the polymer composite systems, the strength and stiffness increased with the addition of nanofillers, meanwhile, the toughness decreased due to reduction in strain at break, which often restricts their applications in stretchable and flexible electronics. Herein, we report a method for fabricating PVDF/GO composite nanofibers with significantly enhanced mechanical strength and modulus without losing its toughness/stretchability. Isocyanate treated GO (i-GO) nanosheets were incorporated as nanofillers into PVDF nanofibers (PVDFNFs) using solution blending and electrospinning techniques. i-GO exhibit strong interfacial interaction with PVDF due to its reduced hydrophilicity and excellent dispersibilty in organic solvents. FTIR results revealed that the addition of i-GO induce the formation of PVDFNFs with high content of electroactive phases. Interestingly, the tensile strength, modulus and as well as strain-at-break increased with the addition i-GO. Furthermore, the composites displayed enhanced piezoelectric outputs than that of reference PVDFNFs during the static load analysis. The enhanced performance of the composites can be attributed to the strong interaction between i-GO and PVDF achieved through incorporation of chemically modified GO. The reported composites in this study hold a great potential in the field of flexible and stretchable piezoelectric sensors and nanogenerators.

Dramatic Increase in Polymer Triboelectrification by Transition from a Glassy to Rubbery State Artis Linarts, Andris Sutka, Kaspars Malnieks and Linards Lapčinskis; Riga Technical University, Latvia

Triboelectric nanogenerators (TENG) are intriguing energy harvesting devices that convert mechanical energy into electricity and could power small portable devices or charge batteries [1]. Here we report contact electrification of glassy polymers at different temperatures and observing a dramatic three orders of magnitude increase in surface charge when passing the transition temperature to a rubbery state. Transition is accompanied by a larger force required for separation due to material softening and increased stickiness. This enhances material transfer during contact/separation cycles and indicates covalent bond breaking as the mechanism for increased polymer triboelectrification. Undeniably, surface roughness plays a great role

in contact electrification, however in our study its impact is overrated when compared to the influence of physical properties.

Matching the Directions of Electric Fields from Triboelectric and Ferroelectric Charges in Nanogenerator Devices for Boosted Performance Kaspars Malnieks, Andris Sutka, Linards Lapčinskis and Artis Linarts; Riga Technical University, Latvia

The field related to triboelectricnanogenerator (TENG) devices is emerging rapidly. Many original and creative TENG concepts have been presented in the literature for harvesting mechanical energy and converting it into electricity (Lee et al., 2019). The working principle of TENG devices is straightforward. Due to electrode oscillation or movement, a potential difference is created, which causes a current flow in the external electric circuit. TENG devices can be integrated into fabrics, wearables, interior objects, membranes (to harvest energy from sound), and even implantable devices.
To enhance the performance of TENG, different approaches have been used. The most obvious way is to increase the specific contact area via nanostructuring (Zhang et al.). Another possibility is the modification of surface or physicochemical properties of the triboelectric material (Sutka et al., 2019). The performance can be also enhanced by using ferroelectric polymer or composite films as the contacting surfaces (Bai et al.). State-of-the-art performance of ferroelectric material-based TENG devices can be expected when the ferroelectric material layers on contacting sides of the device are inversely polarized (Sutka et al). However, previous works related to TENG devices based on ferroelectric materials overlook the dipole that forms between the triboelectric surface charges on contacting surfaces. As soon as we consider this additional factor, it follows that the electric field direction from ferroelectric dipoles should match the direction of the electric field from triboelectric surface charge to achieve maximum electric field strength and electrostatic induction.
Polydimethylsiloxane (PDMS), ethylene-vinyl acetate copolymer (EVA), poly(vinyl acetate) (PVAc), and poly(methyl methacrylate) (PMMA) were used in our studies to prepare TENG devices. The polymer films were spin coated on indium tin oxide (ITO) conductive electrode and contacted against another ITO. The polymer films were given ferroelectric properties by adding 7.5 vol% $BaTiO_3$ nanoparticles. The sign of triboelectric surface charges formed on pure polymers after contacting against ITO was determined by measuring the current between the underlying electrode and the ground in Faraday cup mode. Polymers PDMS, PVAc, and EVA obtain a negative charge on their surface whereas for PMMA a positive charge is observed when contacted ITO. The sign of the net triboelectric charge did not change when $BaTiO_3$ nanoparticles were incorporated into the polymers. All poled $BaTiO_3$/polymer composites exhibit piezoelectric properties. The piezoelectric charges of 2.9 pC/cm^2 , 10.9 pC/cm^2 , 3.7 pC/cm^2 , and 2.4 pC/cm^2 were measured for BaTiO3/EVA, BaTiO3/PDMS, BaTiO3/PVAc, and BaTiO3/ PMMA composites, respectively. The higher piezoelectric response of $BaTiO_3$/PDMS could be attributed to its larger deformability under the constant loading force. Composite layer in each of these TENG devices was tested as non-poled and also positively and negatively poled, so that ferroelectric dipole is matched and mismatched with the previously determined surface charge.
As example $BaTiO_3$/PDMS TENG device performed excellently, and the output was superior to any other presented in this study. The peak open-circuit voltage (V_{OC}) of device with matched dipoles reached 460 V, instant energy and power densities of this TENG device reached 9.7 mJ/m^2 and 143.2 mW/m^2 , respectively. For comparison, a TENG device from the same polymers without $BaTiO_3$ NPs shows V_{OC} as small as 16 V and three orders of magnitude smaller energy and power densities of 0.012 mJ/m^2 and 0.104 mW/m^2. Also, the TENG device from the same inversely polarized composite films but with mismatched dipoles exhibited significantly lower output—V_{OC} of 300 V and instant energy and power densities of 4.0 mJ/m^2 and 91.6 mW/m^2 from the same contacting area.

Towards Engineering Mixed Oxide Thin Films Using a Genomic Approach—A Case Study of Ta_2O_5-Based Coatings Mariana A. Fazio, Le Yang and Carmen Menoni; Colorado State University, United States

Mixed oxide thin films have found their way into numerous applications ranging from high-k dielectrics to gas sensors to optical coatings with tunable properties. The field is vast and most research conducted on mixed oxide coatings has been approached from the experimental side, leading to an arduous and time-consuming trial-and-error process. In the last decade, emerging computational methods have been conductive to accelerated materials discovery. In particular, the genomics approach behind open access initiatives such as the Materials Project aims to provide materials scientists with a new set of tools: large databases of computational calculations of known and predicted materials. This web-based database leads the way for *in silico* material design that can guide experimentation.

In this work, we carried out an extensive study of tantala (Ta_2O_5) amorphous thin films doped with Al, Si, Sc, Ti, Zn, Y, Zr, Nb and Hf grown by reactive sputtering. The influence of the dopant and post-deposition annealing on the film properties and structure was characterized by grazing-incidence x-ray diffraction, x-ray photoelectron spectroscopy and spectroscopic ellipsometry. Using the Materials Project database, compositional phase diagrams based on density functional theory calculations were constructed for all mixed oxide systems and the annealing process was evaluated via grand potential phase diagrams with varying oxygen chemical potential. The computational calculations agree well with experimental results, predicting formation of ternary compounds after annealing in some systems. When no ternary phase can be stabilized, the dopant acts as an amorphizer agent increasing the crystallization temperature of tantala. In the case where the dopant forms an oxide with similar formation enthalpy to tantala we experimentally observed effects of oxygen competition that lead to formation of phases that are predicted be unstable. Overall, the predictions based on the Materials Project database provide valuable information for tailoring dopant type and concentration in mixed oxide thin films towards specific applications that might require increased thermal stability or to adjust processing conditions for ternary oxide production.

F.EN01.06.11

Characterization of MnO_2-MWCNT Nanocomposite Morphology for Supercapacitor Applications Rian Tucci[1,2], Thomas Sadowski[1,2], Rahul Singhal[3,2] and Christine Broadbridge[1,2]; [1]Southern Connecticut State University, United States; [2]Connecticut State Colleges and Universities (CSCU) Center for Nanotechnology, United States; [3]Central Connecticut State University, United States

Supercapacitors, with long cycle lives and long-term efficiency, have potential to become an appealing alternative to lithium-ion batteries; however, the specific energy of these devices lags well behind current state-of-the-art lithium-ion batteries. Nevertheless, numerous opportunities exist to optimize supercapacitors through the manipulation of the structure and morphology of novel materials. The implementation of hybrid supercapacitors, a device which combines a pseudo-capacitor with an electrical double layer capacitor, are of interest because material composites have greater charge storage capabilities than their components alone. The most effective hybrid capacitors for charge storage are ones possessing high specific capacitance (capacitance per unit mass). The optimization of a composite for high specific capacitance requires changes to intrinsic material properties, either by changing chemical or physical structures. The current study was aimed at the manipulation of the nanostructure of a manganese dioxide (MnO_2) – multi walled carbon nanotube (MWCNT) composite material via modulation of MWCNT composite concentration. The composite nanostructure was characterized using transmission electron microscopy (TEM), x-ray diffraction (XRD), charge-discharge tests, and cyclic voltammetry. Ten composites, each with different initial MWCNT concentrations, were synthesized via hydrothermal method. All ten concentrations were imaged via TEM. Of those ten, three were chosen to be characterized with electrochemical methods and XRD: 4.8%, 16.9%, and 33.7% mass MWCNT. TEM imaging reveals a nanostructure of polycrystalline MnO_2 adsorbed onto MWCNT. Results indicated that, on average, the thickness of MnO_2 coating decreased as percent mass MWCNT increased. At 33.7% MWCNT mass, MWCNT agglomeration became hard to mitigate and dominated MnO_2 adsorption structure. This is supported by XRD of 33.7% sample showing emergence of (002) plane of CNT, indicating widespread non-coating of MnO_2 in composite. Charge-discharge tests were conducted in with a 1 V window at 0.5, 1, and 2 A/g. Charge-discharge tests with 1 A/g indicate highest specific capacitance for 16.9% mass MWCNT at 150 F/g, compared to 70 and 45 F/g with 4.8% and 33.7% mass MWCNT, respectively. Preliminary results indicate that as MWCNT concentration increases, there is a decline in the average MnO_2 aggregation thickness, with this thickness potentially impacting the specific capacitance of the resulting device.

Emergent Polar Vortex and Light Switching Behavior in Nanolayered $SrTiO_3$/$PbTiO_3$ Crystal Ken-ichi Nomura[1], Thomas Linker[1], Rajiv Kalia[1], Aravind Krishnamoorthy[1], Aiichiro Nakano[1], Kohei Shimamura[2], Fuyuki Shimojo[2], Subodh C. Tiwari[1] and Priya Vashishta[1]; [1]University of Southern California, United States; [2]Kumamoto University, Japan

Oxide perovskite is an excellent platform for energy, sensing, and electronics applications, and their dielectric property has been extensively studied to date. Recently, superlattices of dielectric (*e.g.* $SrTiO_3$) and ferroelectric (*e.g.* $PbTiO_3$) materials have been shown to exhibit various emergent properties. An example is a newly discovered materials state of which could overcome fundamental limitations on the power consumption of field-effect transistors. Another emergent property is novel topological states of polarization such as vortex-antivortex arrays and with quantized skyrmion number. The formation of the polarization structures involves nanometric domains with opposite polarization orientation separated by domain walls (DWs). Highly complex DW characteristics as well as DW interactions dictates the design and control of functional ferroelectric devices. Furthermore, these topological phases can be switched on and off by ultrafast light pulses, opening up a fascinating

opportunity for light-activated pathways to thermally-inaccessible and emergent metastable states. The scientific challenge here is to understand the intricate interplay between lattice polarization, strains in complex superlattice and polarization-vortex geometries, and excited electrons which triggers the light-induced structural transitions from first principles.
In this talk, I will discuss non-adiabatic quantum molecular dynamics (NAQMD) simulations of light switching behavior of topological states in a $SrTiO_3/PbTiO_3$ superlattice, as well as artificial neural network (ANN) MD simulations to study the structure and dynamics of polar vortex arrays encompassing sufficient length scales to represent realistic supercrystalline dimensions.
This work was supported as part of the Computational Materials Sciences Program funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, under Award Number The simulations were performed at the Argonne Leadership Computing Facility under the DOE INCITE and Aurora Early Science programs and at the Center for High Performance Computing of the University of Southern California.

Lattice Dynamics and Raman Spectrum of $BaZrO_3$ Constance Toulouse and Mael Guennou; Université du Luxembourg, Luxembourg

$BaZrO_3$ is one of the end-members of remarkable perovskite systems: the binary $Ba(Zr,Ti)O_3$, studied for its relaxor-to-ferroelectric crossover, and the pseudo-ternary $(Ba,Ca)(Ti,Zr)O_3$, identified as promising for lead-free piezoelectrics. Pure $BaZrO_3$ exhibits the simple cubic structure down to 2 K, but theoretical DFT studies show that the cubic phase is slightly unstable, with an unstable phonon mode that should give rise to an antiferrodistortive transition driven by octahedral tilts. It has been also suggested that such distortions exist as distorted nano-domains. Experimentally, because of its very high melting point, investigations of $BaZrO_3$ have been mostly limited to polycrystalline samples. Here, we revisit its structure and properties using recently grown single crystals. In particular, we studied the unstable phonon mode by neutron scattering, and performed Raman measurements in a wide range of temperatures and pressures (up to 20 GPa). With the support of detailed calculations of the lattice dynamics, we show that the Raman spectrum does not confirm the hypothesis of distorted nano-domains, but instead can be explained by second-order scattering.

F.EN01.06.15
Cellulose Nanoparticles in Energy Storage Applications Prathima P. Tumkur and Govindarajan Ramesh; Norfolk State University, United States

In recent years, environmentally friendly supercapacitors are gaining importance amongst researchers due to environmental concerns. Cellulose is one of the environmentally friendly biomaterials having properties such as renewability, degradability, biocompatibility, and costeffectiveness that has drawn a considerable amount of attention in the energy applications. In the present work, chemically synthesized cellulose nanoparticles were used in the energy storage applications to develop a supercapacitor. A mixture of carbon and cellulose nanoparticles was used as the electrode materials which were coated on a stainless-steel disk and assembled in a coin cell to develop a supercapacitor. Various electrolytes were used in the assembly to determine the best suitable one to obtain improved specific capacitance with large cyclic stability.

F.EN01.06.17
Late News: MOCVD of Functional Dy-Doped BiFeO3 Film Grown on Single Crystal Quentin Micard[1], Giacomo Clementi[2], Ausrine Bartasyte[2], Paul Muralt[3], Guigliemo G. Condorelli[1] and Graziella Malandrino[1]; [1]University of Catania - INSTM, Italy; [2]FEMTO-ST Institute, University of Bourgogne Franche-Comté, France; [3]EPFL, Switzerland

The deposition of $BiFeO_3$ has been widely investigated in the recent years. Among multiferroic materials $BiFeO_3$ is of a special interest since its ferroelectric and magnetic transition temperatures are well above the room temperature ($T_C \approx 1100$ K and $T_N \approx 650$ K) [1]. Depositions of $BiFeO_3$ films by chemical routes: sol-gel, chemical solution deposition (CSD) and physical methods: sputtering, pulsed laser deposition (PLD) on single crystals such as $SrTiO_3$ or $LaAlO_3$ are well established. Despite its major role in industry MOCVD process is not as much investigated as other deposition techniques, but it has the major advantage to be easily scaled up. Recent works have been focused on A-site doping with rare-earth ions [2].

This work reports a simple MOCVD process for Dy-doped $BiFeO_3$ thin films on conductive Nb-doped $SrTiO_3$ (100) substrates. A multicomponent mixture composed of $Bi(phenyl)_3$, $Dy(hfa)_3$diglyme and $Fe(tmhd)_3$ (phenyl = $–C_6H_5$, H-hfa = 1,1,1,5,5,5-hexafluoro-2,4-pentanedione, diglyme = 1-methoxy-2-(2-methoxyethoxy)ethane, H-tmhd = 2,2,6,6-tetramethyl-3,5-heptandione), has been used as precursor source. Nb:$SrTiO_3$ is acting simultaneously as a substrate and a bottom electrode, top gold electrodes have been sputtered after film deposition.

The piezoelectric, pyroelectric, and ferroelectric properties strongly depend on the structural and compositional properties of the deposited film with attention to the Dy doping. This correlation has been done using X-ray diffraction (XRD), for the structural characterization, field-emission scanning electron microscopy (FE-SEM), atomic force microscopy (AFM), and energy dispersive X-ray (EDX), X-ray photoelectron spectroscopy (XPX) analyses for the morphologic and chemical characterizations, respectively. For the functional study, the permittivity, piezo-, pyro- and ferro-electric response of deposited films have been investigated by impedance spectroscopy, Piezoelectric Force Microscopy (PFM), pyroelectric measurement and P-V loop, respectively. Significant correlation between Dy doping and film properties have been observed and promising pyro-electric coefficients were measured.

Late News: Controlled Synthesis, Piezoelectric, Magnetic and Dielectric Characterization of Novel Europium Titanate Nanoscale Structures—Implications for Energy Storage and Transfer Benard Kavey and Gabriel Caruntu; Central Michigan University, United States

Europium titanate is known to crystalize in the pyrochlore crystal structure with the general formula $A_2B_2O_7$. Within the crystal structure, the A-site cations are occupied by Eu^{n+} ions whereas the B-sites are occupied by Ti^{n+} ions in which the spins of the atoms are arranged on the vertices of tetrahedrons linked together at their corners. The high degree of freedom of rotation and vibration in the three-dimensional framework of tetrahedrons allows for a stronger spin interaction in the crystal lattice. The result of this interaction brings about a variety of magnetic properties that largely depends on the A-site cations, in this case, Eu^{n+} ions. In this work, novel piezoelectric europium titanate nanorods have been synthesized by using a simple solvothermal route in the temperature range 160-180 ºC. TEM micrographs of the as-prepared samples show nanorods with lengths ranging from 0.3 to 1.2 µm and an average diameter of 40±5 nm. The nanorods become more elongated but rather thinner (length range = 0.5 – 1.6 µm, and diameter = 10±5 nm) when the as-synthesized powder was annealed at 800 ºC. Powder X-ray diffraction pattern of the nanorods showed pure and highly crystalline pattern consistent with the diffraction patterns seen in $Eu_2Ti_2O_7$ nanocrystals. Dielectric spectroscopy of the pelletized $Eu_2Ti_2O_7$ revealed high-k dielectric constant up to e = 4000 at room temperature. In this study, scanning probe microscope was used to measure the magnetic interactions in the solution-processed $Eu_2Ti_2O_7$ nanorods thin-film. AFM topography images showed that the fabricated nanocrystals thin-film have an average thickness of 180 nm on a silicon substrate. The corresponding magnetic force microscope (MFM) images, were obtained my raising the magnetized MFM probe by 25 nm (delta height) above the sample surface in the tapping/lift mode. Since the probe tip uniformly scans at a height of 25 nm above the sample surface, the topography signal of the sample surface was drastically minimized allowing for the magnetic interactions to be mapped. This method allowed for the detection of the nanoscopic magnetic domains by measuring the interaction between the cantilever tip and sample surface. The widespread magnetic interactions can be visibly seen as a change in contrast (phase shift) in the amplitude and phase images.

Late News: Synthesis of Novel Lithium Adducts as Precursors for Lithium Niobate Films by DLI-MOCVD Nishant Peddagopu[1], Patrizia Rossi[2], Paola Paoli[2], Ausrine Bartasyte[3] and Graziella Malandrino[1]; [1]INSTM, University of Catania, Italy; [2]University of Florence, Italy; [3]University of Franche-Comté, France

Lithium niobate ($LiNbO_3$) nanomaterials have recently attracted considerable attention due to their wide range of applications in the fields of ferroelectrics, piezoelectrics, and nonlinear optics. This material has been referred to as the “silicon of photonics” due to its exceptional optical properties. Applications for quantum photonics, surface acoustic wave devices, ferroelectric based devices, etc. require the availability of $LiNbO_3$ in thin-film form. To this aim, various techniques have been applied such as capillary liquid epitaxial technique [1], RF- magnetron sputtering [2], spin-coating [3], and metalorganic chemical vapor deposition (MOCVD) [4]. MOCVD represents one of the most appealing processes in view of its easy

scalability, but its application requires the use of precursors with appropriate mass transport properties. Despite these promising advantages, industrial applications of an MOCVD process are still limited, likely because the commercial availability of starting molecular compounds is insufficient. Very few lithium precursors are known for vapor phase processes, either MOCVD or atomic layer deposition.
In this work, we report on the syntheses, through a single-step reaction, of novel adducts of lithium hexafluoroacetylacetonato {Li(hfa)} with polyethers (monoglyme = $\{CH_3OCH_2CH_2OCH_3\}$, diglyme = $\{CH_3O(CH_2CH_2O)_2CH_3\}$, triglyme = $\{CH_3O(CH_2CH_2O)_3CH_3\}$ and tetraglyme $\{CH_3O(CH_2CH_2O)_4CH_3\}$ [5]. They have been characterized by elemental analyses, FT-IR spectroscopy, ^{1}H, and ^{13}C NMR. Single crystal X-ray diffraction studies provide evidence of interesting coordination moieties [7]. Lithium niobate films have been deposited on sapphire and Si using direct liquid injection (DLI-) MOCVD reactor. X-ray diffraction and scanning electron microscopy characterizations have allowed assessing the film quality.
The mass transport properties of these adducts have been investigated through thermogravimetric (TG) analysis. The TG curve of the "Li(hfa)monoglyme" shows a step mass loss with a residue of 6% at 338 ºC. Thermal analysis data revealed a discrete behavior, when precursors are used in a suited temperature range, regarding conventional MOCVD applications, while its solubility and clean decomposition make these complexes interesting precursors for liquid assisted processes such as liquid-delivery and aerosol-assisted MOCVD or sol-gel applications.
The depositions have been carried in a pulsed liquid injection MOCVD reactor using the different lithium precursors and a correlation between the precursor nature and film properties have been derived.

Phosphorus-Based Anode Materials via Electrostatic Spray Deposition for High-Performance Lithium-Ion Batteries
Amin Rabiei Baboukani[1], Iman Khakpour[1], Vadym Drozd[2] and Chunlei Wang[1]; [1]Florida International University, United States; [2]Center for the Study of Matter at Extreme Conditions (CeSMEC), United States

In the past few years, due to rapidly increased global demand for energy storage devices such as advanced electronics, electric vehicles (EVs), and implantable medical devices, it is essential to develop novel materials for energy storage technologies. Lithium-ion batteries (LIBs) have been the most popular and commercially available energy storage devices. However, anodes of LIBs still suffer poor theoretical capacity of graphite (372 mAh g^{-1}). Recently, phosphorus as an anode material has attained much attention owing to its high theoretical capacity (2596 mAh/g) via Li_3P alloying formation. White P (WP), black P (BP), and red P (RP) are the main three allotropes of solid phosphorus. WP is not stable in the air, flammable, and very toxic, which impose safety concerns for LIBs. BP is the most thermodynamically stable form of phosphorus with an orthorhombic crystal structure. However, the synthesis of BP via high-pressure and high-temperature process is expensive, which restricts its practical application. Compare to WP and BP, RP is non-toxic, low cost, eco-friendly, and easy to handle, making RP a promising anode for LIBs. Nevertheless, the application of RP in LIBs is obstructed by two serious issues: low electrical conductivity of RP ($\sim 10^{-14}$ S cm^{-1}), and huge volume change (more than 300 %) during lithiation and delithiation causing the pulverization of the active materials which leads to significant capacity fading, and poor cycling performance. Compositing phosphorous with carbonaceous materials and construing stable architecture are the two main methods that have been evaluated to resolve the issues and improve the electrochemical performance of P-based electrode materials. Moreover, the chemical bond of P to the conductive matrix could contribute to the integrity of the electrode during cycling In this research, for the first time we developed a binder-free P-based anode materials with sulfurized polyacrylonitrile (SPAN) as functional polymer composite fabricated through ball-milling and electrostatic spray deposition (ESD) method. SPAN-based electrodes have shown attractive electrochemical performance such as good cycling life and Coulombic efficiency due to its chemical compatibility for energy storage devices. In addition, due to the low bonding energy of S-S (265 kJ mol-1) and its high reactivity to form additional chemical bonds with RP, the conductive SPAN could be an ideal composite to increase the conductivity and control the volume expansion of RP in LIBs. The electrochemical performance of the fabricated anode materials evaluated via electrochemical impedance spectroscopy, cyclic voltammetry, and galvanostatic charge/discharge tests. The RP-SPAN hybrid electrode exhibited excellent specific capacity up to 1605 mAh g^{-1} at 0.1 A g^{-1} at 100 cycles, which is one of the best reported performances among the RP-based

composite electrode in LIBs. Moreover, a specific capacity of 320 mAh g^{-1} was maintained at 3 A g^{-1}. Due to the SEM images, the hybrid electrode still maintains its microstructural integrity without obvious degradation after cycling, indicating that the volume change didn't affect the structural stability. Our results show that the ESD method is an effective approach to prepare RP-based composite with favorable morphology and composition in order to buffer mechanical stress and alleviate crack formation during cycling. The RP-SPAN hybrid delivered high specific capacity, most likely due to the synergetic effect of chemical bonding and improved kinetics. The developed anode material and its material and electrochemical characterizations will be discussed in detail at the conference.

F.EN06.07.03
Surface Modified Graphite Electrodes for Limiting Lithium Plating and Enabling Fast Charging of Li-Ion Batteries Killian Tallman[1], Bingjie Zhang[1], Shan S. Yan[2], Amy Marschilok[1,2], Kenneth Takeuchi[1], David Bock[2] and Esther Takeuchi[1,2]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

Lithium metal plating on graphite anodes has been identified as a mechanism contributing to diminished capacity retention of Li-ion batteries under conditions of repeated fast charge. Due to mass transfer limitations, instead of lithium ion insertion in the graphite anode Li metal can deposit on the graphite anode surface when the electrode is highly polarized. The result is inactive Li metal which limits cell cycle life and raises risk of internal short-circuits due to dendrite growth. The objective of this research was to mitigate Li-plating during fast charging by increasing the overpotential of Li-deposition via interfacial surface modification. The hypothesis tested was that deposition of Cu or Ni metal on the surface of graphite electrodes can increase the Li nucleation overpotential due to crystalline mismatch and suppress Li-plating.
Thin metal films of Cu or Ni were deposited on graphite anodes. The films were characterized by a variety of methods including atomic force microscopy, scanning electron microscopy, X-ray photoelectron spectroscopy and X-ray absorption near edge structure spectroscopy. Lithium ion cells with the treated graphite anodes as well as control cells were assembled and evaluated using galvanostatic cycling. Benefit in capacity retention for the treated electrodes was demonstrated. Further, Li-plating was quantified over a series of experiments and supported the electrochemical results. The findings of this study establish that with rational design of an electrode interface, the overpotential for Li-deposition can be modulated, providing a new conceptual approach for reducing Li-plating on graphite anodes.

Nanocomposite of SnO_2/CeO_2 Nanostructured Electrode for Efficient Li-Ion Storage Application Samuel Danquah, Messaoud Bahoura and Sangram K. Pradhan; Norfolk State University, United States

Cerium oxide (CeO_2) nanocomposite material for Li-ion battery is synthesized using hydrothermal method. To fabricate a hybrid nanostructure electrode, CeO_2 is coated on tin oxide (SnO_2) nanorods (NR), which is grown using a vapor-liquid-solid (VLS) technique on a steel substrate. The structure of SnO_2/CeO_2 nanocomposite was confirmed by X-ray diffraction (XRD), field emission scanning electron microscopy (FESEM). The surface morphology of the hybrid nanostructure electrode confirms that, single-crystalline SnO_2 nanorods are grown vertically with spine-like structures, a few microns in length, as evident from FESEM. The electrochemical performance of SnO_2/CeO_2 shows an enhanced charge storage capability. The coin cell shows improved capacity with a higher number of charging and discharging cycles. This SnO_2/CeO_2 hybrid composite electrode shows better specific capacitance value as compared to the pristine SnO_2 electrode and pristine CeO_2 electrode.

F.EN06.07.06
Nanoscale Three-Dimensional Imaging of Degradation in Composite Si-Containing Anodes Zoey Huey[1,2], Caleb Stetson[1,2], Sang-Don Han[1], Donal P. Finegan[1], Yeyoung Ha[1], Chun-Sheng Jiang[1], Andrew Norman[1], Steven DeCaluwe[2] and Mowafak Al-Jassim[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States

The use of silicon (Si) in the anodes of next-generation lithium ion batteries (LIBs) has the potential to dramatically improve electrochemical performance over current LIBs with graphite anodes, due to the higher specific capacity of silicon.[1] However, widespread implementation of Si-containing anodes is inhibited by issues such as significant volume expansion of Si during lithiation and an unstable solid-electrolyte interphase (SEI), resulting in unreliable performance and poor cycle life. Currently, composite anodes with both Si and graphite active materials are used to increase capacity and mitigate some of the limitations associated with Si. In composite electrodes with a heterogeneous distribution of components with varying electrical properties (including Si, graphite, conductive carbon additive, and binder), it is important to understand the local distribution of each component to correlate with electrochemical processes, particularly localized degradation and heterogeneous aging, and to optimize performance. The heterogeneous distribution of these components leads to localized lithiation, nonuniform SEI formation and material degradation, and complex electron transfer pathways,

which all impact anode cycling and performance.

To investigate Si-containing composite anodes in the nanoscale, we employ scanning spreading resistance microscopy (SSRM), a form of scanning probe microscopy (SPM) that probes local electronic resistivities. By examining the contrast in intrinsic electronic resistivity between the anode components, separate phases can be distinguished and understood within the composite structure. Previous work has been conducted on composite Si-graphite electrodes using SSRM, as well as with X-ray tomography, to study degradation after cycling.[2,3] SSRM is able to measure composite electrode components over a wide range of relative intrinsic resistivities with nanometer-scale resolution and a smaller sampling volume than X-ray based methods, making it ideal for distinguishing anode components and determining their spatial positions. This work studies the effects of electrochemical cycling on component distribution and aging by comparing the electrical and structural evolution of composite Si-graphite electrodes before and after charge-discharge cycling. Additionally, we compare the resistivity maps to STEM-EDS and EELS results for both pristine and cycled electrodes to understand chemical changes that occur within the observed structure. By analyzing structural and chemical changes that occur during cycling, we identify degradation mechanisms and potential design improvements to increase capacity and cycle life next-generation composite anodes.

Multiscale Modeling of Ni-Rich Cathode Materials—From Electrons, Ions, Atoms to Particles Yuqin Wu and Yue Qi; Michigan State University, United States

Ni-rich Li[Ni-Mn-Co]O_2 is a promising cathode material due to its high discharge capacity, high voltage and low cost, but its application is hindered by the poor thermal stability and low capacity retention. To guide the design of Ni-rich cathode materials, multiscale modeling analysis was used to determine its atomic structure, band structure, open-circuit voltage, and mechanical properties and to predict the critical size of Ni-rich cathode single particles that are mechanically stable. First, density functional theory (DFT) calculations were performed to identify the base structure of pure $LiNiO_2$ layered compounds based on three different space groups, namely Rm, C_2/m, and P_2/c. It was found the calculated band structures of the widely applied Rm structure of LiNiO2 is metallic, contrary to the experimentally reported insulating behavior. P_2/c structure, which allows a disproportionation of the oxidation state of Ni (Ni^{2+} and Ni^{4+}), is the most energetically stable and insulating layered structure of LiNiO2. Therefore, model structures representing Ni-rich NMC cathode materials were built by partially replacing Ni with Co or Mn in the base P_2/c $LiNiO_2$ structure. The electronic structure of model Ni-rich NMC cathode shows that Ni tends to be Ni^{3+} when neighboring with Co^{3+}, while becoming Ni^{2+} next to an Mn^{4+}. Based on the model Ni-rich cathode structures, the elastic constants and fracture energy were also computed from DFT. The information served as input to a continuum diffusion induced stress model to predict when a crack starts to propagate and leads to the fracture of a single Ni-rich NMC particle. The predicted results show good agreement with single-particle observations.

F.EN06.07.08
Enabling Lithium Metal Anode in Non-Flammable Phosphate Electrolyte with Electrochemically-Induced Chemical Reactions Haochuan Zhang, Jingru Luo, Miao Qi, Haoyi Li and Qi Dong; Boston College, United States

Lithium metal anode holds great promise in the next-generation battery but it suffers from great challenges in efficiency and safety. Previous research has developed various methods to mitigate these issues but most of them are still based on tradition flammable electrolyte systems. Here we demonstrate that reversible Li plating/striping process, which cannot be implemented in non-flammable phosphate electrolyte previously, can be realized by introducing oxygen as an additive in triethyl phosphate (TEP) electrolyte. The symmetric Li||Li cell can achieve more than 300 cycles at current density of 0.5 mA/cm^2 with O_2 existence. Mechanistic study reveals that the electrochemically induced chemical reactions between reactive O_2 species and TEP molecules alter the decomposition pathway of TEP. The possible products, Li_3PO_4/poly-phosphate thereby serve as beneficial SEI components to enable stable Li metal operation in non-flammable electrolyte. Demonstration of Li-O_2 and Li-ion battery also shows that it is promising to deploy phosphate-based electrolyte in future high-energy density batteries efficiently and safely.

Late News: A New Method for Evaluating Li-Ion Battery Anode Materials Based on Surface Compositional and Structural Characterization of Li Thermal Diffusion Jozef Ociepa, Paige Harford, Ryan Charlinski, Guenevere O'Hara and Bart Checinski; OCI Vacuum Microengineering Inc., Canada

There is a global effort to develop safer lithium-ion batteries with a high energy density and long lifetime. Material properties, their mutual interactions, and active interfaces are key factors in battery performance. Popular methods involve the mixing of different ingredients and development of a suitable fabrication process. Significant effort has been spent to understand the reaction mechanism of battery materials, but this is very challenging due to high system complexity. Different techniques have been developed to follow these reactions, and most significantly, the reactions between Li and electrode materials. Our team has developed a new method to characterize Li thermal diffusion and structural interaction on the surfaces of potential anode and cathode materials. This method is based on surface crystallographic and compositional characterization of deposited ultra-thin film of Li on potential single crystal anode material. For surface crystallography we are using Low Energy Electron Diffraction (LEED) and for composition Auger Electron Spectroscopy (AES). This characterization monitors Li diffusion into the electrode surface and changes in surface crystalline structure and composition providing data on Li interaction with the crystalline anode material structure. This dynamic interaction of Li is monitored at the nanoscale level and gives the direct response how Li atoms interact with the substrate. The diffusion of evaporated Li on single crystals of HOPG, Si(111)-(211)-(100), SiC-6H, Diamond and LiNbO3 have been performed. The results shows that HOPG is the excellent reference substrate for this method as Li diffuses at room temperature and surface crystallography of HOPG remains unchanged. The structural reaction of Li with Si is very strong causing LEED pattern to disappear and there is no Li diffusion at room temperature. The data for SiC-6H and LiNbO3 shows better Li diffusional behavior than on Si but not as good as on HOPG. This method of using a single crystal substrate and basic surface characterization techniques is providing simple nanoscale access into the chemical reactions between Li and the substrate material that will result in better understanding of diffusional Li respond to high capacity anodes with new chemistry content.

F.EN06.07.12
Late News: Structure and Electrochemistry of Transition Metal Substituted Lithium Vanadyl Phosphate for Lithium-Ion Batteries Krystal J. Lee, Marc Francis V. Hidalgo, Yanxu Zhong, Mateusz Zuba, Natasha Chernova, Guangwen Zhou, Hao Liu and M.S. Whittingham; Binghamton University, United States

Li-ion intercalation compound enlisting multi-electron redox is a promising strategy to maximize the storage capacity of LIBs. Lithium vanadyl phosphate, $LiVOPO_4$, is one such material that can intercalate up to two Li^+ ions per vanadium ion through the change in vanadium valence from V^{5+} to V^{3+}, which translates to a theoretical capacity of 305 mAh/g and an energy density above 900 Wh/kg. However, Li-ion intercalation in the high voltage region (V^{5+}/V^{4+}) is kinetically limited by the sluggish Li-ion diffusion, and thus impedes the use of $LiVOPO_4$ in practical applications. Transition metal substitution has been a technique used to enhance the performance of battery cathodes by changing its intrinsic properties and stabilizing the crystal structure. The goal of this work is to explore experimentally if substitution with chromium and niobium can enhance the electrochemical performance of $LiVOPO_4$. X-ray diffraction and inductively coupled plasma atomic emission spectroscopy indicate the substituent is successfully incorporated into the structure. The effects of transition metal substitution on the crystal structure and the electrochemical performance of $LiVOPO_4$ will be discussed.

F.EN06.07.13
Molybdenum Disulfide Anode of Lithium-Ion Battery for High Stability and Rate Capability Chanho Park, Han S. Kang, Seung Won Lee, Hyeokjung Lee, Kyuho Lee and Cheolmin Park; Yonsei University, Korea (the Republic of)

Development of a lithium-ion battery (LIB) is of great interest with an anode based on transition metal dichalcogenide nanosheets due to their intrinsically high capacity. The stability of a LIB is, however, detrimental with the nanostructured MoS_2 anode resulting from the gradual decrease of electrical conductivity with time due to the re-stacking of the nanosheets. In this work, we present a novel MoS_2 anode with molecularly architecture graft polymer binder having functionalized groups, enabling the high stability of a LIB. The fluorinated graft polymer synthesized by one-step atomic transfer radical polymerization allows not only for exfoliating MoS_2 nanosheets in the liquid phase to guarantee the stable sheet-to-sheet separation by preventing re-aggregation but also for providing self-assembled ionic channels through which lithium ions in electrolyte readily reach close to the surface of the nanosheets. The electrochemical reduction of lithium ions efficiently occurs at the layered nanostructure of MoS_2 facilitated by the functionalized polymer binder, giving rise to a high-performance LIB with the high rate capability and stability. Our binary anode of MoS_2 nanosheets self-assembled with the graft polymer enables high cell capacity even without the requirement of conductive additives which are frequently employed

for ensuring high conductivity and thus comparable cell capacity, making our approach one-step closer to commercial energy applications.

High Efficiency Water Oxidation Through Oxide Bilayers with Electronically Coupled Phase Boundaries Aida Raauf, Dennis Grödler, Lasse Jurgensen and Sanjay Mathur; University of Cologne, Germany

New semiconductor metal oxides capable of driving water-splitting reactions by solar irradiation alone are required for sustainable hydrogen production. Whereas most metal oxides only marginally deliver the photochemical energy to split water molecules, uranium oxides are efficient photoelectrocatalysts due to their absorption properties (E_g ~ 2.0 - 2.6 eV) and easy valence switching among uranium centers that additionally augment the photocatalytic efficiency. Although considered a scarce resource, the abundance of uranium compounds in the environment is manifested in the huge quantities of stored UF_6 gas, produced as waste streams in the nuclear fuel enrichment process. Here we demonstrate that thin films of depleted uranium oxide (U_3O_8) and their bilayers with hematite (a-Fe_2O_3) are high activity water oxidation catalysts due to electronically coupled phase boundaries. The electronic structure of uranium oxides showed an optimal band edge alignment in U_3O_8//Fe_2O_3 bilayers (DFT calculations) resulting in improved charge-transfer at the heterojunction as supported by TAS and XAS measurements. The enhanced photocurrent density of the heterostructures with respect to well-known hematite offers unexplored potential of uranium oxide in artificial photosynthesis.

F.EN09.11.03

Enhanced Photocatalytic Oxygen Evolution Reaction—Surface Modification of the Multiferriocs $BiFeO_3$ Nanostructure Using IrO_2 Nanoparticles Wegdan Ramadan[1] and Detlef Bahnemann[2,3,4]; [1]Alexandria University, Egypt; [2]Institut für Technische Chemie, Leibniz Universität Hannover, Germany; [3]Saint-Petersburg State University, Laboratory ‘‘Photoactive Nanocomposite Materials’’, Russian Federation; [4]Laboratorium fur Nano- und Quantenengineering, Gottfried Wilhelm Leibniz Universitat Hannover, Germany

$BiFeO_3$ (BFO) is a multiferriocs that combines antiferromagnetic and ferroelectric order well above room temperature. It is narrow band gap semiconductor (~ 2.2-2.7 eV) hence, it can harvest significant amount of visible light. Combining such desired properties on simple ternary compound makes it easier to utilize in many different folds. However, the performance of BFO in the field of photocatalysis is still poor due to the fast recombination of the photogenerated charges which will negatively affect their performance. Here we report on the photocatalytic oxygen evolution reaction, OER, of $BiFeO_3$ nanoparticles synthesized by sol gel. Oxygen evolution reaction is challenging because production of one molecule of gaseous oxygen, O_2, requires four holes (oxidize two molecules of water), and occurs on a time scale approximately 5 orders of magnitude slower than that required for H_2 evolution. There are two important issues to address when photocatalysis intended for water redox reaction to takes place; sacrificial agents to be used and the co-catalyst to be loaded on surface. For the former and in case of OER a sacrificial agent acts as an electron acceptor. Although many choices of sacrificial electron donner are available for water reduction to produce H_2, the choices are narrowing down to only few for sacrificial electron acceptors used for water oxidation to produce O_2. Ag^+ and Fe^{+3} ions are commonly used for this purpose and to a lower extend sodium persulfate, $Na_2S_2O_8$. The redox potential of Ag^+, $Fe^{3+}$and S_2O_8 at pH zero are 0.8 V, 0.77 V and 2.05 V, respectively. It is reported that both the quantum efficiency and the stability of the colloidal nanocrystals in solution improve with increasing redox potential of the scavenger.The higher redox potential leads to faster scavenging, which in turn increases quantum efficiency and stability of the catalyst since electron hole recombination and oxidation or reduction of the catalyst become less important.This finding is important for choosing hole/electron scavengers and for comparing efficiencies and stabilities for different photocatalytic nano systems. Hence the resolve to $Na_2S_2O_8$ as electron scavenger. Mott Schottky measurements and the Uv-Vis spectroscopy showed that the band positions of BFO, the conduction band and valence band lie at 0.46V and 2.69 V with respect to NHE, respectively.To enhance BFO photocatalytic OER, IrO_2 nanoparticles as a co-catalyst were loaded on the surface using impregnation method. OER showed two folds enhancement upon loading with 2wt% IrO_2. IrO_2 is one of the best catalysts for OER, unfortunately it is also one of the most expensive rare elements, so their applicability is limited by the high cost. Reducing IrO_2 content onto the system should be an option to make its application feasible and cost effective and loading on IrO_2 nanoparticles on the surface could be feasible solution. Scanning the loaded IrO_2 content on BFO from 0.5 wt% up to 4 wt% showed a maximum of the evolved oxygen at 2wt % followed by a decrease in activity. XPS showed the 4f peaks of Ir, it shows symmetric two peaks at binding energies 64.9 and 61.87 eV corresponding to the 4f 5/2 and 4f 7/2 of Ir (IV) respectively. TEM indicated non uniform distribution of it on the surface. Charge carrier lifetime and dynamics for pure BFO and IrO_2 loaded BFO have been studied by means of laser transient absorption spectroscopy, TAS, laser pulses of 20 ns and of λ = 540 nm were used. 2wt.% IrO_2 loading showed the fastest decay of holes compared to other loading percentage indicating a significant role of the IrO2 nanoparticles mediating the hole transfer process of the solar irradiated BFO system. This loading percentage corresponds to the observed highest OER. Band

positions between BFO and IrO_2 favors the formation of heterojunction at the interface between IrO_2 and $BiFeO_3$ that enhances the separation of the photogenerated charges and the photocatalytic OER performance.

F.EN09.11.05
Probing the Effects of Electrolyte Anions on the Adsorption of CO on Polycrystalline Cu Electrodes with Surface-Enhanced Infrared Absorption Spectroscopy Vincent J. Ovalle and Matthias Waegele; Boston College, United States

On Cu electrodes, the electrochemical conversion of CO_2 to hydrocarbons occurs via surface-adsorbed CO. Understanding the molecular factors that determine the adsorption of CO on Cu under electrochemical conditions is therefore essential to improving the product selectivity of this electrocatalytic process. Previous studies probing the adsorption of CO on Cu electrodes have suggested that, at low overpotentials, CO likely competes with anions from the electrolyte for surface sites. However, prior work has not systematically explored the effects of anion concentration and identity on the coverage of CO on the electrode. In this work, we examine the impact of adsorbing and non-adsorbing anions (Cl^-, SO_4^{2-}, ClO_4^-) at varying concentrations (10 mM and 1 M) on the adsorption and desorption of CO from polycrystalline Cu electrodes. Using surface-enhanced infrared absorption spectroscopy (SEIRAS), we observed the interplay between adsorbed CO and interfacial anions through the lens of the anion hydration shells, CO coverage, and CO stretch frequency under electrochemical conditions. In the presence of 10 mM anion, the potential dependent CO coverage and stretch frequency during a cyclic voltammogram (CV) is virtually independent of the anion identity. By contrast, at 1 M anion, the CO coverage and stretch frequency are distinctly dependent on the anion identity of the electrolyte. With weakly adsorbing and non-adsorbing anions (SO_4^{2-} and ClO_4^-), the CO saturation coverage is lowered by ≈35% compared to the corresponding 10 mM experiments. We attribute the lower coverage to quasi-specifically adsorbed anions that block adsorption sites. With 1 M Cl^-, the CO saturation coverage is only lowered by ≈12% relative to the coverage in the presence of 10 mM Cl^-. This moderate decrease is attributed to a decrease in the binding strength of CO to Cu in the presence of co-adsorbed Cl^-, which is evidenced by the ~19 cm^{-1} blue shift in the CO stretch frequency. In contrast to all other electrolytes, there is no hysteresis in the adsorption/desorption profiles of CO in the presence of 1 M Cl^-. This hysteresis between the forward and reverse scans in the CV is due to a CO-induced reversible reconstruction of the Cu electrode surface. In the presence of Cl^-, this reconstruction is suppressed. We discuss our findings in the context of the effects of halides on the product selectivity of the CO_2 reduction reaction on Cu electrodes. Our study provides critical insight into the structure of the electric double layer and its evolution during the CO adsorption process.

F.EN09.11.06
Identifying the Prevalent Surface Facets of Rough Cu Electrodes During CO Reduction Electrocatalysis Charuni Gunathunge, Jingyi Li, Xiang Li, Julie Hong and Matthias M. Waegele; Boston College, United States

The surface morphology of rough Cu electrodes can profoundly affect the product selectivity and activity for the reduction of CO and CO_2 to hydrocarbons. Because of the scarcity of in situ methods for probing the atomic-level surface structure under electrochemical conditions, it is still debated how the atomic-level surface morphology gives rise to desirable catalytic activity and selectivity. In this work, we introduce a novel method for the determination of the prevalent surface facets on rough metal electrodes under electrochemical conditions. As model systems, we employed two types of rough Cu thin-film electrodes that are widely applied in surface-enhanced infrared absorption spectroscopy (SEIRAS). With differential electrochemical mass spectrometry (DEMS), we show that Cu films that are electrochemically deposited on Si-supported Au films (CuAu–Si) exhibit an onset potential for ethylene that is ∼200 ± 65 mV more cathodic than the one of copper films (Cu–Si) that are electrolessly deposited onto Si crystals. With SEIRAS, we find that lineshapes of the CO stretch mode of surface-adsorbed CO exhibit greatly different potential-dependences for the two types of electrodes. Lineshape analysis reveals the presence of different prevalent terraces on these two types of electrodes. On the basis of this finding, we rationalize the higher overpotential for the formation of ethylene on the CuAu-Si film. We expect this novel methodology to be broadly applicable for the in situ surface characterization of rough metal electrodes. This structural information is critical for the development of rough metal electrodes with desirable catalytic characteristics.

***In Operando* Study of the Role of Ni Nanoparticles and Their Coarsening on the Catalytic Activity of Solid Oxide Fuel Cell Anodes Using Distribution of Relaxation Times Analysis** Boshan Mo, Jillian Rix, Uday Pal, Srikanth Gopalan and Soumendra Basu; Boston University, United States

Mitigating activation polarization and maintaining long-term stability in solid oxide fuel cell (SOFC) electrodes represent major challenges in improving their intermediate-temperature operation and applications. It has been shown that the infiltration of nanoparticle electrocatalysts increases the number of electrochemically active sites to decrease charge transfer

polarization losses and improve performance. In this study, nickel and mixed ionic and electronic conducting (MIEC) phases were infiltrated into Ni-YSZ and Ni-doped YSZ anodes of symmetric cells, and their performances characterized in-operando using electrochemical impedance spectroscopy (EIS). The kinetics of various charge transfer processes are modeled by distribution of relaxation times (DRT) analysis of the EIS spectra, allowing for an understanding of the role of the nickel nanoparticles and the consequences of nickel coarsening on the catalytic activity of the anode.

F.EN09.11.09

Electrochemomechanical Effects of Aqueous Cation Intercalation into Prussian Blue Saeed M. Saeed[1], Shelby Boyd[1], Wan-Yu Tsai[2], Ruocun Wang[1], Nina Balke[2] and Veronica Augustyn[1]; [1]North Carolina State University, United States; [2]Oak Ridge National Laboratory, United States

Prussian blue ($Fe_4[Fe(CN_6)]_3$) and its analogues are of interest as electrode materials for electrochemical energy storage. The open cubic framework of Prussian blue allows for long cycle life and reversible intercalation kinetics during cation insertion/extraction with capacities of up to 125 mAh/g in aqueous electrolytes. However, this performance is highly dependent on the electrolyte cation, and prior results indicate that a smaller hydrated cation radius leads to the best cyclability. The hypothesis guiding this study is that the cycling stability with smaller hydrated cations is tied to lower structural deformation of Prussian blue during electrochemical intercalation. In this study, we investigate the electrochemomechanics of Prussian blue due to the intercalation of three different aqueous cations, K^+, Na^+, and Li^+. *Operando* atomic force microscopy (AFM) is used to measure the mechanical deformation of the electrode during electrochemical cycling as a function of electrolyte and cyclic voltammetry sweep rate. This technique confirms that the electrochemical stability as well as the local deformation of the Prussian blue is dependent on the hydrated cation radius, with smaller cations giving rise to larger deformation. The superior cycling stability seen during K^+ insertion is commensurate with the high mechanical stability measured via *operando* AFM. This presentation will provide an understanding of the coupling between electrolyte cation size and electrochemomechanical response of a framework-type energy storage material.

Metal-Organic Frameworks as Sacrificial Template—Novel Bimetallic Co-W-S Chalcogenide Confined in N, S Codoped Porous Carbon Matrix for Highly Stable Electrochemical Supercapacitors Aya M. Mohamed[1,2], Ahmed O. Abo El Naga[3], Hanna B. Hassan[1], Tamer Zaki[3] and Nageh K. Allam[2]; [1]Cairo University, Egypt; [2]American University in Cairo, Egypt; [3]Egyptian Petroleum Research Inst, Egypt

Transition metal dichalcogenides are gaining much interest in the energy storage sector due to the 2D nature and conductivity of the materials. However, single transition metal dichalcogenides are not stable, preventing their practical use in real devices. Herein, we demonstrate the synthesis of binary metal dichalcogenides (Co-W-S) via carbonization of (ZIF-67) metal organic framework encapsulated with phosphotungstic acid (PTA@ZIF-67). The morphology and surface functional groups of the as-synthesized Co-W-S composite are characterized via (FESEM), (HRTEM), and (FTIR). Furthermore, the crystal structure and the elemental composition of the fabricated Co-W-S composite are elucidated using (XRD) and (XPS) analyses. Upon testing its electrochemical performance as a supercapacitor electrode, the fabricated Co-W-S@N,S co-doped porous carbon (N,S-PC) shows exceptional specific capacitance (1929 Fg^{-1} at 5 mVs^{-1}). Furthermore, the constructed asymmetric supercapacitor device using Co-W-S@N,S-PC and activated carbon as positive and negative poles, respectively displays superior energy density and power density of 32.9 Wh Kg^{-1} and 700.2 W kg^{-1}, respectively with a high Columbic efficiency over 10000 charge/discharge cycles at 10 A g^{-1}.

***In Situ* Raman Scattering of Photovoltaic Iron-Hydroxide Nanostructures in Dye-Sensitized Solar Cells** Mikel Tucker, Kit Sze, Saroj Pramanik and Yucheng Lan; Morgan State University, United States

Iron hydroxide is a promising photovoltaic material because of its abundance on earth, chemical stability in aqueous media, and outstanding optical absorbance. Here, iron hydroxide nanostructures are synthesized by the atmospheric micro-plasma and characterized. The nanostructures are fabricated into dye-sensitized solar cells and their photovoltaic behaviors are measured. The *in-situ* Raman scattering of the integrated nanostructures is investigated under various experimental conditions. The *in-situ* investigation would enhance our understanding of the dynamic behaviors of the photovoltaic nanomaterial in solar cells.

F.EN09.11.12

Operando Metrology with Photoelectron Spectroscopy and Organic Field-Effect Transistors for Interfacial Charge Transfers of Organic Semiconductor Kyung-Geun Lim[1], Jeong Won Kim[1] and Jaeyoon Baik[2]; [1]Korea Research Institution

of Standards and Science (KRISS), Korea (the Republic of); [2]Pohang Accelerator Laboratory (PAL), Korea (the Republic of)

Many chemical transitions of organic semiconductors occur at the interface during device operations. Charges are transfered or accumulated at the interface between organic semiconductors and intimate functional materials as function of operating conditions. However, the kinetic materials properties at the interface of organic semiconductor are hardly observed with real-time operational transition. Operando metrology is used to analyze charge transfers at the interface of organic semiconductors by photoelectron spectroscopy during operating bottom gate top electrode p-type organic field-effect transistors (OFETs). The interfacial chemical potential shift of organic semiconductor is simultaneously compared according to electrical behaviors. The electronic activation in the nearest effective monolayers of organic semiconductors at the interface is explained to correlate with gating, doping, or transporting behaviors of OFETs. This operando metrology will shed a light on many veiled intermediate transitions during the operatation of organic semiconductors.

Fabrication of Nanoscale Multilayered Thin-Film Thermoelectric Materials and Devices Lauren Williams, Rodricka Miller, Alandria Henderson and Zhigang Xiao; Alabama A&M University, United States

We report the growth of nanoscale multilayered thermoelectric thin films and the fabrication of integrated thermoelectric devices for high-efficiency energy conversion and solid-state cooling. Nano multilayered Bi_2Te_3/Sb_2Te_3, Sb/Sb_2Te_3, and Te/Bi_2Te_3 thermoelectric thin-film materials were grown using the e-beam evaporation. The multilayered thin films were prepared with 100 to 300 layers, where each layer is about 3 to 5 nm thick. The effects of DC substrate bias on the growth of films such as the crystalline structures in the films were studied. Integrated thermoelectric devices with a high density of thermoelectric elements were fabricated with the nanoscale multilayered thin films using the clean room-based microfabrication techniques such as UV lithography. Plasma-enhanced atomic layer deposition (PE-ALD) was used to grow zirconium dioxide (ZrO_2) as the insulation layer in the device fabrication. X-ray diffraction and high-resolution tunneling electron micrograph (HR-TEM) were used to analyze the nanoscale multilayered thin films. The fabricated device was cooled in liquid nitrogen or annealed at 150 ^oC for 30 min, respectively. HR-TEM was used to analyze the cross-section of the nanoscale multilayered thin films for the three cases: as-grown, after being cooled in the liquid nitrogen, and after being annealed, showing that the cooling made the multilayer structures to be sharper while the annealing made the multilayer structures to become weaker. The thermoelectric characteristics of the devices were measured and analyzed for the three cases of as fabricated, after being cooled, and after being annealed, respectively, showing that the integrated thermoelectric device had the highest efficiency of thermal-to-electrical energy conversion after being cooled in the liquid nitrogen.

F.EN09.11.14
Late News: Correlating Cu-Based Catalyst Properties to Activity and Selectivity from *Operando* Studies of CO Electroreduction in a Gas-Fed Device Soohong Lee[1], Ian Sullivan[2], Chengxiang Xiang[2] and Walter Drisdell[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]California Institute of Technology, United States

Identifying the catalyst properties that determine catalyst activity and selectivity is of significant importance, as an understating of the catalytic mechanism can provide a rational catalyst design principle for efficient energy devices. However, understanding the relationships between catalyst properties and performance remain challenges in general because of the co-existence of multiple factors that are irrelevant to the catalytic cycle, and the dynamic nature of the catalytic chemistry which is responsive to reaction rates. To investigate the complex dynamic catalyst structure, an *operando* characterization under realistic operation, particularly at electrochemical conditions approaching those used to evaluate and benchmark electrocatalysts, is needed. Here, we report a comprehensive study of catalyst properties that can determine the electrochemical CO reduction reaction (CORR) in a gas-fed cell. We first employed *operando* X-ray absorption spectroscopy (XAS) synchronized with simultaneous measurements of catalyst performance by gas chromatography (GC) to investigate the relationship between valence states of Cu-based catalysts and activity for ethylene (C_2H_4) production. By introducing an anodic oxidation process, which enhanced CORR performance, we demonstrated that the oxidation states do not correlate with the activity or selectivity of Cu-based catalysts. We also found that an increase in the number of active sites estimated by electrochemical surface area (ECSA) was not proportional to the C_2H_4 yield, whereas hydrogen evolution reaction (HER) activity is positively correlated to the ECSA changes. Based on the post-mortem microscopic investigations of Cu-based catalysts, we suggest that the increased C_2H_4 activity and selectivity may arise from a morphological reconstruction that originates from the electrochemical oxidation-reduction process. The rapid reduction of the initial oxide structure into metallic Cu at the early stage of the CORR could generate a more active structure. This electrochemical oxidation-reduction process was used as a regeneration method that recovered the original catalyst activity and selectivity in the gas-fed cell without requiring cell disassembly.

F.EN09.11.15
Late News: Determining the Effect of Local Heterogeneity on the Activity and Selectivity of Au1-xPdx Particles for the Hydrogenation of Alkynes with *In Situ* and *Ex Situ* Transmission Electron Microscopy Alexandre Foucher and Eric Stach; University of Pennsylvania, United States

Heterogeneous catalysis plays a crucial role in the production of chemicals and requires the design of active and selective nanostructures. In situ transmission electron microscopy (TEM) can determine morphology or chemistry changes in novel catalysts during a chemical reaction. In this work, bimetallic Au1-xPdx particles supported on a raspberry colloid templated (RCT) silica support were studied under oxidative and reactive conditions with a temperature of up to 500 °C and a pressure of 1 bar. Pd is the minority component, representing no more than 25 weight percent of the total metallic loading, and the particles have an average size of 5.5 nm. The remarkable stability of this system, with limited particle migration and coalescence phenomena, was demonstrated. Sharp facets perpendicular to [100] and [111] directions are present when Pd's concentration is below four atomic percent. When the concentration of Pd exceeds four atomic percent, the particles have a spherical shape, and high-resolution spectroscopy revealed the presence of small Pd clusters on the surface of the as-prepared particles with an average size of 1-2 nm. In situ results combined with ex situ TEM and infrared spectroscopy show the growth of small Pd clusters on the nanoparticles' surface that explain changes in activity and selectivity observed after treating the sample with oxygen or hydrogen. These observations demonstrate how a combination of operando methods, aberration-corrected microscopy, and direct electron detection can be used to guide the design of future catalytic structures.

F.EN09.11.16
Late News: Assessing the Durability and Composition of Pt-Based Ternary Nanoalloys in Proton Exchange Membrane Fuel Cells Using *In-Situ/Operando* High-Energy XRD Technique Dominic Caracciolo, Shiyao Shan and Chuan-Jian Zhong; SUNY Binghamton, United States

Due to the rising demand for sustainable energy, there has been a global drive for developing clean energy from renewable sources (solar, wind, etc.) which will reduce our dependence on fossil fuels. Fuel cells represent an important vector in the development of clean and renewable energy, but major challenges for the mass commercialization of fuel cells are the high cost and poor durability of the catalysts at the cathode, which requires the prohibitive Pt as a catalyst to overcome the sluggish oxygen reduction reaction kinetics. This presentation will discuss recent results of our investigations of low-Pt binary and ternary nanoalloy electrocatalysts using different characterization techniques, including in operando synchrotron X-ray diffraction technique in standard electrochemical cells and proton exchange membrane fuel cells (PEMFC). The focus is to develop the fundamental understanding of the nanophase structures of the catalysts, which provide insights into the correlation between the durability and the composition of the nanoalloy catalysts in the PEMFCs.

F.EN09.11.17
Late News: Self-Constructed MnCo2O4 via Atomic Layer Deposition as an Efficient Bifunctional Catalyst for Zn-Air Battery Arim Seong and Guntae Kim; Ulsan National Institute of Science and Technology, United States

The discovery of electrocatalysts for efficient oxygen reduction reaction (ORR) and oxygen evolution reaction (OER) is pivotal to the growth of a new generation of energy technologies. In this study, for the first time, we present an effective strategy for a nano-dispersed low amount of Co_3O_4 materials (*i.e.,* 2.67 wt %) on $La_{0.5}Sr_{0.5}MnO_{3-\delta}$ catalyst substrate for synthesizing an efficient bifunctional ORR/OER catalyst by utilizing an advanced ALD technique. Interestingly, the cation diffusion between LSM and Co_3O_4 introduces a self-intercalated $MnCo_2O_4$ spinel structure at the interface. The existence of $MnCo_2O_4$ was assisted by TEM-EDS, XANES. Benefiting from the $MnCo_2O_4$ interlayer, the LSM-20-Co catalyst exhibits excellent maximum power density (146.5 mW cm^{-2}), specific capacity (755.0 mA gZn^{-1}) and outstanding stability over 450mn without any increase of charge-discharge voltage gap. Consequently, the LSM-20-Co catalyst is an attractive bifunctional catalyst as an efficient air cathode catalyst for the alkaline metal-air system and provides insight into the rational design of a thin metal oxide with the ALD process.

Lifetime Prediction of PV Modules—When is it Useful and When is it a Distraction? Sarah R. Kurtz; University of

California Merced, United States

Lifetime prediction is a critical first step as the basis of a warranty or risk assessment. Research that identifies a PV module's primary degradation or failure mechanism, quantifies the associated acceleration factors, and applies those to operating conditions is a straightforward approach to lifetime prediction. The value of this process is obvious and researchers around the world are investigating degradation and failure mechanisms of PV modules with this goal in mind. Making a lifetime prediction is actually quite easy: we can predict 25 years ±25 years for pretty much all PV products on the market, but such a prediction is useless. Making a lifetime prediction with a small uncertainty that leads to a useful prediction is much harder. This talk will describe why lifetime prediction is difficult, when it is essential, when it is a distraction, and how we expect lifetime prediction may evolve in the future.

9:30 AM *F.EN02.04.03
From Modules to Atoms—Characterization of Silicon Photovoltaic Module Reliability Guided by Luminescence and Thermal Imaging Dana Kern[1], Steve Johnston[1], Helio Moutinho[1], Dirk C. Jordan[1], Jenya Meydbray[2], Laura Spinella[1], Michael Owen-Bellini[1], Kent Terwilliger[1], Archana Sinha[3], Laura Schelhas[3], Chun-Sheng Jiang[1], Chuanxiao Xiao[1], Matthew Young[1] and Mowafak Al-Jassim[1]; [1]National Renewable Energy Laboratory, United States; [2]PV Evolution Labs, United States; [3]SLAC National Accelerator Laboratory, United States

With the lifespans of photovoltaic (PV) modules expected to last >20 years, rapid and spatially-resolved characterization methods are essential for understanding module reliability and degradation processes. Luminescence and thermal imaging have been gaining popularity both for fast, outdoor-compatible module inspection and for more detailed post-mortem analysis of failure mechanisms. Importantly, many failure mechanisms are not evident by visual inspection, and characterization of electrical properties alone is insufficient to identify the weakest features of cell or module design. This is especially true as PV technologies and module packaging schemes become more advanced and degradation becomes more subtle. Here, we present various examples of PV module degradation mechanisms in field-weathered modules, where we (1) locate problem areas with luminescence and thermal imaging, (2) core these areas out of the module, and (3) use various microscopy methods to identify chemical and structural causes of power loss. We particularly highlight causes of voltage loss or series resistance increases that vary depending on the technology, and we show studies including conventional Al back surface field (Al-BSF), silicon heterojunction with intrinsic thin layer (HIT), and passivated emitter and rear contact (PERC) modules. These results highlight the utility of imaging methods for improving module reliability.

The Many Faces of Characterization in Developing a Commercial Perovskite on Silicon Tandem Solar Cell Laura Miranda; Oxford PV, United Kingdom

Perovskite solar absorbers have the potential to disrupt the photovoltaic industry predominantly with their simultaneous promise of high efficiency and low cost. Whilst these two properties ensure a steady stream of research and development opportunities, commercial scaling requires assuring that the devices are sufficiently characterized to be confident of their long-term performance. Oxford PV has been addressing the challenges associated with commercially scaling its perovskite on silicon tandem solar cell design. Key practices that have been adopted during the development of highly efficient, reliable, and cost-competitive solar cells are the use of rigorous characterization tools and techniques, and the development of necessary models. This talk will highlight some of the challenges and considerations associated with bringing perovskite on silicon tandem solar cells from a laboratory prototype to a commercial product ready for manufacturing and how characterization has shaped and continues to inform that process.

4:20 PM *F.EN02.11/F.EL06/FEL08.02
Passivation Strategies and Interlayers for Perovskite-Based Tandem Photovoltaics Ulrich W. Paetzold, Saba

Gharibzadeh, Tobias Abzieher, Ihteaz M. Hossain, Hang Hu, Thomas Feeney, Somayeh Moghadamzadeh, Mahdi Malekshahi Byranvand,, Bahram Abdollahi Nejand, Paul Fassl and Bryce Sydney Richards; Karlsruhe Institute of Technology, Germany

Single-junction crystalline silicon solar cells dominate the photovoltaics market today, but their power conversion efficiencies (PCEs) are approaching the practical limit for this technology. The emergence of hybrid organic-inorganic metal halide perovskite semiconductors over the past decade has opened a window of opportunity to advance the performance of the market-dominating photovoltaic technologies through the development of tandem solar cells. These tandem solar cells promise high PCEs (>33%). To reach this landmark, a number of scientific and technological challenges related to high-efficiency perovskite-based tandem solar cell architectures, stable and high-quality perovskite semiconductor materials, and light management concepts need to be addressed. In this presentation, our progress on passivation strategies and novel interlayers to reduce the voltage losses in wide-bandgap and low-bandgap perovskite solar cells (PSCs), and in turn to increase the PCE of perovskite-based tandem photovoltaics, will be presented.
The search for efficient passivation interlayers for wide-bandgap perovskite top solar cells in *n-i-p* architecture directed our research in the past towards solution-processed 2D/3D perovskite heterostructures. Making use of these heterostructures for interface passivation, wide-bandgap PSCs (E_g ~1.72 eV) with record open-circuit voltage for this bandgap and very high PCEs of up to 19.4% were demonstrated [1]. The reduced voltage deficit is a result of the decreased non-radiative recombination losses at the perovskite/hole-transport layer (HTL) interface. The solution-processed 2D/3D perovskite heterostructure is compatible with 3D perovskite absorber layers of a wide range of bandgaps (1.65 eV ≤ E_g ≤ 1.85 eV) [2]. Using this strategy in 4-terminal perovskite/silicon and perovskite/CIGS tandem solar cells, high PCEs > 27% [3], and > 25% [2] were demonstrated, respectively, thereby significantly exceeding the record PCESs reported for the respective single-junction solar cell technologies.
Beyond these past results, at the MRS fall meeting we will further present our latest work on novel interlayers and passivation strategies to minimize the voltage loss in wide-bandgap (1.65 eV ≤ E_g ≤ 1.75 eV) as well as low-bandgap (E_g ~ 1.26 eV) perovskite solar cells in *p-i-n* architecture. The *p-i-n* architecture is a key to realize high-performance 2-terminal perovskite/silicon as well as perovskite/perovskite tandem solar cells. Moreover, we will present a novel route to deposit uniform ultra-thin polymer passivation layers onto perovskite thin films by chemical vapor deposition (CVD) [4]. The CVD polymerization promises reliable, scalable, and homogeneous deposition for future large-area processing of perovskite-based tandem solar cells.

Towards Highly Efficient Monolithic 2- and 3-Terminal Perovskite Silicon Tandem Solar Cells Lars Korte, Eike Koehnen, Philipp Wagner, Philipp Tockhorn, Marko Jost, Amran Al-Ashouri, Lukas Kegelmann, Marcel Roß, Bernd Stannowski and Steve Albrecht; Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

Integrating metal halide perovskite top cells with crystalline silicon (c Si) bottom cells into monolithic tandem devices has recently attracted increased attention due to the high efficiency potential of these cell architectures. To further increase the tandem device performance to a level well above the best single junctions, optical and electrical optimizations as well as a detailed device understanding for such architectures need to be developed [1]. Here we present our recent results on such monolithic tandem cells in the common 2-terminal (2T) as well as in a novel 3-terminal (3T) contacting scheme.
In the 2T design, we recently demonstrated a certified power conversion efficiency (PCE) of 29.15% [2,3]. I will discuss some key elements to this result: using a silicon heterojunction cell electron contact on the rear side, enabling the integration of a perovskite top cell in the p-i-n configuration; employing self-assembled monolayers (SAMs) as hole selective contacts for further reduction of non-radiative recombination losses, etc. With the latter, efficiencies of up to ~ 21 % were demonstrated for p-i-n perovskite single junctions [3].
In 3T tandems, one of the three contacts is shared by both subcells, allowing for the individual operation of both subcells in a

monolithic device with a single substrate, thus combining the characteristic advantages of 2T and 4-terminal (4T) devices: high combined photogeneration currents as in state-of-the-art 2T tandems, and ideally independent electrical operation similar to 4T tandems, making the cell more robust against varying spectra. I will discuss our recent proof-of-concept study [4], demonstrating a 3T perovskite/silicon tandem cell by manufacturing an n-i-p perovskite top cell on an interdigitated back contact (IBC) silicon heterojunction solar cell. In our proof-of-concept device, the combined PCE of ~ 17% is still limited both optically and electrically, and it will be discussed how optimizations of the cell stack can bring this architecture to a PCE level comparable to 2T tandems. Furthermore, I will demonstrate that the subcells can indeed be operated largely independently at their individual maximum power points, allowing to extract the maximum power output for varying spectral conditions similar to 4T cells. A minimized series resistance at the shared electron contact on the cell's rear side is identified as the crucial parameter for independent operation of the subcells, and I will discuss pathways to approach the simulated efficiency potential by an optimized device design.

Advances in Material Properties for Perovskite-Perovskite Tandems Giles Eperon[1,2]; [1]Swift Solar, United States; [2]National Renewable Energy Laboratorty, United States

Multijunction all-perovskite solar cells offer a route towards efficiencies of III-V materials at low cost by combining the advantages of low thermalization loss in multijunction architectures with the beneficial properties of perovskites - namely low processing cost, high throughput fabrication, and compatibility with flexible substrates. Here, I will discuss why flexible all-perovskite tandems are a very attractive iteration of the perovskite technology. I will focus on what is needed to make a good perovskite-perovskite tandem on a flexible substrate, and the advances that we have made towards this goal.
I will cover advances including a) the development and understanding of wide bandgap materials that leverage a novel bandgap-tuning strategy (without increasing bromine, hence avoiding significant phase segregation) to reach the ideal bandgaps for all-perovskite tandems, resulting in efficient devices that are stable to the combined stresses of heat and light; b) advances that we have made in interlayer design, working towards more ideal material properties for reducing shunt resistance; and c) the integration of these approaches to develop >23% efficient monolithic all-perovskite tandems on rigid substrates and 21% efficient devices on flexible plastic substrates.

Solution Processed Perovskite Subcell in Monolithic Perovskite/Si Tandem Solar Cells and Their Cost and Stability Concerns Qi Chen[1] and Huanping Zhou[2]; [1]Beijing institute of Technology, China; [2]Peking University, China

Among all commercialization routes for perovskite photovoltaics (PV), the perovskite/Si tandem is of particular interest as it capitalizes the mature silicon industry with decades of experience. Here we report low-temperature solution process for efficient two-terminal perovskite/Si tandem solar cells, wherein electrical and optical properties of the tunneling junction are carefully modulated. Moreover, we improve materials stability by introducing Eu^{2+}/Eu^{3+} "redox shuttle" to suppress the Pb^0/I^0 impurities which inevitably occurred during device operation. In addition, we carefully analyze the cost of tandem devices in terms of levelized cost of energy (LCOE) by adopting the "bottom-up cost model". It reveals perovskite PV exhibit low materials cost, which reduces the LCOE substantially in tandem devices. We conclude that further efforts are required to simultaneously improve the efficiency and lifetime of perovskite modules, which ultimately endows the competitiveness of perovskite tandem solar cells.

Thin Films for Silicon Based Photovoltaic Under Zoom Martin Ledinsky; Institute of Physics AS CR, Czechia

Thin films, based on amorphous and microcrystalline silicon or silicon oxides, are the key players in the future silicon photovoltaics. They very well passivate the surface of crystalline silicon, enabling high open circuit voltages and fill factors of finalized cells. Two most promising strategies are Silicon Heterojunction solar cell (SHJ) and Tunel Oxide Passivated Contacts (TOPCon) based cells.
Interdigitated back contacted SHJ solar cell (IBC SHJ), is the current silicon efficiency world record holder with 26.7%. The record IBC SHJ cell is fabricated by many photolithography steps, not fully compatible with mass production. Thus straightforward shadow masks technology has been developed. In order to check the profiles of ~10 nm thin passivating/selective contacts prepared by shadow mask process on rough substrates, Raman spectroscopy based thickness measurement with resolution bellow 0.2 nm was introduced [1]. Alternative, industrially relevant way, to image the silicon film thickness by photoluminescence imaging will be introduced.
In the same time it is important to probe the structural and local electrical properties of these films. For this end conductive atomic force microscope (C-AFM) in the tomography regime is suitable for characterisation of mixed phase amorphous/nanocrystalline ultrathin films as well as the tunnelling oxide contacts. 3D visualisations of high temperature passivated back contacts (TOPCon) will be used as an example.
But since the silicon wafer based technology approaches the practical efficiency limit (the theoretical is at ~29%), the only way how to go beyond 30% is combination of two cells in a so called tandem. By doing that the theoretical limit is shifted to over 40%. Suitable candidates for the top cell accompanying well mastered silicon bottom cell are halide perovskites. We will discuss the extraordinary properties of this material family [2]. Finally, we introduce a simple semiconductor property dictating the maximal open circuit voltage obtainable with the given material [3]. In this way we can rapidly preselect suitable candidates for top tandem cell.

5:15 AM F.EN02.01.02
Spatial Mapping of Electrical Parameters with Micrometer Resolution in Interdigitated Back Contact Solar Cells Siddhartha Garud[1], Matevz Bokalič[2], Cham thi Trinh[1], Bernd Rech[1], Daniel Amkreutz[1] and Marko Topič[2]; [1]Helmholtz-Zentrum Berlin, Germany; [2]University of Ljubljana, Slovenia

Light-beam induced current (*LBIC*) measurements with a bias voltage or current are used to obtain photogenerated charge collection profiles at different points in the I-V curve of a solar cell. Such measurements can be analysed to obtain local electrical parameters such as dark saturation current and series/shunt resistance and identify aspects for improving solar cell performance.

In the present work, such an analysis technique was developed for solar cells made from 14 µm liquid-phase-crystallized silicon. In particular, it compares a reference cell with the current best cell exhibiting 657 mV open-circuit voltage (V_{OC}) and 32.7 mA/cm^2 short-circuit current density (J_{SC}) (with an anti-reflection foil on the illumination side). Since the cell architecture used is 'silicon heterojunction interdigitated back contact' (SHJ-IBC), the implemented circuit model is designed for an IBC architecture. The circuit is fit to the measured data on a MATLAB script, which will be available for downloading and adapting to other solar cell architectures and materials. The *LBIC* setup was built in-house at the University of Ljubljana. It uses an alternating current (AC) measurement with a direct current (DC) bias and produces full cell images at different bias points. A 40 µm step size was used. The setup offers a minimum step size of 1 µm and an illumination spot diameter <= 10 µm.

Each pixel is treated as an independent one-diode model, surrounded by 2 one-diode model representing the remaining (dark) cell. With this approximation, full cell maps of the following parameters of a one diode model were obtained: dark saturation current (I0), ideality factor (n), effective series resistance, shunt resistance and photo-generated current. While treating each pixel as an independent, illuminated solar cell, local I-V curves were simulated, giving full cell maps of V_{OC}, J_{SC}, maximum power points (V_{MPP} and I_{MPP}) and efficiency (η). The following key observations were made:

1. Top 50 percentile of 40 µm x 40 µm pixels show a J_{SC} between 32-33.5 mA/cm^2, V_{OC} between 600-640 mV, fill-factor (*FF*) between 73-76 % and η 14-15.1% in the reference cell and J_{SC} between 33.6-34 mA/cm^2, V_{OC} between 658-700 mV, *FF* between 71-76% and η between 15.7 %-16.5% in the best cell. Due to the presence of crystal defects, local shunts and lower charge collection under the electron contact fingers, the resultant full cell parameters for the reference cell are J_{SC}: 28.5 mA/cm^2, V_{OC}: 617 mV, *FF* 65.4 % and η 11.5 % and for the best cell are J_{SC}: 30.3 mA/cm^2, V_{OC}: 652 mV, *FF* 64.6 % and η 12.8 % (as measured under a AAA-rated sun simulator).
2. Grain boundaries exhibit J_{SC} of approximately 7-9 mA/cm^2, V_{OC} of approximately 340-400 mV, 50%-70% *FF* and 1.5-5 % η , subject to the size and recombination activity. Similarly, stacking faults in the reference cell exhibit average values of 26 mA/cm^2 J_{SC}, 515 mV V_{OC}, 70 % *FF* and 9.5 % η.
3. Laser firing used to lower contact resistance on the electron contact fingers does not lower the over-all V_{OC} of a cell because it is primarily limited by grain boundaries present in the cell.
4. Electroluminescence imaging shows a gradient towards the direction of the electron contact busbar primarily due to high series resistance in the electron contact fingers. This gradient is also visible in the *LBIC* images taken at voltage bias > 0.6 V and is reflected in the local series resistance fitted by the model.

A comparison with the best efficiency cell (15.1 % with anti-reflection foil) is ongoing in which similar trends are expected, but with higher power conversion efficiency. In conclusion, this method successful models current paths of photogenerated charge carriers within the cell and to external electrodes in an IBC architecture. The high resolution maps of electrical parameters quantify the excellent performance of intra-grain regions and limitations primarily due to crystal defects and minority carrier (hole) diffusion length under the electron contact.

5:25 AM F.EN02.01.03
Defect Analysis of Crystalline Si Solar Cells by Learning Radiation-induced Defects in Si Masafumi Yamaguchi, Takefumi Kamioka, Nobuaki Kojima and Yoshio Ohshita; Toyota Technology Institute, Japan

Although 26.7% efficiency has been attained with hetero-junction and back contact (HBC) structure and by using bulk minority-carrier lifetime of around 10 msec, high efficiency of more than 29% is expected to be realized as a result of decreasing non-radiative recombination loss. This paper presents analytical results for high efficiency potential of crystalline Si solar cells, analyzed by using knowledge (C_i-O_i center, B_i-O_i center, E' center and Pb center), in radiation-induced defects in Si.
One of problems to attain the higher efficiency crystalline Si solar cells is to reduce non-radiative recombination loss. The open-circuit voltage drop compared to bandgap energy (Eg/q-Voc) is dependent upon non-radiative voltage loss (Voc, nrad) that is expressed by external radiative efficiency (ERE). Open-circuit voltage is expressed by
$V_{oc} = V_{oc,rad} + (kT/q)\ln(ERE)$, (1)
where the second term shows non-radiative voltage loss, and $V_{oc,\,rad}$ is radiative open-circuit voltage and 0.87V was used in this study. Correlation between Voc values for HIT, HBC, PERL and multi-crystalline Si cells and ERE values in the references estimated by eq. (1) suggests that crystalline Si solar cells have still non-radiative loss and further improvements in efficiency are thought to be possible by improving minority-carrier lifetime [1]. Calculated values of minority-carrier lifetime is expressed by the following equation
$1/\tau = BN + CN^2$, (2)
where B is radiative recombination probability and 2×10^{-15} cm^3/s for Si, N is carrier concentration and C is the Auger coefficient and is 1.6×10^{-30} cm^6/s for Si. Correlation between calculated values and obtained values of minority-carrier lifetime suggests that further improvement in minority-carrier lifetime is expected to be realized. Really, high bulk lifetime of around 100 msec has been obtained by the MCZ (Magnetic-field-applied Czochralski) method and decreasing carbon concentration to less than 10^{14} cm^{-3} in Si. C_i-O_i center induced by 1-MeV electron irradiations have been used for calibration of carbon concentration in Si. Higher minority-carrier lifetime of around 100msec by decreasing carbon and oxygen precipitate concentrations will provide lower voltage drop of around 0.3V and higher Voc of around 800mV and thus higher efficiency Si solar cells of more than 28%.
Regarding light-induced degradation of Si solar cells, although B_i-O_i center in Si was previously thought to act as defect center for light illumination degradation, B_i-O_i center doesn't act as a non-radiative recombination center according to our

previous studies [2] for radiation-induced defects in Si. Defect introduction rates of B_i-O_{2i} center induced by light illumination are compared with those of B_i-O_i center induced by 1-MeV electron irradiations in this study.
Surface recombination degradation of Si solar cells under light illumination is also another important issue for realizing highly reliable Si solar cells. In this study, surface recombination degradation of Si solar cells due to 1-MeV electron irradiations is compared with surface degradation of Si solar cells under light illumination by considering Pb center generation due to 1-MeV electron and ultraviolet light exposures.
In summary, understanding defects in Si solar cells by learning radiation-induced defects in Si is thought to useful for further development of high-efficiency and highly reliable Si solar cells.

Defect Phase Diagram of ffacet and Line Junctions of Σ3 Grain Boundaries in Si Liverios Lymperakis[1], Masud Alam[2,1] and Jorg Neugebauer[1]; [1]Max-Planck-Institut für Eisenforschung GmbH, Germany; [2]Interdisciplinary Centre for Advanced Materials Simulation, Germany

Interfaces such as grain boundaries (GB) that break the transitional symmetry of a crystal play a dominant role in the properties of materials. The role of GBs is substantial in multi- and polycrystalline optoelectronic and photovoltaic materials: Multi-crystalline Si (mc-Si), which nowadays dominates the Si based photovoltaics industry has a density of 10^4/cm GBs. These defects, as well as their interaction with impurities constitute a major limiting factor in the efficiency of the aforementioned devices. More specifically it has been shown that recombination at GBs constitute a major channel for electrical losses in high performance mc-Si solar cells. Σ3 tilt GBs in Si is a family of interfaces with special fundamental and technological interest. The Σ3{111} twin boundaries (TB) have negligible boundary energy and are electrically inactive. They are therefore preferred over other electrically active boundaries. However, Σ3{112} GBs exist in two stable/metastable states, the symmetric (S-Σ3) and the asymmetric (A-Σ3), with the former having deep states into the fundamental bandgap. Furthermore, facet junctions of the TB with the A-Σ3 show a unique anisotropic segregation mechanism, that goes beyond the classical picture of planar McLean type segregation [1]. Nevertheless, a prerequisite to get full control on the properties of these interfaces is to gather a deep understanding of the corresponding faceting mechanisms.

In the present work we employ density functional theory (DFT) and large scale modified embedded atom method (MEAM) potential calculations to investigate the structure, energetics and strain associated with these boundaries. Based on the our DFT calculations we parametrize a MEAM potential suitable to describe GB energetics and long range elastic interactions in Si. Our calculations revealed that Σ3 tilt GBs with the [110] rotation axis are intrinsically unstable against faceting towards {111} and {112} facets. Furthermore, based on these calculations we derive a facet and line junction phase diagram that describes and predicts the reconstructions of these extended defects as function of facet length and boundary inclination angle. This diagram reveals that large (small) inclination angles with respect to {111} plane and/or large (small) facet lengths favor junctions with A-Σ3 (S-Σ3) facets, respectively. This is explained in terms of (i) the large anisotropy in the energies of S- and A-Σ3 and (ii) the presence (lack) of extended defects at the {111} and A- (S-) {112} line junctions, respectively: While the low energy of the A-Σ3 facets favors these boundaries over their symmetric counterparts, line junctions of TBs with A-{112} facets are accommodated by edge type dislocations. The long range repulsive interactions make these facets highly unfavorable at small facet lengths. On the other hand, S-Σ3 GBs are commensurate to the Σ3 coincidence site lattice and the energy of the corresponding faceted junction is independent of the facet length. These findings shed light upon GB faceting phenomena and have important implications on the GB mobility mechanisms, the electronic properties as well as on selective impurity segregation at line junctions and facets in mc-Si: At large inclination angles the A-Σ3 GBs will adopt the maximum length allowed by the microstructure and grain size. Furthermore, the highly strained core region and its topology at the line junctions will strongly influence impurity segregation at these regions. On the other hand, at small inclination angles, the deep states introduced by the S-Σ3 facets will act as a recombination centers and will be detrimental for the device efficiency. Based on the aforementioned results will further discuss the implications on impurity segregation at the flat and facet junctions Σ3GBs as well as on their mobility.

Spectroscopic Investigation of Spin-Active Defect in Czochralski Silicon Responsible for Light-Induced Degradation Abigail R. Meyer[1], P. Craig Taylor[1], Matthew Page[2], David L. Young[2], Paul Stradins[2] and Sumit

Agarwal[1]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States

Light-induced degradation (LID) is a decrease in the minority carrier lifetime in boron-doped Czochralski (Cz) silicon solar cells due to injection of excess carriers. It is well accepted that LID occurs due to a defect involving a substitutional boron atom and an oxygen dimer. There are three characteristic stages of LID: an annealed state where defects are metastable and non-recombination-active, a degraded state where defects are recombination active, and a stabilized state where defects are permanently non-recombination-active. While a technological solution to mitigate LID is slowly being implemented into industrial manufacturing lines, the fundamental mechanism for lifetime stabilization and the structure of the LID defect remain speculative. Empirical studies relate B and O to the defect structure, but atomistic evidence is lacking. If the defect structure and mechanism of LID is discovered, mitigation strategies could be quickly studied and implemented improving the long-term reliability of high-efficiency, B-doped Si solar cells.
In this work we utilize electron paramagnetic resonance (EPR) spectroscopy, magnetic susceptibility, and lifetime spectroscopy to study the structure of the LID defect and the degradation mechanism. We report on the EPR spectra of Cz and float-zone (FZ) Si in different stages of LID. Firstly, we show that the paramagnetic signal at low temperature (6 K) is dependent on the state of LID and on the sample doping. The light-degraded state in *p*-type Cz Si shows a strong, sharp paramagnetic defect signature (g-value = 2.003) compared to samples in the annealed state, where the EPR spectra is relatively featureless. In contrast, the broad EPR active signature related to boron interaction with lattice, is present in the annealed state but diminishes after light exposure. Both EPR signals change under indoor light exposure at room temperature and therefore are sensitive to initial stages of LID. We see a smaller decline in the wide-spectrum boron/lattice interaction EPR signal in *p*-type FZ Si and none in *n*-type Cz Si. We hypothesize the decrease in the oxygen concentration in the *p*-type FZ sample results in incomplete quenching of the boron acceptor spins. We suggest that these changes in the EPR spectra are related to the BO defect that causes LID. Additionally, we utilized *p*-type FZ with an order of magnitude higher B doping to investigate the effect of the B/O concentration ratio on extent of quenching of B_a spins after indoor light exposure. We observe that in the *p*-type FZ Si sample that is more heavily doped with B (B/O ~ 10:1) the B_a spin signal is almost unaffected by LID compared to the more lightly doped B-doped *p*-type FZ Si sample (B/O ~ 1:1). Therefore, if the B atoms are in excess, there are simply not enough O atoms to quench all the B_a spins and the EPR signal remains. Therefore, O is involved in this paramagnetic to diamagnetic transition of the B_a in the Si bulk and for this transition to occur, BO complexes are required. Finally, we show that magnetic susceptibility measurements confirm that in the annealed state of LID, the *p*-type Cz Si sample is paramagnetic, and in the degraded state, diamagnetic, which is consistent with our EPR findings. Thus, for the first time, EPR and magnetic susceptibility have been used to show manipulation of the LID defect after dark-annealing and light exposure.

5:55 AM F.EN02.01.06
A Scanning Nonlinear Dielectric Microscopic Investigation of Potential-Induced Degradation in Monocrystalline Silicon Solar Cells Yasuo Cho[1], Sachiko Jonai[2] and Atsushi Masuda[2]; [1]Tohoku University, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan

Crystalline silicon (Si) solar cells currently occupy an important place in the solar cell market. However, potential-induced degradation (PID) of crystalline Si photovoltaic (PV) modules has recently been observed in large systems comprising significant numbers of PV modules. In these PV systems, numerous such modules are interconnected in series, such that potential stress is imparted to some of the modules with consequent high power losses. PID in Si PV modules based on p-type crystalline Si solar cells has been previously investigated in detail [1]-[5].
About estimated changes in solar cell during PID, for example, it has been reported that, due to the penetration of Na into the solar cell, a deep level is formed in the depletion layer or the base layer (p layer) and, as a result, carrier recombination through the level occurs [4]. Na is known to create a level in Si at a position 0.35 eV from the valence band. It also has been suggested that current shunt path is formed by intrusion of Na into stacking faults penetrating the pn junction (or that Na invading Si forms stacking faults) [5].
Even so, there is still a lack of understanding of the PID mechanism in solar cells, and obtaining more information regarding this phenomenon will require measurements of carrier distributions on a microscopic scale. One of the authors previously succeeded in quantitatively analyzing such distributions in monocrystalline Si solar cells using scanning nonlinear dielectric microscopy (SNDM) [6][7].
In the present study, the microscopic carrier distributions in monocrystalline Si solar cells exhibiting PID were investigated using this same technique. In addition, an enhanced version of this technique referred to as super-higher-order (SHO)-SNDM was employed to visualize depletion layer distributions in such cells both with and without PID.
As a result, reductions in carrier density in accordance with the extent of PID were clearly observed, and quantitative measurements demonstrated that the electron concentration was reduced by serval order of magnitude due to PID. Depth profile measurements showed that the solar cells were affected by PID to a significant depth of approximately 90 μm, equal

to almost half the cell thickness, suggesting that Na^+ migration proceeded easily upon the application of a high voltage. The SHO-SNDM data showed that the depletion layer of the non-PID sample was thinner than that of a PID sample, indicating that the carrier concentration in the former was greater.
This work demonstrates that SNDM is a very useful means of investigating the PID effect through the measurement of carrier distributions in monocrystalline silicon solar cells.

Analysis of the Physical and Photoelectrochemical Properties of c-Si(p)/a-SiC:H(p) Photocathodes for Solar Water Splitting María del Carmen Mejia, Luis Francisco Sanchez, Francisco Rumiche and Jorge A. Guerra; Pontificia Universidad Católica del Perú, Peru

In the present work, the effect of surface states and bulk opto-electronic properties of Al doped c-Si(p)/a-SiC:H(p) heterojunction photocathodes were evaluated on the photocatalytic performance for photoelectrochemical water splitting, before and after thermal treatments. The absorber a-SiC:H(p) thin film of around 320 nm was deposited onto p-type Si and fused silica substrates by reactive Radio frequency magnetron co-sputtering using high purity SiC and Al targets under Ar-H_2 atmosphere. a-SiC:H(p) thin films on Si substrates were chosen to perform morphological, structural and photoelectrochemical characterization. Whereas the samples prepared onto fused silica substrates, were used to perform optical characterization. The absorption coefficient and optical bandgap energy were determined since they play an important role in the device performance. Optical properties of the a-SiC:H(p) films were assessed systematically by means of UV-Vis transmittance measurements. Fourier transform infrared spectroscopy measurements were performed to track the hydrogen content, molecular bond-densities and changes in the structural properties of the a-SiC:H(p) layer for the distinct annealing temperatures. Van der Pauw electrical measurements revealed an improvement in the electrical behavior of the photocathode device after performing the annealing step at 600ºC. Ohmic contact, which is a key requirement for an optimal photoelectrochemical cell performance, was achieved after the annealing step at this temperature.

Annealing treatments induced changes in electrical, structural and optical properties of the material. These changes were reflected in the achieved good photocathode performance. Thus, an abrupt enhancement of the photocurrent was observed during the device photoelectrochemical test in 1 M H_2SO_4 solution under chopped light illumination. Reaching a saturation value of 17 mA/cm^2 at -1.75 V vs. Ag/AgCl (3.5 M KCl). In this research we propose that this enhancement is associated to a charge transfer kinetic mechanism influenced by surface states and the p-type Si substrate. The latter most likely due to the space charge region extension beyond the absorber layer until reaching the substrate, as it was demonstrated by means of electrochemical impedance spectroscopy measurements and some of our estimations. Current density-potential and electrochemical impedance spectroscopy measurements in dark, revealed a reduction of the SiO_2 native layer at cathodic potentials higher than -1 V vs. Ag/AgCl (3.5 M KCl). This last effect might contribute to the high charge transfer kinetic of the system. In that sense, our findings so far conduct to believe that SiO_2 layer reduction triggers a favorable semiconductor-electrolyte interface, possessing less overpotential barriers that facilitates photocurrent generation. We believe that these results will help to the developing of Si/SiC junction devices in tandem for solar-to-hydrogen energy conversion.

Neutral-Colored Transparent Crystalline Silicon Solar Cells Kangmin Lee, Namwoo Kim, Han-don Um and Kwanyong Seo; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Transparent solar cells, which combine visible transparency and solar energy conversion, are being developed for applications in which conventional opaque solar cells are unlikely to be feasible, such as windows of buildings or vehicles. However, transparent solar cells developed to date have limitations in efficiency and stability. Crystalline silicon (*c*-Si) is one of the best candidates to develop transparent solar cells with high efficiency and stability, because conventional *c*-Si solar cells are known to exhibit high efficiency and long-term stability compared with other solar cells. However, the opaque characteristic of the *c*-Si wafer hinders the development of transparent solar cells using *c*-Si. In this presentation, we introduce a novel approach to develop neutral-colored transparent *c*-Si solar cells that exhibit the highest efficiency among neutral-colored transparent solar cells developed to date. Also, we review recent progress in transparent solar cells along with strategies that enable the transparency of conventional solar cells, including thin film technology, selective light transmission technology, and luminescent solar concentrator technology. From fundamental research to commercialization of the transparent solar cells, three main perspectives should be considered: (1) high power conversion efficiency at the same average visible transmittance; (2) aesthetic factors, which should not detract from applications such as buildings and vehicles; and (3) feasibility for real-world applications, including modularization and stability evaluation. We present the distinct analysis criteria for these main perspectives and discuss their importance.

5:15 AM F.EN02.02.02
PV Cells Based on Arrays of Subwavelength Light Concentrators Ashish Prajapati; Ben Gurion University of the Negev, Israel

Texturing the front surface of thin film photovoltaic cells with ordered or disordered arrangements of subwavelength structures is beneficial in terms of efficient light harvesting as well as efficient carrier extraction. Previous studies demonstrated efficient broadband absorption of solar radiation with surface arrays of subwavelength inverted cones (light funnels – LFs). In the current work, we use threedimensional finite-difference time-domain electromagnetic calculations as well as three-dimensional device calculations to examine carrier extraction from photovoltaic cells that are composed of LF arrays on top of underlying substrates. For the selected geometry under examination, we show a broadband absorption enhancement of 14% for the LF photovoltaic cell compared with a cell based on the respective optically optimized nanopillar arrays. However, we show that the nominal power conversion efficiency is 60% higher in the LF cell which is due to the enhancement of both open-circuit voltage and short-circuit current. The higher open-circuit voltage in the LF cell is due to the higher injection of photocarriers, and the higher short-circuit current is a result of the unique LF geometry that supports efficient carrier extraction due to the naturally occurring gradients of the quasi-Fermi levels and minority carrier conductivity that allow for enhanced contact selectivity. We believe that this work paves the way towards a new approach for carrier collection in photonic devices for energy applications.

5:25 AM F.EN02.02.03
Multifunctional Effect of *p*-Doping, Anti-Reflection, and Encapsulation by Polymeric Acid for High Efficiency and Stable Carbon Nanotube-based Silicon Solar Cells Il Jeon[1,2], Yang Qian[1], Esko Kauppinen[3], Yoonmook Kang[4], Haeseok Lee[4], Donghwan Kim[4] and Shigeo Maruyama[1]; [1]The University of Tokyo, Japan; [2]Pusan National University, Korea (the Republic of); [3]Aalto University, Finland; [4]Korea University, Korea (the Republic of)

Silicon solar cells among different types of solar energy harvesters have entered the commercial market owing to their high power conversion efficiency and stability. By replacing the electrode and the p-type layer by a single layer of carbon nanotubes, the device can be further simplified. This greatly augments the attractiveness of silicon solar cells in the light of raw material shortages and the solar payback period, as well as lowering the fabrication costs. However, carbon nanotube-based silicon solar cells still lack device efficiency and stability. These can be improved by chemical doping, antireflection coating, and encapsulation. In this work, the multifunctional effects of p-doping, antireflection, and encapsulation are observed simultaneously, by applying a polymeric acid. This method increases the power conversion efficiency of single-walled carbon nanotube-based silicon solar cells from 9.5% to 14.4% and leads to unprecedented device stability of more than 120 days under severe conditions. In addition, the polymeric acid-applied carbon nanotube-based silicon solar cells show excellent chemical and mechanical robustness. The obtained stable efficiency stands the highest among the reported carbon nanotube-based silicon solar cells.

Indium Gallium Nitride-Silicon Heterojunction Schottky Barrier Solar Cells Choudhury J. Praharaj; BandOptics Materials, United States

We present calculations of performance characteristics of Indium Gallium Nitride-Silicon Heterojunction Schottky barrier solar cells. The effect of growth axis and spontaneous and piezoelectric effects in the Indium Gallium Nitride are taken into account. We consider both wurtzite Indium Gallium Nitride layers on 111 silicon and cubic indium gallium nitride layers on 100 silicon. The short-circuit current generation as a function of depletion-layer thickness is studied along with the effect of Indium Gallium Nitride composition on the Schottky barrier dark current. The absorption of high energy solar photons in a wider band-gap indium gallium nitride layer with the absorption of lower energy photons in the silicon layer provides the best efficiencies for this device as the conduction and valence band discontinuities are of the right sign to provide unimpeded electron and hole flow for collection in a high-efficiency cell. We consider the effect of composition grading on solar cell characteristics.

5:45 AM F.EN02.02.05
Optimization of Silicon Clathrates Films for Photovoltaic Applications Romain Vollondat[1], Arechkik Ameur[1], Stéphane Roques[2], Jean-Luc Rehspringer[2], Dominique Muller[1], Céline Chevalier[3], Abdelilah Slaoui[1] and Thomas Fix[1]; [1]CNRS and University of Strasbourg, ICube Laboratory, France; [2]CNRS and University of Strasbourg, Institut de Physique et Chimie des Matériaux de Strasbourg, France; [3]Institut des Nanotechnologies de Lyon, France

Common forms of elemental silicon (mono-, multi-crystalline and amorphous) materials have been playing a key role in photovoltaic technologies for almost seventy years and are studied thoroughly. Exotic, low-density forms of silicon have recently regained interest due to alluring semiconducting and optical properties as films in regard to the conventional ones. In this work, the focus is put on an allotrope of silicon: silicon clathrate films. Inorganic clathrates are intermetallic structures defined by a 3D porous framework (Si or group IV elements) of polyhedrons, which can enclose guest-atoms (Na or alkali metals). Due to this specific organization, some silicon clathrates can exhibit an interesting direct band-gap in the range of 1.8-2 eV[1], at low guest-atom concentration, which is specifically beneficial for photovoltaic applications.
In this work, we will introduce the preparation and characterization of silicon clathrate films using different silicon reagents (p-doped and intrinsic c-Si (100) and (111) wafer, a-Si on sapphire...). The structural, electrical, optical, surface properties are analyzed and the fabrication conditions optimized to give the best properties and mechanical integrity. Furthermore, various post-synthesis processes are investigated in order to maximize the photovoltaic efficiency of silicon clathrates in regard to the first silicon clathrates basic solar-cell obtained[2]. From Ion implantation experiments and other doping techniques to annealing under press, we will discuss how these treatments could, not only help to strengthen the properties of silicon clathrates, but also to bring some enlightenment about the underlying mechanisms that are still unclear.

5:55 AM F.EN02.02.06
Evaluation of Tellurium-Hyperdoped Silicon for Photovoltaic Applications Sashini S. Dissanayake[1], Shao Qi Lim[2], Philippe Chow[3], Jeffrey Warrender[3], Jim S. Williams[2] and Meng-Ju Sher[1]; [1]Wesleyan University, United States; [2]The Australian National University, Australia; [3]Benet Laboratories - ARDEC, United States

Hyperdoped semiconductors are promising material candidates for intermediate band photovoltaic applications with theoretical efficiency exceeding 50% [1]. Despite of considerable amount of literature reports on the optical and structural characterizations, few studies focus on crucial parameters for device designs such as charge carrier lifetime and mobility. In recent years, ion implantation followed by non-equilibrium pulse laser melting has shown to produce high quality hyperdoped material. The resulting hyperdoped layer is highly substitutional, containing up to 1 atomic % of dopant exceeding the typical solid solubility limit [2]. Previous studies have reported Si hyperdoped with S, Se, Te and Au as promising materials to enhance light absorption to the order of ~10^4 cm^{-1} in sub-band gap wavelength range [3-5]. Furthermore, Te dopant exhibits higher thermal stability than S and Se, and less dopant segregation than Au [6]. This study aims as understanding charge charrier dynamics such as carrier lifetime and mobility of Te-hyperoped silicon (Si:Te).
We study Si:Te on both p-type and n-type substrates with varying laser processing conditions. The optical absorption spectroscopy and secondary ion-mass spectrometry were employed to investigate the sub band-gap absorption and concentration profile. The results show that the absorption values are comparable with the other well studied materials like Au-hyperdoped Si (Si:Au), where sub bandgap absorption increases with increasing dopant dose. Time resolved terahertz spectroscopy (TRTS) is used to study the charge carrier lifetime. Optical pump THz probe is a non-contact photoconductivity

measurement for probing carrier lifetime with picosecond time resolution. We found that Si:Te lifetimes are much longer, consisting of a rapid decay in the order of ps followed by a longer, ns-lifetime component. To explain the observed results, we study two different optical pump wavelengths at 400nm and 266nm to investigate surface recombination, carrier mobility and diffusion properties. The carrier lifetime and mobility results together with optical absorption and structural properties will be discussed to better understand and optimize Si:Te as a material candidate for intermediate band photovoltaics.

Thin-Film Synthesis and Characterization of Silicon Clathrate Yinan Liu, William Schenken, Lakshmi Krishna, Ahmad A A. Majid, Carolyn A. Koh, P. Craig Taylor and Reuben Collins; Colorado School of Mines, United States

Development of new materials with novel optical, electronic, and spin properties is critical to next generation electronic and photonic technologies. Although Si has been the most widely used element in this area, the most stable Si phase, diamond Si, offers an indirect band gap and weak absorption. A cage-like, crystalline Si allotrope, Si clathrate, has been reported to have a direct or nearly direct bandgap with potentially exciting optoelectronic properties. Room temperature and atmospheric pressure metastable clathrates are synthesized in the presence of alkali guest atoms, such as Na, which occupy the interstitial sites in the cages. Low Na concentration Type II Si clathrate Na_xSi_{136} in the powder form has been identified to be a heavily doped semiconductor with Na guest(s) as a shallow donor. Compared with clathrate powder, the thin-film clathrates are more interesting due to their potential for practical application. However, the synthesis of high-quality clathrate films with well-defined properties for studies of band structure, defects, dopant diffusion, and electronic transport has been difficult. A detailed understanding of tunable and controlled thin-film synthesis and its optical properties is critical to eventually realizing the potential of these semiconductors for electronic and optoelectronic devices.
Here, we present a protocol for silicon clathrate thin film synthesis that produces thin, uniform, well adhered type II clathrate films with low Na concentration and a low concentration of competing phases. The films have been formed using a two-step process: formation of the precursor NaSi film and thermal decomposition of the precursor into the clathrate phase. By adding an additional annealing process between the two steps above, Na content was reduced before the thermal decomposition in an effort to reduce the voids and holes in the final film due to Na removal. XRD in combination with Rietveld refinement was used to characterize film crystallinity, phase purity, and Na content. The effect of varying the time and temperature of each of the processing steps was explored. Also, films were formed directly on Si wafers and Si films on alternative substrates, such as sapphire, to simplify electrical and optical characterization. Post growth treatment procedures to remove residual Na contamination were also developed. The films are expected to grow randomly and SEM images confirm morphological variation, but also show regions with sufficient uniformity to allow further measurement with optical and electronic techniques that sample small areas (e.g. photoluminescence (PL) and Time of Flight SIMS). We also obtained the correlation between the thin film thickness and the annealing time of the first step which makes controllable synthesis possible. Characterization of the synthesized thin film samples was performed and compared to low Na content powder samples. The PL spectrum shows a wide emission peak centered around 2 eV, with a full width at half maximum of about 0.54 meV. This peak is near the reported direct bandgap of Si clathrates but extends to higher energy, suggesting a degenerately doped semiconductor with an impurity band moving into the conduction band. Moreover, similar to the Electron Paramagnetic Resonance spectra of the clathrate powder at low temperature, we observe a feature at g~2.002 associated with free carriers and four hyperfine lines with the splitting of 133mT in the thin film due to the interaction of the Na valence electron with the nuclear spin ($I = 3/2$) of Na^{23}. The observation of the hyperfine lines suggests that the Na content in the films is below the metal-insulator transition. The findings in this work reinforce the notion that this Si allotrope could be a next-generation material for semiconductor technology.

Atomic Layer Deposition of Vanadium Oxide Films for Crystalline Silicon Solar Cells Eloi Ros Costals, Gerard Masmitjà, Estefania Almache, Benjamin Pusay, Gema Lopez, Kunai Tiwari, Edgardo Saucedo, Joaquim Puigdollers, Isidro Martin, Cristobal Voz and Pablo Ortega; Universitat Politècnica de Catalunya, Spain

Deposition of TMOs for PV purposes on industrial techniques (e.g. Sputtering, ALD, etc) is a work that has been repetedly

reported by relevant photovoltaic research groups[1][2], however so far literature results indicate that the hole selective properties of evaporated TMOs can not be successfully reproduced by other deposition methods Oposing to this thesis we report the deposition of vanadium oxide (V2O5) films by ALD
effectively performing as hole-selective contact for n-type crystalline silicon solar cells. Reasonable specific contact resistance of 100 mΩcm2 was measured by transfer length method. In addition, capacitance-voltage measurements confirms the presence of a strong inversion layer at the c-Si/V2O5 interface with a build in voltage of 683 mV. Furthermore, soft deposition of ALD achieved high effective lifetime values up to 800
µs as a result of passivation properties of the film. Finally, a proof-of-concept solar cells fabricated exhibiting efficiencies beyond 18% and with similar if not better photovoltaic parameters to evaporated TMOs without the
use of any additional passivation layer in the front contact. The technolgical implementation of ALD as the deposition technique to state of the art TMO solar cells could be the key for the fabrication of full wafer high efficiency dopant free c-Si solar cells.

Late News: *In Situ* Catalyst Doped Silicon Nanowires Solar Cells Krishna Nama Manjunatha; De Montfort University, United Kingdom

Silicon nanowires (SiNWs) have gained great attention in various emerging applications that include solar cells, Li- & Na-ion batteries, electronic memory devices, supercapacitors, and thermoelectric generators [1-3]. Although the semiconductor industry is dictated by silicon, there are many limitations posed by the bulk material limiting its use in emerging electronic devices. Interestingly, these limitations are solved by its micro to nano-sized silicon. Smaller dimensions of SiNWs have provided opportunities in solar cells due to increased absorption by trapping of light, anti-reflection effect, effective charge separation, decoupling the path of light absorption and carrier separation [1, 2]. The use of SiNWs requires a fraction amount of silicon as compared with the traditional Si wafer-based devices, which minimises the cost of production. With the Use of Plasma Enhanced Chemical Vapor Deposition process (PECVD) it is possible to lower the energy consumption for the growth of crystalline SiNWs by efficiently dissociating precursors gases, controlling the process with plasma and growth rate is an order of magnitude faster as compared with the Chemical Vapour Deposition and Molecular Beam Epitaxy. Also, enables the use of relatively cheaper substrates such as glass and plastic. However, currently SiNWs are doped with diffusion processes and/or gaseous precursors (diborane and phosphine). However, our work proposes doping from a metal catalyst [2-3] that is already used as a seed for the growth of nanowires. This method has added advantages including the elimination of toxic gases, avoiding the complexity of counter-doping caused by the catalyst, and reducing costs. Thereby moving towards green manufacturing processes.

This research focuses on understanding and optimisation of controlled growth of self-doped SiNWs (both n-doped and p-doped) by a PECVD process at relatively low temperatures (<300°C). Metals used as a catalyst in the VLS growth process provides some additional advantages along with the nucleation and precipitation if carefully selected. Hence, the selection of catalyst (metal) with ionisation energy level closer to the valence and/or conduction band of Si will contribute to self-doping. In this study, various metals (such as gallium, indium as p-type dopant, and Bismuth as n-type dopant) are used to facilitate the growth and to dope the nanowires. This work also introduces and discusses the novel process to grow simultaneously and selectively in situ *n*- and *p*-type silicon nanowires in a single pump-down PECVD process without the use of dopant gases. To the best of our knowledge, such a process is not reported. Such nanowires are possible to be grown on plastic and glass substrates thus reducing cost and open up a number of opportunities. Optical and electrical analyses including Seebeck and resistivity measurements will be discussed to understand the properties of catalyst doped SiNWs. Morphology and crystallinity by various characterisation techniques such as transmission and scanning electron microscopy, X-Ray diffraction, and Raman spectroscopy are performed. This work is not just limited to the growth process, but also adapting SiNWs to fabricate solar cells. For example, fabricated SiNWs photovoltaic solar cells have shown an efficiency of 6% and there is still room for improvement as the study is at the exploratory stage.

Late News: Energy Conversion of Yb3+, Pr3+-Doped BaF2 Thin Films for Photovoltaics—Synthesis and Luminescent Studies Francesca Lo Presti[1], Anna L. Pellegrino[1], Adolfo Speghini[2] and Graziella Malandrino[1]; [1]University of Catania, Italy; [2]University of Verona, Italy

Photovoltaic technology is considered one of the leading fields for sustainable solar energy production. In recent years, considerable efforts have been done in the development of functional materials for the fabrication of increasingly sophisticated and advanced photovoltaic devices (PV) that can ensure an efficient exploitation of solar spectrum. In this context, lanthanide (Ln)-doped fluoride materials are considered particularly promising for energy conversion applications due to their unique luminescent properties under light irradiation. A proper combination of doping elements allows an efficient luminescent pathway in a large spectral range through up-conversion (UC) or down-conversion (DC) mechanisms. UC and DC processes are the main mechanisms which enhance the efficiency of photovoltaic devices since they make possible to collect the radiation energy outside the absorption range of the photoactive material (usually silicon) by shifting the energy to a more suitable optical region. Among the fluoride-based systems, BaF_2 is considered a suitable host for the UC and DC luminescence of Ln^{3+} ions because of its low phonon energy (similar or even lower than the extensively used hosts such as $NaYF_4$), high chemical stability, wide transparency (i.e. BaF_2 is transparent from 150 nm to 15 μm) and versatile synthetic strategies. It should be mentioned that host materials require lattice matches with Ln^{3+} dopant ions. Trivalent lanthanide ions in particular can be well incorporated into crystal structure of alkaline-earth fluorides due to the similar coordination sphere. However, a charge compensation mechanism is required to balance the additional charge introduced after the replacement of divalent alkaline-earth ions with trivalent Ln dopants.
In the present study, we report the synthesis of Ln^{3+} co-doped BaF_2 thin films (Ln^{3+} = Yb^{3+}, Pr^{3+}) on silicon and quartz substrates, using metalorganic chemical vapor deposition technique (MOCVD). The advantages of this approach include: simplified instrumental apparatus, high deposition rate, high purity and easy industrial scale-up. For the fabrication of BaF_2 thin films co-doped with Yb^{3+}, Pr^{3+}, a multicomponent mixture of metalorganic adducts in an appropriate molar ratio is used as a single molten source. It is possible to easily tune the chemical compositions of the films, to tailor the energy transfer processes, by changing the composition of the precursor mixture, that is the Ba:Yb:Pr ratio in the multicomponent source. X-ray diffraction analysis (XRD), field-emission scanning electron microscopy (FE-SEM) and energy dispersive X-ray analysis (EDX) allowed a structural, morphological and compositional characterization of the films. Finally, the film functional properties have been assessed through luminescence spectroscopy.

Atomic Layer Deposited Niobium Oxide as a Passivating Layer and Selective Contact for Silicon-Based Photovoltaics Connor Leach, Benjamin Davis, Ben Garland and Nick C. Strandwitz; Lehigh University, United States

Atomic layer deposited (ALD) niobium oxide (NbO_x) has shown potential for use as a passivating layer or as a selective contact for silicon-based photovoltaics (PVs). However, there is large gap in understanding of the synthesis-structure-electronic property relationships. It has been shown by Macco et. al. that ALD niobium oxide can provide effective passivation of silicon substrates with an interfacial oxide down to 1 nanometer layer thickness.[1] In a separate work it was also show that ALD niobium oxide can serve as an electron selective contact.[2] In this work, the ALD growth of niobium oxide is optimized for temperature and co-reactants of either ozone (O_3) or water (H_2O). The oxidation states are then determined via X-ray photoelectron spectroscopy (XPS) to determine the exact stoichiometry of the films. The surface recombination velocity of niobium oxide contacts to silicon is measured and related to deposition conditions, film thickness, and post-deposition processing. Some samples are annealed in both inert and oxygen atmospheres and the stoichiometry is determined as well as the crystal structures measured via X-ray diffraction (XRD). This work provides new insight into the applicability of niobium oxides for passivation and selective contact layers for Si photovoltaics.

Effect of Deposition Temperature and Post Deposition Treatment on Carrier Selectivity of Tunnel Oxide Passivated Phosphorus Doped APCVD Polysilicon Contact Jannatul Ferdous Mousumi and Kristopher Davis; University of Central Florida, United States

Carrier selective contact enhances the efficiency of silicon (Si) solar cell by providing surface passivation and an effective majority carrier extraction. Recently, ultrathin silicon oxide (SiO_x) passivated n^+ polysilicon (poly-Si) contact has drawn attention as a promising electron selective contact because of its excellent surface passivation quality, low contact resistivity and high thermal stability compared to amorphous Si (a-Si:H) layer. Record efficiency of 25.7 % has been reported for *n*-type silicon solar cell fabricated using this as a full area rear contact [1].
In this work, we present a tunnel oxide passivated phosphorus doped poly-Si electron selective contact for *n*-type silicon solar cell where the *in*-situ doped poly-Si layer (around 100 nm) is deposited using an in-line high-throughput atmospheric pressure chemical vapor deposition process (APCVD). This in-line APCVD system can perform single-sided deposition in atmospheric environment and is well-suited for industrial mass production. In this process, thermal dissociation of silane (SiH_4) and phosphene (PH_3) gases deposits the phosphorus doped Si layer on top of the ultrathin SiO_x (<2nm) layer which is grown in a wet chemical process and acts as the tunnel oxide. Later, the as-deposited Si layer goes through different post deposition treatments such as annealing, firing, hydrogenation, etc. for solid phase crystallization and passivation quality improvement. We have studied the effect of the deposition temperature and different post deposition treatments on Si surface passivation quality and contact resistivity (ρ_c) of this poly-Si contact. The change in microstructure, dopant profile and crystallinity of the APCVD Si layer due to change in process parameters are observed to understand the process-structure-property relationship of this electron selective contact.

5:20 AM *F.EN02.03.06
Evolution of Silicon Heterojunction Solar Cells Akira Terakawa; Panasonic Corp, Japan

Amorphous/Crystalline Silicon heterojunction (SHJ), which has been invented in 1990 and has been industrialized in 1997 by Sanyo, is regarded as one of the ideal junction technologies for silicon-based solar cells. The conversion efficiencies are exceeding >24% for “standard” bifacial SHJ solar cells, and >25% for back contact SHJ solar cells, respectively, using industrially feasible processes. We are aiming to improve power generation efficiency and reduce power generation cost by combining thinner and larger wafering, reducing optical losses reduction, innovating texturing, hetero-junction and metallization technologies. We are also developing perovskite/SHJ tandem solar cells in order to break the "Silicon Limit." I will review our recent R&D activities.

5:35 AM F.EN02.03.07
Impact of the Bulk Resistivity on Silicon Solar Cells at Different Temperatures and Light Conditions Andre Augusto, Apoorva Srinivasa, Pradeep Balaji, Richard King and Stuart Bowden; Arizona State University, United States

We are reporting the findings of the 18 months project on impact of undoped substrates on high performance silicon solar cells supported by the U.S. Department of Energy. The aim of the project was to develop fundamental understanding and experimentally demonstrate the mechanisms in play when silicon solar cells are manufactured using different bulk resistivities (1 ohm.cm to over 15000 ohm.cm). The project focus was understanding how the performance of the solar cells, with different bulk resistivities, is impacted by in-field temperatures (up to 80 ºC) and light conditions (0.1-1 suns). Today's highest-efficiency solar cells typically operate near the threshold between low and high injection. It is not well understood whether pushing the cell operation point further into a high injection regime throughout the day is beneficial for the solar cell performance. In this study, we present a comprehensive assessment, both experimental and by simulation, of how bulk resistivity, defects, light conditions, and operation temperature impact the performance of the silicon solar cell. Analytical simulations indicate that high bulk resistivity wafers (10 ohm.cm to over 15000 ohm.cm) require bulk Shockley-Read-Hall lifetimes in the millisecond range to outperform wafers with standard bulk resistivities (below 10 ohm.cm). Additionally, for bulk resistivities beyond 10 ohm.cm, the cell efficiency is shown to be weakly dependent of bulk resistivity. This study is

particularly relevant today, as solar cell architectures with better surface passivation and milliseconds lifetimes wafers are commercially available, leveraging potential benefits of using higher bulk resistivities. Previous studies on high bulk resistivities are limited, inconclusive and lacked experimental data above 100 ohm.cm. In this work, we fabricate silicon heterojunction solar cells and samples to study lifetimes on n-type wafers with bulk resistivities from 1 ohm.cm to over 15000 ohm.cm. We measured their performance at different operation temperatures between 30 ^{o}C and 80 ^{o}C and for light intensities between 0.1-1 suns. The temperature coefficients are calculated from voltages at open circuit and maximum power, and from fill factors as a function of temperature. They are shown to be independent of the bulk resistivity and exhibit similar values as previously reported on standard bulk resistivities wafers. The surface saturation current density increases by several orders of magnitude for all bulk resistivities and show a cubic dependence of temperature. This temperature dependence was previously reported on standard bulk resistivities wafers. The significant increase of the surface saturation current density with temperature can be partially explained with a similar increase of the effective intrinsic carrier concentration. We are currently in the last quarter of the project and finalizing the measurements at different light conditions, the conclusions of which will be reported at the conference.

Lifetime Prediction of PV Modules—When is it Useful and When is it a Distraction? Sarah R. Kurtz; University of California Merced, United States

Lifetime prediction is a critical first step as the basis of a warranty or risk assessment. Research that identifies a PV module's primary degradation or failure mechanism, quantifies the associated acceleration factors, and applies those to operating conditions is a straightforward approach to lifetime prediction. The value of this process is obvious and researchers around the world are investigating degradation and failure mechanisms of PV modules with this goal in mind. Making a lifetime prediction is actually quite easy: we can predict 25 years ±25 years for pretty much all PV products on the market, but such a prediction is useless. Making a lifetime prediction with a small uncertainty that leads to a useful prediction is much harder. This talk will describe why lifetime prediction is difficult, when it is essential, when it is a distraction, and how we expect lifetime prediction may evolve in the future.

5:15 AM *F.EN02.04.02
Vehicle Integrated Photovoltaics—Past, Present and Future Martin Heinrich, Christoph Kutter, Felix Basler, Christian Schill, Holger Neuhaus and Harry Wirth; Fraunhofer Institute for Solar Energy Systems ISE, Germany

Vehicle integrated photovoltaics has recently seen a rise in interest due to the increased employment of full or hybrid electric vehicles. The topic itself is not new, already in the 80ies first cars have been equipped with solar cells, such as for the "Tour de Sol" in 1985. However, only within the last few years there has been a peak in announcements and news about this topic. New car manufactures such as SonoMotors or Lightyear as well as established car manufacturers such as Toyota or Hyundai have announced sizeable plans to introduce cars with solar energy support. The current spike in interest is not odd, solar technologies have become historically low priced in recent years and electric cars are more and more available for which an addition of a solar support is most reasonable.
After a brief introduction of the topic with support of a historical review, we provide an overview on the current approach of vehicle-integrated photovoltaics (VIPV) at Fraunhofer ISE. While VIPV for cars focusses currently on the embedding of silicon solar cells within curved laminated glass, the approach for utility vehicles such as trucks and their trailers is vastly different. Here, lightweight and glass-free setups are preferred due to the crash behavior and less intense requirements regarding surface finish. As promising solar cell and interconnection technology for VIPV, we introduce the concept of shingled solar cells, offering benefits regarding efficiency, voltage level, curvature and the overall aesthetics.
To precisely calculate the potential benefits of VIPV we provide insights into the project "PV2Go", where we compile a solar register of roads in Germany, which provides a detailed overview of the shading on roads in Germany. The modelling approach using spatial, geographic as well as digital terrain models is supported by a measurement campaign, where 100 cars are equipped with irradiation sensors.

We round off the topic with an overview of the future potential prospects of VIPV, such as equipping further vehicle parts like motor hood, side doors or even the windows with solar cells. It is concluded that by utilizing next generation solar cells such as tandem cells and further advances in increasing the efficiency of electric vehicles could lead to affordable vehicles with solar as the main source for propulsion.

5:30 AM *F.EN02.04.03
From Modules to Atoms—Characterization of Silicon Photovoltaic Module Reliability Guided by Luminescence and Thermal Imaging Dana Kern[1], Steve Johnston[1], Helio Moutinho[1], Dirk C. Jordan[1], Jenya Meydbray[2], Laura Spinella[1], Michael Owen-Bellini[1], Kent Terwilliger[1], Archana Sinha[3], Laura Schelhas[3], Chun-Sheng Jiang[1], Chuanxiao Xiao[1], Matthew Young[1] and Mowafak Al-Jassim[1]; [1]National Renewable Energy Laboratory, United States; [2]PV Evolution Labs, United States; [3]SLAC National Accelerator Laboratory, United States

With the lifespans of photovoltaic (PV) modules expected to last >20 years, rapid and spatially-resolved characterization methods are essential for understanding module reliability and degradation processes. Luminescence and thermal imaging have been gaining popularity both for fast, outdoor-compatible module inspection and for more detailed post-mortem analysis of failure mechanisms. Importantly, many failure mechanisms are not evident by visual inspection, and characterization of electrical properties alone is insufficient to identify the weakest features of cell or module design. This is especially true as PV technologies and module packaging schemes become more advanced and degradation becomes more subtle. Here, we present various examples of PV module degradation mechanisms in field-weathered modules, where we (1) locate problem areas with luminescence and thermal imaging, (2) core these areas out of the module, and (3) use various microscopy methods to identify chemical and structural causes of power loss. We particularly highlight causes of voltage loss or series resistance increases that vary depending on the technology, and we show studies including conventional Al back surface field (Al-BSF), silicon heterojunction with intrinsic thin layer (HIT), and passivated emitter and rear contact (PERC) modules. These results highlight the utility of imaging methods for improving module reliability.

5:45 AM *F.EN02.04.04
Advances in Silicon Photovoltaic Module Manufacturing—From Manual Tabbing to Cut Cells and High-Power Modules Alison Lennon; University of New South Wales Sydney, Australia

Silicon solar cells have been interconnected by soldering and laminated into modules using essentially the same process that was used in the 1970's. When Suntech commenced the mass manufacture of silicon photovoltaic modules in China in 2006, soldering was performed manually due to the low-cost of labour. However, automated stringing and tabbing machines quickly became the norm in Chinese manufacturing for the commonly produced two-busbar cells. Since then we have seen numerous advances in module engineering as silicon photovoltaics has become a low-cost form of electricity generation across the world. Starting from 3 busbar patents to large-sized modules fabricated from cut-cells designed to increase the module area efficiency especially for utility scale photovoltaics. It is now not just the module power that matters, it is module specific yield or how much electricity (kWh) will be generated per unit of purchased power (kW). This presentation will trace the advances in silicon photovoltaic module manufacturing over the years and discuss the current challenges of rapidly changing module architectures to service both rooftop and utility-scale applications.

6:00 AM *F.EN02.04.05
Photovoltaics Crystalline Silicon Wafer Trends and Their Impact on Module Performance Frederic Dross, Adrien Pellarin, Thibaut Lemoine, Jenny Yang and Alexandre Minuzzo; STS, United States

Despite being labelled as "first generation" by some of the most eminent experts, crystalline-silicon technology has been dominating the photovoltaics industry for several decades and shows no sign of giving up its leading position. There are many reasons for that and the fast ramp up of production volumes combined with an aggressive learning curve makes it hard for challengers to compete. But another element should not be underestimated when considering the dominance of crystalline silicon: the constant improvement of the base material, the crystalline silicon wafer.
In this presentation, we will identify the main trends the silicon wafers have experienced along the years: the secular battle between mono and multi, the reduction of thickness incentivized in periods of raw material shortage, the increase of grain size to reduce effect of grain boundaries followed by a reduction of the grain size to avoid intra-grain defects, etc. We will also discuss the market rationale as well as the technical implications of the most recent trends in this domain: rapid increase of the wafer size, cutting of wafers into smaller pieces and emerging interest for n-type technologies.
The discussion will rely 10-years of in-factory experience, and data collection (module bill-of-materials and performance metrics) that STS is enjoying to address the impact of each crystalline silicon wafer trend on all aspects of the module performance.

6:15 AM *F.EN02.04.06
DuraMAT—Leveraging Field Data, Advanced Characterization, Multi-Scale Modeling, Accelerated Testing and Material Development to Improve Module Reliability Teresa M. Barnes; National Renewable Energy Laboratory, United States

The Durable Module Materials Consortium (DuraMAT) launched in November of 2016 with five years of funding as part of the Energy Materials Network. DuraMAT is a multi-lab consortium, led by NREL and Sandia with SLAC and LBL as core research labs. The overarching goal of DuraMAT is to discover, develop, de-risk, and enable the rapid commercialization of improved materials, designs, predictive tests and models for photovoltaic modules that increase performance, extend lifetime, and enable new applications. Our core objectives are focused on establishing and applying critical capabilities to address big challenges for PV module durability. These challenges include the community's inability to make meaningful service life and durability predictions for PV modules with our current testing protocols and knowledge. It is incredibly difficult to make meaningful predictions for 30+ year outdoor durability for cutting edge products with a six month product development cycle! Improving outdoor durability and our ability to predict it requires more durable materials and designs, better tests to screen for weaknesses, modeling, materials and module characterization data, and a way to combine all of this data with historical performance data to extract meaningful results.

6:30 AM F.EN02.04.07
Multiscale Characterization to Gain Insight into Failure Modes and Degradation Mechanisms in Silicon Photovoltaics Nafis Iqbal, Dylan Colvin and Kristopher Davis; University of Central Florida, United States

With the increasing global demand for silicon photovoltaics (PV), new cell and module technologies are quickly emerging in the market. The implementation of these technologies requires investigation of the long-term performance in order to maintain PV module reliability standards. In this work, we perform multiscale characterization to gain insight into the different failure modes and degradation mechanisms commonly observed in PV modules. Multiscale characterization methods can be used to link observed degradation to specific loss mechanisms (i.e., optical, recombination, resistive) and to the root causes (i.e., changes in chemistry and/or microstructure). We investigate a range of module types with different cell technologies like traditional Al-BSF (Aluminum Back Surface Field) and newly emerging mono/multi-crystalline PERC (Passivated Emitter and Rear Cell). Both field exposed and damp-heat aged modules are investigated to track the long-term degradation. Module and cell level current-voltage (*I-V*), Suns-V_{OC}, photoluminescence (PL) and electroluminescence (EL) imaging have been performed on aged and control modules. For the aged modules, cell darkening has been observed in the EL images which can be related to high resistance and fill factor (FF) losses. For the older modules, this darkening happens across the entire cell area, whereas for newer modules with new generation silver (Ag) paste, the darkening is mainly observed to start from the busbars. Our analysis suggests this degradation is related to metallization corrosion. To gain more insight into this failure mode, samples have been cored out from the modules followed by the removal of encapsulation to perform materials characterization. Top-down and cross-sectional SEM and EDS analysis have been performed on the degraded Ag fingers. Furthermore, XPS analysis on the top of the bulk Ag finger and on the glass-layer (after etching away the Ag) has been performed. We observe that the degradation results in delamination of the Ag finger from the cell with voids and gaps forming within the metal-Si interface. EDS and XPS analysis show tin (Sn) in the busbar region and oxidation of the Ag finger. Further investigations are being performed to understand the effect of Sn migration and oxidation on the corrosion and delamination process.

Building Efficient Single-Junction and Tandem Solar Cells from Silicon and Perovskites Using Passivating Contacts Stefaan De Wolf; King Abdullah University of Science and Technology, Saudi Arabia

In silicon and perovskite solar cells, the presence of surface states at their electrical contacts is increasingly recognized as a key factor limiting device performance [1,2]. In this presentation, I will first discuss how such surface states result in Fermi-level pinning and surface recombination. Passivating-contact technology aims at minimizing the interface-gap state density,

resulting in improved operating voltages and low contact resistances. I will focus on recent advancements in this topic, both for crystalline silicon and perovskite solar cells. In a second part of my presentation, I will discuss the fabrication of efficient monolithic tandem solar cells, combining silicon and perovskite solar cells, aimed at very high-efficient photovoltaics at affordable cost. Specific emphasis will be laid on different possible strategies to build efficient tandems from fully-textured silicon bottom cells; the use of such macro-scale textured bottom cells brings optical advantages, but also brings perovskite/silicon tandems close to industrial implementation [3]. In a final part, I discuss the field performance of such devices and draw conclusions from this for future device development.

Sustainability Aspects and Circular Economy Approaches of Modern Crystalline Silicon and Perovskite Silicon Tandem Modules Karsten Wambach; bifa Umweltinstitut GmbH, Germany

Silicon PV modules have become a worldwide commodity nowadays. New module types and production technologies are rapidly introduced and the consumption of costly or valuable materials is minimized with increasing conversion efficiencies of sunlight to electricity. The latest approaches utilize, for example, advanced silicon and perovskite silicon tandem cells to increase the conversion efficiencies to more than 30% of the incident sunlight. These 2 examples are selected to assess the current and forthcoming challenges in the reuse and waste treatment sector of end-of-life modules in this presentation. The five topics covered are:

Regulations and standards
Economic and environmental aspects
Decommissioning of PV plants
Preparation for re-use
Recycling and end-of-waste criteria

The PV modules have a long lifetime of beyond 25 years, but with increasing installations sound end-of-life treatment solutions have to be introduced and any potential environmental burdens have to be reduced as far as possible. Even though the waste amounts are rather small compared to other waste streams like electronics, a sound circular economy should be developed with a good eye for the market demands, resources, costs and environment. This approach requires a detailed analysis of the components and materials used in a PV module and an environmental risk and value analysis.

Usually end-of-live PV modules are considered as electronic waste. The approaches to establish a sound waste treatment economy are manifold. E.g., mandatory end-of-life collection and waste treatment systems are already in force in all EU countries and in some areas of USA. At the end of the life of a PV module the collection and treatment is frequently covered by general waste, waste electronic and electrical equipment (WEEE) laws. International and local regulations exist in trans-boundary shipments of used modules and wastes. The waste regulations are applied in combination with the globally harmonized system (GHS). Examples of current practices of waste treatment with recycling and/or landfill disposal are presented. A brief overview about a possible classification of the wastes according to the European list of wastes is presented for both example module types and their possible output materials. End-of-waste criteria for intact modules having entered the waste regime are discussed and, additionally, the major recycling outputs like glass, metals and semiconductor materials are included.

New standards like ANSI/NSF 457-2019 “Sustainability Leadership Standard for Photovoltaic Modules and Photovoltaic Inverters, or CENELEC EN50625-1-4 (2018) on collection, logistics & treatment requirements for WEEE, and other have been introduced. Like in the automotive and the electronics industry stewardship systems and product databases including the individual components are proposed and producer responsibility principles are realized. This is closely linked to the introduction of new assessment methodologies like the European Environmental Footprint (PEF). Recommendations for the cases of a second life of the modules including reuse and repair are under development. The presentation includes an

overview about these topics.

5:30 AM F.EN02.05.03
Interplay Between Temperature and Bandgap Energies Determines Outdoor Performance of Perovskite/Silicon Tandem Solar Cells Erkan Aydin[1], Thomas G. Allen[1], Michele De Bastiani[1], Lujia Xu[1], Jorge Avila[2], Michael Salvador[1], Emmanuel Van Kerschaver[1] and Stefaan De Wolf[1]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]Universidad de Valencia, Spain

Perovskite/silicon tandem solar cells promise power conversion efficiencies (PCE) beyond the Shockley–Queisser limit of single-junction devices, however, their actual outdoor performance is yet to be studied and understood. Here we fabricate two-terminal (2T) monolithic perovskite/silicon tandem solar cells with certified PCE values of 25% and current densities of 19.8 mA/cm^2 and test them outdoors at elevated temperatures in a hot and sunny climate. With these data, we then calibrated a device-temperature model. By combining this model with relevant meteorological data, we simulated the tandem temperature over a complete year (2016), giving a realistic framework for tandem-performance analysis. Later, we experimentally characterized our tandems in a controlled laboratory environment under various temperatures and illumination spectra, with specific attention paid to their impact on current matching. Finally, to gain further insight, we developed a temperature-dependent radiative-efficiency model to support our findings. We find that the temperature dependence of the bandgaps (E_g) of both crystalline silicon and perovskite – which follow opposing trends – shifts the devices away from current matching for 2T tandems optimized at standard test conditions (STC, *i.e.*, AM1.5G spectrum, 1000 W/m^2, 25 °C). Consequently, we argue that the optimal perovskite bandgap at STC is lower compared to earlier findings. Through temperature-dependent radiative-efficiency modeling, we show that the ideal bandgap of the perovskite in perovskite/silicon tandems is E_g <1.68 eV (at STC) for optimal field performance at operational temperatures >55 °C. This implies that Br-lean perovskites with narrower bandgaps at STC – and, therefore, better phase stability – hold great promise for the commercialization of perovskite/silicon tandem solar cells.

SESSION F.EN02.06: Thin Wafer and Light Management
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-EN02

5:00 AM *F.EN02.06.01
Internal and External Solar Cell Light Management—The Forgotten Photons Rebecca Saive; University of Twente, Netherlands

I will present different strategies to improve the efficiency and power yield of solar cells, both by reducing optical losses of the cell itself as well as by optical design of the surroundings.
As solar researchers during the past decade, we have been privileged to witness solar energy transitioning from a niche technology into the most promising and affordable way to meet our demand for electricity. In many regions of the world, solar cells have reached grid parity with conventional fossil fuel based electricity sources and the cost of solar energy is further declining. Finally, the transition to renewable energy sources is no longer driven by environmental concerns only, but also offers competitive return of investment.
Simultaneously to this rapid cost decline, the efficiency of solar cells has been increasing steadily. Thanks to very careful interface design and reduction of surface recombination, silicon solar cells are on a strong track to approach the practical Auger limit.
Nevertheless, creative approaches from many directions still enable new record efficiencies and power per cost enhancements. Here, I will present some of our strategies to improve the power output of conventional photovoltaic panels by controlling and managing the photon influx. First, I will talk about effectively transparent contacts (ETCs), the only front contact technology eliminating close to all shading losses while providing high conductivity. ETCs are triangular microscale silver contacts featuring high aspect ratio (>1:2.5) and specular side walls which redirect incoming sunlight towards the active area of the solar cell instead of reflecting it away. We have integrated ETCs with different types of solar cells, and observed up to 7% power output enhancement. Upscaling and commercialization of the ETC technology by the start-up ETC Solar is underway.
As the second topic, I will present our experimental study of spectro-angular solar irradiance and the influence on the yield of solar power plants in different locations and configurations. In particular, I will present comparisons between monofacial and

bifacial solar cells with respect to the measured spectrum and angle dependent irradiance. Bifacial cells show to be superior both under cloudy as well as under sunny conditions. Under sunny conditions, the benefit mainly arises from ground reflection. The ability of surface to reflect light, also known as albedo, heavily influences the output of bifacial solar cells. The output is strongly dependent on the spectral reflection properties of the albedo material and it can be shown that an ideal spectral albedo material exists. We are designing and fabricating ideal albedo materials with the goal to achieve affordable low x concentration in bifacial solar cells.

5:15 AM F.EN02.06.02
Towards High Solar Cell Efficiency with Low Material Usage—15 % Efficiency with 14 µm Liquid Phase Crystallized Silicon Siddhartha Garud, Cham thi Trinh, Bernd Rech and Daniel Amkreutz; Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

A bottom-up approach to creating silicon solar cells has the potential to not only avoid kerflosses incurring in wafer slicing, but also the energy involved in kerfless slicing techniques. Liquid-phase-crystallized silicon (LPC-Si) is one such approach in which amorphous/nanocrystalline silicon is deposited on glass up to a desired thickness (5-40 µm) and crystallized with a line-shaped energy source, which is a laser in this work. LPC-Si of ~14 µm has previously demonstrated power conversion efficiency up to 14.2 % despite illumination through glass, using a heterojunction interdigitated back contact cell architecture (HJ-IBC) [1]. The first part of this work reports efforts to create thicker heterojunction interfaces for better surface passivation. A ‘multilayer’ a-Si surface passivation is also shown which consists of three cycles of a-Si(i) deposition, each one followed by a short hydrogen plasma treatment but with different hydrogen dilution levels. The second part covers laser firing on the electron contact. It enables a controllable trade-off between charge collection and fill-factor by creating a low resistance Ag-Si electron contact, while preserving a-Si:H (i) passivation in other areas [2,3]. Short-circuit current density (J_{SC}) was observed to be up to 33.1 mA/cm^2, surpassing all previously recorded values for this technology. Open-circuit voltage (V_{OC}) of up to 658 mV also exceeded every previous value published at a low bulk doping concentration of 1 x 10^16 cm^{-3}. Laser firing reduced J_{SC} by 0.6 mA/cm^2 on average but improved fill-factor (*FF*) by 22.5 % absolute on average, without any significant effect on V_{OC}. Collectively, these efforts have helped achieve a new in-house record efficiency for LPC-Si of 15.1 % with 31.4 mA/cm^2 J_{SC}, 645 mV V_{OC} and 74.7 % *FF*. The best cell in terms of J_{SC} (32.7 mA/cm^2) and V_{OC} (657 mV) lacked only in series resistance and shows potential to surpass the current best cell performance in the near future. While excluding the effects of series resistance by measuring a Suns-V_{OC} curve, this cell shows a pseudo-efficiency of 17 %. Therefore, current efforts are focused on creating larger electron contact widths and heterojunction layers optimised for lower contact resistance.

Lift-off Techniques for Kerfless and Thin Monocrystalline-Silicon Solar Cells—A Snapshot of History Valerie Depauw and Hariharsudan Sivaramakrishnan Radhakrishnan; imec, Belgium

To be able to continue its steady reduction of solar module cost, the photovoltaic industry must keep increasing the usage efficiency of all the materials, particularly that of silicon (Si). For the latter, the three main levers are increasing cell efficiency, reducing cell thickness and reducing all the losses along the wafer manufacturing chain. To reach below today’s average consumption of 4 g/Wp, incremental improvements can be still be envisaged. However, going far below that value, down to 1 g/Wp, requires disruptive technologies. The 2019 ITRPV roadmap is thus predicting the increase in appearance of kerfless multi- and monocrystalline wafers on the market.

A wide range of kerfless wafering methods have been developed as alternatives to the traditional Czochralski wafer manufacturing process. These disruptive concepts can supply wafers thinner than 100 µm and increase the Si utilization rate by shortcutting the Cz process chain. These various methods can be classified according to the process step at which they introduce the shortcut, and at which silicon is available in different states: solid/ingot, liquid/melt or gas. At the end of the

chain, are kerfless wafering methods, such as spalling, that propose alternatives to wafer sawing. One step upstream are methods that enable growing multi- or monocrystalline wafers directly from the melt, without ingot growth, such as ribbon growth techniques or Epilift. And further upstream, skipping the energy-intensive poly-Si production step, are methods that grow wafers from the gas (silane) phase, such as epi-Si lift-off. Except for the ribbon-growth methods, all rely on the lift-off of a thin silicon wafer or seed layer with manifold re-uses of the parent substrate (wafer or ingot). The first reported lift-off silicon foil, by Milnes and Feucht, dates back to 1975. Forty-five years later, the concept has been explored in countless labs and has resulted in dozens of creative ways of producing thin and high-quality silicon layers. Only very few have the potential however to make it from lab to fab.

We have recently reviewed this rich field of silicon lift-off techniques for photovoltaics and propose to give an overview of all the different innovative ways that have been imagined and realized to fabricate thin silicon slabs with minimal silicon wastage, and to try and understand what has determined their fade-out or survival. And what may determine their survival or revival in the future. Today, even though the drive for the entry of kerfless lift-off methods in the PV market is still rather low and hindered by different technological hurdles, they may, with their lower carbon dioxide footprint, be better suited to the world of tomorrow.

5:40 AM F.EN02.06.04
Hyperuniform Designs for Enhanced Light Trapping in Ultra-Thin Si Solar Cells Nasim Tavakoli[1], R. J. Spalding[2], Pepijn Koppejan[1], G. Gkantzounis[2], C. Wan[2], Ruslan Rohrich[1,3], Evgenia Kontoleta[1], A. Femius Koenderink[1], Riccardo Sapienza[4], Marian Florescu[2] and Esther Alarcon-Llado[1]; [1]AMOLF, Netherlands; [2]Department of Physics, Advanced Technology Institute, University of Surrey, United Kingdom; [3]Advanced Research Center for Nanolithography (ARCNL), Netherlands; [4]Imperial College London, United Kingdom

Introducing thin, light-weight and high efficiency photovoltaics (PV) will make solar cells more suitable to be integrated in urban landscapes or even small gadgets and would largely contribute to solving the global warming threat that we are facing today. Stacking of solar cells with different characteristic bandgaps is the most common strategy to increase efficiency to surpass the Shockley-Queisser limit, but such tandem devices are typically heavy weight, rigid and costly. An effective approach to tackle this problem is nanopatterning the absorbing layer.

In this work we introduce various hyperuniform designs incorporated on a 1-um thin silicon film as an effective way to control scattered light into particular range of angles to be efficiently absorbed in silicon. These structures are first designed by a 6-fold optimization to achieve 2D designs, and later Meep simulations to optimize absorption spectra in 3D structures. We experimentally show the redirection of light into the engineered range of angles as a ring in the k-space, which matches greatly with the expected structure factors. Further, using an integrating sphere we measure 65% sunlight absorption in the free-standing 1 um c-Si with fabricated hyperuniform designs. The equivalent photocurrent derived from our measurement is far above the highest found in literature, and the estimated photovoltaic efficiency for a state-of-the-art ultra-thin solar cell incorporating our designed nanotexturing is above 20%. This is a highly remarkable efficiency for such a thin indirect-bandgap material and establishes a new breakthrough in thin light-weight and flexible solar cells.

5:00 AM *F.EN02.07.01
Improved Infrared Light Management with Amorphous Silicon in High Efficiency Silicon Heterojunction Solar Cells Weiyuan Duan, Karsten Bittkau, Andreas Lambertz, Paul Steuter, zhirong yao, Kaifu Qiu and Kaining Ding; IEK5-Photovoltaik, Forschungszentrum Jülich GmbH, Germany

Silicon heterojunction (SHJ) solar cells coupled with hydrogenated intrinsic amorphous silicon (a-Si:H) layers enable high open-circuit voltages (V_{oc}) of up to 750 mV, but suffer from short-circuit current density (J_{sc}) losses due to parasitic absorption in a-Si:H, transparent conductive oxide (TCO) layers and shadowing of the metal fingers. Significant improvement in V_{oc} is expected only for thinner wafer. Increasing J_{sc} is a more promising route to further improve cell efficiency. Besides the use of high bandgap materials such as nanocrystalline silicon oxide or low carrier density TCO layers to reduce parasitic absorption, an improved light trapping that enables more light to be absorbed within the silicon wafer

represents another important opportunity for J_{sc} improvement, which becomes even more significant when thinner wafers are used. In this work, a thin intrinsic a-Si:H layer was introduced after metallization of SHJ solar cell, formed a TCO/a-Si:H back reflector. Unlike sophisticated structures such as diffraction gratings, black silicon or other kind of nanophotonics, TCO/a-Si:H back reflector is much easier to be fabricated. Compared with the very often used silver back reflector, a-Si:H is less expensive and can still keep some of the bifaciality of the cells.

The intrinsic a-Si:H layer was deposited by plasma enhanced chemical vapor deposition (PECVD). It has a refractive index of around 4 at infrared (IR) wavelengths extracted from ellipsometry measurement. Sentaurus TCAD simulation was used for the rear optics in terms of optimizing the thickness of TCO/a-Si:H stack. We systematically investigated how the TCO/a-Si:H back reflector increases rear internal reflectance by measuring reflectance and external quantum efficiency before and after deposition of the a-Si:H layer. As predicted from simulation, due to increased IR reflection, J_{sc} was 0.4 mA/cm^2 higher with TCO/a-Si:H back reflector when applied on SHJ solar cells using 110 mm thickness wafer, while fill factor (*FF*) and V_{oc} remained constant. Combined with an optimized front MgF_2 double antireflection coating, we could demonstrate a 0.9 mA/cm^2 improvement in J_{sc}, which boosts the cell efficiency by 0.5%. Ultimately, a M2 size total area cell efficiency of 23.7% has been achieved with V_{oc} of 745 mV, J_{sc} of 39.4 mA/cm^2 and *FF* of 80.8% on 110 um thin wafer. It's worth noting that the cell still kept a bifaciality of more than 50%. The reflector concept introduced here has a possibility to be used in advanced double-glass module encapsulation.

Efficient Hole-Selective Passivating Contacts for Si Photovoltaics Takuya Matsui and Hitoshi Sai; AIST, Japan

Hydrogenated amorphous silicon (a-Si:H) is a key material in realizing efficient passivating contacts for Si solar cells known as the silicon heterojunction (SHJ) technology. However, one drawback of the SHJ solar cells is that the a-Si:H, particularly when doped with boron, gives rise to a parasitic optical absorption loss due to its high absorption coefficients in the visible wavelengths. This adverse effect is pronounced in bifacial solar cells, as this type of device allows illumination from both the front and the rear surfaces. Here we pursued alternative materials focusing on hole-selective passivating contacts: one is the hydrogenated nanocrystalline Si (nc-Si:H) and the other is the novel metal-oxide material. For the nc-Si:H material, it is demonstrated that the replacement of (*p*)a-Si:H by (*p*)nc-Si:H provides not only an increase of J_{sc}, but also improvements in V_{oc} and FF. This results in an efficiency increase by 0.6% absolute compared to our reference cell with (*p*)a-Si:H, and a best cell efficiency of 23.5%. The factors that alter the optimum hole contact layer thickness depending on the material and deposition condition will be discussed. For the metal-oxide material, we have developed an atomic-layer-deposited TiO_x nanolayer that functions as an efficient and transparent hole-selective passivating contact, leading to proof-of-concept solar cells with efficiencies above 20%. This new function of TiO_x is opposite from the previous understanding that it acts solely as electron contact.

Atomic Layer Deposited Metal Oxide Bilayers for Metal-Insulator-Semiconductor Photovoltaics Benjamin Davis and Nick C. Strandwitz; Lehigh University, United States

The use of metal-insulator-semiconductor (MIS) tunnel diodes as photovoltaics (PVs) relies on the Schottky barrier between the metal and semiconductor, which induces band bending in the semiconductor absorber allowing for efficient separation of electrons and holes. In the years following early MIS PV research in the 1970s and 1980s, the advent of atomic layer deposition (ALD) has provided a tool for enhanced control of ultrathin film deposition. One method to potentially improve MIS PV performance is the use of ALD oxide bilayers as tunnel insulators. Oxides with different oxygen areal densities have been demonstrated to form interfacial dipoles, manipulating the Schottky barrier. Previous studies have only explored the impact of dipoles between a single ALD oxide and interfacial SiO_x. The present work combines two ALD oxides, one (AlO_x) with oxygen areal density higher than that of SiO_x and another (LaO_x) with oxygen areal density lower than that of SiO_x according to literature. It has been hypothesized that the greater oxygen areal density difference would result in a greater impact on the Schottky barrier. It is demonstrated that, compared to AlO_x alone, an ALD LaO_x/AlO_x stack increases the average n-Si/Ni Schottky barrier height from 0.63 to 0.70 eV, and the average p-Si/Al barrier height from 0.81 to 0.90 eV. LaO_x was the oxide in direct contact with the Si substrate. The observation that the barrier height increases for both substrate types suggests that the effect is due to the ability of LaO_x to depin the Fermi level rather than an interfacial dipole.

5:40 AM F.EN02.07.04
Exploiting Fixed Charge to Control Schottky Barrier Height in Si\|Al_2O_3\|MoO_x—Based Tunnel Diodes Ben Garland, Benjamin Davis and Nick C. Strandwitz; Lehigh University, United States

Carrier selective contacts have become one of the leading advancements in photovoltaics with the most efficient structures exceeding 26% conversion efficiency. Selective carrier conduction implies that one type of charge carrier is preferentially collected at an electrical contact. Carrier selectivity increases the efficiency of solar cells by reducing recombination at metal contacts and avoiding highly doped emitter layers. Popular selective contact materials are often transition metal oxides (TMOs) due to high optical transparencies and large work functions that are useful for hole selective contacts to silicon. In contrast to previous articles, recent studies have indicated that the interface of p-type silicon and the molybdenum oxide (MoO_x) exhibits a significant Schottky barrier that decreases the efficiency of hole-selective contacts by impeding majority carrier hole collection. To alleviate this issue, atomic layer deposited (ALD) alumina (Al_2O_3) might be added between Si wafer and MoO_x with the expectation to generate a negative interface fixed charge (N_f) after annealing, decreasing band bending. ALD Al_2O_3 also has the ability to passivate interface traps with diffusion of precursor hydrogen during annealing. In this work, we hypothesize that insertion of a tunneling ALD Al_2O_3 layer between MoO_x and p-type Si will enable Schottky barrier height (Φ_{bh}) minimization that is tunable with N_f, enabling a high efficiency hole-selective contact.
Since there should not be quantifiable N_f in tunneling Al_2O_3 using capacitance-voltage (C-V) analysis, non-tunneling n-Si|Al_2O_3|Al MOSCAP structures were used to determine ideal processing for maximum negative N_f. The ALD growth of Al_2O_3 utilized trimethylaluminum and H_2O at 4 deposition temperatures. Half of the samples were annealed at 425°C in a nitrogen atmosphere prior to the application of Al contacts. After N_f quantification, p-Si|Al_2O_3|MoO_x|Al tunnel diodes with thin (~1 nm) as-deposited and annealed Al_2O_3 layers were fabricated to determine Φ_{bh}. Current density-voltage-temperature (J-V-T) and Mott-Schottky $1/C^2$-V measurements were used to establish a range for Φ_{bh}. Both methods showed that the as-deposited tunneling Al_2O_3 diodes had a higher Φ_{bh} compared to the diodes with annealed tunneling Al_2O_3, and therefore also supported the existence of a Φ_{bh} at the Si|MoO_x interface. Future work will involve using larger barrier height diodes using n-Si to more accurately calculate Φ_{bh} and confirm or reject the phenomenon observed.

5:50 AM *F.EN02.07.05
Organic-Silicon Heterojunction for Solar Cell and Integrated Flexible Energy Devices Baoquan Sun; Soochow University, China

Numerous alternative materials and solar cell device structures have been widely explored in order to reduce the cost of photovoltaic (PV) manufacture. Organic-inorganic component solar cells based on nanostructured semiconductor have built up in past two decades, which may promise the potentially low cost and high performance. However, the device performances are generally lower than its pristine all-inorganic PV devices, resulting from the numerous surface defect and improper organic-inorganic phase segregation. Here, we demonstrate that hybrid PVs based on organic conjugated molecular and nanostructured silicon can achieve a high power conversion efficiency by controlling the interface contact as well as surface passiviation.
An advantage of this type heterojunction devices presents the excellent light harvest capability of nanostructured as well as benefiting likely simple fabrication process. Especially, the composite of conjugated organic materials and nanostructured inorganic materials are potential candidates for cost-effective and efficient solar-energy-harvesting devices[1]. This device can be operated by a light-modulated field effect solar cell, which can improve the device performance under accumulation of light illumination[2]. In addition, this type device can be easily integrated with other type energy device, for example, an energy harvesting structure that integrates an organic-silicon heterojunction solar cell and a triboelectric nanogenerator (TENG) device is built to realize power generation from both sunlight and raindrop[3]. In addition, a self-charging power unit based on an organic-Si heterojunction solar cell and an organic supercapacitor, which simultaneously achieved both photoelectric conversion and energy storage[4]. Finally, we will demonstrate that low temperature processed conductive silver-based ink has wide application usage for low temperature processed solar cell and related plastic electronics.

Evaluation of Carrier Transport Mechanism by Systematic Defect Level Modulation in TiOx Protective Layers of n-Si/TiOx/Ni Photoanodes for Water Splitting Songwoung Hong[1,2], Woo Lee[1,2], Seungwoo Song[1] and Ansoon Kim[1,2]; [1]Korea Research Institute of Standards & Science, Korea (the Republic of); [2]University of Science and Technology, Korea (the Republic of)

Photo-corrosion of anode participating the oxygen evolution reaction (OER) in photoelectrochemical cell (PEC) for water splitting is one of the obstacles for the long term stability and efficient solar to hydrogen conversion. In order to prevent the phot-corrosion, “electrically leaky” thick TiO_2 film was deposited onto a n-Si photoanode surface. However, the carrier transport mechanism through the thick dielectric layer and the influence of oxygen vacancy-related midgap states on the mechanism are still unclear. In order to verify the carrier transport through the midgap states of thick TiO_2 film, we only modulated the defect density of the protective TiO_2 film with no significant change of optical, physical, and chemical properties. It has been demonstrated that the defect density of the TiO_2 film is proportional to water-splitting activity. This result enables to explain the hole transport mechanism of the previously reported electrically leaky TiO_2 protection layer in n-Si photoanode. For the defect-level optimization, titanium sub-oxide (*sub*-TiO_x) protection layer with higher defect density compared to the TiO_2 layer was also investigated. The controlled incorporation of defects into TiO_x dramatically enhances the hole transport from the photoanode surface to electrolyte solution. The relationship between band structure and PEC activity of the photoanode system was explored depending on the defect density of the protection layer. Mott-Schottky analysis of this system suggests that the defect level of TiO_x films influences the band bending of n-Si, which governs the accessible density of defect states and the carrier recombination.

6:15 AM F.EN02.07.07
Improvement in the Passivation Quality of Titanium Oxide Electron-Selective Contacts by Tantalum Doping Seira Yamaguchi[1], Hyunju Lee[1,2] and Yoshio Ohshita[1]; [1]Toyota Technological Institute, Japan; [2]Meiji University, Japan

We report on improvement in the passivation quality of titanium oxide (TiO_x) by doping with tantalum (Ta). TiO_x has been considered one of the most promising materials for electron-selective contacts (ESCs) for crystalline silicon (c-Si) solar cells. There has been a high efficiency of 23.1% successfully achieved for a c-Si solar cell with a TiO_x rear-side ESC [1]. To realize higher efficiencies, it is necessary to further improve the passivation quality. One possible candidate for realizing such improvements is Ta doping. Ta doping reportedly causes a negative shift of the flat band voltage of TiO_x films [2], and the passivation quality of TiO_2 ESCs can therefore be improved by Ta doping. In addition, tantalum oxide (TaO_x) has long-term stability against UV light irradiation [3,4], and it is possible that Ta doping may also improve the long-term stability. In this work, we focus on an improvement in the passivation quality of TiO_x ESCs by doping with Ta.

We deposited TiO_x:Ta films by atomic-layer deposition on the both-sides of n-type c-Si substrates which were in advance oxidized in 30% hydrogen peroxide solution at 80 °C. Ta doping was realized by inserting a unitcycle of TaO_x monolayer into unitcycles of TiO_x. In this study, Ta doping concentration is characterized by a ratio of the number of TaO_x unitcycles to that of TiO_x unitcycles. The thickness of TiO_x:Ta passivation films was basically set to 3.5 nm. After the deposition, the TiO_x:Ta-passivated c-Si substrates were annealed at 130 °C in air. The effective minority-carrier lifetimes (τ_{eff}s) were acquired from quasi steady-state photoconductance measurements, which were used as an indicator for the passivation qualities of the TiO_x:Ta ESCs.

The All the samples passivated with undoped TiO_x films and with TiO_x:Ta films with unitcycle ratios of 0.05, 0.09, 0.17, and 0.50 showed improvements in the τ_{eff} by annealing at 130 °C. However, the τ_{eff} of samples with TiO_x:Ta after annealing was, in most cases, higher than that of samples with undoped TiO_x. This indicates that doping with Ta improves the passivation quality of TiO_x ECSs. In addition, TiO_x:Ta with a relatively low amount of Ta doping tended to have high passivation qualities. The TiO_x:Ta with a unitcycle ratio of 0.05 showed the highest τ_{eff} of 784 μs in this study, which corresponded to an effective surface recombination quality of 24.9 cm/s. The TiO_x:Ta with a unitcycle ratio of 0.50 exhibited a rather lower passivation quality than that of the undoped TiO_x, which indicates excess Ta doping rather degrades the passivation quality.

The above results imply that TiO_x:Ta is one of the promising materials for ESCs. The results of experiments to elucidate the mechanism of the improvements in the passivation quality will be presented.

Advances in Material Properties for Perovskite-Perovskite Tandems Giles Eperon[1,2]; [1]Swift Solar, United States; [2]National Renewable Energy Laboratorty, United States

Multijunction all-perovskite solar cells offer a route towards efficiencies of III-V materials at low cost by combining the advantages of low thermalization loss in multijunction architectures with the beneficial properties of perovskites - namely low processing cost, high throughput fabrication, and compatibility with flexible substrates. Here, I will discuss why flexible all-perovskite tandems are a very attractive iteration of the perovskite technology. I will focus on what is needed to make a good perovskite-perovskite tandem on a flexible substrate, and the advances that we have made towards this goal.
I will cover advances including a) the development and understanding of wide bandgap materials that leverage a novel bandgap-tuning strategy (without increasing bromine, hence avoiding significant phase segregation) to reach the ideal bandgaps for all-perovskite tandems, resulting in efficient devices that are stable to the combined stresses of heat and light; b) advances that we have made in interlayer design, working towards more ideal material properties for reducing shunt resistance; and c) the integration of these approaches to develop >23% efficient monolithic all-perovskite tandems on rigid substrates and 21% efficient devices on flexible plastic substrates.

The Many Faces of Characterization in Developing a Commercial Perovskite on Silicon Tandem Solar Cell Laura Miranda; Oxford PV, United Kingdom

Perovskite solar absorbers have the potential to disrupt the photovoltaic industry predominantly with their simultaneous promise of high efficiency and low cost. Whilst these two properties ensure a steady stream of research and development opportunities, commercial scaling requires assuring that the devices are sufficiently characterized to be confident of their long-term performance. Oxford PV has been addressing the challenges associated with commercially scaling its perovskite on silicon tandem solar cell design. Key practices that have been adopted during the development of highly efficient, reliable, and cost-competitive solar cells are the use of rigorous characterization tools and techniques, and the development of necessary models. This talk will highlight some of the challenges and considerations associated with bringing perovskite on silicon tandem solar cells from a laboratory prototype to a commercial product ready for manufacturing and how characterization has shaped and continues to inform that process.

5:30 AM *F.EN02.08/F.EL06.07/F.EL08.10.03
Passivation Strategies and Interlayers for Perovskite-Based Tandem Photovoltaics Ulrich W. Paetzold, Saba Gharibzadeh, Tobias Abzieher, Ihteaz M. Hossain, Hang Hu, Thomas Feeney, Somayeh Moghadamzadeh, Mahdi Malekshahi Byranvand,, Bahram Abdollahi Nejand, Paul Fassl and Bryce Sydney Richards; Karlsruhe Institute of Technology, Germany

Single-junction crystalline silicon solar cells dominate the photovoltaics market today, but their power conversion efficiencies (PCEs) are approaching the practical limit for this technology. The emergence of hybrid organic-inorganic metal halide perovskite semiconductors over the past decade has opened a window of opportunity to advance the performance of the market-dominating photovoltaic technologies through the development of tandem solar cells. These tandem solar cells promise high PCEs (>33%). To reach this landmark, a number of scientific and technological challenges related to high-efficiency perovskite-based tandem solar cell architectures, stable and high-quality perovskite semiconductor materials, and light management concepts need to be addressed. In this presentation, our progress on passivation strategies and novel interlayers to reduce the voltage losses in wide-bandgap and low-bandgap perovskite solar cells (PSCs), and in turn to increase the PCE of perovskite-based tandem photovoltaics, will be presented.
The search for efficient passivation interlayers for wide-bandgap perovskite top solar cells in *n-i-p* architecture directed our research in the past towards solution-processed 2D/3D perovskite heterostructures. Making use of these heterostructures for interface passivation, wide-bandgap PSCs (E_g ~1.72 eV) with record open-circuit voltage for this bandgap and very high PCEs of up to 19.4% were demonstrated [1]. The reduced voltage deficit is a result of the decreased non-radiative recombination losses at the perovskite/hole-transport layer (HTL) interface. The solution-processed 2D/3D perovskite heterostructure is compatible with 3D perovskite absorber layers of a wide range of bandgaps (1.65 eV ≤ E_g ≤ 1.85 eV) [2]. Using this strategy in 4-terminal perovskite/silicon and perovskite/CIGS tandem solar cells, high PCEs > 27% [3], and > 25%

[2] were demonstrated, respectively, thereby significantly exceeding the record PCESs reported for the respective single-junction solar cell technologies.
Beyond these past results, at the MRS fall meeting we will further present our latest work on novel interlayers and passivation strategies to minimize the voltage loss in wide-bandgap (1.65 eV ≤ E_g ≤ 1.75 eV) as well as low-bandgap (E_g ~ 1.26 eV) perovskite solar cells in *p-i-n* architecture. The *p-i-n* architecture is a key to realize high-performance 2-terminal perovskite/silicon as well as perovskite/perovskite tandem solar cells. Moreover, we will present a novel route to deposit uniform ultra-thin polymer passivation layers onto perovskite thin films by chemical vapor deposition (CVD) [4]. The CVD polymerization promises reliable, scalable, and homogeneous deposition for future large-area processing of perovskite-based tandem solar cells.

Towards Highly Efficient Monolithic 2- and 3-Terminal Perovskite Silicon Tandem Solar Cells Lars Korte, Eike Koehnen, Philipp Wagner, Philipp Tockhorn, Marko Jost, Amran Al-Ashouri, Lukas Kegelmann, Marcel Roß, Bernd Stannowski and Steve Albrecht; Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

Integrating metal halide perovskite top cells with crystalline silicon (c Si) bottom cells into monolithic tandem devices has recently attracted increased attention due to the high efficiency potential of these cell architectures. To further increase the tandem device performance to a level well above the best single junctions, optical and electrical optimizations as well as a detailed device understanding for such architectures need to be developed [1]. Here we present our recent results on such monolithic tandem cells in the common 2-terminal (2T) as well as in a novel 3-terminal (3T) contacting scheme.
In the 2T design, we recently demonstrated a certified power conversion efficiency (PCE) of 29.15% [2,3]. I will discuss some key elements to this result: using a silicon heterojunction cell electron contact on the rear side, enabling the integration of a perovskite top cell in the p-i-n configuration; employing self-assembled monolayers (SAMs) as hole selective contacts for further reduction of non-radiative recombination losses, etc. With the latter, efficiencies of up to ~ 21 % were demonstrated for p-i-n perovskite single junctions [3].
In 3T tandems, one of the three contacts is shared by both subcells, allowing for the individual operation of both subcells in a monolithic device with a single substrate, thus combining the characteristic advantages of 2T and 4-terminal (4T) devices: high combined photogeneration currents as in state-of-the-art 2T tandems, and ideally independent electrical operation similar to 4T tandems, making the cell more robust against varying spectra. I will discuss our recent proof-of-concept study [4], demonstrating a 3T perovskite/silicon tandem cell by manufacturing an n-i-p perovskite top cell on an interdigitated back contact (IBC) silicon heterojunction solar cell. In our proof-of-concept device, the combined PCE of ~ 17% is still limited both optically and electrically, and it will be discussed how optimizations of the cell stack can bring this architecture to a PCE level comparable to 2T tandems. Furthermore, I will demonstrate that the subcells can indeed be operated largely independently at their individual maximum power points, allowing to extract the maximum power output for varying spectral conditions similar to 4T cells. A minimized series resistance at the shared electron contact on the cell's rear side is identified as the crucial parameter for independent operation of the subcells, and I will discuss pathways to approach the simulated efficiency potential by an optimized device design.

Solution Processed Perovskite Subcell in Monolithic Perovskite/Si Tandem Solar Cells and Their Cost and Stability Concerns Qi Chen[1] and Huanping Zhou[2]; [1]Beijing institute of Technology, China; [2]Peking University, China

Among all commercialization routes for perovskite photovoltaics (PV), the perovskite/Si tandem is of particular interest as it capitalizes the mature silicon industry with decades of experience. Here we report low-temperature solution process for efficient two-terminal perovskite/Si tandem solar cells, wherein electrical and optical properties of the tunneling junction are carefully modulated. Moreover, we improve materials stability by introducing Eu^{2+}/Eu^{3+} "redox shuttle" to suppress the Pb^0/I^0 impurities which inevitably occurred during device operation. In addition, we carefully analyze the cost of tandem devices in terms of levelized cost of energy (LCOE) by adopting the "bottom-up cost model". It reveals perovskite PV exhibit low materials cost, which reduces the LCOE substantially in tandem devices. We conclude that further efforts are required to simultaneously improve the efficiency and lifetime of perovskite modules, which ultimately endows the competitiveness of perovskite tandem solar cells.

Mesoscale Interactions in Electrodeposition Stability of Metal Electrodes Partha P. Mukherjee and Bairav S. Vishnugopi; Purdue University, United States

Lithium metal electrodes in the presence of liquid electrolytes suffer from unmitigated growth of dendrites that pose safety concerns and lead to electrochemical performance limitation. It necessitates fundamental understanding of the mechanistic origins of interface instability at the mesoscale. This work relies on a detailed mesoscale analysis of the role of disparate mechanisms including electrolyte transport, self-diffusion and electrochemical reaction on the nucleation and growth of electrodeposition. The contrasting influence of temperature on the electrodeposition stability is examined. Finally, the role of mesoscale interactions in devising potential pathways toward electrodeposition stability is elucidated.

Magnesium Metal Electrodeposition and Electrodissolution with Polymer Electrolytes Bumjun Park and Jennifer L. Schaefer; University of Notre Dame, United States

Lithium metal and magnesium metal batteries have potential for high system energy density due to the high gravimetric and volumetric charge capacity of these metal anodes. Magnesium metal offers several advantages and disadvantages with respect to lithium metal as an anode. Magnesium is more abundant and resources are geographically widespread. Magnesium

metal is less chemically reactive than lithium metal and electrodissolution/deposition happens at elevated potentials, yet issues with inefficiency and side reactions still remain. While lithium metal polymer batteries have been investigated intently for decades, magnesium metal polymer batteries have received little attention. There exist great difficulties in producing magnesium polymer electrolytes that both effectively transport magnesium and support reversible electrodeposition and dissolution of magnesium metal. In this talk, I will review our recent research on ion transport and electrochemistry in traditional salt-doped magnesium polymer electrolytes and magnesium poly(ionic liquid) electrolytes.

5:55 PM *F.EN03.04.06
Electrochemical Activation and Passivation of Magnesium Metal Anodes Masaki Matsui; Kobe University, Japan

Magnesium metal anode has a high volumetric capacity of 3833 $mAhcm^{-3}$, rechargeable magnesium battery is expected as an advanced battery system alternate to Li-ion batteries. The SEI-free surface of the magnesium metal leads to the uniform nucleation process resulting in the dendrite free growth during the electrodeposition process. On the other hand, the passivation of the magnesium metal surface initiates the locally-focused current. As a consequence, a risk of dendritic growth of the magnesium metal remains in the electrodeposition process. Here we investigated the nucleation process of magnesium metal on magnesium metal substrates. The initial anodic polarization forms several corrosion pits at the surface of the magnesium substrate. We found that these pits become the preferable sites for the following magnesium deposition. The results suggest that the initial electrochemical activation process is crucial to obtain the uniform plating of magnesium metal.

Interelectrode Temperature Differences used to Promote Reversible Lithium Electroplating and Stripping Corey T. Love[1], Robert Atkinson III[2], Rachel Carter[1] and Todd Kingston[3]; [1]U.S. Naval Research Laboratory, United States; [2]EXCET, Inc., United States; [3]NRL/NRC Post-doctoral Research Associate, United States

The challenges with metal anodes for high-energy batteries will likely be overcome as a result of advancements in three research areas: materials structure-property relationships, electrode architectural design and informed operational controls. We have been focusing our efforts on the operational considerations, specifically temperature control, to promote reversible Li plating and stripping. Modulating temperature, both through thermal gradients and transients, has a direct effect on the performance and stability of the electrochemical plating and stripping processes of Li metal. Applying a modest thermal gradient impacts the lithium plating morphology and dictates whether unstable, one-dimensional Li electroplating or stable, more homogeneous electroplating occurs (1). This talk will expand upon our understanding of gradient-influenced plating/strippping behavior and present operational temperature controls necessary for prolonged battery performance and safety. Additionally, thermal regimes applied to improve electrode kinetics and diffusion will show the opportunity to enable fast charging of Li metal and metal-free eletrodes coupled with a $LiFePO_4$ positive electrode. We use a suite of materials and electrochemical characterization tools (XPS, XRD, optical microscopy, computed tomography and EIS) to guide our understanding of Li metal behaviors in the battery environment.

6:35 PM *F.EN03.04.01
Chances and Challenges in Zinc Electrode Rechargeability Hajime Arai and Atsunori Ikezawa; Tokyo Institute of Technology, Japan

Zinc is abundant, widely used as structural materials, non-toxic, safe and inexpensive. It has the most negative potential among metals that can be recharged in aqueous electrolyte solutions and high capacity density, and hence is an attractive candidate as a negative electrode material. In alkaline media, the thermodynamically stable discharge product is ZnO, a semiconductor (not insulator), and there is acceptable volume expansion upon its formation (ca. +60%). When anion conductors such as alkaline solutions are used as the electrolyte, as is often the case, the formation of ZnO is at the negative electrode side, which causes tolerable volume changes of the negative electrode when compared to the total metal dissolution and/or deposition at the positive electrode side. The corresponding positive electrode materials can be proton-acceptor types such as NiOOH and oxygen in aqueous alkaline electrolytes. Recent trials include zinc ion acceptors such as organic metal frameworks with zinc ion conductive ionic liquid electrolyte. This presentation mainly focuses on alkaline-based aqueous systems.
The main drawback of the zinc electrode is its insufficient durability, suffered from the morphology changes such as dendrite growth, shape change and densification. This is mostly caused by the formation of highly soluble species $Zn(OH)_4^{2-}$, a kinetically favorable discharge product, that diffuses away from the original positions and precipitates wherever it favors.

Even if zinc oxide is saturated in the alkaline electrolyte, zinc supersaturation occurs; it stays longer than the time scale of the charge-discharge reactions, even for months. There are several ways to restrict the zinc dissolution, such as complex formation (e.g. calcium zincate [1]), protective film formation (e.g. anion exchange membrane [2]) and the use of electrolyte additives (e.g. pH controller, indifferent salts and organic solvents [3-4]). Though the durability depends on the utilization rates and loaded mass (mAh/cm2), cycle life of more than several hundred cycles be achieved in ideal cases. Mechanical pressure on the electrode (e.g. separator wrapping) is a simple but effective way in restraining the morphology changes. In contrast to electrical charging, mechanical charging is a unique method for air battery systems, mostly for electric vehicles, where soluble zinc species are removed from the cell and regenerated by off-site processes [5].
Passivation during high rate discharging is also problematic, but can be mitigated by constructing composite electrodes with high surface areas. Hydrogen evolution as the self-discharge can be restricted by adding inhibitors such as indium and bismuth.
Analytical methods to clarify the zinc electrode reaction processes are of particular interest, since degradation proceeds with nearly no sign in the electrochemical responses. Since zinc is oxidized in air, in situ (in-cells) or operando (in-current-flow) analyses are favorable. *Operando* X-ray diffraction (XRD) is helpful in detecting the formation of crystalline ZnO during discharging [6]. XRD mapping analysis indicates how the shape change proceeds [7]. *Operando* X-ray fluorescence imaging, utilizing the zinc visibility in hard X-ray absorption, is effective in observing zinc behavior with space resolutions [8]. Optical analysis is promising to observe macroscopic changes of the zinc species that significantly affects the electrode durability [9].

Characteristic Electrochemical Features of Interfaces on Calcium Foils Aaron M. Melemed and Betar Gallant; Massachusetts Institute of Technology, United States

Batteries based on calcium (Ca) metal anodes offer a possibility of improved sustainability and safety with attractive electrochemical metrics. However, Ca battery development is still in its infancy due to basic chemical limitations. When Ca metal comes in contact with an organic electrolyte, a native solid electrolyte interphase (SEI) forms which passivates, and in some instances fully deactivates, the electrode surface. Considering that Ca deposition and dissolution is widely believed to be a surface-film-controlled process, understanding Ca^{2+} transport through this native SEI is paramount. In this talk, characteristic features occurring in cyclic voltammetry (CV) with Ca foils will be discussed as a function of interface composition in a benchmark electrolyte system, $Ca(BH_4)_2$ in tetrahydrofuran (THF). This electrolyte was found recently by others to support reversible plating/stripping under continuous CV conditions (at 25 mV/s) on planar metal (Au or Pt) working electrodes. As opposed to plating/stripping onto a gold substrate, the first CV cycle on Ca foil reveals a persistent native passivation layer — reflective of the foil preparation process — which manifests as significant reduction and oxidation overpotentials. This native interface can be degraded through the initial electrochemical steps, by processes that depend on whether plating or stripping is first conducted, along with the associated electrochemical protocol. The effect of this first activation step on the resulting electrochemistry will be discussed. Subsequently, the interface evolves to reflect one predominantly governed by CaH_2, which enables further study of the dynamics of this interface under different cycling conditions (scan rate and the imposition of various resting times) on Ca foil. Upon continued cycling, access into the underlying bulk Ca is possible. While this process remains limited by the interface and yields lower current densities than with fresh Ca plating/stripping on Au electrodes, the underlying Ca is not entirely deactivated as concluded by earlier studies, but rather depends on the surface conditioning process and the electrolyte. To further investigate the role of the interface, I will also describe experiments in which nanoscale CaF_2 (~100 nm), an inorganic component found to be present in other Ca SEI, was intentionally formed on Ca foils prior to immersion in an attempt to decouple the foil from the surrounding electrolyte and modulate interface behaviors. Critical differences in interface chemical and electrochemical stability, along with electrochemical performance under CV conditions, will be discussed, and prospects for improving the cyclability of practical Ca foil electrodes will be explored.

From Ion-to-Atom-to-Dendrite—Formation and Nanomechanical Behavior of Electrodeposited Lithium Julia R. Greer[1], Michael A. Citrin[1], Heng Yang[1], Simon Nieh[2], Joel M. Berry[3] and David J. Srolovitz[4]; [1]California Institute of Technology, United States; [2]Front Edge Technology, United States; [3]Lawrence Livermore National Laboratory, United States; [4]City University of Hong Kong, Hong Kong

Lithium is an ideal battery anode, with theoretical specific capacity of 3860 mAh/g; replacing conventional graphitic anodes with Li in Li-ion batteries can increase energy density by ~50%. A significant drawback of Li anodes is dendrite formation during cycling, which can lead to short circuiting (a safety hazard and cell death) and to "dead Li," which drastically reduces cycle life.
A complete dearth of experiments that probe mechanical behavior of electrodeposited Li exists. Most experiments on mechanical properties have focused on thin films and on Focused Ion Beam-carved Li. We developed *in-situ* experimental methodology that allows to electrochemically charge small-scale battery cells and to observe, in real-time, the formation of Li dendrites and to probe their mechanical response. Experiments reveal: (1) Li nano-deposits are single crystalline and (2) strengths of Li nano-pillars are 16.0 ± 6.82 MPa, which is 24x greater than bulk. This strength enhancement can be explained in terms of the ubiquitous "smaller is stronger size effect" nano-sized single crystalline metals. This work expands the existing strength vs. size property space for Li and helps explain why dendrites can penetrate through much stiffer and harder ceramic solid electrolytes, theorized for several years but never unambiguously demonstrated
Development of high energy density solid-state batteries with Li metal anodes has been limited by uncontrollable growth of Li dendrites in liquid and solid electrolytes. This, in part, may be caused by a dearth of information about mechanical properties of Li, especially at the nano- and micro-length scales and microstructures relevant to Li batteries. We investigate formation, microstructure, and mechanical properties of nano-sized Li electrodeposited in a commercial LiCoO2/LiPON/Cu solid-state thin film cell, grown *in-situ* in a scanning electron microscope (SEM) equipped with nanomechanical capabilities. Experiments reveal that Li was preferentially deposited at the LiPON/Cu interface, along the valleys that mimic the domain boundaries of underlying $LiCoO_2$. This pattern of Li formation is consistent with the higher driving force for Li nucleation at the valleys uncovered by electrochemical simulations of Li ion transport in this system. Further charging of the cell resulted in Li nuclei piercing through the 30 nm-thick Cu layer and growing into vacuum through the crack openings. Cryogenic electron microscopy analysis of electrodeposited Li revealed its single crystalline microstructure, and *in-situ* nano-compression experiments on individual Li nano-pillars with diameters of 360-759 nm revealed their average Young's modulus to be 6.76 ± 2.88 GPa and an average yield stress of 16.0 ± 6.82 MPa, ~24x higher than what has been reported for bulk polycrystalline Li. We discuss mechanical deformation mechanisms and strength of nano-sized electrodeposited Li in the framework of its microstructure and dislocation-governed nano-scale plasticity of crystals and place it in the parameter space of existing knowledge on small-scale Li mechanics. The enhanced strength of Li at small scales may help explain why Li can penetrate through and fracture much stiffer and harder ceramic solid electrolytes.

11:50 AM *F.EN03.03.02
On the Mechanisms of Stress Relaxation and Intensification at the Lithium/Solid-State Electrolyte Interface Erik G. Herbert[1], Nancy Dudney[2], Maria Rochow[1], Violet Thole[1] and Stephen Hackney[1]; [1]Michigan Technological University, United States; [2]Oak Ridge National Laboratory, United States

Under electrochemical cycling, stress intensification and relaxation within small, confined volumes at the Li/solid-state electrolyte (SSE) interface are thought to be critical factors contributing to mechanical failure of the SSE and subsequent short-circuiting of the device. Nanoindenation has been used to examine the diffusion limited pressure Li can support in the absence of active dislocation sources at high homologous temperatures. Based on the underlying physics of this deformation mechanism, a simple perturbation model coupling local current density, elastic stress and diffusional creep relaxation is introduced. Combining this analysis with the indentation results, it is possible to describe a 'defect danger zone,' a length scale which is too large for effective diffusional creep relaxation, but too small for efficient dislocation multiplication. In this instance, the properties of the SSE become critical in controlling localized pressure at the interface.

In contrast to the 'first generation,' pioneering analysis of the Li/electrolyte interface by Monroe and Newman, more recent analyses of the Li/SSE interface mechanics examine a similar but uniquely different problem in that they consider non-uniform electrochemical properties and/or filling of morphological defects at the interface during Li charging such that the initial amplitude of the Li protrusion is fixed by a pre-existing interface defect or undulation. Meaningful comparisons between multiple 'second-generation' approaches can be challenging. Although they generally address the same problem, assumptions about the interface defect geometry and the self-limiting mechanical and electrochemical behavior of Li place significant limitations on the conclusions and the general applicability of the proposed solution. Despite their differences, the second-generation approaches arrive at generally the same conclusion: Within confined or localized volumes of Li at the interface, Li can support pressures significantly higher than its bulk yield strength (stresses as high as 200 MPa). Such stress concentrations at the interface are of critical concern because they facilitate mechanical failure of the SSE by fracture. The key question then becomes, why is the stress concentration so large relative to the bulk yield strength of Li? Two potential explanations are offered by the second-generation approaches: geometry effects and length scale effects. These effects are not unique to Li. Any metallic anode will experience these effects in a manner that depends on its absolute melting temperature, elastic modulus, yield strength, and self-diffusion coefficient.

Although the length scale effects of high purity Li have only been recently documented, the basic concept of "smaller is stronger" is well documented. As described by Brenner in 1956 and later quantified by Phani et al. in 2013, the yield strength of a metal in small volumes can be described from a purely statistical point of view, as the stress required to plastically flow depends on the probability of finding the necessary dislocations within the stressed volume. Load-displacement data from nanoindentation experiments performed in high purity Li at a homologous temperature of 0.67 graphically illustrate this concept. Similar results obtained in high purity indium, a mechanical surrogate to Li, further illustrate the competition for stress relief. Collectively, an important outcome from these 'second generation' approaches is that SSEs with nominally uniform electrochemical properties and flat, smooth surfaces will promote planar, nominally stress-free plating and stripping of Li. Unfortunately, brittle SSE materials will likely experience the same statistical failure issues as structural ceramics. The most robust devices will also implement SSEs that are engineered to provide localized stress relief, potentially through mechanisms such as densification, shear banding and time dependent recovery.

12:10 PM F.EN03.03.03

A New Paradigm for Preventing Lithium Dendrite Penetration Through Solid Electrolytes Yue Qi[1], Chunmei Ban[2] and Stephen J. Harris[3]; [1]Michigan State University, United States; [2]University of Colorado Boulder, United States; [3]Lawrence Berkeley National Laboratory, United States

We introduce a new concept to suppress penetration of lithium dendrites through solid electrolytes (SE) by putting the surface of the SE into a state of compressive stress. For a sufficiently high residual compressive stress, cracks have difficulty forming at the surface, and cracks that do form tend to close, inhibiting dendrite penetration. Introduction of compressive surface residual stress solves stress corrosion cracking problems in metals and static fatigue problems in ceramics and glasses. An example of the latter is Gorilla Glass, which is strongly resistant to cracking because of surface compressive stresses. However, the technique will not work if Li ion transport through a SE in compression is substantially reduced. Our DFT and MD calculations for LLZO indicate that the introduction of even high residual compressive stresses (up to 10 GPa) will have only a very modest effect on Li ion transport kinetics, suggesting that the approach is viable. In addition to inhibiting penetration and fracture in solid electrolytes, compressive stresses on the order of GPa will tend to suppress lithium plating inside of solid electrolytes because of an increased overpotential for the Li ion reduction reaction. We discuss and compare several experimental methods for introducing compressive residual stresses at the surfaces of solid electrolytes. We believe that the information here can provide a new avenue for developing high-performance and stable solid electrolytes

12:30 PM F.EN03.03.04

***In Situ* Investigations of Stress Evolution During Plating and Stripping of Lithium Metal** Jung Hwi Cho[1], Xingcheng Xiao[2], Kai Guo[3], Yuanpeng Liu[4], Huajian Gao[5] and Brian Sheldon[1]; [1]Brown University, United States; [2]General Motors, United States; [3]Massachusetts Institute of Technology, United States; [4]Harbin Institute of Technology, China; [5]Nanyang Technological University, Singapore

Poor stability of Li metal / liquid electrolyte or Li metal / solid electrolyte interfaces leads to chronic problems, such as dendrite formation and capacity loss. The impact of electro-chemo mechanical phenomena on interface stability and dendrite formation are believed to be critical, but are challenging to investigate directly. In-situ curvature measurements are an important tool that can be used to monitor these stresses during battery cycling. Using this technique during Li plating and examining film thickness effects, it is possible to separate contributions from the bulk lithium metal and the solid electrolyte

interphase (SEI). These investigations show that the stresses created in the SEI films are much larger than those in the Li metal. Furthermore, these stresses in the SEI can destabilize the electrode / electrolyte interface.
Recently, a variety of methods have been employed to improve the performance and safety of Li metal based batteries by using various artificial SEI layers and/or implementing solid electrolytes. Several of these approaches were also investigated with stress evolution measurements during lithium plating and stripping. This work includes the use of both soft (PEO) and hard (LiF) artificial surface layers. These results indicate that stresses in both the surface film and the bulk lithium evolve differently when artificial SEI layers are employed. Initial attempts to monitor stress evolution with oxide solid electrolytes will also be presented.

12:50 PM F.EN03.03.05
Plastic Deformation and Microstructural Evolution of Pure Lithium Under Various Stress States Juner Zhu[1,1], Tobias Sedlatschek[1], Junhe Lian[1,2], Wei Li[1], Tomasz Wierzbicki[1] and Martin Bazant[1]; [1]Massachusetts Institute of Technology, United States; [2]Aalto University, Finland

Pure lithium in lithium metal batteries is often examined in research projects aiming at improving today's battery technology significantly. But the knowledge about the mechanical properties and the microstructural evolution of pure lithium is incomplete with two particular limitations. First, the available data extensively focuses on the elastic-plastic behavior in some uniaxial loading conditions, the multi-axial plasticity and fracture of pure lithium are rarely taken into consideration. Second, existing studies are mostly performed at the two ends of the length scale axes, either at the nano-scale where dendritic initiation and growth happen or at the bulk-scale where lithium foil is used as an electrode. There is a clear gap at the scale of one single grain or microstructural imperfection. This work aims at providing a systematic study of the multi-axial plasticity and microstructural evolution of pure lithium at the scale of 100 um to 1 mm under various stress states. To manufacture the required complex-shaped experimental specimens for five different stress states including uniaxial tension, notch tension with two different radii, central hole tension, and pure shear, a method that allows safe laser cutting of thick lithium foils in argon atmosphere is developed. The tests are conducted in pure argon as well as in air to quantify the oxidation behavior of lithium. Two active slip systems are observed during deformation and cross-slip is regularly present. Lithium fractures in an extremely ductile manner when the thickness is reduced to zero due to necking. Numerical simulations of the five loading conditions were performed using a multi-axial plasticity model recently developed by Narayan and Anand, which shed light on the full-field deformation and stress information of the samples for fracture examinations. Finally, the developed plasticity model is applied to a lithium-solid electrolyte interface model that couples contact condition, mechanical deformation, and electrochemistry to study the effect of external pressure on the cycling performance of lithium-metal all-solid-state batteries.

Mechanical Properties of Alkali Metal Anodes Coleman D. Fincher[1,2], George Pharr[1] and Matt Pharr[1]; [1]Texas A&M University, United States; [2]Massachusetts Institute of Technology, United States

While room temperature metallic anodes possess the potential to enable batteries with enormous capacities, their mechanical behavior ultimately plays a key role in the failure modes for both liquid and solid electrolyte battery systems. That is, not only do alkali metal deposits threaten to deform and penetrate the battery separator in liquid electrolyte systems, but the degree of interfacial contact at the solid-state electrolyte/ anode interface possesses significant pressure dependence for solid-state systems. In this talk, we present a comprehensive multi-length scale assessment of the mechanical behavior of lithium, sodium, and potassium metal. Beyond the mechanical properties, we also discuss some practical implications of the anode's mechanical properties in battery systems.

The Importance of Nothing in Porous, 3D-Wired Metal Anodes Debra R. Rolison, Brandon J. Hopkins, Christopher Chervin, Jeffrey Long and Joseph Parker; US Naval Research Laboratory, United States

Our team uses an architectural design metaphor to redesign materials and electrodes relevant to electrochemical energy science. Because batteries must balance multiple functions (molecular mass transport, ionic/electronic/thermal conductivity,

and electron-transfer kinetics), wiring these functions in three dimensions can move established battery chemistries in new directions. By designing metallic zinc into a sponge form-factor, with co-continuous void and solid, zinc-based alkaline batteries are now rechargeable at high rate and to deep utilization of zinc — without forming separator-piercing dendrites. We solved the historic lack of rechargeability of the zinc anode in alkaline electrolytes because the local current density throughout the sponge never broaches that necessary to launch dendritic growth. All thanks to an inner core of metallic zinc that electronically wires the 4 $m^2 g^{-1}$ of zinc surface area while the pore structure retains the zincate/ZnO discharge product nearby for recovery on the charge step. The nonperiodic, metallically interconnected "sponge" form factor distributes current more uniformly than ad hoc powder composites and ensures extensive charge-discharge cycling without deleterious dendrite formation.

5:15 AM F.EN03.01.02
Vertically Aligned Nanotube Arrays Featured with Confined Space and Uniform Curvature Enabling Dendrite Free Li Metal Batteries Daxian Cao[1], Karnpiwat Tantratian[2], Lei Chen[2] and Hongli Zhu[1]; [1]Northeastern University, United States; [2]University of Michigan-Dearborn, United States

In past decade, because of ultrahigh capacity and lowest reduction potential, Lithium (Li) metal anode has regained great interest aiming to meet the urgent demand for high energy density rechargeable batteries. However, the dendritic growth of Li during cycling causes serious safety concerns and fast performance decay, which primarily restricts its application. Among various strategies about dendrite suppression, the design that introducing Li in a scaffold to fabricate a 3D Li structure is widely accepted. Therefore, the structural features of the scaffold dominate the behavior of Li metal anode. Herein, low-tortuosity, vertically aligned, and well-spaced TiO_2 nanotube arrays with ultrauniform curvature are selected as the host for Li metal anode, and the effect of the surface curvature and nanotube spacing on Li deposition are studied from experiment to theory. The Li metal behaves a unique electrodeposition manner that Li metal homogeneously deposits on the nanotubular wall, causing each Li nanotube to grow in circumference without obvious sign of dendritic formation. The uniform curvature of the anode structure, as well as the space confinement, are the keys to achieve highly stable, dendrite-free Li metal anodes. When this novel Li metal anode was coupled with $LiFePO_4$ cathode in a full cell, an excellent specific capacity of 132 mAh g^{-1} and coulombic efficiency of ~99.85% over 400 cycles are achieved under a high charging rate at 1C. This work sheds light on the effect of structure feature on the stabilization of Li metal anode and takes an inspiring step toward reliable Li metal anode.

5:25 AM F.EN03.01.03
3D Nanoporous Graphene Based Metal Anodes for High-Energy-Density Rechargeable Metal Batteries Gang Huang[1], Jiuhui Han[1], Isaac Johnson[2] and Mingwei Chen[2,1]; [1]Tohoku University, Japan; [2]Johns Hopkins University, United States

The key bottlenecks hindering the practical implementations of metal anodes in high-energy-density rechargeable batteries are the uncontrolled dendrite growth and infinite volume changes during charging and discharging, which lead to short lifespan and catastrophic safety hazard. In principle, these problems can be mitigated or even solved by loading active metals, such as Li, Na and Zn, into a high-surface-area, conductive and porous scaffold. However, a suitable material that can synchronously host a large loading amount of these active metals and endure large current density has not been achieved. Here we report a three-dimensional bicontinuous nanoporous graphene, prepared by nanoporous metal based CVD, as the sought-after scaffold material for metal anodes. The high surface area, large porosity and high conductivity of the nanoporous graphene concede not only dendrite-free stripping/plating but also abundant open space accommodating volume fluctuation of active metals. This ingenious scaffold endows the composite anodes with a long-term cycling stability and ultrahigh rate capability, significantly improving the charge storage performance of high-energy-density rechargeable metal batteries.

5:35 AM F.EN03.01.04
***In Operando* Study for Lithium Metal Deposition in Porous Carbon Scaffolds with Different Lithiophilicity** Juran Noh, Jian Tan, Digvijay R. Yadav, Peng Wu, Kelvin Xie and Choongho Yu; Texas A&M University, United States

Conventional graphite anodes for Li-ion batteries are the most demanding targets for further improvement in order to increase their energy densities. Lithium metal anodes have a much higher energy density but suffer from dendrite formation and volume expansion. To alleviate these problems, three-dimensional (3D) porous carbon scaffolds could be attractive alternatives if lithium metal is deposited in the inside of the porous structures. Nevertheless lithium insertion into porous structures have not been well understood because of difficulties in direct observation during the process. Here we present in-operando study coupled with simultaneously recorded voltage/current profiles for clarifying lithium insertion into porous carbon nanotube (CNT) structures depending on surface characteristics, lithiophobic, lithiophilic, and hybridized

lithiophobic/philic surface properties. It was found that lithiophobic graphitic surfaces interfered lithium insertion into the porous media despite the high conductivity along the CNT scaffold. Lithiophilic 3D scaffolds rendered lithium deposited on the outer mouth of the porous electrode, clogging pores and engendering dendrites. This can be attributed to preferential deposition of lithium on lithium metal due to sluggish charge transfer through insulating carboxyl functional groups on graphitic layers. On the other hand, when lithiophilic trenches were created on the lithiophobic graphitic wall of CNT, lithium was uniformly deposited on the surface and then filled up the pores, reaching a high areal capacity of 16 mAh cm^{-2} even with a high current density of 8 mA cm^{-2} without noticeable dendrite appearance and volume expansion. The functional group near the trench attracts lithium ions into trenches/pores while the preserved graphitic surface allows for charge transfer, giving rise to promising high energy density anode with lithium-impregnated scaffolds by both lithium intercalation and deposition.

5:45 AM F.EN03.01.05
Late News: Electronegativity-Guided Atomic Doping for Air-Stable and Dentrite-Free Li Metal Anode Tao Xu and Yingwen Cheng; Northern Illinois University, United States

The diverse electronegativity among metals provides a rich toolkit to modulate the reactivity of metals via doping different metals while still keeping their metallic behavior for electrochemical purposes. Here we describe a general approach for modulating Li metal properties and enabling stable Li metal batteries by doping with ~0.1 at% Ag or Al. Unlike alloys, our dopant metal (Ag or Al) are atomically dispersed in Li via a non-equilibrium ultrasonication and quenching method during the synthesis and the atomic level dispersion of Ag is evidience by synchrotron X-ray absorption method. The dopants were atomically dispersed in the vacant face-centered sites of the body-centered cubic Li crystals and pull electrons strongly due to higher electronegativity (Ag: 1.98; Al: 1.61 vs. Li: 0.98). As a result, the doped Li anodes have increased work function with reduced chemical reactivity and remained shiny in dry air for months. They also exhibited enhanced Li+/Li redox kinetics and generated thinner but stronger solid-electrolyte interphases in carbonate electrolytes. The dopant atoms are lithophilic and have stronger binding with Li adatoms,
which guide uniform Li deposition and ensures dendrite-free Li interface during battery cycling. Overall, the doped anodes enabled stable operations of not only high current symmetric cells but also practical full cells in which Ni-rich layered cathodes were paired with 30 mm anodes and 7 mL electrolytes. The doping approach is facile and scalable, and opens up new and promising opportunities for designing
practical high energy density metal batteries.

F-EN03

5:00 AM F.EN03.02.01
Lithium Deposition Underneath Interfacial Coating Layers Grace Whang[1], Qizhang Yan[2], Jian Luo[2] and Bruce S. Dunn[1]; [1]University of California, Los Angeles, United States; [2]University of California, San Diego, United States

The formation of lithium dendrites has long stood in the way of accessing lithium's unmatched combination of low reduction potential and high specific capacity for next generation lithium ion batteries. While there has been a body of research directed towards the use of interfacial coatings to improve upon lithium deposition morphologies, one interesting and often overlooked approach to circumvent dendritic growth is the possibility of plating lithium underneath the coating layers. The mechanism of lithium plating underneath offers a refreshing perspective on reframing the question of how to best suppress dendrites and furthermore presents a direction that could greatly benefit from more fundamental understanding.

In this study, we report on a novel mechanism that leads to of plating of lithium underneath a coating layer. A lithium-tin system was chosen as a model coating system due to its ability to form lithium-rich intermetallic which exhibit high Li diffusivity and plays a critical role when considering lithium transport across microns lengths scale. To assess the role of the Lithium-Tin coating on the kinetics of the lithium electrode, Galvanostatic Linear Polarization(GLP) was used to extrapolate the exchange current density using a linear approximation of the Butler-Volmer equation. For the lithium electrode with a Li-Sn coating, the exchange current density of 0.522 ± 0.011 mA cm^{-2} was twice as large as that of a bare lithium control indicating that charge transfer kinetics for plating on the lithium tin coated electrodes are more favorable relative to bare lithium. This relationship can also be seen in the large differences in charge transfer resistance observed in impedance

measurements.

To study how the enhanced kinetics of the coating layer influences lithium plating, Li-Sn coated and bare lithium electrodes were plated at various current densities for a substantial plating capacity of 4mAh cm^{-2} corresponding to ~20 μm of lithium assuming uniform deposition. Unlike bare lithium which always plates on the lithium surface, lithium-tin composite coatings can lead to lithium plating underneath the Li-Sn layer given that there is favorable Li transport kinetics across it. From our studies, there exists a current density 'transition point' from which plating occurs below the surface of the coating layer. By combining planar SEM of the surface and cross section of the electrode using Cryo-FIB SEM, we show that current densities below the exchange current density lead to lithium deposition underneath the Li-Sn surface with no evidence of lithium deposits on the surface of the coating. The extension of this model to other systems is presented.

5:10 AM F.EN03.02.02
"Mirror-Like" Electrodeposition of Lithium Metal Under a Low-Resistance Artificial Solid Electrolyte Interphase Layer Fei Hu, Zhuo Li, Shaofei Wang and Wyatt Tenhaeff; University of Rochester, United States

Lithium metal is one of the most promising anode materials for energy dense electrochemical energy storage. However, non-uniform electrodeposition and dendritic growth of Li metal result in low Coulombic efficiency and potential short circuits, which are critical challenges that impede development of practical Li metal batteries. To suppress dendrite growth of Li metal, one strategy is to encapsulate the Li metal with an artificial solid-electrolyte interface (ASEI) layer. The ideal ASEI layer should possess high mechanical strength to prevent the intrusion of Li dendrite, high Li transference number, low bulk/interfacial resistance, and high ionic yet negligible electronic conductivity. Moreover, recent studies show that the morphology of the ASEI layer is critical and that a smooth homogeneous surface is beneficial. A thin film solid electrolyte, lithium phosphorous oxynitride (LiPON), satisfies these requirements. It has a relatively high shear modulus of 7.7 GPa, unity Li^+ transference number, wide electrochemical stability window (0 - 5.5V vs. Li/Li^+), ionic conductivity of ~2×10^{-6} S cm^{-1}, electronic conductivity of ~8×10^{-13} S cm^{-1}, and can fabricated as a smooth isotropic, homogenous thin film via physical vapor deposition. However, it remains a challenge to observe uniform, mirror-like electrodeposition of Li metal under the sole protection of LiPON layers.
Herein we report a multifunctional ASEI design that combines the benefits of a LiPON coating with the enhanced Li morphology conferred by Li_xAu alloys. The 100 nm-thick Au interlayer alloy with Li into a solid buffer layer, which reduces the nucleation energy for Li electrodeposition, resulting in improved Li deposition uniformity. The LiPON layer prevents reactions between the deposited Li and liquid electrolyte. The integrity of the LiPON protective layer was assessed using *in operando* impedance spectroscopy and *ex situ* SEM and EDS measurements. At a current density of 0.1 mA cm^{-2}, it was shown that the LiPON layer remained intact for Li capacities of at least 3 mAh cm^{-2}. The deposited Li was confined under the LiPON layer creating a smooth, uniform interface, resulting in a shiny Li surface that was "mirror-like." It was shown that the Au layer is essential to achieving this morphology; discrete, heterogenous Li deposits were observed using Cu current collectors. At higher current densities (up to 1 mA cm^{-2}) and capacities (6 mAh cm^{-2}), the LiPON protective coating fractured and nonuniform Li morphologies were observed. Efforts to further optimize this multifunctional ASEI design and engineering application towards long-cycling Li metal batteries will be discussed in the future.

5:20 AM F.EN03.02.03
Inter-Layer-Calated Thin Li Metal Electrode with Improved Battery Capacity Retention and Dendrite Suppression Junjie Niu; University of Wisconsin-Milwaukee, United States

A light-weighting, stable Li metal is critical to high energy-density lithium ion batteries (LIBs). In this presentation, we introduce an inter-layer-calated thin Li metal (ILC-Li) electrode using non-delaminated 2D $Ti_3C_2T_x$ MXene stacks coated on an ultra-thin Li host (***Nano Lett. 2020, 20, 2639–2646***). The excellent electrical conductivity (higher than graphite) and expanded inter-layer space of about 1.34 nm of the MXene provide a fast e^-/Li^+ transport to allow Li homogeneous deposition while the layer limits the Li growth along perpendicular direction, thus largely mitigating the dendrite growth. Also, the large surface area of the multi-layer MXene stacks with high mechanical flexibility ensures a high Li capacity and reliable Li nucleation/growth upon plating/stripping. The highly reversible Li deposition/extraction through the confined 2D configuration greatly reduces the dead lithium and electrolyte consumption by forming a thin solid-electrolyte-interphase (SEI) layer. As the result, a small overpotential of less than 135 mV in symmetric cells was achieved after >1050 cycles (>2100 hours) with a very high current density of 10 mA cm^{-2} and an areal capacity of 10 mAh cm^{-2} while the cell with Li foil showed a larger potential over 400 mV in only 50 cycles with a low current density of 3 mA cm^{-2}. In a full cell paired with nickel-manganese-cobalt oxide (NMC) or nickel-cobalt-aluminum oxide (NCA) as cathode, the battery with ILC-Li electrode exhibited a clearly improved capacity retention when compared with Li foil, particularly with lean electrolyte

conditions of as low as 2.5 µl mAh^{-1}. The less inorganic-rich SEI layer shown by X-ray photoelectron spectroscopy depth profiling indicates a reduced electrolyte consumption, thus leading to a high energy density up to 366.6 Wh/Kg. In contrast to other coating technologies, the current approach is manufacture scalable by using large sizes of MXene stacks via a facile process, which displays a promising potential in higher energy-density LIBs.

A Dynamic, Electrolyte-Blocking and Single-Ion-Conductive Network as an Artificial Solid Electrolyte Interphase for Lithium Metal Anode Zhiao Yu[1], David Mackanic[1], Yi Cui[1,2] and Zhenan Bao[1]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

Lithium (Li) metal is an ideal candidate as the anode of Li batteries due to its potential to provide high specific energy. However, Li metal anode is challenging to implement due to several drawbacks. First, Li easily reacts with electrolytes to form a solid electrolyte interface (SEI). The heterogeneous nature of SEI results in local fluctuation of Li^+ flux and current density, which lead to the formation of dendrites. Second, large volume change during Li stripping/plating creates cracks in the brittle SEI, forms dead Li, and causes further electrolyte consumption. These effects lower the Coulombic efficiency (CE) and devastate the cycle life of Li metal anodes. In order to mitigate the abovementioned degradation pathways, strategies pursued include modifying electrolyte components, utilizing solid electrolytes, employing a shielding cation layer, or chemically pretreating Li metal. Nevertheless, it remains challenging to achieve a stable SEI on Li metal; and therefore, the artificial SEI attracts more attention as an alternative strategy to replace the native SEI on Li.

An ideal artificial SEI must have several key properties. First, previous work proposed benefits of having high modulus coatings on Li; however, our recent work suggested flowability and dynamic property allow SEI to adapt to large volume change during Li stripping/deposition, and result in uniform Li deposition macroscopically. Second, uniform and fast Li^+ single-ion conduction in the artificial SEI is found to be beneficial to reduce “hot spots”, increase critical Li deposit size, and stabilize the Li metal anode. Finally, the SEI needs to be both chemically and electrochemically inert itself and mitigate electrolyte penetration to minimize deleterious Li-coating and Li-electrolyte side reactions. Nevertheless, few artificial SEIs possess all the desirable properties such as dynamic adaptivity, high ion conductivity, and chemical passivation. Additionally, the majority of the reported Li-metal artificial SEIs are only compatible with ether-based electrolytes, making them incompatible with high-voltage, high-energy-density lithium nickel manganese cobalt oxide (NMC) cathodes that are used in today’s commercial Li-ion batteries.

Herein, we propose an artificial SEI design based on a dynamic polymeric network with high Li^+ single-ion conductivity. In this network, tetrahedral $Al(OR)_4^-$ (R = soft organic linker) anions are used for the first time as a dynamic motif while providing counter anions for Li^+. With this dynamic single-ion-conductive network (DSN) as an artificial SEI, we demonstrate over 400 stable plating/stripping cycles in Li||Cu cell using commercial carbonate-based electrolyte. Greater than 85% capacity retention for over 160 cycles in a Li||NMC full battery was achieved using directly coated Li foils and commercial, high active material proportion NMC cathode sheets. This work demonstrates for the first time the promise of dynamic single-ion conductor as a stable and scalable artificial SEI for practical Li metal batteries.

From Ion-to-Atom-to-Dendrite—Formation and Nanomechanical Behavior of Electrodeposited Lithium Julia R. Greer[1], Michael A. Citrin[1], Heng Yang[1], Simon Nieh[2], Joel M. Berry[3] and David J. Srolovitz[4]; [1]California Institute of Technology, United States; [2]Front Edge Technology, United States; [3]Lawrence Livermore National Laboratory, United States; [4]City University of Hong Kong, Hong Kong

Lithium is an ideal battery anode, with theoretical specific capacity of 3860 mAh/g; replacing conventional graphitic anodes with Li in Li-ion batteries can increase energy density by ~50%. A significant drawback of Li anodes is dendrite formation during cycling, which can lead to short circuiting (a safety hazard and cell death) and to “dead Li,” which drastically reduces cycle life.
A complete dearth of experiments that probe mechanical behavior of electrodeposited Li exists. Most experiments on

mechanical properties have focused on thin films and on Focused Ion Beam-carved Li. We developed *in-situ* experimental methodology that allows to electrochemically charge small-scale battery cells and to observe, in real-time, the formation of Li dendrites and to probe their mechanical response. Experiments reveal: (1) Li nano-deposits are single crystalline and (2) strengths of Li nano-pillars are 16.0 ± 6.82 MPa, which is 24x greater than bulk. This strength enhancement can be explained in terms of the ubiquitous "smaller is stronger size effect" nano-sized single crystalline metals. This work expands the existing strength vs. size property space for Li and helps explain why dendrites can penetrate through much stiffer and harder ceramic solid electrolytes, theorized for several years but never unambiguously demonstrated
Development of high energy density solid-state batteries with Li metal anodes has been limited by uncontrollable growth of Li dendrites in liquid and solid electrolytes. This, in part, may be caused by a dearth of information about mechanical properties of Li, especially at the nano- and micro-length scales and microstructures relevant to Li batteries. We investigate formation, microstructure, and mechanical properties of nano-sized Li electrodeposited in a commercial LiCoO2/LiPON/Cu solid-state thin film cell, grown *in-situ* in a scanning electron microscope (SEM) equipped with nanomechanical capabilities. Experiments reveal that Li was preferentially deposited at the LiPON/Cu interface, along the valleys that mimic the domain boundaries of underlying $LiCoO_2$. This pattern of Li formation is consistent with the higher driving force for Li nucleation at the valleys uncovered by electrochemical simulations of Li ion transport in this system. Further charging of the cell resulted in Li nuclei piercing through the 30 nm-thick Cu layer and growing into vacuum through the crack openings. Cryogenic electron microscopy analysis of electrodeposited Li revealed its single crystalline microstructure, and *in-situ* nano-compression experiments on individual Li nano-pillars with diameters of 360-759 nm revealed their average Young's modulus to be 6.76 ± 2.88 GPa and an average yield stress of 16.0 ± 6.82 MPa, ~24x higher than what has been reported for bulk polycrystalline Li. We discuss mechanical deformation mechanisms and strength of nano-sized electrodeposited Li in the framework of its microstructure and dislocation-governed nano-scale plasticity of crystals and place it in the parameter space of existing knowledge on small-scale Li mechanics. The enhanced strength of Li at small scales may help explain why Li can penetrate through and fracture much stiffer and harder ceramic solid electrolytes.

5:15 AM *F.EN03.03.02
On the Mechanisms of Stress Relaxation and Intensification at the Lithium/Solid-State Electrolyte Interface Erik G. Herbert[1], Nancy Dudney[2], Maria Rochow[1], Violet Thole[1] and Stephen Hackney[1]; [1]Michigan Technological University, United States; [2]Oak Ridge National Laboratory, United States

Under electrochemical cycling, stress intensification and relaxation within small, confined volumes at the Li/solid-state electrolyte (SSE) interface are thought to be critical factors contributing to mechanical failure of the SSE and subsequent short-circuiting of the device. Nanoindenation has been used to examine the diffusion limited pressure Li can support in the absence of active dislocation sources at high homologous temperatures. Based on the underlying physics of this deformation mechanism, a simple perturbation model coupling local current density, elastic stress and diffusional creep relaxation is introduced. Combining this analysis with the indentation results, it is possible to describe a 'defect danger zone,' a length scale which is too large for effective diffusional creep relaxation, but too small for efficient dislocation multiplication. In this instance, the properties of the SSE become critical in controlling localized pressure at the interface.

In contrast to the 'first generation,' pioneering analysis of the Li/electrolyte interface by Monroe and Newman, more recent analyses of the Li/SSE interface mechanics examine a similar but uniquely different problem in that they consider non-uniform electrochemical properties and/or filling of morphological defects at the interface during Li charging such that the initial amplitude of the Li protrusion is fixed by a pre-existing interface defect or undulation. Meaningful comparisons between multiple 'second-generation' approaches can be challenging. Although they generally address the same problem, assumptions about the interface defect geometry and the self-limiting mechanical and electrochemical behavior of Li place significant limitations on the conclusions and the general applicability of the proposed solution. Despite their differences, the second-generation approaches arrive at generally the same conclusion: Within confined or localized volumes of Li at the interface, Li can support pressures significantly higher than its bulk yield strength (stresses as high as 200 MPa). Such stress concentrations at the interface are of critical concern because they facilitate mechanical failure of the SSE by fracture. The key question then becomes, why is the stress concentration so large relative to the bulk yield strength of Li? Two potential explanations are offered by the second-generation approaches: geometry effects and length scale effects. These effects are not unique to Li. Any metallic anode will experience these effects in a manner that depends on its absolute melting temperature, elastic modulus, yield strength, and self-diffusion coefficient.

Although the length scale effects of high purity Li have only been recently documented, the basic concept of "smaller is stronger" is well documented. As described by Brenner in 1956 and later quantified by Phani et al. in 2013, the yield strength of a metal in small volumes can be described from a purely statistical point of view, as the stress required to plastically flow depends on the probability of finding the necessary dislocations within the stressed volume. Load-displacement data from

nanoindentation experiments performed in high purity Li at a homologous temperature of 0.67 graphically illustrate this concept. Similar results obtained in high purity indium, a mechanical surrogate to Li, further illustrate the competition for stress relief. Collectively, an important outcome from these 'second generation' approaches is that SSEs with nominally uniform electrochemical properties and flat, smooth surfaces will promote planar, nominally stress-free plating and stripping of Li. Unfortunately, brittle SSE materials will likely experience the same statistical failure issues as structural ceramics. The most robust devices will also implement SSEs that are engineered to provide localized stress relief, potentially through mechanisms such as densification, shear banding and time dependent recovery.

5:30 AM F.EN03.03.03
A New Paradigm for Preventing Lithium Dendrite Penetration Through Solid Electrolytes Yue Qi[1], Chunmei Ban[2] and Stephen J. Harris[3]; [1]Michigan State University, United States; [2]University of Colorado Boulder, United States; [3]Lawrence Berkeley National Laboratory, United States

We introduce a new concept to suppress penetration of lithium dendrites through solid electrolytes (SE) by putting the surface of the SE into a state of compressive stress. For a sufficiently high residual compressive stress, cracks have difficulty forming at the surface, and cracks that do form tend to close, inhibiting dendrite penetration. Introduction of compressive surface residual stress solves stress corrosion cracking problems in metals and static fatigue problems in ceramics and glasses. An example of the latter is Gorilla Glass, which is strongly resistant to cracking because of surface compressive stresses. However, the technique will not work if Li ion transport through a SE in compression is substantially reduced. Our DFT and MD calculations for LLZO indicate that the introduction of even high residual compressive stresses (up to 10 GPa) will have only a very modest effect on Li ion transport kinetics, suggesting that the approach is viable. In addition to inhibiting penetration and fracture in solid electrolytes, compressive stresses on the order of GPa will tend to suppress lithium plating inside of solid electrolytes because of an increased overpotential for the Li ion reduction reaction. We discuss and compare several experimental methods for introducing compressive residual stresses at the surfaces of solid electrolytes. We believe that the information here can provide a new avenue for developing high-performance and stable solid electrolytes

5:40 AM F.EN03.03.04
***In Situ* Investigations of Stress Evolution During Plating and Stripping of Lithium Metal** Jung Hwi Cho[1], Xingcheng Xiao[2], Kai Guo[3], Yuanpeng Liu[4], Huajian Gao[5] and Brian Sheldon[1]; [1]Brown University, United States; [2]General Motors, United States; [3]Massachusetts Institute of Technology, United States; [4]Harbin Institute of Technology, China; [5]Nanyang Technological University, Singapore

Poor stability of Li metal / liquid electrolyte or Li metal / solid electrolyte interfaces leads to chronic problems, such as dendrite formation and capacity loss. The impact of electro-chemo mechanical phenomena on interface stability and dendrite formation are believed to be critical, but are challenging to investigate directly. In-situ curvature measurements are an important tool that can be used to monitor these stresses during battery cycling. Using this technique during Li plating and examining film thickness effects, it is possible to separate contributions from the bulk lithium metal and the solid electrolyte interphase (SEI). These investigations show that the stresses created in the SEI films are much larger than those in the Li metal. Furthermore, these stresses in the SEI can destabilize the electrode / electrolyte interface.
Recently, a variety of methods have been employed to improve the performance and safety of Li metal based batteries by using various artificial SEI layers and/or implementing solid electrolytes. Several of these approaches were also investigated with stress evolution measurements during lithium plating and stripping. This work includes the use of both soft (PEO) and hard (LiF) artificial surface layers. These results indicate that stresses in both the surface film and the bulk lithium evolve differently when artificial SEI layers are employed. Initial attempts to monitor stress evolution with oxide solid electrolytes will also be presented.

5:50 AM F.EN03.03.05
Plastic Deformation and Microstructural Evolution of Pure Lithium Under Various Stress States Juner Zhu[1,1], Tobias Sedlatschek[1], Junhe Lian[1,2], Wei Li[1], Tomasz Wierzbicki[1] and Martin Bazant[1]; [1]Massachusetts Institute of Technology, United States; [2]Aalto University, Finland

Pure lithium in lithium metal batteries is often examined in research projects aiming at improving today's battery technology significantly. But the knowledge about the mechanical properties and the microstructural evolution of pure lithium is incomplete with two particular limitations. First, the available data extensively focuses on the elastic-plastic behavior in some uniaxial loading conditions, the multi-axial plasticity and fracture of pure lithium are rarely taken into consideration. Second, existing studies are mostly performed at the two ends of the length scale axes, either at the nano-scale where dendritic initiation and growth happen or at the bulk-scale where lithium foil is used as an electrode. There is a clear gap at the scale of

one single grain or microstructural imperfection. This work aims at providing a systematic study of the multi-axial plasticity and microstructural evolution of pure lithium at the scale of 100 um to 1 mm under various stress states. To manufacture the required complex-shaped experimental specimens for five different stress states including uniaxial tension, notch tension with two different radii, central hole tension, and pure shear, a method that allows safe laser cutting of thick lithium foils in argon atmosphere is developed. The tests are conducted in pure argon as well as in air to quantify the oxidation behavior of lithium. Two active slip systems are observed during deformation and cross-slip is regularly present. Lithium fractures in an extremely ductile manner when the thickness is reduced to zero due to necking. Numerical simulations of the five loading conditions were performed using a multi-axial plasticity model recently developed by Narayan and Anand, which shed light on the full-field deformation and stress information of the samples for fracture examinations. Finally, the developed plasticity model is applied to a lithium-solid electrolyte interface model that couples contact condition, mechanical deformation, and electrochemistry to study the effect of external pressure on the cycling performance of lithium-metal all-solid-state batteries.

6:00 AM F.EN03.03.06
Mechanical Properties of Alkali Metal Anodes Coleman D. Fincher[1,2], George Pharr[1] and Matt Pharr[1]; [1]Texas A&M University, United States; [2]Massachusetts Institute of Technology, United States

While room temperature metallic anodes possess the potential to enable batteries with enormous capacities, their mechanical behavior ultimately plays a key role in the failure modes for both liquid and solid electrolyte battery systems. That is, not only do alkali metal deposits threaten to deform and penetrate the battery separator in liquid electrolyte systems, but the degree of interfacial contact at the solid-state electrolyte/ anode interface possesses significant pressure dependence for solid-state systems. In this talk, we present a comprehensive multi-length scale assessment of the mechanical behavior of lithium, sodium, and potassium metal. Beyond the mechanical properties, we also discuss some practical implications of the anode's mechanical properties in battery systems.

Chances and Challenges in Zinc Electrode Rechargeability Hajime Arai and Atsunori Ikezawa; Tokyo Institute of Technology, Japan

Zinc is abundant, widely used as structural materials, non-toxic, safe and inexpensive. It has the most negative potential among metals that can be recharged in aqueous electrolyte solutions and high capacity density, and hence is an attractive candidate as a negative electrode material. In alkaline media, the thermodynamically stable discharge product is ZnO, a semiconductor (not insulator), and there is acceptable volume expansion upon its formation (ca. +60%). When anion conductors such as alkaline solutions are used as the electrolyte, as is often the case, the formation of ZnO is at the negative electrode side, which causes tolerable volume changes of the negative electrode when compared to the total metal dissolution and/or deposition at the positive electrode side. The corresponding positive electrode materials can be proton-acceptor types such as NiOOH and oxygen in aqueous alkaline electrolytes. Recent trials include zinc ion acceptors such as organic metal frameworks with zinc ion conductive ionic liquid electrolyte. This presentation mainly focuses on alkaline-based aqueous systems.
The main drawback of the zinc electrode is its insufficient durability, suffered from the morphology changes such as dendrite growth, shape change and densification. This is mostly caused by the formation of highly soluble species $Zn(OH)_4^{2-}$, a kinetically favorable discharge product, that diffuses away from the original positions and precipitates wherever it favors. Even if zinc oxide is saturated in the alkaline electrolyte, zinc supersaturation occurs; it stays longer than the time scale of the charge-discharge reactions, even for months. There are several ways to restrict the zinc dissolution, such as complex formation (e.g. calcium zincate [1]), protective film formation (e.g. anion exchange membrane [2]) and the use of electrolyte additives (e.g. pH controller, indifferent salts and organic solvents [3-4]). Though the durability depends on the utilization rates and loaded mass (mAh/cm2), cycle life of more than several hundred cycles be achieved in ideal cases. Mechanical pressure on the electrode (e.g. separator wrapping) is a simple but effective way in restraining the morphology changes. In contrast to electrical charging, mechanical charging is a unique method for air battery systems, mostly for electric vehicles, where soluble zinc species are removed from the cell and regenerated by off-site processes [5].
Passivation during high rate discharging is also problematic, but can be mitigated by constructing composite electrodes with

high surface areas. Hydrogen evolution as the self-discharge can be restricted by adding inhibitors such as indium and bismuth.
Analytical methods to clarify the zinc electrode reaction processes are of particular interest, since degradation proceeds with nearly no sign in the electrochemical responses. Since zinc is oxidized in air, in situ (in-cells) or operando (in-current-flow) analyses are favorable. *Operando* X-ray diffraction (XRD) is helpful in detecting the formation of crystalline ZnO during discharging [6]. XRD mapping analysis indicates how the shape change proceeds [7]. *Operando* X-ray fluorescence imaging, utilizing the zinc visibility in hard X-ray absorption, is effective in observing zinc behavior with space resolutions [8]. Optical analysis is promising to observe macroscopic changes of the zinc species that significantly affects the electrode durability [9].

Morphological Evolution of Li Metal Anode in Lithium Metal Batteries—Studied by Synchrotron X-Ray Tomography Fu Sun; Qingdao Institute of Bioenergy and Bioprocess Technology Chinese Academy of Sciences, China

The electrochemical performance and serviceable life-span of lithium metal batteries (LMBs) are largely governed by the Li metal anode. Particularly, low Columbic efficiency, inferior cycling stability, short life time and potential safety concerns of LMBs are acknowledged to be closely linked to the employed Li anode. As a result, tremendous efforts have been devoted to enhance the electrochemical cycling ability of Li anode and the performance of LMBs have been significantly improved during the last decade. Nevertheless, breakthroughs in propelling the LMB technology from laboratory research to practical commercialization are still missing, which can be mostly attributed to the incomplete understanding of the underlying working/decaying mechanisms of Li anode. To fill in this knowledge gap, a variety of probing techniques, e.g., (Cryo-) TEM, SEM, XPS, NMR, FTIR have been employed to study the underlying working/decaying mechanisms of Li anode during electrochemical cycling, yielding significant amount of valuable insights. Unfortunately, linking these novel insights of the Li anode to the LMB's performance is still challenging, hence, a comprehensive and in-depth understanding of the correlation between the Li anode and the overall LMB performance remains elusive.

In the current talk, the studies of the morphological evolution of Li anode and its correlation to the LMB's performance studied by Synchrotron X-ray tomography will be shown. *In operando* monitoring of the Li-Li symmetrical cells reveals the morphological evolution mechanism of the electrochemically generated/dissolved Li, as well as the underlying internal short circuits. In addition, the effect of the electrochemically generated Li on different types of separators has been also disclosed and it was found that both the mechanical and physical properties of the separator play an important role during Li electrodeposition. Moreover, the close correlation between the morphological evolution of Li anode and the LMB's electrochemical performance has been established: it was found that the irreversible transformation from original Li bulk to the electrochemically inactive Li electrodeposits results in the observed performance decay. It is hoped that these discoveries could open up new design principles and opportunities to accelerate the practical applications of LMBs.

5:30 AM *F.EN03.04.03
Lithium Metal Anodes—The Dynamic Evolution of Electrochemical, Morphological and Mechanical Phenomena Neil P. Dasgupta; University of Michigan, United States

Lithium (Li) metal anodes have experienced a resurgence of research in recent years, which has been fueled by advances in electrolyte chemistry (both solid and liquid), interfacial engineering, and rational design of electrode architectures[1,2]. This has enabled Coulombic efficiency values to push above 99.5%, and cycle life to extend into relevant ranges for transportation applications[3]. However, while performance metrics are beginning to approach relevant values for consideration of their use in electric vehicles, several fundamental questions remain on how Li metal anodes dynamically evolve during cycling, especially at high current densities. Towards this goal, there is a continued need for new methods to quantitatively measure the evolving morphology, mechanical response, and electrochemical overpotentials of Li metal anodes under realistic

conditions.

In this talk, I will discuss recent insights that have been gained on how morphological evolution of non-planar geometries couple with mechanical stresses, both during both electrodeposition and dissolution[4]. To contextualize the critical role of coupled electro-chemo-mechanical phenomena, examples of dynamic Li metal deformation will be discussed during cycling in solid and liquid electrolytes. Specifically, a multi-modal suite of *operando* analytical techniques will be employed to describe the role of mechanical stresses during the formation of "dead" Li, crack propagation in ceramic solid electrolytes during high-rate cycling, and reversible cycling of Li metal to achieve high Coulombic efficiencies[5–8].

To compliment the cross-sectional perspective provided in our previous *operando* optical microscopy investigations, recent cell designs that enable plan-view *operando* of Li metal dynamics will be demonstrated for both liquid and solid electrolyte systems. In liquid electrolytes this allows for new insight into the influence of surface microstructure on nucleation of both dendrites and pits, and the critical role of surface heterogeneity on Coulombic efficiency[9]. In solid electrolytes, plan-view imaging enables direct visualization of Li metal filament propagation in garnet LLZO ceramics, and four distinct filament morphologies are identified[10]. Equipped with this fundamental understanding, the talk will aim to address the following critical question in the field: *how, when, where,* and *why* does "dead" Li form, and can we control this irreversible Li loss during battery operation?

Characteristic Electrochemical Features of Interfaces on Calcium Foils Aaron M. Melemed and Betar Gallant; Massachusetts Institute of Technology, United States

Batteries based on calcium (Ca) metal anodes offer a possibility of improved sustainability and safety with attractive electrochemical metrics. However, Ca battery development is still in its infancy due to basic chemical limitations. When Ca metal comes in contact with an organic electrolyte, a native solid electrolyte interphase (SEI) forms which passivates, and in some instances fully deactivates, the electrode surface. Considering that Ca deposition and dissolution is widely believed to be a surface-film-controlled process, understanding Ca^{2+} transport through this native SEI is paramount. In this talk, characteristic features occurring in cyclic voltammetry (CV) with Ca foils will be discussed as a function of interface composition in a benchmark electrolyte system, $Ca(BH_4)_2$ in tetrahydrofuran (THF). This electrolyte was found recently by others to support reversible plating/stripping under continuous CV conditions (at 25 mV/s) on planar metal (Au or Pt) working electrodes. As opposed to plating/stripping onto a gold substrate, the first CV cycle on Ca foil reveals a persistent native passivation layer — reflective of the foil preparation process — which manifests as significant reduction and oxidation overpotentials. This native interface can be degraded through the initial electrochemical steps, by processes that depend on whether plating or stripping is first conducted, along with the associated electrochemical protocol. The effect of this first activation step on the resulting electrochemistry will be discussed. Subsequently, the interface evolves to reflect one predominantly governed by CaH_2, which enables further study of the dynamics of this interface under different cycling conditions (scan rate and the imposition of various resting times) on Ca foil. Upon continued cycling, access into the underlying bulk Ca is possible. While this process remains limited by the interface and yields lower current densities than

with fresh Ca plating/stripping on Au electrodes, the underlying Ca is not entirely deactivated as concluded by earlier studies, but rather depends on the surface conditioning process and the electrolyte. To further investigate the role of the interface, I will also describe experiments in which nanoscale CaF_2 (~100 nm), an inorganic component found to be present in other Ca SEI, was intentionally formed on Ca foils prior to immersion in an attempt to decouple the foil from the surrounding electrolyte and modulate interface behaviors. Critical differences in interface chemical and electrochemical stability, along with electrochemical performance under CV conditions, will be discussed, and prospects for improving the cyclability of practical Ca foil electrodes will be explored.

5:55 AM *F.EN03.04.05
Mesoscale Interactions in Electrodeposition Stability of Metal Electrodes Partha P. Mukherjee and Bairav S. Vishnugopi; Purdue University, United States

Lithium metal electrodes in the presence of liquid electrolytes suffer from unmitigated growth of dendrites that pose safety concerns and lead to electrochemical performance limitation. It necessitates fundamental understanding of the mechanistic origins of interface instability at the mesoscale. This work relies on a detailed mesoscale analysis of the role of disparate mechanisms including electrolyte transport, self-diffusion and electrochemical reaction on the nucleation and growth of electrodeposition. The contrasting influence of temperature on the electrodeposition stability is examined. Finally, the role of mesoscale interactions in devising potential pathways toward electrodeposition stability is elucidated.

6:10 AM *F.EN03.04.06
Electrochemical Activation and Passivation of Magnesium Metal Anodes Masaki Matsui; Kobe University, Japan

Magnesium metal anode has a high volumetric capacity of 3833 $mAhcm^{-3}$, rechargeable magnesium battery is expected as an advanced battery system alternate to Li-ion batteries. The SEI-free surface of the magnesium metal leads to the uniform nucleation process resulting in the dendrite free growth during the electrodeposition process. On the other hand, the passivation of the magnesium metal surface initiates the locally-focused current. As a consequence, a risk of dendritic growth of the magnesium metal remains in the electrodeposition process. Here we investigated the nucleation process of magnesium metal on magnesium metal substrates. The initial anodic polarization forms several corrosion pits at the surface of the magnesium substrate. We found that these pits become the preferable sites for the following magnesium deposition. The results suggest that the initial electrochemical activation process is crucial to obtain the uniform plating of magnesium metal.

Interelectrode Temperature Differences used to Promote Reversible Lithium Electroplating and Stripping Corey T. Love[1], Robert Atkinson III[2], Rachel Carter[1] and Todd Kingston[3]; [1]U.S. Naval Research Laboratory, United States; [2]EXCET, Inc., United States; [3]NRL/NRC Post-doctoral Research Associate, United States

The challenges with metal anodes for high-energy batteries will likely be overcome as a result of advancements in three research areas: materials structure-property relationships, electrode architectural design and informed operational controls. We have been focusing our efforts on the operational considerations, specifically temperature control, to promote reversible Li plating and stripping. Modulating temperature, both through thermal gradients and transients, has a direct effect on the performance and stability of the electrochemical plating and stripping processes of Li metal. Applying a modest thermal gradient impacts the lithium plating morphology and dictates whether unstable, one-dimensional Li electroplating or stable, more homogeneous electroplating occurs (1). This talk will expand upon our understanding of gradient-influenced plating/strippping behavior and present operational temperature controls necessary for prolonged battery performance and safety. Additionally, thermal regimes applied to improve electrode kinetics and diffusion will show the opportunity to enable fast charging of Li metal and metal-free eletrodes coupled with a $LiFePO_4$ positive electrode. We use a suite of materials and electrochemical characterization tools (XPS, XRD, optical microscopy, computed tomography and EIS) to guide our understanding of Li metal behaviors in the battery environment.

Metallic Lithium as a Potential Electrode for High Energy Batteries with Metal Polysulfides Hikari Sakaebe; National Institute of Advanced Industrial Science and Technology (AIST), Japan

Increase in the energy density of batteries has been a pressing issue, and metallic lithium is a key electrode material for

establishment of such high-energy battery systems. Long history of research has focused on the “dendritic morphology”, but we would still need to continue the basic research for full-scale practical use. Suppressing the dendritic morphology of electrodeposited lithium is so important and surface modification study has been intensively conducted.
In the basic theory of electrodeposition, balance of Li^+ diffusion and charge transfer kinetics control the morphology and authors confirmed this by lithium plating experiments in ionic liquids [1-3]. Surface modification may adjust this balance or mechanically avoid the growth of dendritic lithium.
We have to consider another point, so called “cross-talk” in the cell. Lithium has the most negative potential among all elements, and electrolytes should be decomposed partly. This is strongly connected to the film formation and then to the cycling efficiency of lithium electrode. Furthermore, the side reaction products may affect the total performance of the cell. In the metal polysulfide/Li cell, a sign of the cross-talk was found and it would lead to the life of the cell [4, 5]. This is quite different from the shuttle mechanism of Li polysulfides in the conventional Li-S cell.

Lithium Dendrite Initiation in Penetration Microchannels Youngju Lee and Peng Bai; Washington University in St. Louis, United States

Dendritic growth inside lithium metal batteries is the major issue that prevents the utilization of Li metal anode despite its high energy density. Due to the heterogeneous nature of dendritic growth, the penetrations inside practical batteries occur through few isolated channels, as analysis on multiple postmortem images of the penetrated separators or solid electrolytes advocates. Utilizing the pulled glass capillary cells and COMSOL simulations, we assessed the penetration dynamics focusing on the concentration polarization within the isolated channels with different geometries. We discovered that the varying cross-sectional area has a major impact on the characteristic time for ion depletion on the advancing electrode front, which was previously discovered as the initiation time of dendritic growth. While the ion depletion times still showed a power-law relationship with current densities as the classical Sand equation predicts, the scaling exponent varied, showing a monotonic relationship with the wall curvature near the electrode front. Our findings explain the presence of dendritic growth observed during the system-defined non-transport limited states, as well as deviations of the dendrite initiation time from the classical electro-diffusion equation behaviors. We also propose a new strategic direction for suppressing the dendritic growth and realizing stable lithium metal batteries based on our discovery.

Textured Metal Electrodeposition at Rechargeable Battery Anodes—Towards Affordable Energy Storage Systems Kent Zheng and Lynden Archer; Cornell University, United States

The development of affordable energy harvesting and storage technology has in recent times emerged as a Grand challenge in addressing the irreversible depletion of fossil fuel supplies. It has also emerged as a crucial barrier that must be overcome to lower humanity’s carbon footprint by electrifying transportation and by utilizing renewables-sourced power on the electric grid. One promising solution is to build integrated Photovoltaics(PV)-Battery systems that are high-performing and cost-effective. Currently, the levelized cost of PV energy generation has dropped to $0.05/kWh, which is comparable with gasoline, while the cost of energy storage (i.e. the battery) is over one order of magnitude higher, making the integrated system economically uncompetitive. Zn-ion battery has a low levelized cost of $0.3/kWh relative to vanadium flow battery, Li-ion battery, lead-acid battery and sodium-ion battery($0.7, $0.5, $0.8, $0.7/kWh, respectively).[1] It is obvious that one can further reduce the levelized cost of a battery by prolonging the cycle life in order to maximize its accumulated energy throughput.[2] Analyses show that, to attain this goal, an at least >99% reversibility much be achieved at the Zn metal anode; however this value is usually <80% in conventional Zn batteries.

In this talk, I will report a type of textured metal anodes that exhibit unprecedented levels of reversibility, > 99.9%. As a first demonstration, I will discuss my recent progress in creating Zn metal batteries that overcome the inherent propensity of the

metal to form highly porous microstructures composed of randomly oriented plates. The porous, loosely-connected metal electrodeposits can be only partially reused in the next discharge, leading to a considerable permanent materials lost and the <80% reversibility. Therefore, a compact, planar Zn metal electrodeposition morphology is necessary in order to meet the reversibility requirement. We then show that this characteristic morphology is attributable to the hexagonal close-pack crystal structure of Zn; it tends to expose its close-packed (002) crystal facet, which is parallel to the micro-plates observed. On this basis, we hypothesize that the desirable compact Zn morphology can be obtained by aligning the (002) Zn plates horizontally with respect to the electrode surface. As I will present in the talk, this goal can be fulfilled either by (a) designing an epitaxial substrate that has low lattice misfit with (002) Zn facet,[3] or by (b) introducing a hydrodynamic flow normal to the electrode surface.[4] The resultant (002)-textured Zn electrodes claim >99.9% reversibilities over 10,000 cycles. As a final note, we demonstrate that this concept of textured electrodeposition can be readily generalized to other metals of interest in batteries, e.g. Al.

Aluminum Metal Anode Rechargeable Batteries with Chloroaluminate Ionic Liquids Tetsuya Tsuda[1], Junya Sasaki[1], Yuya Uemura[1], Toshikatsu Kojima[2], Hiroshi Senoh[2] and Susumu Kuwabata[1]; [1]Osaka University, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan

It is well-known that mass production of aluminum metal is conducted by Hall-Héroult process using high temperature Na_3AlF_6-AlF_3-NaF (or LiF) molten salt system with Al_2O_3. Aluminum metal is one of the most widely used metallic materials for supporting our modern life. However, it is not easy to obtain Al metal without Hall-Héroult process, because Al_2O_3 is thermodynamically very stable as shown in Ellingham diagram and handling temperature for the molten salt is ca. 1273 K. Interestingly, the use of organoaluminum compounds and aluminum halides make it an open possibility to electrochemically deposit Al metal at lower temperature, even below 298 K. Now, chloroaluminate melts consisting of aluminum halides and chemical compounds have attracted attention as Al electroplating baths. Among them, Lewis acidic $AlCl_3$–1-ethyl-3-methylimidazolium chloride ionic liquid (IL) is mostly employed because of its favorable physicochemical properties including negligible vapor pressure, flame resistance, and high ionic conductivity.[1] Note that Lewis acidic means the $AlCl_3$ molar fraction is over 50 mol%. In this organic chloroaluminate IL electrolyte, Al metal deposition/stripping reversibly proceeds by the following reaction:

$$4[Al_2Cl_7]^- + 3e^- \leftrightarrow Al + 7[AlCl_4]^-$$

Similar electrochemical reaction is recognized in a Lewis acidic inorganic 61.0-26.0-13.0 mol% $AlCl_3$–NaCl–KCl IL (eutectic point: 366 K).[2] The electrochemical behavior on the Al metal deposition/stripping in these ILs strongly suggests that we can use it for creating Al metal anode rechargeable batteries. Besides, Al metal has several advantages as an anode material, such as very high theoretical capacity (2980 mAh g^{-1}, 8046 mAh cm^{-3}), less expensive and mass consumable material, and moderate reactivity in air. Therefore, the number of publications on Al metal anode rechargeable battery (AARB) is increasing for this half a decade.[3,4] AARBs commonly use chloroaluminate anions to control both cathodic and anodic reactions. Cathode is a key for designing good AARBs. Currently layered sp^2 carbon materials, which can reversibly cause the insertion/deinsertion of chloroaluminate anions, $[AlCl_4]^-$ and/or $[Al_2Cl_7]^-$, are often employed as cathode active materials.[1]

$$n\mathrm{C} + [\text{chloroaluminate anion}]^- \leftrightarrow \mathrm{C}_n[\text{chloroaluminate anion}] + e^-$$

Such carbon materials show desirable cathodic behaviors, for example, high coulomb efficiency and rapid charge-discharge. But, their charge-discharge capacities seem to be insufficient (~ 90 mAh g^{-1} in Lewis acidic organic chloroaluminate ILs at 298 K;[1,4] ~ 130 mAh g^{-1} in Lewis acidic inorganic ones at 393 K[2]). In this context, novel high capacity cathode active materials for AARB are being developed. Recently we found out that the sulfur-carbon composite material (SPEG) synthesized from the mixture of sulfur and polyethylene glycol[5] show appealing electrochemical behaviors, especially high

rate capability and excellent cycling durability, in an inorganic 61.0-26.0-13.0 mol% $AlCl_3$–NaCl–KCl IL. In this presentation, features of the promising cathodes for the AARBs and impact of the ionic liquid electrolytes on the cathodes will be discussed.

Our research on AARBs is being supported by the MIRAI program (grant number JPMJMI17E9), Japan Science and Technology Agency (JST).

Overcoming the Challenges of Sodium Metal Anodes for Low-Temperature Operation Weiyang Li; Dartmouth College, United States

Low-temperature (LT) batteries using sodium (Na) metal anodes are highly promising for diverse applications under extreme climate conditions owing to the high specific capacity and low cost of the electrode materials. Unfortunately, the insufficient ionic conductivity of the electrolyte together with the Na dendrite growth at LT significantly influences the performance of Na metal anodes. Herein, we present a novel electrolyte, which not only possesses a superior ionic conductivity at −20 °C but also can derive a robust SEI to effectively suppress the dendrite growth and electrolyte decomposition over cycling, contributing to the realization of battery operation under a lean electrolyte condition. Accordingly, the Na metal anode exhibits an ultrahigh reversible capacity of 50 mAh cm^{-2} at 2 mA cm^{-2} rate at −20 °C. Furthermore, in the Na metal-$Na_3V_2(PO_4)_3$ full-cells, a relatively high capacity of 98 mAh g^{-1} after 1000 cycles and stable Coulombic efficiency over 99.6% at 2C rate are achieved at −20 °C.

5:15 AM F.EN03.05.02
Degradation of Lithium Anode in Lithium-Sulfur Batteries—Evolution of SEI Layer and Loss of Lithium Inventory Sanjay Nanda and Arumugam Manthiram; University of Texas-Austin, United States

The commercial viability of lithium-sulfur batteries is mainly caused by the poor plating and stripping efficiency of the lithium-metal anode. Lithium metal tends to deposit in mossy/dendritic morphology with high surface area. The liquid electrolyte irreversibly decomposes on the reducing lithium surface, consuming both the lithium and electrolyte supply in the cell. Nevertheless, the mechanisms underlying loss of lithium inventory and the role of the lithium-electrolyte interfacial layer (SEI) remain unclear. A clear mechanistic understanding of lithium degradation with cycling in Li-S batteries is necessary to develop strategies towards stabilizing lithium deposition in this unique system.

Here, the anode-free full cell configuration, which combines a fully lithiated Li_2S cathode with a bare nickel foil as the current collector, is used to study the dynamics of lithium deposition. The cycle life of anode-free full cells is dependent on the active lithium inventory in the system, as there is no excess lithium in the system (N/P ratio = 1). By deconvoluting the cycling regimes limited by lithium and sulfur, the lithium inventory loss rate per cycle can be quantitatively estimated. This parameter provides a useful and reliable descriptor of lithium degradation with cycling in cells with a limited lithium inventory.

Analysis using time-of-flight secondary ion mass spectrometry (ToF-SIMS) of the deposited lithium in the anode-free full cells showed that the integrated intensity for Li_2^-, which is indicative of metallic lithium, displayed almost no change with

cycling. Thus, a poor correlation between available lithium inventory and amount of metallic lithium detected is discovered. This indicates that the loss of lithium inventory is primarily due to the formation of electrochemically inactive "dead" metallic lithium (Li^0), and not due to undesirable side reactions with the electrolyte forming SEI components (Li^+). ToF-SIMS also revealed the growth of a thick layer of electrolyte decomposition products on the surface of the deposited lithium. Since the decomposition products are not ionically conducting, the metallic lithium underneath is rendered electrochemically inactive or "dead".

It is also found that various hydrogen-containing decomposition products in the bulk of the deposited lithium, such as LiH and LiOH, show a sharp decrease in concentration with cycling. This may be ascribed to the considerable gas evolution that occurs during cycling. These gases include H_2, CH_4, and C_2H_4. This could play an important role in lithium degradation by blocking off ionic and electronic conduction to the trapped metallic lithium, especially if the gases themselves are trapped in void spaces of the porous lithium deposit.

Thus, the mechanisms that underlie the loss of lithium inventory in Li-S batteries are illuminated by a novel application of the anode-free full cell configuration and analytical tools such as ToF-SIMS. The evolution of the lithium-electrolyte interfacial layer (SEI) and its role in causing lithium degradation is demonstrated. It is hoped that the insights generated in this work can motivate efforts towards enabling stable operation of lithium-metal anodes and long cycle life for energy-dense Li-S batteries.

Building Artificial Solid Electrolyte Interphase with High-Uniformity and Fast Ion Diffusion for Ultralong-Life Sodium Metal Anodes Qianwen Chen, Heng He, Weiman Zhuang and Limin Huang; Southern University of Science and Technology, China

Na metal is regarded as a promising anode for Na batteries owing to its high specific capacity and natural abundance. However, rapid dendrite growth and low reversibility hinder its practical applications. Building an artificial solid electrolyte interphase (SEI) is an effective strategy to stabilize a Na metal anode, yet it is still deficient at high current density and cycling capacity. Here, two artificial SEI layers were constructed through the analogous reactions between Na metal and pure $SnCl_4$ liquid ($SnCl_4$-Na electrode) or diglyme solvent with $SnCl_2$ additive ($SnCl_2$-Na electrode) to investigate the key parameters for an excellent artificial SEI. Both simulations and experiments demonstrate that high-uniformity and high Na^+ diffusion properties of $SnCl_4$-derived protective layer are significant for stabilizing Na metal anodes under rigorous test conditions. Therefore, the $SnCl_4$-Na electrode protected by homogenous and high Na^+ diffusion Na-Sn alloy and NaCl achieves an ultralong cycle life for 4000 h and small voltage hysteresis (~100 mV) with a cycling capacity of 3 mAh cm^{-2} at 2 mA cm^{-2}, which is much better than that of the $SnCl_2$-Na electrode. Moreover, even with a cycling capacity of 5 mAh cm^{-2} at 5 mA cm^{-2}, the $SnCl_4$-Na electrode still can stably run for ~1500 h. Benefiting from the durable SEI layer, a stable capacity of ~350 mAh g^{-1} is observed on a $SnCl_4$-Na|FeS_2 full cell for 380 cycles.

5:35 AM *F.EN03.05.05
Structure and Dynamics of the Solid Electrolyte Interphase on Li Metal Anodes Lauren Marbella; Columbia University in the City of New York, United States

Li metal batteries have the opportunity to enable high energy density technologies, including Li-air, Li-S, and all-solid-state batteries. However, Li metal anodes suffer from microstructural growth that leads to a loss of Coulombic efficiency and, in some cases, short circuiting and cell death. The composition and structure of the solid electrolyte interphase (SEI) that forms on the surface of Li metal is not well understood, but is believed to play a key role in controlling, and possibly initiating, Li microstructural growth. Here, we use solid-state NMR spectroscopy to provide a detailed characterization of discrete organic and inorganic species that comprise the SEI on Li metal anodes. We examine the SEI and Li ion dynamics through the interphase on Li metal after galvanostatic cycling/polarization in various electrolyte formulations and correlate these changes with differences in Li microstructural growth patterns. Insight into molecular-level changes in SEI composition and dynamics for distinct electrolyte mixtures allows us to rationalize how specific electrolyte components may mediate Li microstructural growth.

5:50 AM F.EN03.05.06
The Role of the Interface in Stabilizing Reaction Intermediates for Hydrogen Evolution and SEI Formation in Aprotic Electrolyte Ivano E. Castelli; Technical University of Denmark, Denmark

Understanding the battery interface is a key-point for improving the lifetime of Li-ion batteries (LIB) as well as design novel

electrode materials, beyond LIB. Here, we investigate the SEI formation on the single-crystal metal facets in an organic aprotic electrolyte, by combining idealized experiments with realistic quantum mechanical simulations of the interface (ab-initio molecular dynamics, AIMD). We discover that the LiF formation, accompanied by H_2 evolution, is caused by a reduction of HF impurities and requires the presence of Li at the interface, which catalyzes the HF dissociation. The measured potential of the electrochemical response for these reduction reactions correlates with the work function of the electrode surfaces and that the work function determines the potential for Li^+ adsorption. The reaction path is investigated further by electrochemical simulations suggesting that the overpotential of the reaction is related to stabilizing the active structure of the interface having adsorbed Li^+. Li^+ is needed to facilitate the dissociation of HF which is the source of protons. Further experiments on other proton sources, water, and methanesulfonic acid show that if the hydrogen evolution involves negatively charged intermediates, F^- or HO^-, a cation at the interface can stabilize them and facilitate the reaction kinetics. When the proton source is already significantly dissociated (in the case of a strong acid), there is no negatively charged intermediate and thus the hydrogen evolution can proceed at much lower overpotentials. This reveals a situation where the overpotential for electrocatalysis is related to stabilizing the active structure of the interface, facilitating the reaction rather than providing the reaction energy. Using these data, we generate neural network potentials to extent the length and time scale of AIMD and to fully understand the implications that these findings have for the SEI formation.

6:00 AM *F.EN03.05.07
Characterization of Solid Electrolyte Interphase Formed in the Electrolytes Developed for Rechargeable Lithium-Sulfur Battery Yasushi Katayama, Takaaki Matsumoto, Tomohiro Uchiya, Mika Nishikawa and Nobuyuki Serizawa; Keio University, Japan

Rechargeable lithium sulfur battery has attracted much attention as a next generation battery due to a high theoretical energy density and low cost. In the discharge process, sulfur is reduced to Li_2S with formation of polysulfides as intermediate species. In the case of conventional organic electrolytes used for commercial lithium-ion batteries, polysulfides dissolve in the electrolytes, leading to the self-discharge by the diffusion of polysulfides from the cathode to anode, namely a shuttle effect. The self-discharge has been reported to be prevented by forming a solid electrolyte interphase (SEI) based on functional additives like lithium nitrate. However, the consumption of the additives spoils the prevention of the shuttle effect for long-term cycling. It has been reported that the solubility of polysulfides is very low in the electrolytes composed of lithium bis(trifluoromethylsulfonly)amide (LiTFSA) and such organic compounds as tetraglyme (G4) and sulfolane (SL). Although the superior performance of sulfur cathodes has been reported in these electrolytes, the applicability of a lithium anode in the electrolytes has not been investigated from a fundamental point of view. In the present study, SEIs formed in LiTFSA-G4 and LiTFSA-SL were characterized by electrochemical impedance spectroscopy (EIS), Fourier transform infrared spectroscopy (FT-IR), X-ray photoelectron spectroscopy (XPS), and transmission electron microscopy (TEM). The formation of a SEI on a Cu substrate was suggested by holding the potential at 0 V vs. Li|Li(I) in LiTFSA-G4 by EIS. The SEI is considered to grow with the elapse of time for holding the potential at 0 V, indicating the decomposition of the electrolyte was sluggish. The SEI with the thickness of about 100 nm was observed on the Cu substrate after the SEI formation. The SEI was suggested to be composed of the organic components derived from the reductive decomposition of the electrolyte. FT-IR and XPS indicated that $TFSA^-$ was included in the SEI. On the other hand, the formation of LiF was not confirmed by XPS, indicating the electrochemical decomposition of $TFSA^-$ was not predominant while the decomposition of $TFSA^-$ after Ar^+ etching was found to give a peak assignable to LiF. A similar SEI was also found to be formed on a Cu substrate in LiTFSA-SL with addition of a diluent, 1,1,2,2-tetrafluoroethyl 2,2,3,3-tetrafluoropropyl ether (HFE). The thickness of the SEI in LiTFSA-SL-HFE was thinner than that in LiTFSA-G4, suggesting the poor adhesion and/or partial dissolution of the SEI. The formation of LiF was not confirmed by XPS. These results suggested that the SEIs formed in these electrolytes are composed of the ionic species, which are immobilized in the matrix based on the decomposed products of the organic components of the electrolytes.

The Electronic Properties of Grain Boundaries in Solid Electrolyte Interphase and Their Impact on Li-Metal Electrode Passivation Min Feng, Jie Pan and Yue Qi; Michigan State University, United States

Due to the highly reactive and reductive nature of Li-metal, the surface of Li-metal electrodes is typically covered by a layer of solid electrolyte interphase (SEI), which can be formed by electrolyte decomposition or artificial coating. If the SEI cannot passivate the Li-surface, continuous electron leakage through the SEI will lead to more electrolyte decomposition, SEI

growth, metallic Li formation and growth inside of the SEI, all of which contribute to the major durability and safety concerns for Li-metal electrodes. Given the multi-components and mosaic structures of SEI, the extended defects such as grain boundaries and interfaces in SEI are likely to be the electron conduction pathways, as the individual SEI components are wide-bandgap insulators in their single crystalline form. Therefore, in this work, the electronic properties of representative grain boundaries (GBs) of the main SEI components (LiF, Li_2O, and Li_2S) on Li in various electrolytes were investigated via density functional theory (DFT) calculations. The GB energy, GB bandgap, excess electron distribution were computed. The total density of states (DOS) of GBs was then aligned with Li Fermi level and Li^+/Li^0 potential level to determine their ability to trap electrons from the Li metal electrode. For a systematic comparison, highly coherent tilt and twist GBs with the same $\sum$ values ($\sum 3$ and $\sum 5$) in coincidence site lattices (CSL) model were studied to represent low energy special GBs; and GBs with melted GB region and the same orientation of the special GBs were used to demonstrate the influence of the amorphous GBs.
It was found that all the GB bandgaps were smaller than the corresponding bulk bandgaps, with an order of amorphous GBs < Tilt GBs < Twist GBs < single crystal. Among all the calculated GBs, the coherent Li_2S Tilt $\sum 3$ (-12-1)/[111] GB and the amorphous LiF GB showed empty electronic states lower than the Li^+/Li^0 depositing level, suggesting that those GB states can trap electrons from Li metal, leading to nucleation of metallic Li inside of the SEI and contributing to the Li dendrite growth. Structural analysis revealed that more under-coordinated atoms in the GBs caused larger bandgap drops and more excess electron localization in the less dense GB regions. These insights suggested that dense SEI structures such as sharp interfaces and well-ordered GBs are preferred to design a fully electronically passivating SEI. Furthermore, to overcome the size limitation of DFT calculations for complex GB structures and facilitate the multiscale simulations, we proposed an analytical model to extrapolate the bandgaps of special GB structures based on the DFT-computable bulk and surface bandgaps. Our predictions of GB bandgaps can be used as inputs for phase field models to simulate Li dendrite growth morphology in both solid and liquid electrolytes.

Formation of a Spontaneous Passivation Layer at the Li Metal/Electrolyte Interface Perla B. Balbuena, Francisco Ospina-Acevedo and Ningxuan Guo; Texas A&M University, United States

The promise of Li metal as one of the best imaginable anodes for the next generation of advanced batteries remains intact. However, this promise becoming a reality is not yet possible because of the various issues associated with its high reactivity. Obviously, the immediate expectation is that a great passivation layer will mitigate the problem. Indeed, the immediate contact of Li metal with a liquid electrolyte leads to the spontaneous formation of a “solid-electrolyte interphase” (SEI). The SEI results from the redox reactions where Li becomes oxidized and the electrolyte components become reduced. In this talk, we will discuss how the various anode and electrolyte properties affect such SEI. We have carried out classical reactive molecular dynamics simulations and density functional theory calculations for many different anode surfaces and various electrolyte compositions. As a result, we have observed nucleation and growth of the SEI under various important conditions. The conclusions are very important to understand the evolution of Li metal anodes during battery cycling.

6:40 AM F.EN03.05.10
The Identity and Role of Interphases in Regulating Mg Anode Morphology Evolution Kevin R. Zavadil, Nathan Hahn, Scott A. McClary, Daniel Long and Katherine L. Jungjohann; Sandia National Laboratories, United States

The spontaneously formed and evolved interphase present on a metal anode dictates the Coulombic efficiency, capacity, rate, and lifetime (cycle and calendar) properties of this electrode. Ideally, we would design electrolytes with a detailed knowledge of interphase function to achieve optimum anode performance. Such knowledge is currently lacking for the more energy dense multivalent metal anodes, such as Mg and Ca, cycled in electrolytes that exhibit promise for viable, full cell chemistries. In this presentation, we describe interphase characterization of Mg metal anodes, where Mg serves as a test case for correlating interfacial phenomena with energy storage performance and morphological evolution. We show that Mg exhibits a range of electrolyte dependent behaviors from classic electrocrystallization, marked by near unity Coulombic efficiency and electrochemical epitaxy, to varying degrees of deposit density and crystallography determined by the interphases present at the anode surface. We employ transmission electron microscopy based on a cell to microscope approach to define the role the interphase plays in controlling metal grain size/shape, crystallography and microstructure with cycling and we relate these attributes to the interphase composition and structure. We demonstrate dramatic changes in deposition and dissolution morphology are possible with subtle changes in electrolyte composition, including controlled levels of trace water, added co-ions, and added co-solvents. Our results suggest a path exists toward directing interphase formation based on enhanced electrolyte design.

6:50 AM F.EN03.05.11
Self-Discharge in Lithium Metal Batteries as a Function of Electrolyte Laura C. Merrill, Samantha G. Rosenberg and Katharine Harrison; Sandia National Laboratories, United States

Lithium metal anodes are of interest due to the high theoretical capacity of lithium (3800 mAh/g) making the lithium anode ideal for use in high energy density applications. Self-discharge is apparent when an electrochemical cell loses capacity at rest, subsequently lowering the energy density. In Li-ion batteries, this can represent up to a 100 % loss in capacity.[1] New Li-ion chemistries using silicon anodes also show evidence of self-discharge.[2-3] Recent work suggests that lithium metal batteries will experience significant capacity losses when at rest in the charged state.[4-6] One of the primary means of self-discharge identified is lithium metal corrosion. This work evaluates self-discharge phenomena in carbonate and ether-based electrolytes commonly used with lithium metal batteries. It is found that the interplay between the solid electrolyte interphase (SEI) and the chemical passivation layer, both of which are electrolyte dependent, determine the extent of self-discharge observed. Specifically, self-discharge is worsened in some electrolytes by the continual breakdown and repair of the SEI upon lithium electrodeposition and dissolution. The use of inorganic artificial SEIs are also studied to mitigate the capacitive losses.

Challenges in Enabling Li Metal Anode—A Composite Electrolyte Approach Xi C. Chen; Oak Ridge National Laboratory, United States

Li metal is the ultimate anode of choice to improve the energy and power densities of current lithium ion batteries due to its high theoretical capacity and low electrochemical potential. However, challenges associated with the high reactivity and dendrite growth of metallic Li must be addressed before its practical applications. The development of a solid-state electrolyte is the key to enabling Li anode. In order to achieve this goal, the solid-state electrolyte must have high ionic conductivity, adequate mechanical modulus, good chemical stability and adhesion with metallic lithium, and thin sheet processability.

Our strategy to enable Li metal anode is a composite electrolyte approach. The goal is to develop a composite solid electrolyte consisting of a processible soft polymer phase and a highly conductive hard ceramic phase to meet the challenging combination of physical, chemical and manufacturing requirements.

Here we introduce the fabrication of two types of composite electrolytes. One type is to disperse model Li^+-conducting ceramic particles (LICGC™) within a polymer electrolyte matrix (poly(ethylene oxide)-based). Aqueous spray coating is used to produce thin, large area and dense composite films with high loadings of ceramic. The interfacial resistance for ion transport between the polymer and the ceramic is quantified using a trilayer model and methods to minimize the interfacial resistance is discussed. In this type of composite electrolyte, the main ion conduction pathway is through the polymer matrix. A second type of composite electrolyte involves creating a three-dimensionally interconnected structure of the ceramic with greatly reduced interparticle resistance. The main ion conduction pathway is through the ceramic in this case. Symmetrical cells and full cells using these electrolytes with Li metal will be compared.

Magnesium Metal Electrodeposition and Electrodissolution with Polymer Electrolytes Bumjun Park and Jennifer L. Schaefer; University of Notre Dame, United States

Lithium metal and magnesium metal batteries have potential for high system energy density due to the high gravimetric and volumetric charge capacity of these metal anodes. Magnesium metal offers several advantages and disadvantages with respect to lithium metal as an anode. Magnesium is more abundant and resources are geographically widespread. Magnesium metal is less chemically reactive than lithium metal and electrodissolution/deposition happens at elevated potentials, yet issues with inefficiency and side reactions still remain. While lithium metal polymer batteries have been investigated intently for decades, magnesium metal polymer batteries have received little attention. There exist great difficulties in producing magnesium polymer electrolytes that both effectively transport magnesium and support reversible electrodeposition and dissolution of magnesium metal. In this talk, I will review our recent research on ion transport and electrochemistry in traditional salt-doped magnesium polymer electrolytes and magnesium poly(ionic liquid) electrolytes.

5:30 AM *F.EN03.06.03
Chemo-Mechanics at Lithium Metal Interfaces in Solid-State Batteries Matthew T. McDowell; Georgia Institute of Technology, United States

Incorporating lithium metal anodes into solid-state batteries (SSBs) is critical for enabling high energy density and specific energy. However, a variety of chemo-mechanical issues at the solid-state electrochemical interface, including interphase growth, contact loss, and lithium morphology evolution, have hindered development of efficient solid-state lithium anodes. Understanding and controlling the dynamic evolution of lithium interfaces is therefore necessary for further development of SSBs. Here, I discuss my group's efforts using *in situ* and *operando* methods to investigate the dynamic evolution of lithium metal and its interphase within SSBs. Multi-modal *in situ* investigation of interfacial reactions combined with electrochemical experiments reveal how the formation of the interphase is linked to chemo-mechanical cell failure in NASICON-based lithium metal cells. *In situ* transmission electron microscopy (TEM) shows that the reaction of $L_{1+x}Al_xGe_{2-x}(PO_4)_3$ (LAGP) with lithium to form an interphase is similar to a conversion reaction, in which lithium insertion causes amorphization and volume expansion of ~130%. *In situ* X-ray tomography experiments of operating LAGP-based cells reveal that the growth of the interphase causes fracture, which is the underlying cause of impedance increase within the cell. Interestingly, we have found that deposited interfacial layers can alter the growth trajectory of the interphase and extend cycling stability of symmetric cells from ~30 hours with unprotected LAGP SSEs to >1000 hours with protected materials. Additional efforts have been focused on the use of *operando* synchrotron X-ray imaging to understand interfacial dynamics and overall cell evolution during cycling in SSBs with different chemistries. Finally, I will discuss our results on understanding lithium anode evolution at different temperatures in liquid and solid systems. Overall, these results provide fundamental insight into the evolution of the lithium/electrolyte interface, and they show that control over interfacial transformation processes could enable the development of solid-state lithium metal batteries.

Sodium Stripping and Plating from Na-β"-Alumina Ceramics Beyond 1000 mA/cm^2 Daniel Landmann, Gustav Graeber, Meike Heinz and Corsin Battaglia; Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Dendrite formation limits the cycle life of lithium and sodium metal anodes and remains a major challenge for their integration into next-generation batteries, even when replacing the liquid electrolyte by a solid electrolyte. Recent studies have pointed out that lithium and sodium metal creep rather than lithium and sodium diffusion is the primary mechanism for replenishing the voids forming in solid metal anodes at the interface to a solid electrolyte upon stripping. Void formation upon stripping causes current constrictions upon plating, promoting dendrite formation. Here we investigate plating and stripping of liquid sodium metal from a ceramic Na-β"-alumina electrolyte at 250 °C, thereby eliminating mass transport limitations due to creep. Employing a porous carbon electrode coating to (1) prevent dewetting of plated liquid sodium from and (2) to supply liquid sodium upon stripping to the sodiophobic Na-β"-alumina surface, we demonstrate extremely high current densities above 1000 mA/cm^2 and cumulative plated capacities of 10 Ah/cm^2 without dendrite formation [1]. These values are two orders of magnitude larger than the corresponding values measured at room temperature [2]. We further show that liquid sodium occupies 60% of the porosity of the carbon coating, while excess sodium accumulates on top of the coating. Increasing the thickness of the carbon coating from 50 µm to 200 µm does not affect the Coulombic efficiency, but reduces the constant current rate capability due to the increased flow resistance for liquid sodium in the porous coating. Our results confirm that eliminating void formation is effective in suppressing dendrite formation.

Factors Influencing Lithium Protrusion Nucleation and Cycle Life in Solid Polymer Electrolytes for Battery Applications Alec S. Ho[1,2], Jacqueline Maslyn[1,2] and Nitash P. Balsara[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Successful prevention of lithium dendrite growth would enable the use of lithium metal as an anode material in next-generation secondary batteries. Mechanically stiff solid polymer electrolytes have been shown to prolong the life of lithium metal cells by partially suppressing lithium dendrite growth. However, we lack fundamental knowledge about the nature of lithium electrodeposition under different electrochemical and electrolyte conditions, as direct observation of this phenomenon is non-trivial.

Synchrotron X-ray microtomography was used to observe lithium metal plating through these solid polystyrene-*block*-poly(ethylene oxide)-LiTFSI electrolyte membranes under a range of electrochemical conditions: regimes of lithium plating behavior as functions of current density and electrolyte thickness through the block copolymer electrolyte were identified. Impurity particles in the lithium metal were observed at the nucleation sites of protrusions, as reported in other work. Next, stable lithium plating at low current density was used to treat the lithium layer at the electrode-electrolyte interface to investigate the effect of impurity particles on protrusion nucleation and lithium deposition. We show that this "lithium filtering" strategy increases the cycle life of lithium symmetric cells in an unexpected way.

Solid-State Ceramic Battery Electrolyte Processing Jennifer Rupp; Massachusetts Institute of Technology, United States

Next generation of energy storage devices may largely benefit from fast and solid Li+ ceramic electrolyte conductors to allow for safe and efficient batteries and fast data calculation. For those applications, the ability of Li-oxides to be processed as thin film structures and with high control over Lithiation and phases at low temperature is of essence to control conductivity. In particular, Li-garnet structures are attractive due to their fast transfer properties and safe operation over a wide electrochemical stability range for batteries. In the first part we focus on low temperature processing of Li-garnet thin films and nanostructures. Examining the structure-Li transport in solid state and asking the provocative question: How do Li-amorphous to crystalline structures conduct? How to alter processing of Li-oxide films to compensate for the challenge that most of Lithium phases lead to sluggish transport and hard phase stabilization? Bringing down battery solid electrolyte processing temperature and decreasing form factor opens new opportunities in battery design and new doors to give more functions for similar material classes for neuromorphic computing. Through the talk, we focus on new processing opportunities to Lithiate thin film structures in crystalline state and to assure cubic and fast conduction on the example of Li-garnet for thin film form using some active Lithiation strategies at film deposition1-3. For this we will review the field of thin film processing and introduce to new processing routes based on vacuum and wet-chemical techniques to control various strategies of Lithiation and phase evolution. Excitingly, one has the opportunity for Li-garnet solid state conductors to not only synthesize crystalline structures, but also amorphous films in various frozen-in states4. Insights on degree of amorphous to crystalline Li-garnet thin films are presented based on model experiments, incl. JMAK and TTT-diagram analysis of Li-garnet structure types. Dependent on either a vacuum or wet-chemical based method chosen the phase evolution differs when synthesizing the glass states, with significant impact on condensation and Li-transport5-6. We find that the different amorphous structures that Li-garnets are no Zachariasen glasses as they violate several of Zachariasen rules by text book: These amorphous Li-garnets differ therefore significantly from LIPON but have a wider room to arrange the higher coordinated polyhedral, network former and builders. In amorphous garnets there is room for manipulation in densification and Li-transport and one may potentially profit from high stability window to design batteries with no grain boundaries at the Li electrolyte interface. Collectively, the insights on solid state energy storage provide evidence for the functionalities that those Li-materials can have in the future. The challenges are deeply connected to low temperature processing and design of structure-transport properties, however, solving those allows us to dream a little more and give materials more functions. 1. Synthesis and Electrochemical Properties of Na-ion Conducting Pseudo-Solid State Ionogel Electrolytes Ryan H. DeBlock[1], David Ashby[2], Grace Whang[1], Danielle Butts[1], Christopher Choi[1] and Bruce S. Dunn[1]; [1]University of California, Los Angeles, United States; [2]Sandia National Laboratories, United States

Ionogels are pseudo-solid state electrolytes in which an ionic liquid electrolyte confined in a mesoporous inorganic matrix leads to a material that possesses the electrochemical, thermal and chemical properties of the ionic liquid despite being a macroscopic solid. Because of their unique architecture, ionogels maintain a nanoscale fluidic state and thus mitigate the interfacial resistances which commonly arise at solid-solid interfaces. The use of sol-gel synthesis enables the materials to be prepared as liquids and to penetrate porous electrodes before becoming solid, an especially beneficial property for solid-state batteries. The incorporation of Li-ion conducting ionogel electrolytes into Li-ion batteries has been reported previously and generally show behavior comparable to that of the ionic liquid electrolyte.

In this work, we report on the development of Na-ion conducting ionogels, a topic which has received only limited investigation to date. We use sol-gel synthesis to form a siloxane-modified silica scaffold that traps an ionic liquid electrolyte comprised of 0.5M NaFSI in 1-Butyl-1-methylpyrrolidinium bis(trifluoromethanesulfonyl)imide [PYR14][TFSI]. The low vapor pressure of the ionic liquid ensures that a dense gel is formed. The interconnected porosity allows for good ionic conductivity (0.7 mS cm^{-1}), although it is somewhat less than the corresponding ionic liquid electrolyte. The activation energy for conduction of 0.3eV is, as expected, higher than that of Li-ion conducting ionogels. The material possesses a 5V electrochemical window and is thermally stable up to 150°C. Using the positive Na-ion electrode material, $Na_3V_2(PO_4)_3$, the charge transfer properties of the ionogel/NVP interface were characterized and found to exhibit low interfacial impedance. This led us to demonstrate the operation of a Na-ion solid state battery which contained a $NaTi_2(PO_4)_3$ negative electrode in conjunction with the NVP. The results shown here underscore the versatility of ionogels as a thermally stable electrolyte with designed ion transport properties for use in future solid-state electrochemical devices

Stabilizing Solid Li and Na Metal Anodes Using Ceramic Membrane Technology Jeff Sakamoto[1], Michael Wang[1], Marie-Claude Bay[2] and Corsin Battaglia[2]; [1]University of Michigan, United States; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

There is tremendous interest in making the next super battery, but state-of-the-art Li-ion technology works well and has inertia in several commercial markets. Supplanting Li-ion will be difficult. Recent material breakthroughs in Li and Na metal solid-state electrolytes could enable a new class of non-combustible solid-state batteries (SSB) delivering twice the energy density (1,200 Wh/L) compared to Li-ion. However, technological and manufacturing challenges remain. The discussion will consist of recent milestones and attempts to bridge knowledge gaps to include: The physical and mechano-electrochemical phenomena that affect the stability and kinetics of the Li and Na metal-solid electrolyte interface Thin film processing and Li integration with LLZO Plating and stripping dynamics of Li and Na metal Despite the challenges, SSB technology is rapidly progressing. Multi-disciplinary research in the fields of materials science, solid-state electrochemistry, and solid-state mechanics will play an important role in determining if SSB will make the lab-to-market transition.

9:00 PM *F.EN04.20.09
Halide-Based Solid-State Batteries—Electrolyte, Stability, Interface and Electrode Xueliang A. Sun; University of Western Ontario, Canada

All-state-state lithium batteries (ASSLBs) have gained worldwide attention because of intrinsic safety and increased energy density. Compared with other types of solid-state electrolytes including oxide-based, polymer-based and sulfide-based electrolytes, recently-developed halide-based solid-state electrolytes (SSEs) have garnered considerable attention for all-solid-state lithium batteries (ASSLBs) due to the high ionic conductivity, high oxidation voltage and good stability toward oxide cathode materials [1]. However, there are still many challenges in halide-based solid-state electrolytes for ASSLBs including controllable and mass-production synthesis, achieving high humidity tolerance and demonstrate high-performance of ASSLBs; in particular, increased understanding of mechanisms during synthesis and tuning their properties of the electrolytes as well as interface with electrode materials[1].

In this talk, **(i)** I will demonstrate synthesis strategy [2-3], in particular, new and salable water-mediated synthesis method [2]. **(ii)** I will report a systematic study on the correlations among structural evolution, Li^+ migration properties, and humidity stability resulting of the halide-based electrolytes, along with in-situ characterization for understanding of the mechanisms [4], **(iii)** Full cell battery performance will be optimized [5], **(iv)** humidity ability [6] and **(v)** other applications such as Li-O2 batteries [7]. In the end, energy densities of ASSLBs using different solid-state electrolytes in ASSLBs will be discussed.

Voids and Dendrites at the Alkali Metal/Solid Electrolyte Interface Peter Bruce, Jitti Kasemchainan, Stefanie Zekoll, Dominic Spencer Jolly, Gareth Hartley, Ziyang Ning, Boyang Liu and Paul Adamson; University of Oxford, United Kingdom

Implementing alkali metal anodes and replacing flammable liquid electrolytes with solids promises to deliver higher energy densities and greater safety than conventional Li-ion batteries. However, challenges at both the metal-electrolyte and cathode-electrolyte interfaces must be addressed to realise this potential. It is imperative to maintain good interfacial contact between the solid-state components to achieve low interfacial resistances. Alkali metal dendrite growth, even at modest rates, when paired with dense, well-sintered solid electrolytes, leads to short circuits, and ultimately cell failure. We have used a number of techniques to investigate the effect of cycling conditions on the formation of voids and dendrites and how the latter is intimately connected to the former. These results and their implications for the operation of a failure free all-solid-state

battery will be discussed.

2:25 PM *F.EN04.03.05
Novel Additives and Polymer Coatings for Stabilizing Li-Metal Anodes Zheng Chen; University of California, San Diego, United States

Li metal is considered as one of the most promising anode materials for high energy batteries, owing to its high theoretical specific capacity and low electrochemical potential. However, notorious issues with the formation of Li dendrites and insufficient coulombic efficiency (CE) during the plating/stripping process prevent its practical applications in rechargeable batteries. These limitations are primarily attributed to fragile and inhomogeneous solid electrolyte interphases (SEIs), which cause continuous consumption of fresh Li and electrolyte during cycling, leading to short battery life. Of late, many efforts have been taken to enhance CE and suppress Li dendrite growth, including design of three-dimensional current collectors, artificial SEI construction on the surface of Li, employment of solid-state electrolytes, separator modification and optimization of electrolyte compositions. In this talk, we will show some recent works in developing novel electrolyte additives and polymer coatings to improve the CE and cycling stability of Li-metal anodes. We demonstrate reasonably stable cell cycling performance under practical conditions such as lean electrolytes and low N/P ratios. The roles of these additives and polymer coatings were also explored to elucidate their function in tuning Li-metal morphology and SEI composition.

6:30 PM F.EN04.10.06
Strong Adhesive Pick-up Technique with Polycaprolactone for Rare 2D Materials Young Shin[1], Suhan Son[2], Sungmin Lee[2], Dohun Kim[2], Je-Geun Park[2] and Philip Kim[3]; [1]Brookhaven National Laboratory, United States; [2]Seoul National University, Korea (the Republic of); [3]Harvard University, United States

We introduce polycaprolactone (PCL) dry transfer which is a powerful material for picking up non- adhesive van der Waals materials such as NiPS3, NbSe2, Fe3GeTe2, ZnPS3 and bismuth strontium calcium copper oxide (BSCCO) and etc. The heterostructures of Van der Waals were composed of layered atomically thin 2D materials that provide access to new properties important to the quantum information sciences. However, one of the main constraints is the stacking techniques. (PPC) has been known as the highest quality in dry transfer because PPC left less residue on vdW heterostructure through high temperature vacuum annealing but yield of the transfer was low. Here, we present the new polymer, polycaprolactone (PCL) for stacking vdW heterostructure with Rare layered 2D materials by dry transfer at low temperature. These 2D materials were easily detached from hexagonal boron nitride (hBN) assisted with PPC during dry transfer process. We succeeded to pick up many rare superconducting or magnetic 2D materials which were hard to be picked up by conventional dry transfer method from the oxide or silicon nitride substrates.

Abstract

7:10 PM *F.EN04.10.07
Strong Magnon-Phonon Hybridization in a 2D van der Waals Antiferromagnet Thuc Mai[1], Kevin Garrity[1], Amber McCreary[1], J. Argo[2], Jeffrey Simpson[1,3], V. Doan-Nguyen[2], Rolando Valdes Aguilar[2] and Angela Hight Walker[1]; [1]National Institute of Standards and Technology, United States; [2]The Ohio State University, United States; [3]Towson University, United States

Low dimensional, van der Waals (vdW) materials, from graphene to 2D magnets such as Fe_3GeTe_2 and CrI_3, show exotic behaviors at the atomic layer limit, including superconductivity, long range magnetism and topological edge states. Their "stackability" further creates new opportunities to explore quantum phenomena previously studied only in 3D crystals. Here we demonstrate that magneto-Raman spectroscopy is a unique measurement capability that is exceptionally well suited to study these exotic 2D materials.
Specifically, in the MPX_3 (M=Fe, Mn; X =S, Se) compounds, inter-layer antiferromagnetic ordering has been suggested to survive in the monolayer limit through the measurement of spin-phonon coupling. Using temperature-, polarization-, and wavelength-dependent Raman scattering, we studied the Neel-type antiferromagnet $MnPSe_3$ through its ordering temperature, and as a function of applied magnetic field. Surprisingly, the previously assigned one-magnon scattering peak showed no change in frequency with an increasing in-plane magnetic field. Instead, the Raman data revealed a more surprising story, including changes in resonant Raman scattering due to magnetic ordering as well as the hybridization of phonons with a 2-magnon scattering continuum. These results, which are supported using first-principles calculations, reveal the complex phase space of the interactions of phonons and magnons with regards to temperature, laser excitation wavelength, and magnetic field.

7:30 PM *F.EN04.13.02
Fundamental Properties of 2D Tellurium Films Peide P. Ye; Purdue University, United States

Tellurium is one of the special elemental materials which have 1D helical atomic structures and formed by van der Waals force between helical atomic chains. 2D tellurium films can be synthesized in a liquid solution. [1,2] In this talk, we will review the fundamental studies of this new 2D material at atomic scale in terms of its electrical, optical, thermal and mechanical properties. The helical atomic structure offers strong anisotropic properties of this 1D van der Waals material. The band-structure of this 2D material also offers some excellent material properties such as a high value of thermoelectric figure-of-merit ZT [3] and high carrier mobilities for both electrons and holes. Magneto-transport properties, such as SdH oscillations and QHE in 2D tellurium, were reported before. [4] More interestingly, topological non-trivial properties as Weyl node at conduction band edge are also unveiled in magneto-transport under 45 Tesla at tens of mK temperatures, showing Berry phase and radial spin texture being significantly different from Rashba or Dresselhaus spin-orbit coupling materials [5,6] The work is in close collaborations with Prof. Wenzhuo Wu at Purdue University. 7:50 PM *F.EN04.10.12
Electronic Properties and Device Applications of Quasi-Two-Dimensional Charge-Density-Wave Materials Alexander Balandin; University of California, Riverside, United States

The charge density wave (CDW) phase is a quantum state consisting of a periodic modulation of the electronic charge density accompanied by a periodic distortion of the atomic lattice in quasi-1D or quasi-2D metallic crystals. Several layered transition metal dichalcogenides (TMDs) exhibit unusually high transition temperatures to different CDW symmetry-reducing phases opening possibility for practical device applications. One of the most promising materials, 1T-TaS_2, has the CDW transition between the nearly-commensurate (NC-CDW) and the incommensurate (IC-CDW) phases at 350 K. The transition from the IC-CDW phase to the normal metal phase is observed at even higher temperature. In this invited talk, I will review our recent experimental results on controlling the CDW phase transitions with an applied electric field and discuss device applications of quasi-2D CDW materials. We have demonstrated the room-temperature voltage controlled oscillators and logic circuits, which operate on the basis of the NC-to-IC CDW transition in 1T-TaS_2 channels, triggered by the applied voltage [1-2]. We found that the 1T-TaS_2 CDW devices reveal exceptional hardness against X-ray and proton radiations [3-4]. We explained this property of the CDW devices by the high carrier concentration in all their phase states, two-terminal design, and the thin-film channel geometry. The low-frequency electronic noise spectroscopy has been used as an effective tool for monitoring the CDW phase transitions, particularly the switching from the IC-CDW phase to the normal metal phase in 1T-TaS2 [5]. The noise spectral density exhibits sharp increases at the phase transition points, which correspond to the step-like changes in resistivity. The noise spectroscopy was instrumental in revealing the "hidden phase transitions" in vertical 1T-TaS2 devices [6]. Preliminary data on the "narrow-band noise" in quasi-2D CDW devices will also be presented.

Moire Superpotentials and Quantum Calligraphy of Single Photon Emitters in van der Waals Heterostructures Berend T. Jonker; Naval Research Laboratory, United States

Single photon emitters (SPEs), or quantum emitters, are key components in a wide range of nascent quantum-based technologies. A solid state host offers many advantages for realization of a functional system, but creation and placement of SPEs are difficult to control. We describe here a novel paradigm for encoding strain into 2D materials to create and deterministically place SPEs in arbitrary locations with nanometer-scale precision [1]. We demonstrate the direct writing of SPEs in 2D semiconductors based on a materials platform consisting of a WSe_2 monolayer on a deformable substrate using an atomic force microscope nano-indentation process. This quantum calligraphy allows deterministic placement and real time design of arbitrary patterns of SPEs for facile coupling with photonic waveguides, cavities and plasmonic structures.

The weak interlayer bonding in van der Waals heterostructures (vdWh) enables one to rotate the layers at arbitrary azimuthal angles. For transition metal dichalcogenide vdWh, twist angle has been treated solely through the use of rigid-lattice moiré patterns. No atomic reconstruction has been observed to date, although reconstruction can be expected to have a significant impact on all measured properties, and its existence will fundamentally change our understanding of such systems. Here we demonstrate via conductive AFM and TEM that vdWh of $MoSe_2/WSe_2$ and MoS_2/WS_2 undergo significant atomic level reconstruction at twist angles $\leq 1°$ leading to discrete commensurate domains divided by narrow domain walls [2], rather than a smoothly varying rigid-lattice moiré pattern as has been assumed in prior work. We show that this occurs because the energy gained from adopting low energy vertical stacking configurations is larger than the accompanying strain energy [3]. Such reconstruction impacts both the local conductivity and the optical properties.

Solid-State Ceramic Battery Electrolyte Processing Jennifer Rupp; Massachusetts Institute of Technology, United States

Next generation of energy storage devices may largely benefit from fast and solid Li+ ceramic electrolyte conductors to allow for safe and efficient batteries and fast data calculation. For those applications, the ability of Li-oxides to be processed as thin film structures and with high control over Lithiation and phases at low temperature is of essence to control conductivity. In particular, Li-garnet structures are attractive due to their fast transfer properties and safe operation over a wide electrochemical stability range for batteries. In the first part we focus on low temperature processing of Li-garnet thin films and nanostructures. Examining the structure-Li transport in solid state and asking the provocative question: How do Li-amorphous to crystalline structures conduct? How to alter processing of Li-oxide films to compensate for the challenge that most of Lithium phases lead to sluggish transport and hard phase stabilization? Bringing down battery solid electrolyte processing temperature and decreasing form factor opens new opportunities in battery design and new doors to give more functions for similar material classes for neuromorphic computing. Through the talk, we focus on new processing opportunities to Lithiate thin film structures in crystalline state and to assure cubic and fast conduction on the example of Li-garnet for thin film form using some active Lithiation strategies at film deposition1-3. For this we will review the field of thin film processing and introduce to new processing routes based on vacuum and wet-chemical techniques to control various strategies of Lithiation and phase evolution. Excitingly, one has the opportunity for Li-garnet solid state conductors to not only synthesize crystalline structures, but also amorphous films in various frozen-in states4. Insights on degree of amorphous to crystalline Li-garnet thin films are presented based on model experiments, incl. JMAK and TTT-diagram analysis of Li-garnet structure types. Dependent on either a vacuum or wet-chemical based method chosen the phase evolution differs when synthesizing the glass states, with significant impact on condensation and Li-transport5-6. We find that the different amorphous structures that Li-garnets are no Zachariasen glasses as they violate several of Zachariasen rules by text book: These amorphous Li-garnets differ therefore significantly from LIPON but have a wider room to arrange the higher coordinated polyhedral, network former and builders. In amorphous garnets there is room for manipulation in densification and Li-transport and one may potentially profit from high stability window to design batteries with no grain boundaries at the Li electrolyte interface. Collectively, the insights on solid state energy storage provide evidence for the functionalities that those Li-materials can have in the future. The challenges are deeply connected to low temperature processing and design of structure-transport properties, however, solving those allows us to dream a little more and give materials more functions. 1. Interface Engineering to Enhance the Performance of All-Solid-State Lithium Metal Batteries Yang Li, Thad Druffel, Mahendra Mahendra Sunkara and Hui Wang; University of Louisville, United States

All-solid-state lithium (Li) metal batteries (ASSLMBs) attract increasing attention due to the use of high-capacity Li metal anode and solid electrolytes (SEs) with high safety. Recently, significant research achievements have been made in developing Li-ion conductors. In particular, sulphide SEs generally offer higher ionic conductivity (10?4?10?3 S cm?1 at room temperature) and lower grain boundary resistance. However, the practical applications of sulfide-based ASSLMBs are significantly hampered due to the interfacial challenges originating from (1) poor solid-solid contact between SE and electrode; (2) significant reaction at SE/Li interface. To solve the these issues and enhance the electrochemical performance of sulfide-based ASSLMBs, here, we employed a polymer interlayer between Li6PS5Cl SE and electrodes. It was found that the contact resistance was remarkably eliminated and the instability of SE against Li metal was resolved owing to the engineered polymer interlayer. In addition, long-term cycling stability was achieved due to the chemical compatibility between SE and this polymer interlayer. This method provides an effective strategy to address the interfacial challenge between sulfide SEs and Li metal, enabling the successful utilization of Li metal and sulfide SEs in ASSLMBs towards next-generation safe and high-energy density energy storage systems.

Mn1-xVxP Solid Solution Phosphides for Alloying/Insertion Dual Reaction Lithium-Ion Battery Anode Kyeong-Ho Kim, Juhyun Oh, Chul-Ho Jung, Miyoung Kim and Seong-Hyeon Hong; Seoul National University, Korea (the Republic of)

Recently, the beneficial combination of two different lithium storage mechanisms in a single compound, referred to as conversion and alloying materials (CAMs), has been noticed to complement the shortcomings of the conversion and alloying mechanisms [1,2]. This could lead to the excellent synergistic effects due to their atomically homogeneous and finer distribution than the physically mixed nanocomposite between two materials. However, the combination between alloying and insertion reaction or conversion and insertion reaction materials has been rarely investigated even it is expected to show superior cycle retention with an intermediate specific capacity than that of CAMs or other anode materials. Unlike the known CAMs, the realization of dual reaction with insertion reaction in a single compound requires a consideration of the crystal structure relation between two different materials, not simple comprising elements in the compound. Since the insertion reaction anodes have sufficient spaces to accommodate the reversible lithium ion insertion/extraction in their crystal structure, the dual reaction material should be designed with the similar crystal structure, which could be the solid solution compounds exhibiting a high solubility limit with an insertion-reaction type structure. The lack of consideration for the structural relation prevents the realization of dual reaction anode with an insertion reaction mechanism in a single compound. In this study, we suggest a new concept of highly stable alloying/insertion dual reaction anode of Mn1-xVxP solid solution by combining alloying reaction type MnP and insertion reaction type VP based on their structural similarity. The crystal structures of MnP and VP are basically similar, but their electrochemical performance as anodes for lithium-ion batteries (LIBs) is entirely different [3,4]. In this regard, the combination of MnP and VP into a single compound could form a fascinating solid solution anode with synergistic effects on electrochemical performance through alloying/insertion dual reaction mechanism derived its structural similarity. The series of Mn1-xVxP compounds (x = 0, 0.25, 0.5, 0.75, and 1.0) are firstly synthesized with a facile high energy mechanical milling and their electrochemical properties as an anode for LIBs were systematically studied and compared with those of MnP/VP mixture composite, particularly focusing on the verification of simultaneous alloying/insertion dual anode reaction in the solid solution compounds. The Mn1-xVxP (x = 0.25) solid solution electrode showed the excellent high-rate cyclability delivering the reversible capacity of 310 mAh g-1 after 400 cycles with a negligible capacity fading at 2 A g-1 by the synergistic effects of two reaction mechanisms. Revisiting the Use of Square Root Scaling in Battery Analyses Stephen J. Harris[1], Peter Attia[2] and William C. Chueh[2]; [1]Lawrence Berkeley National Laboratory, United States; [2]Stanford University, United States

A number of Li battery processes, including growth of Li dendrites, growth of SEI, and the effect of pressure on the internal resistance in solid state batteries, have been understood using a square root scaling, in line with simple models such as diffusion-limited metal/semiconductor oxidation. This model performs sufficiently well for some empirical predictions of capacity fade via SEI growth in lithium-ion batteries, for example. However, the t0.5 model is not theoretically well-justified to describe SEI growth in many cases. Furthermore, this model is not necessarily the best-fitting empirical model for published literature data. In this work, we illustrate these limitations and suggest an alternative approach for accurate estimates and predictions of SEI growth: evaluating and comparing the performance of multiple models. We also provide other examples where a square root scaling has been improperly assumed.

Voids and Dendrites at the Alkali Metal/Solid Electrolyte Interface Peter Bruce, Jitti Kasemchainan, Stefanie Zekoll, Dominic Spencer Jolly, Gareth Hartley, Ziyang Ning, Boyang Liu and Paul Adamson; University of Oxford, United Kingdom

Implementing alkali metal anodes and replacing flammable liquid electrolytes with solids promises to deliver higher energy densities and greater safety than conventional Li-ion batteries. However, challenges at both the metal-electrolyte and cathode-electrolyte interfaces must be addressed to realise this potential. It is imperative to maintain good interfacial contact between the solid-state components to achieve low interfacial resistances. Alkali metal dendrite growth, even at modest rates, when paired with dense, well-sintered solid electrolytes, leads to short circuits, and ultimately cell failure. We have used a number of techniques to investigate the effect of cycling conditions on the formation of voids and dendrites and how the latter is

intimately connected to the former. These results and their implications for the operation of a failure free all-solid-state battery will be discussed.

5:10 AM F.EN04.02.05
Pressure-Driven Evolution of the Interface Between Li-Metal and a Ceramic Solid Electrolyte Such as LLZO Stephen J. Harris[1], Xin Zhang[2], Q. Jane Wang[2], Katharine Harrison[3] and Scott A. Roberts[3]; [1]Lawrence Berkeley National Laboratory, United States; [2]Northwestern University, United States; [3]Sandia National Laboratories, United States

Recent experiments have shown that applying a stack pressure can strongly alter both the electrical and mechanical behavior of Li metal-solid electrolyte (SE) systems. To understand quantitatively the relationship between pressure, Li microstructure, and the Li-SE interface resistance, we have developed a 3D time-dependent contact model for describing the Li-SE interface evolution under a stack pressure. Our simulation simultaneously considers the surface roughness of the Li and the SE, Li elastoplasticity, Li creep, and the Li metal plating/stripping process. Our spatial scale runs from tens of nm to sub-mm, and our time scale runs from 50 ms to 50 hours. We describe quantitatively the competition between charge/discharge and creep, and how that competition controls the interfacial resistance. We demonstrate how to predict whether plating/stripping is stable or unstable under given conditions. And we describe a simple technique that can allow determination of the absolute area-specific resistance of the Li-SE interface. Simultaneous fitting to very recent experiments from two different research groups requires an effective yield strength of the Li used in those experiments of 16 ñ 2 MPa, substantially higher than traditional values.

Stabilizing Solid Li and Na Metal Anodes Using Ceramic Membrane Technology Jeff Sakamoto[1], Michael Wang[1], Marie-Claude Bay[2] and Corsin Battaglia[2]; [1]University of Michigan, United States; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

There is tremendous interest in making the next super battery, but state-of-the-art Li-ion technology works well and has inertia in several commercial markets. Supplanting Li-ion will be difficult. Recent material breakthroughs in Li and Na metal solid-state electrolytes could enable a new class of non-combustible solid-state batteries (SSB) delivering twice the energy density (1,200 Wh/L) compared to Li-ion. However, technological and manufacturing challenges remain. The discussion will consist of recent milestones and attempts to bridge knowledge gaps to include: The physical and mechano-electrochemical phenomena that affect the stability and kinetics of the Li and Na metal-solid electrolyte interface Thin film processing and Li integration with LLZO Plating and stripping dynamics of Li and Na metal Despite the challenges, SSB technology is rapidly progressing. Multi-disciplinary research in the fields of materials science, solid-state electrochemistry, and solid-state mechanics will play an important role in determining if SSB will make the lab-to-market transition.

5:15 AM F.EN04.03.04
Enabling Lithium Metal Anode for Solid-State Batteries by Mechanical Constriction Design Principle Xin Li; Harvard University, United States

Mechanical constriction theory and simulation technique were recently developed by our group to quantitatively describe the expansion of voltage stability window and modification of instability decomposition for solid state batteries based on sulfide solid electrolyte.[1,2,3] In solid state batteries, lithium dendrites form when the applied current density is higher than a critical value. In this talk, an advanced mechanical constriction technique is applied on a solid-state battery constructed with Li10GeP2S12 (LGPS) as the electrolyte and lithium metal as the anode. The decomposition pathway of LGPS at the anode interface is modified by this mechanical constriction and the growth of lithium dendrite is inhibited, leading to excellent rate and cycling performances. A combination of electrochemical battery tests, SEM, XPS and XRD characterizations, and DFT simulations were used. 1. 5:25 AM *F.EN04.03.05
Novel Additives and Polymer Coatings for Stabilizing Li-Metal Anodes Zheng Chen; University of California, San Diego, United States

Li metal is considered as one of the most promising anode materials for high energy batteries, owing to its high theoretical specific capacity and low electrochemical potential. However, notorious issues with the formation of Li dendrites and insufficient coulombic efficiency (CE) during the plating/stripping process prevent its practical applications in rechargeable batteries. These limitations are primarily attributed to fragile and inhomogeneous solid electrolyte interphases (SEIs), which cause continuous consumption of fresh Li and electrolyte during cycling, leading to short battery life. Of late, many efforts have been taken to enhance CE and suppress Li dendrite growth, including design of three-dimensional current collectors, artificial SEI construction on the surface of Li, employment of solid-state electrolytes, separator modification and optimization of electrolyte compositions. In this talk, we will show some recent works in developing novel electrolyte additives and polymer coatings to improve the CE and cycling stability of Li-metal anodes. We demonstrate reasonably stable cell cycling performance under practical conditions such as lean electrolytes and low N/P ratios. The roles of these additives and polymer coatings were also explored to elucidate their function in tuning Li-metal morphology and SEI composition.

5:40 AM F.EN04.03.08
Cu2P a Novel Conversion Anode for Li Ion Batteries Angela F. Harper[1], Matthew Evans[1] and Andrew J. Morris[2]; [1]University of Cambridge, United Kingdom; [2]University of Birmingham, United Kingdom

By utilizing a combination of ab initio random structure searching, genetic algorithms, and prototyping, we have identified a new phase of copper phosphides, Fm-3m Cu2P, which is a potential candidate for a high capacity conversion anode [1]. Within the copper phosphide phase diagram, Cu3P is currently the highest capacity material with a capacity of 363 mAh/g, however Cu2P has a theoretical capacity of 508 mAh/g, which is higher than both Cu3P and the commonly used graphite anodes. Although many conversion anodes exhibit volume expansions above 150%, Cu2P has a limited volume expansion of 99%, similar to Cu3P which has been previously used as an anode for Li-ion and Na-ion batteries. We calculate the dynamical stability of Cu2P using the vibrational effects from 0 K phonon modes, which suggest that Cu2P is stable up to temperatures of 600 K. We predict that Cu2P, if synthesized experimentally, would therefore be a successful conversion anode for future battery applications, and outperform other conversion anodes within the copper phosphide phase diagram.

Understanding the Role of Electrochemically Inactive Dopant in Layered Oxide Cathode Materials for Advanced Sodium-Ion Batteries Junghoon Yang and Sang-Don Han; National Renewable Energy Laboratory, United States

The importance of electrochemical energy storage systems for large-scale application has been growing increasingly over the last decade. Due to high cost, limited source and several technical barriers of the lithium ion system, sodium ion batteries are considered as one of promising candidates for large-scale energy storage systems considering their cost-effective, earth abundant and recyclable characteristics.[1] As cathode materials for sodium ion batteries, sodium transition metal (TM) oxide with layered structures (NaxTMO2, $0.5 < x < 1.0$) demonstrated high energy density similar to cathode for lithium ion batteries.[2] However, the capacity retention of the cell with layered structure cathode is not optimized especially when it is charged and discharged fully to obtain higher capacity. The major reason for this is a phase transition induced by gliding of transition metal slabs, which causes irreversible structural changes gradually during cycling.[3] To address this phase transition problem, we doped electrochemically inactive components in the transition metal sites with precise ratio control. The introduction of the inactive components (by substituting with existing transition metal(s)) consumed some of reversible capacity, but it is able to provide improved capacity retention due to their enhanced structural stability. In addition, we systematically studied the reversible capacity and corresponding phase transition behavior of layered type oxide materials with/without dopant(s) under various voltage window ranges to figure out the role of electrochemically inactive dopants. By

tracing the structural changes using in-situ XRD, we determined the optimized ratio of electrochemically inactive components to minimize and/or detain the phase transition. The results can provide the insights of the phase transition mechanism of layered type cathode materials and the strategies to suppress them by stabilizing the structure, thus enabling rational design of new cathode materials for the development of next generation advanced Na-ion batteries. Smith, B. Fultz, L. F. Nazar, Energy Environ. Sci., 5 (2015) 2512.

5:10 AM F.EN04.04.04
Atomistic Mechanism of Na Intercalation into Amorphous Carbon—A First-Principles Study Yu-Jen Tsai and Chin-Lung Kuo; National Taiwan University, Taiwan

Amorphous carbon is a promising anode materials for Na-ion batteries since it has been reported to exhibit high Na storage capacity (180~420 mAh g-1) as compared to graphite (~35 mAh g-1) and other potential candidates. Previous studies suggested that Na ions can be easily intercalated into amorphous carbon primarily because of its large interlayer distance as well as the presence of vacancy defects. However, the fundamental mechanisms remain unclear yet to date. In this work, we employed first-principles density functional theory calculations to investigate the atomistic mechanism of Na intercalation into amorphous carbon. Furthermore, we recalibrated the dispersion coefficients for C and Na in the DFT-D2 method to reproduce the d-spacing and the Na/Li storage capacity of bulk graphite measured in the experiments. This refined potential was then used to describe the van der Waals interactions between Na and amorphous carbon in this study. Our calculations first revealed that the interlayer spacing is not the main factor that hinders the intercalation of Na into the carbon-based electrodes. When the equilibrium d-spacing of graphite increased from 3.35 to 4.40 Å by weakening the C-C van der Waals interaction, the Na capacity was only slightly raised up from 35 to 70 mAh g-1, which is still much lower than the Na capacity of amorphous carbon. We next investigated the C vacancy effect on the Na capacity of graphene monolayer. Our results showed that the achievable Na capacity limit is only half of the achievable Li capacity limit on both monovacancy and divacancy defects in graphene, indicating a much weaker binding strength of Na to graphene as compared to Li. Moreover, our calculations showed that the Na storage capacity can be effectively enhanced by increasing the degree of structural disorders and non-hexagonal rings in the graphene sheets, which can even turn the neighboring hexagonal rings into the active sites for Na intercalation. Our results suggest that the presence of large amounts of non-hexagonal rings in the bond network is the main driving force that triggers the intercalation of Na into amorphous carbon, which can be more effective than creating vacancies on the surface of the carbon electrodes. It was also found that the amorphous bond network can become much softer as the number of non-hexagonal rings increases. The increased softness of the amorphous bond network can be beneficial in reducing the strain energy induced by Na intercalation, thereby contributing to the Na storage capacity of the amorphous carbon electrode. Accordingly, our study can provide a new insight toward a mechanistic understanding of Na intercalation into the amorphous carbon electrode.

5:20 AM *F.EN04.04.05
Understanding the Influence of Adscititious Water on Metal Oxides Operating in Non-Aqueous Mg-Ion Electrolytes Veronica Augustyn; North Carolina State University, United States

There is a significant interest in understanding the factors that influence multivalent ion intercalation kinetics into oxide host materials. Recently, the addition of water into non-aqueous Mg2+ electrolytes was proposed as a strategy to decrease interfacial charge transfer resistance and increase solid state Mg2+ diffusion into different transition metal-based intercalation hosts. To investigate the role of this adscititious water, we added known amounts of H2O to a non-aqueous magnesium ion electrolyte (Mg(ClO4)2 in acetonitrile) and performed cyclic voltammetry with a tungsten oxide (WO3) electrode. Similar to other reports, we find increased kinetic reversibility as the electrolyte water content increases. The WO3 electrode undergoes reversible electrochromism indicative of an intercalation process. We investigated the nature of the water in the non-aqueous electrolyte using solution 1H NMR and molecular dynamics simulations. To investigate the nature of the intercalated species (and in particular, the potential for proton intercalation) and the energy storage mechanism, we performed ex situ X-ray diffraction, solid state 1H NMR, and inductively coupled plasma-optical emission spectroscopy. Our combined results suggest that adscititious water in non-aqueous electrolytes may increase the surface, and not solid-state, diffusivity and thus lead to enhanced energy storage kinetics.

5:35 AM F.EN04.04.06
Engineering an Aqueous Energy Dense Manganese Dioxide|Zinc Battery to Challenge Lithium-Ion's Dominance Gautam G. Yadav; Urban Electric Power, United States

The current landscape of energy storage systems is dominated by lithium-ion batteries because of their high energy densities,

and continuous improvement in performance through the last few decades for use in a number of applications. They certainly have been a boon for rapid societal development; however, they also have had major disadvantages like high cost, severe toxicity, high chances of flammability and ethical concerns about the use of cobalt. Aqueous batteries containing manganese dioxide (MnO2) and zinc (Zn) have the theoretical capacities to deliver high energy densities comparable to some variations of lithium-ion batteries, have low cost and toxicity, and high material abundance to be used as an alternative battery compared to the current status quo. However, MnO2 and Zn have been highly irreversible and accessing close to their theoretical capacities has been very challenging. The current status quo in aqueous batteries has been to intercalate Zn and H-ions into layered structures to deliver modest capacities, which also has unfortunately resulted in limited energy densities. These layered structures, although novel, face limitations like their layered counterparts in lithium (Li)-ion batteries, where the capacity is limited to the host's intercalation capacity. Low voltage of ~1.1-1.4V is another Achilles heel of aqueous Zn-anode batteries, where it is simply not comparable to the high voltage properties of Li-ion. MnO2|Zn batteries can compete with Li-ion because of its safe and abundant raw materials, nonflammable electrolyte and theoretical energy density, however, sufficient advances are required for it to be considered a true challenger. In this talk, we will present a new strategy to enable a new generation of energy dense aqueous- based batteries, where we exploit the conversion reactions of MnO2 and Zn electrodes to extract significantly higher capacity compared to intercalation systems. Accessing the conversion reactions allows us to achieve theoretical capacities of 617 mAh/g (~30 mAh/cm2) from MnO2 and 810 mAh/g (~30 mAh/cm2) from Zn anodes, respectively. The high areal capacities help to attain unprecedented energy densities of 210 Wh/L, which is the highest of all aqueous-based batteries. We will also present our work on identifying new Mn-based conversion compounds that give higher capacities and demonstrate its application in the case of small-scale automobile. We will also present our breakthrough work on breaking the 2V barrier in aqueous Zn batteries, where we have demonstrated for the first time in the field of energy storage 2.45V and 2.8V MnO2|Zn aqueous batteries capable of accessing the theoretical capacity, which can truly challenge Li-ion's dominance. Finally, we will briefly present our commercialization experience, and how market forces and application have guided the design and research of these batteries.

5:45 AM F.EN04.04.07
Characterizing Mechanical and Microstructural Properties of Novel Montmorillonite-Based Sodium-Ion Conductors Ryan C. Hill[1], Yang-Tse Cheng[1], Erik Spoerke[2] and Amanda Peretti[2]; [1]University of Kentucky, United States; [2]Sandia National Laboratories, United States

Rapidly growing demands for electrical energy storage have motivated active research into new safe, low-cost technologies, such as sodium-based batteries. Solid-state sodium-ion conductors are central elements of emerging molten sodium, solid-state, and even sodium-ion batteries designed for effective long-term applications. Traditional sodium-ion conductors, such as ?-alumina or the sodium super ion conductor, NaSICON, however, can be expensive or difficult to process, they often suffer from limited ionic conductivity at desirable low to intermediate temperatures, and they can be mechanically fragile, limiting their long-term durability. A simple, low-cost alternative ion conducting candidate proposed by researchers at Sandia National Laboratories aims to utilize layered sodium-montmorillonite (MMT) clay and MMT/polymer composites. In this presentation, the microstructural, mechanical and electrochemical properties of the MMT-based solid electrolytes are investigated and correlated. Characterization methods such as x-ray diffraction, atomic force microscopy, and scanning electron microscopy together with measurement techniques such as nanoindentation and bulk and local electrochemical impedance spectroscopy (EIS) inform important structure-property relationships in materials with room temperature ionic conductivities rivaling conventional ceramic electrolytes. Utilizing these techniques, we have discovered that MMT processing can impact the layered microstructure, chemical integrity, and subsequently not only the ionic conductivity, but critically the elastic modulus and hardness of prepared bulk MMT ion conductors. Recognizing the importance of mechanical integrity for high performance, reliable solid-state ion conductors, these studies reveal that many of the processing parameters that degrade ionic conductivity also diminish the mechanical properties in these materials. Understanding these relationships will help guide new studies to engineer the development of robust, highly conductive MMT-based separators.

***In Situ* and *Operando* Electrochemical Investigation of Cobalt-Free, Nickel-Rich Layered Oxide Cathode for Next Generation Lithium-Ion Batteries** Shankar Aryal, Jessica Durham, Albert L. Lipson, Krysztof Z. Pupek and Ozenur

Kahvecioglu; Argonne National Laboratory, United States

Nickel-rich layered oxide cathodes are promising candidates to achieve high energy density lithium ion batteries (LIB) because of lower content of expensive and toxic cobalt. However, transition metal dissolution, increased structural disorder, material amorphization upon cycling and parasitic reactions between organic electrolyte and nickel-rich composition lead to both capacity and voltage fading upon cycling. Extensive work has been reported on NMC532, NMC622 and NMC811 compositions, which are already commercialized. Recently, the battery research community is increasing nickel content in NMC based layered oxide cathodes to increase gravimetric capacity. Nickel-rich cathodes with nickel content above 80% aren't fully understood and their synthesis at larger scales requires optimization. This presentation reports cobalt-free, nickel-rich LiNi0.9Mn0.1O2 cathode material synthesized at a moderate level (500 g), using co-precipitation method in a 1 liter Taylor Vortex Reactor. The physical and chemical properties of the cathode material were measured with scanning electron microscopy (SEM), x-ray diffraction (XRD), and x-ray absorption spectroscopy (XAS). In-operando XAS was measured at Ni and Mn K-edges to examine oxidation state and local geometry of transition metal atoms as a function of state of charge. Additionally, ex-situ XAS and synchrotron XRD before and after long term cycling were utilized to understand the degradation mechanism and provide insight for designing cathode material with better performance.

Li-Ion Cathodes Based on Disordered Rock Salt Structures, Oxides and Oxyfluorides Damien P. Guegan[1], Jean-François Colin[1], Adrien Boulineau[1], Sebastien Martinet[1] and Pierre-Etienne Cabelguen[2]; [1]Université Grenoble Alpes, France; [2]Umicore, Belgium

This work explores a new class of material for Li-ion cathodes, based on disordered rock salt structures, in particular the composition Li1.2Mn0.6Nb0.2O2 and the oxyfluoride versions Li1.2Mn0.6Nb0.2O2-xFx. The classical approach of layered oxides, as their name indicates, consist in a superposition of separated layers of transition metals (TM) and Li in an oxygen network. On the contrary disordered rocksalt materials still compose of an oxygen network but in which all cations share their positions. This structure of material was ignored for a long time, the reason being that it generally did not seem to allow for Li ions conduction. However this structure very easily accommodate with Li-rich compositions. Based on previous studies carried out by the Ceder's group[1], it was demonstrated that in the case of Li-rich materials Li ions conduction was possible. Therefore, this class of materials was the perfect choice to attain higher energy densities via the increase of Li content. Considering that in Li-rich materials the redox capabilities of the TM are smaller than the Li content, we usually observe oxygen redox activity for these materials. Depending on the composition of the material, this contribution can go from very to hardly reversible[2]. Knowing that the oxygen contribution is inevitable, two approaches are valid to improve cycling performances: stabilise the oxygen or increase the redox part of the TM. To achieve both we introduce fluoride in the oxygen network. This work aims to deepen the understanding of the material structure and electrochemical behaviour via an experimental approach. We synthesised various samples of disordered rock salt materials using the solid-state approach. The oxide material is metastable and the synthesis requires special apparatus. The oxyfluoride is even more constrained with the use of high temperatures and corrosive precursors such as LiF and (TM)Fx. Materials synthesised were then characterised using advanced microscopy and spectroscopy technics, especially, a particular structure with short range order (SRO) was observed by TEM (transmission electron microscope) despite the long range order observed using XRD (X-ray diffraction). These structural observations are explained and are put in perspective with the electrochemical performances. In regards to oxygen stability, which is one of the main structural issues in Li-rich materials, we investigate the benefits of a fluoride doping. The cycling performances indicate an influence of surface reactivity and conductivity. To respond to such limitations new coating strategies were set in place. A carbon coating has led to improved electrochemical performances, which can come from either surface protection or enhanced electronic conductivity (or combination). Synergy of Epoxy Chemical Tethers and Defect-Free Graphene in Enabling Stable Lithium Cycling of Silicon Nanoparticles David Mitlin; The University of Texas at Austin, United States

We report a new approach for nanosilicon-graphene hybrids with uniquely stable solid electrolyte interphase. Expanded graphite is gently exfoliated creating "defect-free" graphene that is non-catalytic towards electrolyte decomposition, simultaneously introducing high mass loading (48wt.%) Si nanoparticles. Silane surface treatment creates epoxy chemical tethers, mechanically binding nano-Si to CMC binder through epoxy ring-opening reaction while stabilizing the Si surface chemistry. Epoxy-tethered Silicon pristine-Graphene hybrid "E-Si-pG" exhibits state-of-the-art performance in full battery

opposing commercial mass loading (12 mg cm-2) LiCoO2 (LCO) cathode. At 0.4 C, with areal capacity of 1.62 mAh cm-2 and energy of 437 Wh kg-1, achieving 1.32 mAh cm-2, 340.4 Wh kg-1 at 1C. After 150 cycles, it retains 1.25 mAh cm-2, 306.5 Wh kg-1. Sputter-down XPS demonstrates survival of surface C-Si-O-Si groups in E-Si-pG after repeated cycling. The discovered synergy between support defects, chemical-mechanical stabilization of Si surfaces, and SEI-related failure may become key LIB anode design rule.

5:30 AM F.EN04.05.06
A Controllable, Affordable and Scalable Method for Synthesizing Silicon-Carbon Composites for Lithium-Ion Batteries Joseph Schwan[1], Giorgio Nava[1], Matthew Boebinger[2], Matthew T. McDowell[2] and Lorenzo Mangolini[1]; [1]University of California, Riverside, United States; [2]Georgia Institute of Technology, United States

From as far back as 1971 researchers have been intensively working on developing strategies for integrating silicon into commercial lithium-ion batteries with the goal of developing more energy-dense energy storage devices. Relatively quickly, the research community determined that silicon-carbon nanocomposites were a promising avenue to address this technical challenge, allowing for long cycle-life electrodes as well as overcoming the swelling experienced by silicon.1 However, the majority of proposed synthesis methods of these complex and intricate nanostructures have proven to be too expensive, slow, or unable to scale to meet potential demand. Within this contribution we present a cost-effective solution suitable for large-volume production through a chemical vapor deposition -CVD- process based on a cheap acetylene precursor and largely available off-the-shelf silicon nanoparticles -SNPs. Key advantages of this method are the precise and decoupled control of both the carbon layer thickness and its graphitization degree. This is achieved by separating the CVD process into two steps: first the SNPs are placed into a furnace and exposed to pure acetylene at 650oC permitting thermal cracking of the precursor and causing a uniform deposition of amorphous carbon on the particles, with shell thickness depending on the amount of time spent in CVD; next the reactor is drained of acetylene, refilled with argon at low pressure, and brought up to 1000oC to instigate graphitization. Notably, this approach achieves the described result of a silicon-core coated with a uniform graphitic shell without any protective oxide shell or the formation of silicon carbide phases, both of which would negatively affect the battery performance. By taking advantage of the flexibility of the described approach, we were also able to delve into the effects on electrochemical performance and charging mechanism resulting from the interplay between a silicon-core and carbon-shell of varying graphitization degree. Through the use of core-shell particles with identical silicon cores and carbon layer thicknesses, but by varying the degree of shell graphitization (i.e. amorphous carbon and highly graphitic carbon), this work highlights how this simple property of the carbon-coating bears a profound influence on the material's electrochemical characteristics. In-situ TEM lithiation experiments revealed insights into the surprisingly poorly understood interaction between silicon and carbon in lithium-ion batteries, showing that a highly graphitized carbon layer significantly promotes the lithium ion diffusion dynamics into the silicon core with respect to an amorphous coating. As a result, lithium-ion battery anodes produced with graphitic-carbon coated SNPs exhibit markedly enhanced coulombic efficiencies and capacity retention upon cycling with respect to amorphous-carbon coated SNPs.2 Finally, the optimized composite produced with our CVD method can operate both as a pure high-charge-density anode material as well as a "drop-in" additive for graphite-dominant anodes. The pure composite boasts 1800mAh g-1 in half-cell testing and a first cycle coulombic efficiency -FCCE- of 87%, while replacing 10% in weight of a standard graphite anode increases capacity from 330mAh g-1 to 600mAh g-1 with FCCE of 90% and capacity retention of 81% over 100 cycles. 5:00 AM *F.EN04.06.01
The Vital Role of Electrolyte Design in Enabling Conversion Chemistries for Beyond Li-Ion Batteries Graham Leverick[1], Emily J. Crabb[1], Arthur France-Lanord[1], Ryan Stephens[2], Jeffrey Grossman[1] and Yang Shao-Horn[1]; [1]Massachusetts Institute of Technology, United States; [2]Shell International Exploration and Production Inc., United States

While the modern Li-ion battery is a scientific and engineering marvel, having enabled substantial technological innovation

spanning from mobile electronics to commercially viable electric vehicles, the intercalation chemistry of the Li-ion battery has a fundamental upper limit on its achievable energy density owing to the fact that the same structure must remain stable in the fully lithiated and delithiated states. While further advances within the Li-ion chemistry are possible, significantly higher theoretical energy densities are achievable with conversion chemistries, such as Li-O2 and Li-S batteries1, where the structure and/or phase of the electrode materials change with its state of charge. While the importance of electrolyte electrochemical/chemical stability and ionic conductivity has been known since the very first batteries, owing to the partial solubility of reaction intermediates in conversion chemistries (such as Li+-O2- and Li2Sx), electrolyte can play an even more critical role in determining their reaction pathway and kinetics. In this talk, the various mechanisms through which electrolyte has been found to interact with the Li-O2 battery chemistry are explored. This includes recent results on the influence of solvent, counter anion and lithium ion concentration on the thermodynamics and kinetics of oxygen reduction2 as well as solvent-water-halide interactions and their impact on the performance of lithium halide redox mediators3-5. This work highlights that a complex combination of solvent, salt and additives can alter the thermodynamics and kinetics of redox reactions, the understanding of which can be extended beyond the Li-O2 battery reactions studied here to any small molecule redox reaction. 5:15 AM F.EN04.06.03

Transforming an Electrolyte into an Electrode—Fe Substituted Na β''-Al_2O_3 Danielle Butts[1], Juergen Schoiber[2], Günther Redhammer[2] and Bruce S. Dunn[1]; [1]University of California, Los Angeles, United States; [2]University of Salzburg, Austria

Na-ion batteries present a promising alternative to Li-ion batteries due to the low cost and abundancy of sodium and the existence of well-studied Na-superionic conductors. The design of new Na-ion battery electrode materials, however, is severely limited by the larger size of Na^+ compared to Li^+. One approach to designing new electrode materials for Na-ion solid-state batteries is to modify solid-state electrolytes. That is, because solid-state electrolyte materials are known for their high levels of ionic conductivity and minimal levels of electronic conductivity, they are not even considered as candidates for electrode materials which require both ionic and electronic conduction. However, if the chemistry of fast ion conductors can be suitably modified to produce electronic conduction and their defect structures are maintained so that their high ion conductivities are preserved, then these materials represent a unique opportunity to creating a new class of battery electrode materials. An electrolyte-centered material design method takes advantage of not only the inherently fast ionic conduction within the material but also of a more continuous chemical potential across the electrode-electrolyte interface for solid-state batteries, leading to increased interfacial stability. The research presented in this paper demonstrates that partial substitution of aluminum by iron in the superionic conductor Na β''-Al_2O_3 (stabilized as $Na_{1.67}Li_{0.33}Al_{11}O_{17}$) results in a mixed ionic-electronic conductor. A series of Fe-substituted compositions exhibit reasonable capacities as a negative electrode for Na-ion batteries. Fe-substitution for up to 80% of the aluminum sites is possible through a combination of sol-gel chemistry and high-temperature heat treatment, resulting in Fe^{2+}/Fe^{3+} in both the octahedral (O) and tetrahedral (T) sites of the spinel block. Structural refinement and Mössbauer spectroscopy have helped to elucidate the nature of Fe-substitution within the structure and its limitations. Successful octahedral site doping with Fe-ions appears to be the key to appreciable electronic conduction due to the shorter bond distances between O-O sites compared to T-T and O-T of the spinel block. The electrochemical properties of ~50% Fe-substituted Na β''-Al_2O_3 ($Na_{1+x}(Al,Fe)_{11}O_{17}$) have been investigated in non-aqueous electrolytes, demonstrating 115 mAh g-1 at C/5 and 72 mAh g^{-1} at 20C (0.2-2.5 V vs Na/Na^+) through Fe^{2+}/Fe^{3+} redox, while maintaining the β'' structure. Electrochemical analysis indicates a capacitive-like charge storage mechanism and excellent capacity retention at high rates, despite the micron-sized particles.

5:25 AM F.EN04.06.04

Laminating Ti3C2Tx MXene on Ultrathin Li-Metal as Li Storage Host in Lithium-Ion Batteries Xi Chen, Mingwei Shang and Junjie Niu; University of Wisconsin-Milwaukee, United States

Due to the high specific capacity of 3860 mAh g-1 and low electrochemical potential of -3.04 V vs standard hydrogen electrode, Li metal as anode is one of most attractive approaches in high energy-density lithium ion batteries (LiBs). Nevertheless, mossy/dendritic Li growth induces numerous safety issues and the sustained SEI formation causes Li depletion,

which greatly limits further applications. We present the lamination of Ti3C2Tx MXene film on 30 microns Li metal foil using a rolling process, which significantly improves the battery cycling performance in both symmetric and full cells. The excellent Li+/e- transport behavior of the 2D MXene provides the LiCx-Ti intercalated surface, interlayer spacing and inter-block spacing for Li metal storage. The improved electrical conductivity also reduces un-uniform distribution of current density, leading to a homogeneous Li plating/stripping along with a suppressed mossy/dendritic Li growth and reduced Li and electrolyte depletion from continuous SEI formation. Moreover, the coexisted organic-rich and inorganic-rich SEI of both cycled MXene-Li and Li foil electrodes were investigated via XPS depth profiling spectroscopy. A full cell battery paired with commercial LiNi0.8Co0.15Al0.05O2 (NCA) cathode with lean electrolyte condition and an N/P ratio as low as 1.5 was also studied. The 2D MXene coated Li metal anode presents a great potential in high energy-density batteries for portable devices and electric vehicles.

5:35 AM *F.EN04.06.06
High Capacity Conversion Materials—Operando Characterization of Key Factors Governing the Electrochemistry Esther Takeuchi, Kenneth Takeuchi and Amy Marschilok; Stony Brook University, United States

There are multiple types of electrochemical storage mechanisms in energy storage materials. The most widely adopted is the insertion mechanism where on reduction, a positive ion inserts into the structure of the host material and is removed from the structural lattice upon oxidation. A second type of mechanism is conversion where a chemical reaction leads to a new material or phase on reduction with reformation of the original material on oxidation. Insertion materials contain space in the lattice to accommodate Li+ or other positive ions and can be depicted as nLi+ + ne? + MxOy? LinMxOy. Functionally, these materials exhibit reversible or quasi-reversible electrochemistry with the transfer of limited numbers of electrons/lithium ions per metal center resulting in moderate lattice expansion but also providing moderate capacity. Conversion materials differ in that they often involve multielectron transfers per active center represented here for a metal oxide type material as MxOy + 2yLi+ + 2ye?? yLi2O + xM resulting in significantly higher theoretical capacity. However, the challenge with many conversion reactions is the degradation of delivered capacity with continued electrochemical oxidation and reduction. The mechanisms of conversion reactions will be examined including those of densely packed ferrites with spinel or inverse spinel structures where the theoretical capacity exceeds 900 mAh/g. In-situ and operando methods that demonstrate the governing roles of crystallite size, aggregation, and interfacial reactivity on rate capability and capacity retention will be featured.

5:50 AM F.EN04.06.07
Understanding the Conversion Mechanism of FeF2 Cathodes Using Monodisperse, Single-Crystalline Nanorods Albert W. Xiao, Hyeon Jeong Lee, Isaac Capone, Alex Robertson, Jack Fawdon and Mauro Pasta; University of Oxford, United Kingdom

Transition metal fluorides display the combination of high capacity and high electrode potential that are essential to boosting the energy density of lithium ion batteries. However, their application as cathode materials has been hindered by an incomplete understanding of their electrochemical capabilities and limitations. Herein, we present a system of single crystalline, monodisperse iron (II) fluoride nanorods and detail how their morphology and uniformity make them ideal for mechanistic study. High-resolution analytical transmission electron microscopy reveals intricate morphological features, lattice orientation relationships, and oxidation state changes that redefine the conversion reaction with unprecedented spatial resolution. We first introduce the presence of surface specific reactions and examine how they critically influence phase evolution, diffusion kinetics and cell failure. Next, we examine how the reversibility of the conversion reaction is governed by topotactic cation diffusion through an invariant lattice of fluoride anions and the nucleation of metallic particles on semi-coherent interfaces. Finally, we demonstrate how this new understanding informs a more effective application of metal fluorides and establishes a framework for improving reaction hysteresis, kinetics and reversibility. To ensure a pertinent result, ex-situ data was extracted from coin cells that deliver near theoretical capacity (570 mAh g-1) and extraordinary cycling stability (>90 % capacity retention after 100 cycles). The role of the electrolyte in enabling this performance as well as the collection of meaningful HRTEM data is briefly discussed.

6:00 AM F.EN04.06.09
Fe2O3 Coated with Thermally Etched Carbon Nanotubes as High Rate Capable Anode for Lithium-Ion Battery Dipsikha Ganguly and Ramaprabhu Sundara; Indian Institute of Technology Madras, India

Over the past few decades lithium ion batteries have become utmost technological importance for energy storage devices for stationary applications and electric vehicles. Currently, Graphite is the widely used anode materials for lithium ion batteries due to its low intercalation voltage and high stability. But due to its low specific capacity research is focussed to find alternative anode materials for lithium ion batteries. Among the transition metal oxides, ?-Fe2O3 as anode material is

extensively studied owing to its high theoretical capacity (1006 mAh. g-1), environment-friendly, good catalytic properties and stability. But capacity fading is found to be inhibitory to be used as the anode materials for lithium ion battery. In order to reduce the capacity fading, different porous carbon supports have been reported in the literature. In this work, we have synthesised ?-Fe2O3 coated with thermally etched carbon nanotubes (?-Fe2O3/TECNTs) using solid state pyrolysis method. In the presence of nanotube structure, high rate capability is observed for ?-Fe2O3/TECNT anode material due to the fact that lithium insertion/de-insertion in carbon matrix at lower voltage is governed by the intercalation mechanism while for ?-Fe2O3, lithium interaction is mainly observed due to the conversion reaction. The rate capability studies in the range 0.05-20 A/g shows 100% retention of capacity even after extensive cycling. Also, good cyclic stability and 100 % coulombic efficiency are achieved in the presence of carbon matrix. Further to analyse the role of carbon nanotubes, amount of carbon matrix is varied which also corroborates the crucial role of carbon in enhancing the electrochemical performance of lithium ion battery.

6:10 AM F.EN04.06.10
Deterministic Design of Energy Storage Electrodes Through Oxide Electrodeposition in CNT Foam Scaffolds Ishita Kamboj, Michael A. Spencer, Ozkan Yildiz, Philip D. Bradford and Veronica Augustyn; North Carolina State University, United States

The use of deterministic design is a growing area of interest to achieve both high energy and power density for energy storage electrodes. Traditionally manufactured energy storage electrodes consist of a multi-component slurry containing an electrochemically active material as well as conductive carbon and polymer binder additives cast onto a flat conductive substrate. Inhomogeneity in the dispersion of the slurry components limits areal power and energy densities due to tortuous and poorly controlled electron and ion transport pathways. In this work, a nanostructured, high capacity transition metal oxide (MoO3) is electrodeposited onto a conductive carbon nanotube (CNT) foam scaffold to attain high mass loading energy storage electrodes with fast Li+ intercalation kinetics. CNT foams provide surface area for the electrodeposition of MoO3 while maintaining sufficient electrical conduction throughout electrodes. Ample porosity between the CNTs provides good ion transport pathways. The MoO3 is a model Li+ intercalation oxide with a high gravimetric capacity that can be easily electrodeposited from aqueous solutions. This presentation will describe how control over the properties of the CNT foam and MoO3 electrodeposition are used to tailor the energy storage performance of the electrode architecture, along with characterization to understand the how the structure of the electrode affects its energy storage behavior. Overall, this research seeks to understand the relationships between electrode architecture and energy storage behavior to achieve simultaneous high power and high energy density.

Gallium Nitride Based Nuclear Batteries—Long-Term Radiation Effects on the Contact Interface Lance Hubbard[1], Christian Cowles[1], David Blanchard[1], Jesse Johns[1], Andrew Prichard[1], Gary Sevigny[1], Jarrod Allred[1], Bethany Mathews[1], Erin Fuller[1] and David Schwellenbach[2]; [1]Pacific Northwest National Laboratory, United States; [2]Mission Support and Test Services (MSTS), Los Alamos Office, United States

Nuclear batteries, or betavoltaic cells (BV), convert the energy of beta radiation directly into electricity via a semiconductor stack. The decades-long lifetime and high-energy density open a broad range of applications that are not able to use chemical batteries. Such low-power electronic applications (nW-mW) are the internet-of-things, internal medical devices, and unattended equipment in space and other hostile environments. We are developing simulation methods to model radiation sources and degradation of the contact interface under beta irradiation. Methods were developed to adequately simulate radiation sources for BVs with Monte Carlo N-Particle (MCNP) and CASINO. Methods were also developed to adequately simulate electron generation and device performance with ATLAS. The simulations have been used to design the accelerated aging experiments of tritium beta-induced degradation at a GaN contact.

5:10 AM F.EN04.07.04
Engineering Ceramic Electrolyte Interfaces for Low-Temperature Molten Sodium Batteries Martha M. Gross, Amanda Peretti, Stephen Percival, Leo J. Small and Erik Spoerke; Sandia National Laboratories, United States

Ceramic electrolytes exhibiting high sodium-ion conductivity are a key component in the development of low temperature molten sodium batteries. Traditionally, molten sodium batteries utilize Na+-ion conducting solid electrolytes such as ?-Al2O3 or NaSICON. These ceramics require high operating temperatures of ~300°C, not only for improved Na+-ion conductivity, but also to facilitate wetting of molten sodium on the solid electrolyte. Lowering the operating temperature to near 100°C drastically reduces interfacial wetting of the molten sodium to the ceramic electrolyte, increasing interfacial resistance in the cell and ultimately producing poor battery performance. Here, we describe the use of engineered coatings to enhance wetting of molten sodium on NaSICON ceramic electrolyte and improve charge transfer across this key interface. We observe that these coatings dramatically lower cell-limiting interfacial resistance, and thereby increase battery cycling current densities and overall battery performance at low operating temperatures. Continued optimization of such engineered, interfacial coatings promises continued advances of low temperature sodium batteries. Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

5:20 AM F.EN04.07.05
Spinel Structured High Entropy Oxide Nanoparticles as Bi-Functional Catalyst for Lithium-Air Batteries Guruprasad S. Hegde and Ramaprabhu Sundara; Indian Institute of Technology Madras, India

High entropy materials are the "multi-metallic cocktails" in metallurgy, which are having five or more than five metals, all in equal proportions. Due to the high configurational entropy arising from such conditions, these types of materials form a simple single-phase structure. The high entropy alloys are high strength, corrosion resistant materials which find application in several industries. However, the exploration on the other class of high entropy oxides have caught the attention of the researchers only recently. High entropy oxide nanoparticles with multifunctional properties can have potential applications in several technologies. In this work, a high entropy oxide nanoparticle (HEO) in a simple bottom up process is synthesized and the possibility of application of such materials as cathode electrocatalysts in Li-O2 batteries is explored. Reversible formation and decomposition of Li2O2 during the respective discharge and charge operations is the main challenge in the development of a secondary Li-O2 battery. Several approaches to address this issue include development of an efficient bifunctional catalyst material in aprotic media and liquid phase redox mediators. In the present work, we have prepared HEO containing Co, Cr, Ni, Al, Fe by a simple sol-gel process. The oxide crystallizes in spinel (Fd3m) phase. The synthesized material is characterized extensively to understand the structure and morphology. Li-O2 cells are fabricated with synthesized HEO coated on a gas diffusion layer as cathode, a redox mediated electrolyte (1M LiTFSI and 0.1M LiI in tetraethylene glycol dimethyl ether) and lithium metal as anode. The detailed investigations result in a capacity of 1000 mAh g-1 for a constant current of 250 mA g-1 in the capacity limited cyclic stability test for 50 cycles.

ReaxFF—A Predictive Tool for Study of a Solid-Electrolyte Interphase on the Silicon-Based Anodes of a Lithium-Ion

Battery Mahdi Khajeh Talkhoncheh and Adri v. Duin; The Pennsylvania State University, United States

Lithium-ion secondary batteries (LIBs) are one of the most popular electrochemical systems, especially in home-electronics and electric vehicles due to their relatively high energy density, high operating voltage, and low self-discharge. Further advancements of Lithium-ion batteries are imperative in order to improve their capacities and life cycles. Silicon anode materials are regarded as one of the most promising candidates for Lithium-ion batteries based on their substantial specific capacity in comparison with conventional graphite anodes. However, a severe drawback is the large volume changes of anodes during the charge (up to ?300% volume expansion during lithiation) and discharge (delithiation) cycles. These changes cause high mechanical stress, breakdown of the conductive layers of composite electrodes, and undesirable side reactions within batteries. In addition, the solid electrolyte interphase (SEI) formed on the silicon anodes surfaces are unstable and cannot efficiently protect the electrodes from reacting with electrolytes. The importance of SEI on battery performance motivates us to study the interphase interaction in batteries. In this work, the formation of SEI components such as C2H4, CO2, and CO gases, and organic and inorganic products are predicted by using Reactive molecular dynamics (ReaxFF) simulations. For this investigation, we analyzed the effect of different types of Si anodes (pristine Si and SiOx), compositions of various carbonate electrolytes and additives on SEI formation. Additionally, the degree of lithiation and temperature effects on gas evolution are investigated. Overall, these simulation results indicate that ReaxFF will be a very useful tool for the development of novel electrolytes or additives in Lithium-ion batteries.

5:25 AM F.EN04.08.04
***In Situ* TEM Observation of Structural and Chemical Evolution of Interphase in Rechargeable Batteries** Chongmin Wang; Pacific Northwest National Laboratory, United States

Electron microscopy and spectroscopy diagnosis, both in-situ and ex-situ, appears to be one of the essential methods for gaining insights as how an electrode material evolves and eventually fails, therefore feeding back for designing and creating new materials with enhanced battery performances. In this presentation, I will focus on recent progress on ex-situ, in-situ and operando S/TEM studies for probing into the structural and chemical evolution of electrode for lithium ion batteries, especially layer structured transition meal oxide cathode and Li metal anode. I will highlight several recent key observations, which appear to be well documented, while essentially are poorly understood, and therefore act as the bottleneck for the advances of cathode and anode for better batteries. It would be expected that this presentation can stimulate new ideas as how to attack these bottlenecks to advance the cathode based on layer structured materials and Li anode.

Atomistic Modeling and Simulations of the Lithiation Behavior of the Si Anode in Li-Ion Batteries Using Reactive Force Field Li-Yi Pan and Chin-Lung Kuo; National Taiwan University, Taiwan

Si-based materials have recently received great interest for their much higher theoretical Li capacity than graphite. However, their practical use is still largely hampered by many of their inherent problems, particularly for the massive volume expansion and the anisotropic lithiaion behavior that result in the pulverization of the Si electrode upon lithiation. To solve this problem, it would require a detailed understanding of the fundamental mechanism of the Si-based anode during the lithiation processes. Regarding this aspect, molecular dynamic (MD) simulation is a powerful tool to explore the structural evolution and dynamic properties of the Si-based anode upon lithiation. However, molecular dynamic simulation requires a reliable force-field model to accurately describe the atomic interactions between the constituent elements. In this study, we have developed a new ReaxFF parameter set for the Li-Si alloy system based on first-principles calculations. This new potential parameter set has been examined through a series of validations, which has proved to accurately predict the fundamental properties of Li, Si, and LixSi alloys, including the structure parameters, elastic moduli, and formation energies, etc. We then employed this newly developed model in conjunction with MD simulations to investigate the lithiation kinetics and the associated underlying mechanisms for the Si-based anode. Our MD simulations first show that this newly developed ReaxFF model can accurately describe the anisotropic lithiation behavior of the Si-based anode as observed in the experiments. The distinct properties in each facets were further analyzed to find out the mechanism of the anisotropic lithiation. More specifically, the Li insertion energy barrier is found to be the controlling factor in the initial stage lithiation. The high surface Si density of Si(111) facet leads to its high Li insertion energy barrier, which makes it "almost immobile" as observed in our MD simulations, consistent with the experimental results. Meanwhile, the local Li/Si ratio and the stress concentration generated at the Si/LixSi interface (phase boundary layer), which affects the bond-breaking and Li insertion rate, was found to play a critical role in the steady-state lithiation process. These structural characteristics lead to the distinct lithiation rates and anisotropic morphologies on different crystallographic orientations of Si. Finally, our results show that the anisotropic lithiation behavior of the Si anode is primarily determined by the lithiation kinetics on different facets of Si rather than the thermodynamic factors as suggested by early first-principles calculations.

Understanding the Lithiation Pathways in Si and Ge Clathrates Using Synchrotron X-Ray Characterization Andrew M. Dopilka[1], Candace K. Chan[1], Amanda Childs[2] and Svilen Bobev[2]; [1]Arizona State University, United States; [2]University of Delaware, United States

Clathrates are comprised of a cage framework of covalently bonded Group IV elements in which guest atoms reside in the center of each cage. Clathrates are typically known for their superconducting or thermoelectric applications, while their electrochemical properties are relatively unexplored. Our group has been investigating the electrochemistry of Si and Ge clathrates for Li-ion battery anodes and have found that in some cases the Li-alloying pathways and reactions are distinctly different than those seen in the diamond Si/Ge case. For example, the Ba8Al16Si30 Type I clathrate does not undergo a Li-alloying reaction1 while the Ba8Ge43 clathrate does2. In the case of Ba8Ge43, the reaction pathway appears to follow an amorphous phase transformation. This is different than diamond cubic Ge which undergoes several phase transformations to crystalline phases3. In the case of the Type II Si clathrate (NaxSi136), the alloying reaction depends on the Na content. When the cages are full of Na (Na24Si136, the alloying reaction looks similar to diamond cubic Si4, where if the cages are empty (Si136) the voltage profile is significantly more sloped5, more similar to the alloying of amorphous Si. In this work, we employ synchrotron x-ray pair-distribution function analysis (PDF), X-ray diffraction, and in-situ heating experiments to elucidate the structural differences between Ba8Ge43 and Si136 and their diamond cubic analogues at similar states of charge. The PDF method allows us to probe the local structure of the amorphous phases that are present in the lithiated samples. In situ heating experiments enable us to observe structural changes to amorphous phases upon moderate heating. The insight learned from the structural characterizations are then used to explain the differences in the electrochemistry between the Si and Ge clathrates and their diamond cubic analogues. The results show that at various states of lithiation of Ba8Ge43, Ba8Ge43 is converted to a an X-ray amorphous phase while diamond cubic Ge undergoes crystalline phase transformations similar to previous work3. Interesting, when heating the fully lithiated Ba8Ge43 phase and monitoring with X-ray diffraction, crystalline peaks corresponding Li15Ge4 appear at 420 K. Upon further heating to 480 K, the reflections corresponding to Ba4Li2Ge6 and other binary Ge-Li phases appear. These results suggest that the amorphous phases that are part of the final lithiation state have local structures similar to that of crystalline phases which can than be accessed upon moderate heating (480 K). These results would aid in giving insight to the fundamentals of how the initial structure of group IV materials affect their Li-alloying properties and structures. Ab Initio Investigation of Li and Na Migration in Guest-Free, Type I Clathrates Andrew M. Dopilka[1], Candace K. Chan[1] and Xihong Peng[2]; [1]Arizona State University, United States; [2]Arizona State University Polytechnic Campus, United States

Group IV clathrates have cage structures that host guest atoms and exhibit a wide range of interesting properties including superconductivity, hydrogen storage, and thermoelectricity. Recently, there have been interest in the possibility of clathrates and other group IV frameworks as anodes for Li-ion and Na-ion batteries. The type and presence of guest atoms have a direct influence on the properties that are observed. For Li-ion battery applications, we found with DFT (density functional theory) calculations that the presence of Ba inside the clathrate cages in Ba8Ge43 impedes Li mobility by raising the migration

barrier for diffusion. If Ba was absent, the barrier was much lower suggesting the need for guest atoms to be absent for diffusion to be feasible1. In this work, the favorable Li and Na positions are determined in the type I clathrate frameworks (Si46, Ge46, and Sn46) and then the nudged elastic band (NEB) method is used to evaluate the Li and Na mobility. The results show that it is energetically favorable for a Li atom to occupy the center position inside the small Tt20 cages while preferring the off-center positions in the larger Tt24 cages. The lowest Li migration barriers are found to be 0.35, 0.13 and 0.37 eV for Si46, Ge46, and Sn46, respectively, with the dominant diffusion pathway along channels of Tt24 cages connected by hexagonal faces. Li accessibility to the Si20 cage in Si46 appears to be restricted in the dilute regime due to a high energy barrier (2.0 eV) except for the case in which Li atoms are present in adjacent cages; this lowers the migration barrier to 0.77 eV via a mechanism where a Si?Si bond is temporarily broken. In contrast, Na atoms show preference for the cage centers and display higher migration barriers than Li. Overall, the Tt24 channel sizes in the guest-free, type I clathrates are ideal for fast Li diffusion, while Na is too large to migrate effectively between cages, except in the case of hexagonal migration of Na in Sn46 (0.43 eV). The energy landscape for Li inside the type I clathrates is uniquely different than that in diamond cubic structures, leading to significantly lower energy barriers for Li migration. These results suggest that open frameworks of group IV elements may enable facile Li migration and, in some cases, facile Na migration. By the gained understanding the structural requirements for fast ion diffusion in group IV open frameworks, new materials can be identified that have potential use as Li-ion or Na-ion anodes. High Energy Density and Ultrastable Lithium-Sulphur Batteries Ying Chen[1], Baozhi Yu[1], Ye Fan[1], Tao Tao[1] and Chunping Hou[2]; [1]Deakin University, Australia; [2]North Minzu University, China

Lithium-Sulfur (Li-S) batteries exhibit a very high theoretical specific capacity of 1675 mA h g-1 and high energy density of 2650 W h Kg-1, which are 2~3 times higher than the current Li ion batteries and thus are considered next-generation batteries. The major challenges of current Li-S batteries are cathode degradation related to the "shuttle" effect and Li dendrite formation on anode surface, leading to the low Coulombic efficiency, poor cyclic stability, and serious safety problems. We have used new nanomaterials to solve these issues and improved substantially the performance of Li-S batteries. The shuttle effect has been reduced by adding a BN nanosheet-graphene interlayer on cathode surface to trap lithium polysulfide ions (Fan 2017). Coating the separator with a thin layer of negatively-charged BN nanosheets can prevent polysulfide migration through the separator effectively, further suppressing the shuttle effect (Fan 2019); Dendrite formation is successfully avoided by constructing a 3D Li anode using a 3D host of MnO2-decorated graphene foam (Yu 2018). These research effort have substantially improved the battery performance with a long cycle life of over 1000 cycles, a high Coulombic efficiency of 98.9%, and high rate capacities (7C) both in symmetric-cell and full-cell cells (Tao 2018). High-Throughput Neural Potential Exploration of Ether-Ion Chemical Space Wujie Wang, William H. Harris and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States

The use of ether species has shown great promises for equimolar (super-concentrated) ionic liquid for novel organic electrolyte applications and as model systems for solid-state polymer electrolyte [1-5]. However, the moderately-sized combinatorial space for designing supramolecular chemistry for ether-ion interactions is on the order of 10^3 ~ 10^4 and has remained largely unexplored. We applied graph neural network-based potentials to accelerate the exploration of novel species for equimolar ionic liquid using a self-consistent strategy that accelerates the sampling and training of transferable neural networks[6-10]. The proposed method combines deep neural network training and active sampling of both chemical and configurational space in an end-to-end fashion to 1) bypass expensive ab initio MD sampling and 2) leverage the transferable configurational information across species. This workflow has discovered novel molecules for potential novel organic electrolyte applications for several different ions including Lithium and Sodium and shows great promises in theory-guided engineering for supramolecular chemistry. P-Type Contacts on 2D Semiconductors Manish Chhowalla; University of Cambridge, United Kingdom

Ultra-clean van der Waals interfaces can be achieved between soft indium metal and monolayer 2D transition metal dichalcogenide semiconductors. Such interfaces lead to low contact resistance and n-type field effect transistors with high mobilities- in excess of 100 cm2-V-1-s-1. It has been, however, challenging to make similarly clean interfaces between refractory metals with high work functions to achieve efficient hole injection. Here, I will present our efforts on realizing p-type contacts using high work function metals and alloys. We show that it is possible to deposit a thin layer of indium and then a high work function metal on top of it to form an alloy by annealing at 200oC. This method preserves the ultra-clean interface between the monolayer semiconductor and alloy while increasing the work function so that p-type devices can be realized. We also demonstrate clean interfaces using metals such as Au and Pt via direct deposition. These interfaces reveal low contact resistance and also high mobility p-type devices.

The Synthesis of Submillimeter and Two-Dimensional vdW Manganese Metal-Organic Framework via Bi-Phase Strategy Yuxia Shen, Bin Mu and Sefaattin (Sef) Tongay; Arizona State University, United States

Synthesis of van der Waals (vdW) metal-organic framework (MOF) nanosheets with controlled crystallinity and interlayer coupling strength are one of the bottlenecks in 2D materials that have limited its successful transition to large-scale applications. Especially for MOFs involving transition metals possessed versatile oxidation states have been highly rated in electrocatalytic applications. Here, the synthesis of vdW MnBDC with huge crystal size through a novel bi-phase strategy is demonstrated. The results show Mn2+ and BDC- species diffusing along vertical directions in described bi-phase system slows down the reaction speed and enhances the crystallinity of MnBDC significantly. Moreover, the existence of capping agent - pyridine promotes the nanosheets that are stacking in 2D landscape and controls over the crystallinity further by competing with ligands carboxylic acid. The attained MnBDC crystals exhibit classic vdW nature, submillimeter of lateral size and great crystallinity. The high quality of vdW MnBDC nanosheets enables us to perform thickness-dependent kelvin probe force microscopy and optical absorption to discover the electron transition and interlayer hybridization in 2D MOF nanosheets for the first time. Further, we conducted a series of electrocatalytic characterizations to investigate the catalytic water splitting efficiency of MnBDC. Theoretical calculation and experimental results highlighted the contributions of 2D crystal structure and multiple oxidation states of MnBDC crystals.

Investigating Influence of Oriented Metal Films on Optical Properties and Excitonic Resonances of Suspended 2D Membranes Todd H. Brintlinger, Jose Fonseca, Andrew Yeats, Joel Grim, Sam Carter, Jim C. Culbertson, Blake S. Simpkins, Daniel Ratchford, Maxim Zalalutdinov, Rhonda M. Stroud and Jeremy Robinson; U.S. Naval Research Laboratory, United States

The choice of growth substrate often has a profound influence on the electronic [1] and optical [2] behavior of atomically thin 2D crystals (2DCs). In order to exploit this influence, we have developed a synthetic technique for creating ordered, porous metal films with various suspended 2DCs, which we dub Oriented Porous mEtallic Networks (OPEN) [3]. These OPEN films exhibit characteristic optical phenomena, including enhanced photoluminescent (PL) intensity in suspended regions and remote quantum emission. Aberration-corrected scanning transmission electron microscopy (STEM) and electron energy loss spectroscopy (EELS) enables us to probe the various resonances of the suspended 2D crystals, the metal/2DC hybrid, and the interfacial region between these two distinct areas. Similar to recent work that uses gold films for generation of large-area 2DCs [4], OPEN films are synthesized by annealing metal films capped by 2DCs. The annealing causes lattice registry between the metal layer and the 2DCs. We show a single MoS2 monolayer can affect the structural order of a comparatively thick (13-25nm) gold thin film. Electron back scatter diffraction and aberration-corrected STEM high-angle annular dark-field (HAADF) imaging of annealed MoS2/Au layers reveals that the gold films become highly textured and in close crystallographic registry with each other. With further annealing, the gold films can locally dewet beneath the MoS2 layer to form the OPEN film structure with suspended regions of monolayer 2DC above the pore sites. The unique optical behavior of these hybrid systems include a 1000x increase in PL intensity in suspended 2DCs vs 2DCs on the metal film, and single-photon emitters manifests in remote quantum emission, with evidence for surface plasmon-polariton (SPP) propagation of > 10 µm. Further, low-loss EELS measurements at 60 kV, reveal that the OPEN films have resonances at ~ 2 eV, which are associated with the so-called A and B excitons in 2DCs, while resonances at several other energies occur in both the interfacial region and the "bulk" MoS2/Au regions. We will discuss the origin of these resonances, and how both the metal overlayer and disordered carbon contamination affect them. References: [1] W Bao et al., Appl Phys Lett 102 (2013), p. 042104. 5:35 AM F.EN04.10.06

Strong Adhesive Pick-up Technique with Polycaprolactone for Rare 2D Materials Young Shin[1], Suhan Son[2], Sungmin Lee[2], Dohun Kim[2], Je-Geun Park[2] and Philip Kim[3]; [1]Brookhaven National Laboratory, United States; [2]Seoul National University, Korea (the Republic of); [3]Harvard University, United States

We introduce polycaprolactone (PCL) dry transfer which is a powerful material for picking up non- adhesive van der Waals materials such as NiPS3, NbSe2, Fe3GeTe2, ZnPS3 and bismuth strontium calcium copper oxide (BSCCO) and etc. The heterostructures of Van der Waals were composed of layered atomically thin 2D materials that provide access to new properties important to the quantum information sciences. However, one of the main constraints is the stacking techniques. (PPC) has been known as the highest quality in dry transfer because PPC left less residue on vdW heterostructure through high temperature vacuum annealing but yield of the transfer was low. Here, we present the new polymer, polycaprolactone (PCL) for stacking vdW heterostructure with Rare layered 2D materials by dry transfer at low temperature. These 2D materials were easily detached from hexagonal boron nitride (hBN) assisted with PPC during dry transfer process. We succeeded to pick up many rare superconducting or magnetic 2D materials which were hard to be picked up by conventional dry transfer method from the oxide or silicon nitride substrates.

5:45 AM *F.EN04.10.07

Strong Magnon-Phonon Hybridization in a 2D van der Waals Antiferromagnet Thuc Mai[1], Kevin Garrity[1], Amber McCreary[1], J. Argo[2], Jeffrey Simpson[1,3], V. Doan-Nguyen[2], Rolando Valdes Aguilar[2] and Angela Hight Walker[1]; [1]National Institute of Standards and Technology, United States; [2]The Ohio State University, United States; [3]Towson University, United States

Low dimensional, van der Waals (vdW) materials, from graphene to 2D magnets such as Fe_3GeTe_2 and CrI_3, show exotic behaviors at the atomic layer limit, including superconductivity, long range magnetism and topological edge states. Their "stackability" further creates new opportunities to explore quantum phenomena previously studied only in 3D crystals. Here we demonstrate that magneto-Raman spectroscopy is a unique measurement capability that is exceptionally well suited to study these exotic 2D materials.

Specifically, in the MPX_3 (M=Fe, Mn; X =S, Se) compounds, inter-layer antiferromagnetic ordering has been suggested to survive in the monolayer limit through the measurement of spin-phonon coupling. Using temperature-, polarization-, and wavelength-dependent Raman scattering, we studied the Neel-type antiferromagnet $MnPSe_3$ through its ordering temperature, and as a function of applied magnetic field. Surprisingly, the previously assigned one-magnon scattering peak showed no change in frequency with an increasing in-plane magnetic field. Instead, the Raman data revealed a more surprising story, including changes in resonant Raman scattering due to magnetic ordering as well as the hybridization of phonons with a 2-magnon scattering continuum. These results, which are supported using first-principles calculations, reveal the complex phase space of the interactions of phonons and magnons with regards to temperature, laser excitation wavelength, and

magnetic field.

6:00 AM F.EN04.10.08
Thermoreflectance Imaging of Thermionic Heating and Cooling at Source and Drain Contacts in β-Ga2O3 and Graphene Nanoribbon Transistors Kerry Maize; Purdue University, United States

Electronic devices based on 2D and quasi-2D materials promise several performance advantages. However, the physical properties and small length scales that enhance low dimensional electronic devices can also make them more susceptible to parasitic effects. Contact resistance and power dissipation [1] are noteable challenges to making practical 2D devices. This study measures thermionic heating and cooling at heterojunctions of 2D nanoribbon semiconductor channel and metal contacts in both β-Ga2O3 FET on insulator [2] and graphene FET on insulator. High resolution thermoreflectance microscope images show temperature difference of 60 K between gold drain and source contacts separated by a 15 micron long, two micron wide, 70 nm thick β-Ga2O3 nanoribbon channel deposited on insulator substrate. [2] Current density was 9×104 A/cm2, power was 3 mW. Thermionic effects at the metal-2D semiconductor contact interface were consistent with current flux, reversing heating and cooling at respective drain-source contacts when applied current polarity was reversed. Heating in the β-Ga2O3 channel increased quadratically with current, consistent with Joule's law. However, temperature dependence on current at the gold-β-Ga2O3 contacts divereged significantly from a simple model combining Joule and Peltier contributions, suggesting thermionic effects at the metal-2D semiconductor interface dominate over any thermoelectric contribution from the β-Ga2O3 channel. [3] Thermionic parasitics at the contacts may be exacerbated by use of low dimensional β-Ga2O3 as channel. The high temperature gradient along the quasi-2D channel could impact transport properties, and device performance and reliability. Thermoreflectance images of a monolayer graphene nanoribbon FET modulated by backgate substrate revealed similar location, magnitude, and polarity dependent thermionic heating and cooling at the metal-graphene source and drain contacts. Thermionic heating and cooling, especially the large spatial temperature gradient between source and drain, would be difficult to measure using purely electrical methods. Future study will look at both geometric dependence and reliability considerations related to parasitic thermionic heating and cooling in 2D material electronic devices. Two-Dimensional Alloys and Heterostructures Pulickel Ajayan; Rice University, United States

There has been tremendous interest in recent years to study two-dimensional (2D) atomic layers which form building blocks of many bulk layered materials. This talk will focus on the use of 2D atomic layer building blocks to create various types of heterostructures and composite architectures that takes advantage of the varied properties of individual layers. The concept of nanoscale engineering and the goal of creating new artificially stacked van der Waals solids and 3D constructs will be discussed through a number of examples including graphene and other 2D layer compositions. The talk will explore the emerging landscape of multi-component 2D layers such as doped, intercalated and alloy systems. The anticipated multifunctional properties of these structures will be discussed.

6:25 AM *F.EN04.10.12
Electronic Properties and Device Applications of Quasi-Two-Dimensional Charge-Density-Wave Materials Alexander Balandin; University of California, Riverside, United States

The charge density wave (CDW) phase is a quantum state consisting of a periodic modulation of the electronic charge density accompanied by a periodic distortion of the atomic lattice in quasi-1D or quasi-2D metallic crystals. Several layered transition metal dichalcogenides (TMDs) exhibit unusually high transition temperatures to different CDW symmetry-reducing phases opening possibility for practical device applications. One of the most promising materials, 1T-TaS_2, has the CDW transition between the nearly-commensurate (NC-CDW) and the incommensurate (IC-CDW) phases at 350 K. The transition from the IC-CDW phase to the normal metal phase is observed at even higher temperature. In this invited talk, I will review our recent experimental results on controlling the CDW phase transitions with an applied electric field and discuss device applications of quasi-2D CDW materials. We have demonstrated the room-temperature voltage controlled oscillators and logic circuits, which operate on the basis of the NC-to-IC CDW transition in 1T-TaS_2 channels, triggered by the applied voltage [1-2]. We found that the 1T-TaS_2 CDW devices reveal exceptional hardness against X-ray and proton radiations [3-4]. We explained this property of the CDW devices by the high carrier concentration in all their phase states,

two-terminal design, and the thin-film channel geometry. The low-frequency electronic noise spectroscopy has been used as an effective tool for monitoring the CDW phase transitions, particularly the switching from the IC-CDW phase to the normal metal phase in 1T-TaS2 [5]. The noise spectral density exhibits sharp increases at the phase transition points, which correspond to the step-like changes in resistivity. The noise spectroscopy was instrumental in revealing the "hidden phase transitions" in vertical 1T-TaS2 devices [6]. Preliminary data on the "narrow-band noise" in quasi-2D CDW devices will also be presented.

This work was supported, in part, by the National Science Foundation (NSF) through the DMREF: Collaborative Research (UC Riverside – Stanford): Data Driven Discovery of Synthesis Pathways and Distinguishing Electronic Phenomena of van der Waals Bonded Solids, and by the University of California – National Laboratory Collaborative Research and Training Program LFR-17-477237, and by the Semiconductor Research Corporation (SRC) contract 2018-NM-2796: One-Dimensional van-der-Waals Metals: Ultimately Downscaled Interconnects with Exceptional Current-Carrying Capacity and Reliability.

Local Strain Associated Localized Exciton Energy in WSe2 Hyowon Moon[1], Eric Bersin[1], Chitraleema Chakraborty[1], Ang-Yu Lu[1], Gabriele Grosso[2], Jing Kong[1] and Dirk R. Englund[1]; [1]Massachusetts Institute of Technology, United States; [2]The City University of New York, United States

The deterministic creation of single-photon emitters in a solid-state system is an important step towards scalable photonic quantum processors [1]. Two-dimensional materials transferred onto nanostructures are promising candidate thanks to their ability to host quantum emitters with high probability at specifically fabricated sites [2,3]. However, the emission energies of quantum emitters, a crucial factor for generating indistinguishable photons and entangled states, are broadly distributed, and the precise relationship between this strain and the resultant emission energy remains elusive. Here, we study the localized emitters hosted in monolayer WSe2 transferred onto micron-sized structures, and the corresponding free-exciton energy shift induced by local strain. The localized emission energy show positive correlation with the strain-modulated free-exciton energy together with minimum offset value ~ 40 meV. Our results show local strain plays a crucial role not only in the formation but also in the emission energy of the localized emitters, elucidates the origin of single-photon emission in two-dimensional semiconductors. Advanced 2D Material Optoelectronic Devices in Integrated Photonics Volker J. Sorger[1], Rishi Maiti[1], Mario Miscuglio[1], Tony Low[2] and Ritesh Agarwal[3]; [1]George Washington University, United States; [2]University of Minnesota, United States; [3]University of Pennsylvania, United States

2D materials have a number of intriguing value proposition that could be harnessed for compact, tunable, high-performance optoelectronic devices when heterogeneously integrated in photonic circuits. Here I review our latest work including; (1) tunable TMD-based microring resonator with engineered critical-coupling condition, (2) a broadband graphene plasmon-slot photodetector (R=0.7A/W), (3) a 200mV bandgap-shifted strain-engineered absorption-enhanced MoTe2 photodetector (R=0.5A/W, low-dark-current <10nA@-1V), (4) a record-high responsivity (R=1.36A/W) slot-plasmon exciton-modulated MoTe2 photodetector, (5) a MoS2 electro-absorption modulator all enabled by our recently developed method of cross-contamination-free yet deterministic dry transfer 2D material 'printer' mimicking a 3D printer for enabling rapid prototyping. These devices are based on heterogeneous integration of 2D materials into Silicon and SiN photonics, with the latter used for on-exciton modulation or exciton absorption.

5:20 AM F.EN04.12.04
A Full Picture of Intrinsic Defects in Monolayer 2D Ferroelectric Materials Bolong Huang; The Hong Kong Polytechnic University, Hong Kong

Following the developments of two-dimensional (2D) graphene with distinct properties, tremendous progress has been achieved for the broad applications of 2D materials in nanoscale electronics and optoelectronics. The layered metal chalcogenides (LMC) contribute to a dominant group of the layered 2D structure with various properties and applications. Pursuing the precise structural identification of functional two-dimensional (2D) layered metal chalcogenides (LMCs) are key factors dominating the origins of the unique electronic and ferroelectric properties. Presently, indium selenide (In2Se3) has become one of the most studied LMC materials due to the flexible phases with broad applications in phase-change memory, lithium batteries, optoelectronic and even photovoltaic devices. In2Se3 is particularly attractive in the atomically thin film research due to the flexible phase modulations and unique electronic behaviors. However, the complicated phase change of In2Se3 and their high sensitivity towards the intrinsic defects still requires the advanced technology to identify the origins of the inhomogeneous charge distribution induced in-plane and out-of-plane ferroelectricity. In this work, we have presented comprehensive theoretical research to reveal the simulated scanning tunneling microscope (STM) images as a toolbox for the experimental results to distinguish the structural features. By detailed analysis of the simulated STM images and phonon behaviors under different defects, this work supplies the insightful structure clues of the nanoscale charge distribution fluctuations, explaining the unique electronic behaviors in mono-layered ?- In2Se3. We also confirm the high possibility of surface defects in the few-layered ?-In2Se3 rather than sub-layered defects. Moreover, the corresponding electron-phonon behaviors of ?-In2Se3 with major intrinsic defects provide pivotal references to explain the unique in-plane and out-of-plane electronic and ferroelectric properties in different applications. The modulations of the electronic properties by different intrinsic defects regarding the charge couplings and bandgap have been revealed, which is of significance in the precise identification and modulation of the ultra-thin LMC based ferroelectric materials, shedding new light for the synthesis of other relevant functional materials for broad applications.

Laser Induced Transformation of PdSe2 for On-Demand Device Fabrication Viktoryia Shautsova, Sapna Sinha, Linlin Hou, Qianyang Zhang, Martin Tweedie, Yang Lu, Yuewen Sheng, Benjamin Porter, Harish Bhaskaran and Jamie Warner; University of Oxford, United Kingdom

Two-dimensional materials with tunable band gap in the range of 0.3-1.5 eV are highly desirable for electronic and optoelectronic applications. Palladium diselenide ($PdSe_2$), a less explored group-10 transition metal dichalcogenide, is one such material of particular interest that demonstrates a gradual transition from a semiconductor (monolayer) to semimetal (bulk) [1, 2]. In this work, we report our recent results on laser-induced phase transformation of a few layer $PdSe_2$ films [3]. We demonstrate that controlled laser irradiation can be used to directly ablate PdSe2 thin films using high power or trigger the local transformation of PdSe2 into a metallic phase $PdSe_{2-x}$ using lower laser power. Scanning transmission electron microscopy is used to reveal the laser-induced Se-deficient phases of $PdSe_2$ material. The process sensitivity to the laser power allows patterning flexibility for resist-free device fabrication. The laser-patterned devices demonstrate that a laser-induced metallic phase $PdSe_{2-x}$ is stable with increased conductivity by a factor of about 20 compared to PdSe2. [1] L. H.

Probing and Pressure Control of the Magnetic States in Atomically Thin van der Waals Magnets Zaiyao Fei and Xiaodong Xu; University of Washington, United States

The discovery of two-dimensional (2D) magnets in van der Waals (vdW) crystals provide a new platform for studying fundamental 2D magnetism and spintronic devices. In this talk, I will first present 2D itinerant ferromagnetism in atomically thin Fe3GeTe2 (FGT). FGT is a ferromagnetic metal in the bulk form, with a strong out-of-plane anisotropy and high Curie temperature of 220-230 K. Our layer-number-dependent studies reveal a crossover from 3D to 2D Ising ferromagnetism for thicknesses less than 4 nm (five layers), accompanied by a fast drop of the Curie temperature from 207 K to 130 K in the monolayer. For FGT flakes thicker than ~15 nm, a distinct magnetic behavior emerges in an intermediate temperature range, which we show is due to the formation of labyrinthine domain patterns. In the second part of my talk, I will present the pressure control of the magnetic states in bi- and tri-layer chromium triiodide (CrI3), which exhibits layered antiferromagnetic ground states at ambient pressure. In bilayer CrI3, pressure can change the stacking arrangement which induces a transition from layered antiferromagnetic to ferromagnetic phases. In trilayer CrI3, we found that pressure can create coexisting domains of three phases, one ferromagnetic and two distinct antiferromagnetic. Our work provides ample opportunities to engineer spintronic devices based on vdW magnets and heterostructures.

5:15 AM *F.EN04.13.02
Fundamental Properties of 2D Tellurium Films Peide P. Ye; Purdue University, United States

Tellurium is one of the special elemental materials which have 1D helical atomic structures and formed by van der Waals force between helical atomic chains. 2D tellurium films can be synthesized in a liquid solution. [1,2] In this talk, we will review the fundamental studies of this new 2D material at atomic scale in terms of its electrical, optical, thermal and mechanical properties. The helical atomic structure offers strong anisotropic properties of this 1D van der Waals material. The band-structure of this 2D material also offers some excellent material properties such as a high value of thermoelectric figure-of-merit ZT [3] and high carrier mobilities for both electrons and holes. Magneto-transport properties, such as SdH oscillations and QHE in 2D tellurium, were reported before. [4] More interestingly, topological non-trivial properties as Weyl node at conduction band edge are also unveiled in magneto-transport under 45 Tesla at tens of mK temperatures, showing Berry phase and radial spin texture being significantly different from Rashba or Dresselhaus spin-orbit coupling materials [5,6] The work is in close collaborations with Prof. Wenzhuo Wu at Purdue University. 5:30 AM F.EN04.13.03
Two-Dimensional Material Tunnel Barrier for Josephson Junctions and Superconducting Qubits Kan-Heng Lee[1], Ariana Ray[1], Hui Gao[1], David A. Muller[1], Srivatsan Chakram[2], Shi En Kim[2], Fauzia Mujid[2], Chibeom Park[2], Yu Zhong[2], David I. Schuster[2] and Jiwoong Park[2]; [1]Cornell University, United States; [2]The University of Chicago, United States

Recent developments in the device architecture and operation of state-of-the-art superconducting qubits has allowed the technology to advance to practical applications in quantum computing. However, the central circuit element in superconducting qubits, the Josephson junction, has mainly focused on using the amorphous AlOx tunnel barrier. New materials for fabricating Josephson junctions are expected to introduce novel functionalities and new circuit elements to superconducting qubits. Two-dimensional (2D) materials are one such promising candidate. The van der Waals layered structures of 2D materials can enable the precise design of the tunnel barrier at the sub-nanometer scale via layer-by-layer stacking of atomically thin monolayers, wherein each layer can be a different 2D material. This ability to generate heterostructure barriers would allow, for example, the design of the tunnel barrier's band structure using 2D materials with

different band gaps and band offsets, or the fabrication of novel quantum circuit components such as ?-junctions using 2D magnets. In order to realize the implementation of 2D materials in these systems, it is essential to have a fabrication method that not only maintains oxide-free interfaces between the easily-oxidized superconductors and the 2D material tunnel barriers, but is also scalable for technological applications. Here, we demonstrate Josephson junctions and superconducting qubits that employ 2D materials as the tunnel barrier [1]. We batch-fabricate and tune the critical Josephson current of the device arrays over orders of magnitudes via layer-by-layer stacking of N layers of MoS2. In addition, we observe a transition of the junction J-V characteristics when N is increased. Based on these junctions, we demonstrate, for the first time, the engineering and operation of MoS2 superconducting qubits using a bulk superconducting microwave resonator. Our work here allows Josephson junctions to access the diverse physical properties of 2D materials, offering a platform to study the effects of these properties in superconducting qubit circuits under different geometries, and engineer novel quantum circuit elements for quantum computing. 5:40 AM F.EN04.13.04
Purely In-Plane Ferroelectricity in SnS Down to the Monolayer Limit Naoki Higashitarumizu[1], Hayami Kawamoto[1], Chien-Ju Lee[2], Bo-Han Lin[2], Fu-Hsien Chu[2], Itsuki Yonemori[3], Tomonori Nishimura[1], Katsunori Wakabayashi[3], Wen-Hao Chang[2] and Kosuke Nagashio[1]; [1]The University of Tokyo, Japan; [2]National Chiao Tung University, Taiwan; [3]Kwansei Gakuin University, Japan

Ferroelectric 2D materials have emerged as a promising platform for nonvolatile memories and nonlinear optoelectrical devices working at the ultimate atomic thickness. However, most of the experimental investigations have been limited in the 2D ferroelectric with out-of-plane polarization, which causes the depolarization field at the metal/ferroelectric interface with decreasing the thickness. Although monolayer SnS has been theoretically expected to be a purely in-plane multiferroic semiconductor with ferroelectricity and ferroelasticity,[1] experimental demonstration is challenging because it is difficult to obtain a high-quality monolayer SnS.[2,3] Bao et al. have recently reported a ferroelectric device of bulk SnS (~15 nm), utilizing an external electric field to break the centrosymmetry.[4] As the few layer SnS has been investigated only by probe measurements owing to its small size of several tens of nanometers, the ferroelectric characteristic of few-to-monolayer SnS is still unidentified. Here, we report an in-plane ferroelectric device of a micrometer-size monolayer SnS grown via physical vapor deposition, where the growth conditions are precisely controlled to balance the adsorption and desorption of SnS. The Raman spectrum for monolayer SnS indicates high crystalline quality and strong anisotropy. As a prerequisite for ferroelectricity, second harmonic generation (SHG) spectroscopy reveals a non-centrosymmetry in monolayer SnS. Room temperature ferroelectric switching in monolayer is successfully demonstrated by the ferroelectric evaluation system. SnS has been commonly regarded to exhibit the odd/even effect, where the centrosymmetry breaks only in the odd-number layers to exhibit ferroelectricity. Remarkably, however, both the SHG signal and ferroelectric switching are observed in both odd and even-number layers below a critical thickness (~15 layers), thus overcoming the odd/even effect. This suggests an unusual stacking sequence lacking centrosymmetry due to a strong interaction between SnS and mica substrate. Given that SnS is the semiconductor with multiferroicity, pyroelectricity, and piezoelectricity, this work will open up possibilities of providing novel multifunctionalities in van der Waals heterostructure devices. 5:00 AM F.EN04.14.01
Direct Graphene Growth for Si-Based Technology Keun Wook Shin, Yeonchoo Cho, Minsu Seol and Hyeon Jin Shin; Samsung Advanced Institute of Technology, Korea (the Republic of)

Graphene is a 2-dimensional carbon layer. Because of its potential properties such as chemical inertness and atomically thin nature, graphene has been considered as a thin diffusion layer in metal interconnect structures. Furthermore, as the feature size of device is decreased to sub-nm size, the contact resistance between metal and Si in source/drain has become one of the critical issues. We demonstrated that reduced contact resistivity of 1.47 nohm-cm2 via insertion of graphene between metal

and Si which approaches the theoretical limit of 1.3 nohm-cm2.[1] In order to adapt graphene to source and drain, direct and selective graphene growth on semiconductor substrates is required. In our previous report, we have already suggested that the directly grown nanocrystalline graphene (nc-G) at 560 oC can act as a liner reducing the resistivity of W as well as a diffusion barrier in a W interconnect structure by realizing W/nc-G/TiN.[2] However, the selective graphene growth on the non-catalytic semiconductor-insulator substrates is barely reported. In this study, we addressed the origin of selective growth of graphene on a semiconductor over the dielectric materials. Based on Ab initio simulations, we found that the adsorption energy of CH4 on SiO2 is much higher than that on Si and Ge. The growth differences of graphene on Ge and SiO2 were also experimentally confirmed. While a continuous graphene layer was formed on the Ge surface at the initial growth stage that became thicker at increasing growth times, an incubation time was required for the nucleation of graphene on SiO2. The interface analysis between nc-G and SiO2 indicates that initially incorporated carbon onto SiO2 cannot contribute to the nc-G growth because of its reaction with SiO2 producing CO. Finally, we selectively grew 3 nm-thick nc-G layer on a SiO2-patterned Ge substrate.[3] In addition, as the feature size of semiconductor devices decreases, hard mask films with high etch selectivity are required to achieve fine pattern transfer during lithography. We are going to address the potential and properties of nc-G layer as a future hardmask film.[4] [1] M.-H. 2D Material Enabled Colloidal Electronics Albert Liu, Pingwei Liu, Daichi Kozawa, Volodymyr Koman, Jingfan Yang and Michael Strano; Massachusetts Institute of Technology, United States

Graphene and other 2D materials possess desirable mechanical and functional properties for incorporation into or onto novel colloidal particles, potentially granting them unique electronic and optical functions. However, this application has not yet been realized because conventional top-down lithography scales poorly for the production of colloidal solutions. Herein, we describe an "autoperforation" technique providing a means of spontaneous assembly for colloidal microparticles comprised of 2D molecular surfaces at scale. Such particles demonstrate remarkable chemical, mechanical and thermal stability. They can function as aerosolizable memristor arrays capable of storing digital information, as well as dispersible and recoverable probes for large-scale collection of chemical information in water and soil. Liu, A. T.;* Liu, P.;* Kozawa, D.; Dong, J.; Yang, J. F.; Koman, V. B.; Saccone, M.; Wang, S.; Son, Y.; Wong, M. H.; Strano, M. S.-Nature Materials (2018) 17, 1005-1012.

5:20 AM *F.EN04.14.03
Scalable Synthesis Approaches Towards 2D Transition Metal Dichalcogenide-Based Molecular Sensors Nicholas Glavin; Air Force Research Laboratory, United States

Two-dimensional (2D) transition metal dichalcogenides (TMDs) are some of the more promising material candidates for future sensors requiring detection of molecular species at extremely low concentrations. This is primarily due to the multifunctional properties including a high surface to volume ratio and strict control of surface reaction sites. In this talk, two different scalable synthesis approaches towards large area TMD films using magnetron sputtering are presented. Firstly, direct sputtering of MoS2 and WSe2 thin onto various substrate and subsequent laser crystallization was shown to enable local control of defect density and crystal structure. Additionally, wafer-scale crystallization of stretchable 2D photodetectors with the use of a broadband pulsed lamp source demonstrate the feasibility of large scale transformation as a means to create unique device constructs. The second large area technique to be discussed is the sputtering of metal precursor films and sulfurization/selenization using various gas phase reaction sources. Heterostructures and superlattice constructs using stacked metal layers with alternating materials were also demonstrated using this technique. Finally, the large area TMD films and heterostructures were evaluated in both electrical and optical molecular sensors constructs for future low analyte detection devices.

5:35 AM *F.EN04.14.04
RF Energy Harvesters Based on Atomically Thin MoS2 Phase Heterostructures Xu Zhang[1], Jesus Grajal[2], Jose Luis Vazquez-Roy[3], Ujwal Radhakrishna[4], Han Wang[5], Jing Kong[4], Mildred Dresselhaus[4] and Tomas Palacios[4]; [1]Carnegie Mellon University, United States; [2]Universidad Politécnica de Madrid, Spain; [3]University Carlos III of Madrid, Spain; [4]Massachusetts Institute of Technology, United States; [5]University of Southern California, United States

The atomically thin two-dimensional materials have emerged as a new type of thin film semiconductors that are promising for flexible electronics, thanks to their unique electronic and mechanical properties. As many important components of flexible electronics (for example, transistors, sensors and memory devices based on two-dimensional materials) have been developed, an efficient, flexible and always-on energy-harvesting solution is highly desirable yet still missing. In this work, we present a fully flexible Wi-Fi band rectenna based on atomically thin MoS2 semiconducting-metallic phase heterojunctions. Through a self-aligned phase engineering technology, we successfully improved the cutoff frequency of MoS2-based rectifiers to 10 gigahertz, which is high enough to cover the increasingly ubiquitous electromagnetic radiation from Wi-Fi and cellular systems. By integrating the MoS2 rectifier with a flexible Wi-Fi band antenna, we realized wireless energy harvesting of electromagnetic radiation at zero external bias. In addition, the phase-engineered MoS2 rectifier can also function as a flexible mixer, realizing frequency conversion beyond 10 gigahertz. This work provides a flexible energy-harvesting building block that can be integrated with various flexible electronic systems.

5:50 AM *F.EN04.14.05
Hybrid van der Waals Interfaces for Photonics and Electronics Deep M. Jariwala; University of Pennsylvania, United States

Van der Waals semiconductor materials and heterostructures possessing room temperature strongly bound exciton states exhibit emergent physical phenomena and are of a great promise for optoelectronic applications. Likewise, their self-passivated surfaces enable facile integration for novel heterostructures for device applications. In the first part of the talk, we will present novel light-matter interactions that are observed at the hybrid interface of two-dimensional (2D) semiconductors and bulk gold (Au) surface. We will demonstrate that nanostructured multilayer transition metal dichalcogenides (TMDCs) by themselves provide an ideal cavity-less platform for exciton-photonics. Hence, we show that by patterning the TMDCs into nanoresonators, strong dispersion and avoided crossing of excitons and photon-polaritons with interaction potentials exceeding 410 meV may be controlled with great precision. We further observe that inherently strong TMDC exciton absorption resonances may be completely suppressed due to excitation of hybrid photon states and their interference. In the second part of this talk we will demonstrate, hybrid 2D/3D semiconductor heterojunctions using MoS2 as the prototypical 2D semiconductor laid upon Si and GaN as the heavily doped 3D semiconductor layers. At the interface of these junctions we demonstrate that Fermi-level is tunable in the transition metal dichalcogenides (TMDCs) to achieve highly tunable rectification ratios in the diodes across seven orders of magnitude i.e from 0.1 to 106. Concurrently, we have also demonstrated that these triodes can effectively serve the purpose of a switching device with on/off ratios exceeding 107. Our results suggest that the 2D/3D semiconductor heterojunction system is highly tunable, near-ideal and effective for electronic applications despite the lack the perfect passivation at the interface. Given the hybrid nature of the device it can serve the function in both switching and rectifying applications. With a wealth of 2D semiconductors now isolated and combined with the availability of controlled complementary doping in 3D semiconductors, our work opens up new opportunities in high performance and multi-functional, hybrid heterostructure devices.

SESSION F.EN04.15: Optoelectronics, Flexible Electronics and Other Devices
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-EN04

5:00 AM F.EN04.15.02
Flexible Large-Scale LEDs Based on MOCVD-Grown WS2 Monolayers as Luminescing Material Dominik Andrzejewski[1], Ruth Oliver[1], Yannick Beckmann[1], Michael Heuken[2], Annika Grundmann[3], Holger Kalisch[3], Andrei Vescan[3], Tilmar Kümmell[1] and Gerd Bacher[1]; [1]Universität Duisburg-Essen, Germany; [2]AIXTRON SE, Germany; [3]RWTH Aachen University, Germany

Semiconducting transition metal dichalcogenides (TMDs) represent a novel and sustainable material class for ultrathin optoelectronic devices. Although various approaches towards light emitting devices have been reported, e.g. based on exfoliated or chemical vapor deposited TMD monolayers, they all suffer from limited scalability required for practical applications. Recently, a first scalable approach has been suggested combining WS2 monolayers grown in a commercial horizontal multi-wafer AIXTRON metal organic chemical vapor deposition (MOCVD) reactor on sapphire (0001) substrates [1] with a vertical p-n device concept [2]. With this, large-scale light emitting devices based on TMDs as active material, organic injection layers on the anode side and an inorganic supporting layer on the cathode side have been demonstrated.[3] One unique property of this ultra-thin semiconductor family is their flexiblility. Taking advantage of this, we realized for the

first time a large-scale WS2 monolayer based light emitting device on a flexible substrate. Our devices are fabricated in a vertical p-n architecture on ITO covered PEN foil, with PEDOT:PSS / poly-TPD hole injection layers on the anode side and a ZnO nanoparticle layer as an electron supporting layer on the cathode side. By applying an external voltage, those devices show diode-like behavior in their I-V characteristic and pronounced red electroluminescence purely originating from the WS2 monolayer. Light emission starts at a turn-on voltage below 3 V from an emissive area of 6 mm2, which is just limited by the size of the cathode contact. By bending the device, an energy shift of the electroluminescence with a gauge factor of 30 meV/% is observed, caused by the strain-induced shift of the bandgap. These novel large-scale and flexible LEDs with a TMD emissive monolayer and an emission energy depending on the bending radius opens a new field of potential applications for flexible optoelectronics. References: [1] A. Grundmann et al., MRS Adv. 4, 593 (2019) [2] D. Andrzejewski et al., Nanoscale 11, 8372 (2019) [3] D. Andrzejewski et al., ACS Photonics 6, 1832 (2019)

5:10 AM *F.EN04.15.03
High Performance OFETs Based on Meniscus Guide Coating—From Growth Mechanisms to Achievements Paddy K. L. Chan; University of Hong Kong, Hong Kong

Organic field effect transistors (OFETs) are the major building blocks of the next generation flexible electronics. From logic gates to health monitoring sensors, different flexible electronics have been developed based on the OFETs. In this talk, I will focus on one of the most promising OFET fabrication methods which has excellent compatibility with large area deposition, the meniscus guided coating (MGC). Four elementary processing parameters (i) shearing speed (v), (ii) solute concentration, (iii) deposition temperature (T) and, (iv) solvent boiling point (Tb) are utilized to analyze crystal growth behavior in the meniscus-guided coating. By carefully varying and studying these four key factors, we can confirm that v is the thickness regulation factor while c is proportional to crystal growth rate. The MGC crystal growth rate is also correlated to latent heat (L) of solvents and deposition temperature in an Arrhenius form. The latent heat of solvents is proportional to Tb. I will also provide a generalized formula to estimate the effects of these fabrication parameters which can serve as the crystal growth guidelines for the MGC approach. It is also an important cornerstone towards scaling up the OFETs for the sophisticated organic circuits or mass production. Furthermore, I will also discuss how to use the ultra-low speed version of MGC to develop 2D monolayer organic crystal and long range in-plane ordering. By using this method, we can obtain 2,9-didecyldinaphtho[2,3-b:2?,3?-f]thieno[3,2-b]thiophene (C10-DNTT) monolayer with single-crystalline domain size ranging from millimeters to centimeters. Intrinsic field-effect mobility around 12 cm2V-1s-1 is achieved. More importantly, the ultrathin thickness minimizes the charge injection barrier for the top-contact electrodes, allowing an ohmic hole injection and a low contact resistance (RcW) of 40±15 ohm-cm, one of the lowest values reported for the n-shape organic semiconductors. The detailed analysis of this ohmic metal/organic contact will be also be discussed.

Waveguide-Integrated, Plasmonic Enhanced Photodetectors Based on the Photo-Thermoelectric Effect in CVD Graphene Jakob Muench[1], Alfonso Ruocco[1], Marco Giambra[2], Vaidotas Miseikis[2], Dengke Zhang[1], Junjia Wang[1], Hannah Watson[1], Gyeong Cheol Park[1], Shahab Akhavan[1], Michele Midrio[2], Andrea Tomadin[3], Camilla Coletti[4], Marco Romagnoli[2], Ilya Goykhman[1] and Andrea C. Ferrari[1]; [1]University of Cambridge, United Kingdom; [2]Consorzio Nazionale per le Telecomunicazioni, Italy; [3]University of Pisa, Italy; [4]Center for Nanotechnology Innovation @ NEST, Italy

The integration of single layer graphene (SLG) with on-chip photonic circuitry may offer improved performance and new functionalities for active components in telecom modules [1]. Graphene based photodetectors (GPDs) promise high-speed [1,2], broad-band operation [3,4] and the direct generation of a photovoltage [1,2,4,5], potentially removing the need of using noise-prone trans-impedance amplifiers (TIAs) [1]. Here we present a micrometer scale, on-chip integrated, plasmonic enhanced photo-thermoelectric [6] GPD for telecom wavelengths operating at zero dark current [1,5]. The GPD is designed and optimized to directly generate a photovoltage and has an external responsivity ? 12.2 V/W with a 3dB bandwidth ? 42 GHz. We utilize Au split-gates with a ? 100 nm gap to electrostatically create a p-n-junction and simultaneously guide a surface plasmon polariton gap-mode. This increases light-graphene interaction and optical absorption and results in an increased electronic temperature and steeper temperature gradient across the channel. Implemented with scalable CVD SLG, our work paves the way to compact, on-chip integrated, power-efficient GPDs for receivers in tele/datacom. [1] M. Romagnoli et al., Nat. Rev. Dimensional Control of Physical Properties in Perovskite Chalcogenides—From Optical Anisotropy to Ultra-Low Thermal Conductivity Jayakanth Ravichandran; University of Southern California, United States

Perovskite Chalcogenides are a new class of semiconductors, which have tunable band gap in the visible to infrared part of the electromagnetic spectrum. Besides this band gap tunability, they offer a unique opportunity to realize large density of states semiconductors with high carrier mobility. In this talk, I will discuss some of the advances made both in my research group and in the research community on the theory, synthesis of these materials and understanding their optoelectronic properties. The basic building block of the perovskite structure is the octahedral cage and the nature of its connectivity gives rise to both the perovskite and related structures with varying dimensionality. I will discuss how low dimensional connectivity can influence areas spanning optoelectronics to thermal transport. First, I will show unusual band gap evolution in two dimensional Ruddlesden Popper perovskites; Second, I will discuss giant optical anisotropy in one dimensional perovskite-like phases, which also show ultralow thermal conductivity. These examples show unique opportunities to explore novel dimensional controlled physical properties in bulk materials. Finally, I will provide a general outlook for future studies on these exciting new class of materials. References: Nature Photonics, 12, 392-396 (2018). Advanced Materials 29, 1604733 (2017). Interface Engineering for 2D Layered Semiconductors Kosuke Nagashio; Tokyo University, Japan

The insulator/2D channel interface property is highly detrimental for the performance of 2D field effect transistors. Although severe interface degradation has been reported so far, a common understanding of the origin of the interface states has not been obtained yet. Here, for the first time, we present the full energy spectra of interface states density for both n- and p-MoS2 FETs, as shown below, based on the comprehensive and systematic studies, i.e., wide thickness range from monolayer to bulk and various gate stack structures including 2D heterostructure with h-BN as well as typical high-k top gate structure (more than 100 devices). For n-MoS2, the lowest interface states density (Dit = 5×1011 cm-2eV-1) was achieved for the heterostructure FET with h-BN, while the interface states density remained high, ~1013 cm-2eV-1, even for the heterostructure FET for p-MoS2. The systematic study elucidates that the strain induced externally through the substrate surface roughness and high-k deposition process is the origin for the interface degradation at the conduction band side, while sulfur-vacancy-induced defect-states dominate the interface degradation at the valance band side. The present understanding on the interface properties provides the key to further improving the performance of 2D FETs. Finally, based on the recent understanding, the perspective on 2D electronics will be discussed.

5:00 AM *F.EN04.16.01
High Speed and Multifunctional Electronics Based on 2D Materials Han Wang[1], Yanqing Wu[2] and Xuefei Li[3]; [1]University of Southern California, United States; [2]Peking University, China; [3]Huazhong University of Science & Technology, China

Electronic devices based on atomic layered two-dimensionalmaterials and related heterostructures have recently attracted greatresearch attentiondue to their unique electronic properties and the feasibility of hybrid integration, which provide the unprecedented opportunities for various van der Waals heterojunctions. We have studied the performance improvement based on black phosphorus and molybdenum disulfide from the carrier velocity and operating frequency. High frequency transistor and circuits operating at gigahertz range based on molybdenum disulfide are demonstrated with record high maximum oscillation frequency. High hole velocity of up to 1.5 x 107cm/s has been demonstrated for short channel BP transistors and transport approaching ballistic limit are predicted for ultimately scaled channel length. Moreover, bandgap engineering using lateral heterojunctions has been carried out with multifunctionality for reconfigurable logic operations, showing great promise for future electronics. Ultrathin indium tin oxide has been also systematically investigated for high performance electronics with high on off rate and frequency response.

From the Top or through the Edge—What is the Most Scalable Contact to 2D Semiconductors? Aaron D. Franklin; Duke University, United States

The most common approach for establishing electrical contacts to 2D semiconductors, such as MoS2, is by fabricating metal contacts on top of the inert crystal surface. From an electron transport perspective, these top-contact interfaces can be awkward, with a van der Waals gap or some difficult-to-control form of interfacial bonding. Pure edge contacts (where the interface between the metal and 2D semiconductor occurs completely along the open bonds of the 2D crystal edge) provide a more natural bonding structure and potentially better carrier transport behavior; however, edge contacts have proven more difficult to realize. In this talk, recent success with establishing clean, pure edge contacts between metals and 2D semiconductors will be discussed, including an approach involving an in situ ion beam within a thin-film deposition system. Evaluation of these edge contacts compared to other approaches will be provided, along with demonstration of how edge-contact scaling affects the performance of 2D transistors compared to top-contact scaling. While there remains much to be learned about these interesting metal-2D edge interfaces, results thus far show significant promise for yielding a more scalable and potentially reproducible contact for 2D-based devices.

5:30 AM F.EN04.16.03
The Applications of 2D Monolayer-Based Atomristors in Non-Volatile Memory, RF Switches and Neuromorphic Computing Xiaohan Wu, Ruijing Ge, Myungsoo Kim, Deji Akinwande and Jack Lee; The University of Texas at Austin, United States

With the ever-increasing demand for new memory technologies, tremendous efforts have been made to develop non-volatile, high-density, fast-operation and flexible memory devices. To continue scaling and reducing cell size, our future towards high-density and flexible memory would be made up of cells with 2D materials. On the other hand, as the devices continue to scale down, the time and energy spent transporting data across "Von-Neumann bottleneck" between memory and processor has become an unavoidable issue, which is believed to be resolved by non-Von Neumann computing system as in human brain. In the last few years, the scaling of dense non-volatile memory crossbar arrays, which has few-nm critical dimensions, has been recognized as one promising way to build the neuromorphic computing system that can mimic the massive parallelism and low-power operation in the human brain. In our work, we reported the observation of non-volatile resistive switching (NVRS) effect in various single-layer atomic sheets, including transition metal dichalcogenides (TMDs) and hexagonal boron nitride (h-BN) atomic sheets which can be labeled as "atomristor" - memristor effect in atomically thin nanomaterials. The atomristors in vertical metal-insulator-metal (MIM) device structure are fabricated using CVD-grown or high-quality exfoliated TMDs and h-BN with various process realization techniques. The memory devices show low switching voltage (down to < 1V), high on/off current ratio (up to ~ 6 orders of magnitude), fast switching speed (< 15ns) and good endurance and retention. What"s more, the intrinsic low resistance values, approaching ~5?, opens up a new application for low-power non-volatile electronic RF switches. With the utilization of MoS2 and h-BN atomristors, the RF switches can be realized with low insertion loss (< 0.2dB) and high isolation (> 15dB) up to 110 GHz. Importantly, the operating frequencies cover the RF, 5G and mm-wave bands, which is suitable for diverse communication and connectivity front-end systems. In this work, the application of the atomristors in neuromorphic computing system will be presented and discussed. The energy consumption is expected to be minimized due to the fast switching speed. Moreover, as a result of the large on/off current ratio, more resistance states are committed to mimic the gradual analog-like change in neuromorphic computing. The discovery of atomristors indicates a potential universal phenomenon of non-volatile resistance switching in 2D monolayers, inspiring the in-depth study of the intriguing mechanisms. In addition, with the desired characteristics presented, the atomristors will stand out as a promising candidate in the applications of flexible electronics, non-volatile memory arrays, low-power RF switches and neuromorphic synapse.

5:40 AM F.EN04.16.05
Ultra-Low Off-State Leakage Current in Monolayer WS2 Transistors Connor Bailey, Ryan Grady, Victoria Chen and Eric Pop; Stanford University, United States

Two-dimensional (2D) semiconducting transition metal dichalcogenides (TMDs) are promising for next-generation electronics due to their layered structure and electrical properties. In particular, they can maintain good carrier mobilities compared to silicon at sub-nanometer thickness [1], making them attractive for digital or flexible electronics applications. Often overlooked is the fact that monolayer (1L) TMDs also have relatively large electronic band gaps and large effective masses [2], potentially enabling transistors with ultra-low off-state currents (Ioff). These could enable significant improvements in standby power consumption, or in dynamic random access memory (DRAM) where retention and performance are dependent on minimizing leakage currents. Ioff in exfoliated multilayer MoS2 [3], and more recently in chemical vapor deposition (CVD) grown monolayer MoSe2 and WSe2 [4] have been reported. However, WS2, which possesses the largest band gap and thus the lowest expected Ioff, has not been investigated. Here we measure, for the first time, record-low Ioff in CVD-grown monolayer WS2 transistors. We first grow such layers directly on amorphous SiO2/Si substrates by CVD utilizing a perlyene-3,4,9,10 tetracarboxylic acid tetrapotassium salt (PTAS) seeding molecule alongside

solid sulfur and WO3 precursors [5]. Material quality was characterized using Raman spectroscopy and photoluminescence (PL), confirming monolayer uniformity. We note that the PL (optical) band gap of monolayer WS2 is ~1.9 eV but its electronic band gap (on SiO2) is ~2.4 eV [6], due to the large exciton binding energy in 2D semiconductors. Back-gated field-effect transistors (FETs) were fabricated using electron-beam lithography with channel lengths down to L ? 100 nm. Au contacts were used and devices were capped with ~15 nm Al2O3 by atomic layer deposition (ALD) to improve stability and hysteresis [7]. In order to avoid the noise floor of our instrumentation when measuring the true off-state leakage, ultra-wide FETs were fabricated with an interdigitated structure resulting in widths up to W = 2275 ?m. These ultra-wide FETs enabled our measurement of Ioff down to ~10 aA/?m at drain bias of VDS = 0.1 V in a device with channel length L = 250 nm. At higher drain bias, we measured Ioff as low as 15 aA/?m in a FET with L = 750 nm at VDS = 1 V, i.e. an average lateral field > 1 V/?m. In both devices, on/off current ratios were >1010, demonstrating viability for memory and power gating applications which require ultra-low leakage transistors. In comparison, silicon transistors have off-state leakage more than three orders of magnitude higher [8]. In summary, we demonstrated the first measurements of "true" off-state leakage current in monolayer WS2 transistors, reaching ~10 aA/?m with on/off current ratio ~1010. These represent the lowest currents measured to date in any monolayer semiconductor, particularly at lateral fields > 1 V/?m, and suggest significant advantages over silicon in ultra-low leakage applications such DRAM and power gating. Design Rules for Memories Based on Graphene Ferroelectric Field-Effect Transistors Kamal Asadi; Max Planck Institute for Polymer Research, Germany

Despite the great progress of ferroelectric gated field-effect transistors (Fe-FETs) based on graphene and other 2D materials, a device model that accurately describes the hysteretic transfer characteristics and provides guidelines on performance enhancement of the Fe-FET is still lacking. Here, we present an experimentally validated analytical model that couples charge displacement of the ferroelectric layer with the charge transport in the graphene layer. The model describes hysteretic transfer characteristics of the FeFETs with good accuracy and predicts that the on/off ratio of the graphene Fe-FET is determined by Dirac bias and the charge carrier mobility. We show unsuitability of an ideal graphene layer for memory application and outline the conditions to achieve the best memory performance in graphene Fe-FETs. Using the insight gained from the model, we theoretically and experimentally demonstrate ternary and quaternary graphene memory elements. The model is generic and can be equally well used for Fe-FETs based on other 2D materials.

SESSION F.EN04.17: New Developments in Mg Batteries
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-EN04

5:00 AM F.EN04.17.01
How Promising are Rechargeable Mg Batteries? A DFT Study on Li and Mg Intercalation in MXene Electrodes Jacob Hadler-Jacobsen[1], Frode H. Fagerli[1], Henning Kaland[1], Zhaohui Wang[1,2], Sverre M. Selbach[1], Kjell Wiik[1], Nils Wagner[1,3] and Sondre Kvalvåg Schnell[1]; [1]NTNU Norwegian University of Science and Technology, Norway; [2]SINTEF Industry, Metal Production and Processing, Norway; [3]SINTEF Industry, Sustainable Energy Technology, Norway

Rechargeable Mg batteries present a “beyond lithium-ion” technology with high theoretical energy density and a comparatively small susceptibility for dendrite formation[1,2]. However, rechargeable Mg batteries suffer from slow migration and irreversible trapping of Mg ions in most cathode materials.

The MXene family is a group of electronically conductive 2D materials which have been investigated as electrode material for both Mg and Li batteries. Here, DFT is used to assess the voltage, specific capacity and migration barriers for Li and Mg ions in MXenes with compositions V_2CO_2, V_2CF_2, $V_2C(OH)_2$, $Ti_3C_2O_2$, $Ti_3C_2F_2$ and $Ti_3C_2(OH)_2$ as reported in our recent work[3]. Bader charge analysis and ionization energies are used to understand the differences in performance. Guidelines for MXene electrode design and views on how to best overcome the fundamental challenges with divalent battery chemistries are presented.

Local Atomic and Electronic Structure's Influence on Migration Along Li and Mg Surfaces Ingeborg Treu Roee, Sverre Magnus Selbach and Sondre Kvalvåg Schnell; Norwegian University of Science and Technology, Norway

Dendrite formation on Li metal anodes leads to reduced Coulombic efficiency, poor cycling stability and short-circuiting, and prevents commercialization of high energy density rechargeable Li metal batteries. The migration energy barrier for transport along the metal surface can describe the tendency of the surface to form dendrites. Density functional theory calculations of the migration energy barrier show inherent differences in transport properties between Li and Mg[1], which may explain the higher propensity of Li to form dendrites compared to Mg[2]. We use density functional theory to show that differences in the atomic and electronic structure of the Li and Mg surface lead to different migration energy barriers[3]. The atomic and electronic surface structure of Li and Mg are in turn affected by the bulk crystal structure, the atomic and electronic structure of the substrate, and surface impurities. We investigate how and why these factors impact the migration energy barrier to shed light on the mechanisms of dendrite formation on the metal anodes. Thus, we may guide the development of dendrite-free metal anodes for battery applications.

5:20 AM F.EN04.17.05
Surface Termination Control of Two-Dimensional MXenes for Rechargeable Magnesium Battery Cathodes Frode H. Fagerli[1], Henning Kaland[1], Jacob Hadler-Jacobsen[1], Zhaohui Wang[1,2], Sverre M. Selbach[1], Tor Grande[1], Nils Wagner[1,2] and Kjell Wiik[1]; [1]Norwegian University of Science and Technology, Norway; [2]SINTEF Industry, Norway

Rechargeable Mg batteries have the potential to take advantage of Mg metal anodes, as they are less prone to dendritic growth compared to Li metal [1]. This leads to the possibility of having high capacity batteries based on Mg-ions, with competitive energy density and materials cost compared to the state-of-the art Li-ion batteries [2]. However, this requires a cathode material that allows for reversible reactions with significant amounts of Mg-ions at a sufficiently high operating potential. Since the first prototype of a rechargeable Mg battery was reported in 2000 [3], only a limited number of cathode materials have been demonstrated to work reversibly, and the energy density has not been sufficient to compete with Li-ion battery technology [2]. In this project, we have investigated the possibility of using two-dimensional MXenes as possible cathode materials for rechargeable Mg batteries, based on their previously reported ion intercalating properties [4,5]. Here, we present the synthesis and surface modification of two MXenes, $Ti_3C_2T_x$ and V_2CT_x (T = F, O or OH), in order to optimize the possibility for Mg-intercalation by increasing the O terminations [6]. Various methods, such as hydrolysation and vacuum annealing, were used to shift the surface terminations towards more oxygen content, where EDX and XPS were used to quantify the different termination groups. The surface modified MXenes demonstrate more promising electrochemical performance compared to the pristine MXene, which is assigned to the improved properties of the O-terminated surfaces.

5:30 AM F.EN04.17.07

Late News: A Computational Comparison of Ca-Ion Battery Electrolytes—Tetrahydrofuran vs Ethylene Carbonate Diana Liepinya[1,2] and Manuel Smeu[2]; [1]University of Maryland, United States; [2]Binghamton University, The State University of New York, United States

Secondary batteries are crucial to contemporary life, powering everything from personal electronics to electric vehicles. The growth of these technologies has led to an unprecedented demand for rechargeable batteries, a market currently dominated by Li-ion batteries. Despite its high performance, Li-ion is an unideal candidate for meeting this growing demand due to the scarcity of its component elements, resulting in higher costs and an inflexible supply chain. Ca-ion batteries would avoid these issues while providing higher volumetric energy density and the potential for improved safety through suppressed dendrite growth. However, their development is limited by a lack of suitable electrolytes. Many electrolytes decompose to form an impermeable layer at the anode, preventing plating and stripping and compromising the cyclability of the battery. Our work aims to elucidate the reactions occurring at the electrolyte-anode interface, which will allow for more informed Ca-ion battery electrolyte selection.

As a starting point for this analysis, we use *ab initio* molecular dynamics (AIMD) to simulate several anode-electrolyte systems. Motivated by recent successes in reversible Ca-ion plating and stripping, tetrahydrofuran (THF) is selected as one of the solvents. We contrast THF with ethylene carbonate (EC), a successful Li-ion solvent and popular choice for Ca-ion battery experiments. In addition to pure solvent, we also investigate 1.2 M solutions of four different salts ($Ca(BH_4)_2$; $Ca(BF_4)_2$; $Ca(BCl_4)_2$; and $Ca(ClO_4)_2$) in each solvent for a total of ten AIMD trajectories. Over a 15 ps trajectory at 450 K in the presence of a Ca anode, pure THF was found to be non-reactive, while pure EC decomposed soon upon contact with the anode. Preliminary results have shown that similar behavior persists upon addition of salt molecules. We supplement these trajectories with density functional theory (DFT) calculations of electronic structure and reaction barriers as well as charge analysis over time. Lastly, we include a final simulation to test the reactivity of THF while gradually adding electrons to the Ca-THF system, reflecting the changes in anode charge during battery cycling. Our multifaceted characterization will both illuminate past experiments' results as well as guide new research, shedding light on a major obstacle in the development of Ca-ion batteries.

SESSION F.EN04.18: Li-Sulfer Batteries

F-EN04

5:00 AM F.EN04.18.01
Lithium Deposition in Lithium-Sulfur Batteries Stabilized by Tellurium as a Cathode Additive Sanjay Nanda, Amruth Bhargav and Arumugam Manthiram; University of Texas-Austin, United States

The lithium-metal anode is the main factor constraining the cyclability of energy-dense lithium-sulfur batteries. The irreversible plating and stripping of lithium in the liquid ether-based electrolyte engenders poor cycling efficiencies and severe parasitic side reactions with the electrolyte. Under conditions of limited lithium inventory and limited electrolyte supply, which are necessary for practically relevant cell designs, this leads to rapid capacity fade and premature cell failure. Commercially viable Li-S batteries with high energy density and long cycle life can only be realized by designing strategies towards stabilizing lithium deposition and reducing electrolyte decomposition.

The generation of soluble polysulfide intermediates that shuttle between the sulfur cathode and the lithium-metal anode renders the chemistry of Li-S batteries fundamentally unique compared to other systems. They transform the chemistry of the lithium-electrolyte interface by reducing on the lithium surface and forming lithium sulfide (Li_2S) and lithium disulfide (Li_2S_2) as components of the SEI layer. These species have been observed to have a unique stabilizing effect on lithium deposition, which is intrinsic to Li-S batteries. This suggests that tuning polysulfide species with other elements or functional groups could be a potential pathway towards further stabilization of lithium deposition in this system.

We discovered that elemental tellurium (Te^0) reacts with ethereal solutions of polysulfides to form mixed *polytellurosulfide* species that are also soluble in the ether-based solvent. On the reducing surface of lithium metal, these polytellurosulfide species decomposed to form red-colored lithium thiotellurate (Li_2TeS_3). As a lithium SEI component, Li_2TeS_3 is anticipated to enable a homogenous lithium-ion flux on the lithium surface, thereby leading to uniform plating of lithium. This is due to the lower diffusion barrier for lithium ions through Li_2TeS_3 when compared with Li_2S, as the electron

density around sulfur is significantly softened when bonded with tellurium.

When Te^0 was added to sulfur/Li_2S cathodes in a 1:10 molar ratio, polytellurosulfide species were generated *in-situ* during cell operation by the reaction of polysulfides with Te^0 additive. These species crossed over to the lithium anode and formed Li_2TeS_3 as a thin interfacial layer on the lithium surface. The favorable properties of this tellurized, sulfide-rich SEI allows lithium to be deposited without undesirable high-surface area mossy/dendritic growths. With a limited lithium inventory (N/P ratio = 1) in an anode-free full cell, which combines a fully-lithiated Li_2S cathode with a bare Ni foil current collector on the anode side, the enhancement in lithium cycling efficiency with the addition of Te^0 drastically reduced capacity fade per cycle by a factor of 7.

It was also found using time-of-flight secondary ion mass spectroscopy (ToF-SIMS) that electrolyte decomposition on the lithium surface was significantly mitigated with the addition of tellurium to the cathode. This enabled the limited electrolyte supply to be maintained for a longer number of cycles. Under lean-electrolyte conditions (E/S ratio = 4.5 µl mg^{-1}) in large-area pouch cells employing a high-loading sulfur cathode (5.2 mg cm^{-2}), tellurium-stabilized lithium deposition allowed the cell to be stably operated for nearly 100 cycles. This was a nearly four-fold improvement over the control cell with no additive.

A unique and reliable strategy for stabilizing lithium deposition and reducing electrolyte decomposition in Li-S batteries is demonstrated. This is achieved by a simple and scalable addition of elemental tellurium to the cathode. The stabilizing layer is formed *in-situ* during cell operation and no expensive or complicated pre-treatments of the lithium surface are required. Importantly, a pathway for commercially viable Li-S batteries with high energy density and long cycle life is realized.

5:10 AM F.EN04.18.03
Sulfur-Inserted Polymer-Anchored Edge Exfoliated Graphite for High Performance Lithium-Sulfur Batteries Nanami Uesugi[1], Natsuho Kazahaya[1], Hiroshi Yoshitani[2], Takuya Wada[2], Hiroji Fukui[2], Yu Katayama[1] and Hiromori Tsutsumi[1]; [1]Yamaguchi University, Japan; [2]Sekisui Chemical Co., Ltd., Japan

Lithium-sulfur batteries hold promising potential for next-generation high-energy-density energy storage. One of their major technical problems is the loss of sulfur active material and its significant volume change during the charge-discharge process, resulting in rapid capacity fading. Here, we introduce sulfur-inserted polymer-anchored edge exfoliated graphite as a new class of positive electrode, which can accommodate the conflicting requirement of physically restrain sulfur dissolution while maintaining structural flexibility to cope with the volume expansion.
The introduction of sulfur between the flexible polymer-anchored graphene layer is achieved by a simple chemical reaction at ambient temperature. The obtained sulfur-carbon composite demonstrates superior sulfur efficiency and cyclability compare to mesoporous carbon-based counterparts. The strong interfacial attraction between sulfur and highly-conductive graphene sheet at the confined interlayer space enables (1) rapid charge transfer and (2) effective inhibition of the polysulfide dissolution, resulting in improved redox reaction reversibility and sulfur efficiency. Furthermore, the structural flexibility of layered structure, derived from polymer-anchor, guarantees the stable cycling by accommodating the significant volume expansion of sulfur active materials.
Therefore, our work provides a simple, proof-of-concept strategy for improving the overall performance of carbon-based positive electrode for lithium-sulfur batteries.

5:20 AM F.EN04.18.04
Preparation and Evaluation of Polymer Electrolytes with Low-solubility of Lithium-polysulfide for Li-S Batteries Hibiki Miyauchi, Kohei Inaba, Keitaro Takahashi and Shiro Seki; Kogakuin University, Japan

Introduciton
Lithium-Sulfur (Li-S) batteries are attracting attention as high energy density rechargeable battery. Elemental sulfur (S_8) have high theoretical capacity (1,672 $mAhg^{-1}$) as positive electrode active material. However, S_8 electrode is degraded by redox shuttle effect of lithium-polysulfide (Li_2S_n), which are generated during charge-discharge reactions. To solve this problem, many electrolyte designs were proposed. As one of many designs, sulfolane (SL) based high Li salt concentration electrolyte solution was reported as low solubility electrolyte of Li_2S_n [1]. The aim of this concept is chemically protection of Li_2S_n dissolution into electrolyte solution. Therefore, we proposed new polymer electrolyte, which protects chemically and physically dissolution and diffusion of Li_2S_n. In this study, we prepared SL based solid gel polymer electrolytes (GPEs), and thermal and ionic conductive properties of the samples were evaluated. Furthermore, Li-S batteries containing GPEs were prepared and evaluated by charge-discharge measurements.

Experimental
Sulfolane (SL), $LiN(SO_2CF_3)_2$ (LiTFSA), and polyether-based P(EO/PO) macromonomer were used as electrolyte materials for GPEs. First, electrolyte solution samples were prepared by mixing LiTFSA and SL at each molar ratio of SL : LiTFSA = x : 1 (x=1, 1.5 and 2, respectively). Next, prepared electrolyte solution and P(EO/PO) macromonomer were mixed at each weight ratio of electrolyte solution : polymer = y : (10-y) (y=7, 8 and 9, respectively), and added DMPA as photo initiator. After that, these materials were radical polymerized by UV irradiation. In this research, GPEs are expressed as (x),yEl+(10-y)Po. Thermal property and ionic conductivity of prepared GPEs were investigated by TG-DTA, DSC and AC impedance measurements.

Results & Discussion
First, in TG-DTA, TG curves of all GPEs were exhibited 3 step weight trends of decreasing. First weight decreasing observed the range of 380 K to 490 K, which might due to evaporation or decomposition of SL. From first weight decreasing, thermal stability was improved with Li salt concentration and electrolyte solution amount. Therefore, a part of Li^+ should be changed coordination site from SL to P(EO/PO).
Next, from impedance measurements, obtained ionic conductivity (σ) showed non-Arrhenius type temperature dependence with all GPEs. All GPEs exhibited high σ compared with genuine solid polymer electrolyte (mixture of P(EO/PO) and LiTFSA) within a range of 244 K to 353 K. (2),9El+1Po sample observed relatively high σ (4.0×10^{-4} Scm^{-1}) at 303 K. σ increased with decrease of Li salt concentration (inverse of x). Also, σ increased with electrolyte solution composition (y) at low temperature region. Therefore, ionic transport mechanism and thermal property should be affected by Li salt concentration and electrolyte solution amount into GPE.
In presentation, charge-discharge properties of Li-S batteries containing GPE will be also discussed.

Pushing Zinc–Air to Outperform Lithium-Based Batteries Brandon J. Hopkins, Christopher Chervin, Jeffrey Long, Debra Rolison and Joseph Parker; U.S. Naval Research Laboratory, United States

Electrically rechargeable zinc–air may achieve higher rechargeable specific energy than Li-ion batteries, but today's air cathodes limit zinc–air performance. To overcome this challenge, researchers have investigated hundreds of air-cathode variations. Unfortunately, the efficacy of these variations remains ambiguous due to non-standardized cycling protocols. We show using a meta-analysis of 100 zinc–air cells that reported areal-energy values span five orders of magnitude. Based on an analytical model we present here, researchers should cycle zinc–air cells at 35 mWh cm_{geo}^{-2} to compete with lithium-ion and 240 mWh cm_{geo}^{-2} to compete with lithium–air. Once the community cycles zinc–air cells at relevant areal-energy values and understands failure mechanisms, lab-scale results will translate to practical advancements.

High-Performance Zinc-Air Batteries Realized by Apically Dominant Mechanism Controlled N-Doped Carbon Nanotube Arrays Zhao Li, Wenhan Niu and Yang Yang; University of Central Florida, United States

Presently, nitrogen-doped carbon nanotube (NCNT) has been widely considered as one of the promising carbon materials replacing the platinum group metal catalysts in energy conversion and storage technologies. It has been essentially concentrated on rational design of NTCNT to overcome the generalized limitations of hydrophobic surface and base-growth model for the enhancement of catalytic performance in renewable energy devices such as zinc-air battery (ZAB). Here, the we demonstrated a concept of an apically dominant mechanism controlled NCNT, encapsulating CoNi nanoparticles (CoNi@NCNT) as highly efficient catalysts for ZAB. Density functional theory calculations reveals that the outstanding catalytic performance of CoNi@NCNT can be ascribed to the synergetic contributions from the apical active sites nearby CoNi and NCNT. Remarkably, the ZAB using CoNi@NCNT as air electrode exhibits an excellent battery performance with

a power density of 127 mW cm^{-2} and energy density of 845 Wh kg_{zn}^{-1}.

Importance of Equilibration Method and Sampling for *Ab Initio* Molecular Dynamics Simulations of Solvent - Lithium Salt Systems in Lithium Air Batteries Emily J. Crabb[1], Arthur France-Lanord[1], Graham Leverick[1], Ryan Stephens[2], Yang Shao-Horn[1] and Jeffrey C. Grossman[1]; [1]Massachusetts Institute of Technology, United States; [2]Shell International Exploration & Production Inc., United States

Lithium-air batteries are an active area of research because of their potential to have a much higher energy density than traditional lithium-ion batteries. However, they are not yet commercially viable due to poor efficiency, high charging voltages, and low cycle lifetimes. Many of these issues could be addressed with a deeper fundamental understanding of the atomistic behavior of these batteries. One tool to model such atomic scale behavior is ab initio molecular dynamics (AIMD) simulations. However, AIMD simulations are limited to timescales of tens of picoseconds due to their high computational cost. As a result, equilibration and sampling methodologies can have a significant effect on the behavior of AIMD simulations. We thus compared two equilibration methods for AIMD simulations of systems of common solvents and salts found in lithium air batteries: (1) using an AIMD temperature ramp and (2) using a classical MD simulation followed by a short AIMD simulation all at the target simulation temperature of 300 K. We also compared two different classical all-atom force fields (PCFF+ and OPLS) and performed multiple simulations for each system. In this presentation, I will discuss how the differences between our simulation results and experimental results for properties such as coordination number illustrate the importance of both equilibration method and independent sampling for extracting experimentally relevant quantities from AIMD simulations.

5:30 AM F.EN04.19.05
Ion-Selective Separators in Alkaline Zinc Batteries for Grid Storage Applications Igor V. Kolesnichenko[1], Matthew Lim[1], David J. Arnot[1], Elijah I. Ruiz[1], Gautam G. Yadav[2], Michael Nyce[2], Sanjoy Banerjee[2] and Timothy N. Lambert[1]; [1]Sandia National Laboratories, United States; [2]The City College of New York, United States

Rechargeable alkaline Zn–MnO_2 batteries are a promising candidate for grid-level energy storage owing to their high theoretical energy density rivaling Li-ion systems (~400 Wh/L), safe aqueous electrolyte, established supply chain, and projected costs as low as $50/kWh at scale.[1] Unfortunately, due to inherent issues at both electrodes, the goal of a Zn–MnO_2 battery with long lifetime (5000+ cycles, equating to 10-15 years of service life) at appreciable energy densities (200+ Wh/L) has not yet been achieved. Over repeated cycling at high capacity utilization, Zn anodes suffer from irreversible redistribution of active material and passivation, while MnO_2 cathodes suffer from irreversible breakdown of the crystal structure and formation of inactive phases.

To mitigate anode degradation, we recently showed that pre-saturating the electrolyte with zincate $[Zn(OH)_4]^{2-}$, which is the soluble discharge product of the anode, improved cycle life of Zn–Ni cells by 100-200% at 14-35% Zn utilization.[2] However, this strategy alone cannot be used with MnO_2 cathodes because zincate reacts with Mn(III) species to irreversibly form $ZnMn_2O_4$, which is insulating and electrochemically inactive. Conventional cellophane and polyolefin separators used in alkaline batteries have no ability to block zincate from migrating to the cathode, whereas ceramic conductors such as NaSICON, which we previously studied in limited-depth-of-discharge Zn–MnO_2 batteries,[3] are impervious to zincate but are thick, brittle, and less conductive overall, limiting their utility.

To address this issue, this presentation will discuss various aspects of our efforts to develop flexible polymeric separators that selectively impede zincate transport without sacrificing overall conductivity. We have synthesized freestanding membranes of polymers incorporating charged functional groups, as well as thin films of ion-selective polymers on commercial separator materials. Using a rapid anodic stripping voltammetry assay,[4] our separator materials show a strong selectivity for hydroxide over zincate transport, while maintaining comparable ionic conductivity to commercial battery separators. Most importantly, our selective separators impart significant performance improvements to both Zn–Ni cells and Zn–MnO_2 cells with Bi/Cu-stabilized cathodes[5] that can be cycled at or near the full two-electron capacity of MnO_2 (617 mAh g^{-1}). Notably, Zn–Ni cells show a 460+% and 115+% increase in cycle life at substantial Zn utilizations of 20% and 50% respectively. In Zn–MnO_2 cells, our separators not only slow down zincate poisoning of MnO_2 but also hinder growth of zinc through the separator pores, which can lead to shorting.

Proposal of High Li Salt Concentration Solvate Ionic Liquid / PEO Matrix Solid-Gel Electrolytes for Keitaro Takahashi, Hibiki Miyauchi, Yuji Yokomaku, Yusuke Ushioda and Shiro Seki; Kogakuin University, Japan

Introduction
Lithium-sulfur (Li-S) batteries are attracted attention as new secondly battery system. The sulfur positive electrode of this system have theoretical capacity of 1672 $mAhg^{-1}$, which shows approximately 10 times higher than conventional Li-ion battery positive electrode material ($LiCoO_2$). A problem of the Li-S batteries is dissolution of sulfur component of positive electrode, which reached as state of reaction intermediate (Li_2S_m: m=2~8) into electrolyte during charge / discharge processes. The dissolution and diffusion of Li_2S_m into electrolyte solution lead significant degradation of cycle characteristics and irreversible side reaction of Li-S batteries. Currently, as functional electrolyte solution that suppresses dissolution of Li_2S_m, "Solvate Ionic Liquid (SIL)" has been proposed [1]. We propose further functional SIL electrolyte for high performance Li-S battery. In order to exhaustive suppress to dissolve/diffuse of Li_2S_m into electrolyte, and we investigated the increase of salt composition in the SIL electrolyte and the solidification by introducing polymer matrix.

Experimental
In this study, all procedures of sample preparation were conducted in an argon-filled glovebox. At first, as highly concentrated SILs, $[Li_a(G4)_1]TFSA_a$ (a = 1 and 1.25) (G4 : CH_3-O-$(C_2H_4O)_4$-CH_3, LiTFSA: $LiN(SO_2CF_3)_2$ = 1 : a) were prepared [2]. Gel electrolyte were prepared by mixing of SILs (a = 1, 1.25), polyether-based P(EO/PO) macromonomer and photo initiator. Composition ratio of gel electrolyte were SILs : polymer = 7 : 3, 8 : 2, 9 : 1 (wt%), respectively. After stirring, samples casted to glass substrate and polymerized by UV irradiation to obtain thin-films, which was transparent and self-standing gel electrolyte films. Prepared electrolyte films ware evaluated by differential scanning calorimetry (DSC) and AC impedance measurements.

Result and discussion
Thermal properties of prepared SILs and gel electrolytes were measured by DSC. For the results, all electrolytes exhibited glass transition temperatures (T_gs). T_g of SIL electrolytes was shifted high temperature with Li salt concentration in electrolyte. Gel electrolyte showed lower T_g than that neat polymer electrolyte (without SIL). From the results, it was considered that mobility of PEO chain was increased by SIL electrolyte solutions. With increasing SIL amount into the gel electrolyte, T_g appeared low temperature side, and therefore, the gel electrolyte with high SIL composition should indicate high ionic conductivity.
Prepared SILs and gel electrolyte was measured dependence temperature of ionic conductivity (s) by AC impedance method. Owing to increase of viscosity with Li salt concentration, s value of high Li salt composition SIL electrolyte (a=1.25) was lower than equimolar SIL (a=1). At 303 K, s of $[Li_1(G4)_1]TFSA_1$: polymer = 8 : 2 electrolyte was 1.5×10^{-3} Scm^{-1}, which was almost same s value with SIL electrolyte solution. Generally, the introduction of polymer matrix in electrolyte solution should suppress the diffusion of Li^+. However, our result exhibited another result.
Gel electrolyte of $[Li_1(G4)_1]TFSA$: polymer = 8 : 2 was applied for charge/discharge test in Li-S cell. The Li-S battery using the equimolar SIL of gel electrolyte was confirmed first discharge capacity of 1,100 $mAhg^{-1}$. However, this system showed

unstable voltage profiles during charge process, and this charge capacity exhibited larger than that discharging capacity. From the unstable and large voltage in this charging process, Li_2S_m dissolution into gel electrolyte and side reactions were estimated. This result correlates with the report of the co-migration of glyme molecule and breaking of Li complex cation with introduction of PEO matrix by NMR spectroscopy [3].

Solid-Electrolyte Interphases on Graphite Electrodes in Li- and K-Systems—A Comparison by Photoelectron Spectroscopy Fabian Jeschull, Franziska Allgayer and Julia Maibach; Karlsruhe Institute of Technology (KIT), Germany

The solid-electrolyte interphase (SEI) formed at the negative electrode in Li-ion batteries (LIB) is a passivation layer that prevents recurrent electrolyte decomposition reactions at the electrode-electrolyte interface.[1] The consumption of the charge carrier inventory due to these irreversible reactions are the origin of capacity fading and increasing internal resistances and ultimately reduce the cycle life of a cell.
For more than three decades the SEI layer of LIB has been characterized and optimized in order to arrive at the outstanding cycle life of high energy density, state-of-the-art LIB. A major contribution to its success is the graphite negative electrode that offers high reversibility, electrode potentials close to that of Li metal at a small volume expansion of the active material particles.[2] Post-Li systems might also benefit from the stability of graphite intercalation compounds and are therefore an interesting material choice for Na- (in ether-electrolytes)[3] and K-batteries[4] as well. However, their performance has not yet reached that of a corresponding Li-cell.[5]

Li- and K-systems are highly comparable because, despite the alkali metal ion, the same electrode and electrolyte formulations can be employed. A comparison between the graphite-electrolyte interface formed in a Li- and K-system, respectively, can thus allow valuable insights on how to work towards a more benign SEI layer formation in K-batteries. For this study, the surface compositions of graphite electrodes cycled in Li- or K-half cells was investigated post-mortem by in-house X-ray photoelectron spectroscopy (XPS). Our results show a comparatively high degree of crosstalk originating from the K-metal counter electrode and a different distributions of the characteristic decomposition products in presence of K- instead of Li-ions. The presentation will further discuss strategies to mitigate charge losses related to SEI layer formation on graphite electrodes as negative electrodes in K-ion batteries.

Synthesis and Electrochemical Properties of Na-ion Conducting Pseudo-Solid State Ionogel Electrolytes Ryan H. DeBlock[1], David Ashby[2], Grace Whang[1], Danielle Butts[1], Christopher Choi[1] and Bruce S. Dunn[1]; [1]University of California, Los Angeles, United States; [2]Sandia National Laboratories, United States

Ionogels are pseudo-solid state electrolytes in which an ionic liquid electrolyte confined in a mesoporous inorganic matrix leads to a material that possesses the electrochemical, thermal and chemical properties of the ionic liquid despite being a macroscopic solid. Because of their unique architecture, ionogels maintain a nanoscale fluidic state and thus mitigate the interfacial resistances which commonly arise at solid-solid interfaces. The use of sol-gel synthesis enables the materials to be prepared as liquids and to penetrate porous electrodes before becoming solid, an especially beneficial property for solid-state batteries. The incorporation of Li-ion conducting ionogel electrolytes into Li-ion batteries has been reported previously and

generally show behavior comparable to that of the ionic liquid electrolyte.

In this work, we report on the development of Na-ion conducting ionogels, a topic which has received only limited investigation to date. We use sol-gel synthesis to form a siloxane-modified silica scaffold that traps an ionic liquid electrolyte comprised of 0.5M NaFSI in 1-Butyl-1-methylpyrrolidinium bis(trifluoromethanesulfonyl)imide [PYR14][TFSI]. The low vapor pressure of the ionic liquid ensures that a dense gel is formed. The interconnected porosity allows for good ionic conductivity (0.7 mS cm^{-1}), although it is somewhat less than the corresponding ionic liquid electrolyte. The activation energy for conduction of 0.3eV is, as expected, higher than that of Li-ion conducting ionogels. The material possesses a 5V electrochemical window and is thermally stable up to 150°C. Using the positive Na-ion electrode material, $Na_3V_2(PO_4)_3$, the charge transfer properties of the ionogel/NVP interface were characterized and found to exhibit low interfacial impedance. This led us to demonstrate the operation of a Na-ion solid state battery which contained a $NaTi_2(PO_4)_3$ negative electrode in conjunction with the NVP. The results shown here underscore the versatility of ionogels as a thermally stable electrolyte with designed ion transport properties for use in future solid-state electrochemical devices

5:35 AM F.EN04.20.05
Molecular-Level Insights of Coupled Aluminum-Ion Intercalation and Charge Transfer Mechanism into Chevrel Phase Electrodes Using Solid-State NMR Spectroscopy Ankur Jadhav, Jeffrey Xu and Robert J. Messinger; The City College of New York, United States

Rechargeable aluminum metal batteries have seen a resurgence of interest as an emerging energy storage technology. Aluminum (Al) is low cost, inherently safe, and the most abundant metal in the earth's crust. Despite these opportunities, technological development of rechargeable aluminum batteries has been hindered due to lack of cathode materials that permit reversible transport of aluminum ions, mainly due to high Coulombic charge on aluminum cations rendering solid-state diffusion of aluminum ions difficult into crystalline materials.
The chevrel phases Mo_6X_8 (X= S, Se) are among the few materials known to electrochemically intercalate multitude of multivalent ions, including trivalent aluminum cations. Thus, understanding the ion intercalation and charge transfer mechanism within this unique structure may provide insights into the design of new intercalation electrodes for rechargeable aluminum-ion batteries. Here, electrochemical and multi-nuclear solid-state nuclear magnetic resonance (NMR) measurements of aluminum-ion intercalation into the chevrel Mo_6S_8 are correlated and quantitatively analyzed, revealing new insights into the ion intercalation mechanism. Solid-state ^{27}Al NMR measurements reveal aluminum ions in two different environments associated with distinct cavities in the chevrel framework. Quantitative analyses of their relative populations establish that they reversibly (de)intercalate into the cavities simultaneously, as opposed to sequentially, upon discharge (charge).
In addition, for Mo_6Se_8 electrodes, we perform ex-situ ^{77}Se and ^{95}Mo Hahn-echo NMR measurements along with single-pulse ^{27}Al NMR at charged and discharged states to probe the crystalline frameworks to experimentally determine the charge transfer mechanism during the intercalation process. Replacing S with Se in the chevrel phase Mo_6X_8 (X=S, Se) enables use of ^{77}Se and ^{95}Mo NMR which reveal changes in the chemical shift of only the ^{77}Se NMR signal suggesting that the electrons prefer going to the Se atoms rather than the Mo atoms, unlike traditional transition metal oxide cathodes where the electrons are stored within the d-orbitals of the transition metal. Thus, for the first time, we demonstrate reversible electrochemical anionic redox as a charge storage mechanism for rechargeable batteries, which preserves the crystalline framework structure and does not involve the breaking and forming of chemical bonds.
Overall, the results yield quantitative molecular-level understanding of aluminum ion intercalation and charge transfer mechanism in a model crystalline transition metal electrode and establish solid-state ^{27}Al NMR as a powerful characterization tool for rechargeable aluminum-ion batteries.

Self-Assembled Nanostructures in Ionic Liquids Facilitate Charge Storage at Electrified Interfaces Xianwen Mao[1] and T. Alan Hatton[2]; [1]Cornell University, United States; [2]Massachusetts Institute of Technology, United States

Driven by the potential applications of ionic liquids (ILs) in many emerging electrochemical technologies, recent research efforts have been directed at understanding the complex ion ordering in these systems, to uncover novel energy storage mechanisms at IL/electrode interfaces. Here, we discover that surface-active ionic liquids (SAILs), which contain amphiphilic structures inducing self-assembly, exhibit enhanced charge storage performance at electrified surfaces. Unlike conventional non-amphiphilic ILs (NAILs), for which ion distribution is dominated by Coulombic interactions, SAILs exhibit significant and competing van der Waals interactions owing to the nonpolar surfactant tails, leading to unusual interfacial ion distributions. We reveal that at an intermediate degree of electrode polarization SAILs display optimal performance, because the low-charge-density alkyl tails are effectively excluded from the electrode surfaces, whereas the

formation of nonpolar domains along the surface suppresses undesired overscreening effects. This work represents a crucial step towards understanding the unique interfacial behavior and electrochemical properties of amphiphilic liquid systems showing long-range ordering, and offers insights into the design principles for high-energy-density electrolytes based on spontaneous self-assembly behavior. 5:55 AM *F.EN04.20.07
Solid State Electrolyte and Interface Design from Multiscale Mechano-Electrochemical Interactions Xin Li; Harvard University, United States

Different from commercial liquid electrolyte batteries, where multiple interfaces can react under no mechanical constriction, the close contact between electrolyte particles and between electrolyte and electrode particles enforces a local mechanical constriction inside these particles as well as on their interfaces. Our work shows how such mechanical constriction effect can modulate battery performances at the material particle, interface coating and device levels. Design principles for advanced solid state batteries based on various types of solid electrolytes and advanced electrodes will be discussed, including sulfide, halide, oxide electrolytes, high voltage cathodes and the lithium metal anode.

6:10 AM *F.EN04.20.09
Halide-Based Solid-State Batteries—Electrolyte, Stability, Interface and Electrode Xueliang A. Sun; University of Western Ontario, Canada

All-state-state lithium batteries (ASSLBs) have gained worldwide attention because of intrinsic safety and increased energy density. Compared with other types of solid-state electrolytes including oxide-based, polymer-based and sulfide-based electrolytes, recently-developed halide-based solid-state electrolytes (SSEs) have garnered considerable attention for all-solid-state lithium batteries (ASSLBs) due to the high ionic conductivity, high oxidation voltage and good stability toward oxide cathode materials [1]. However, there are still many challenges in halide-based solid-state electrolytes for ASSLBs including controllable and mass-production synthesis, achieving high humidity tolerance and demonstrate high-performance of ASSLBs; in particular, increased understanding of mechanisms during synthesis and tuning their properties of the electrolytes as well as interface with electrode materials[1].

In this talk, **(i)** I will demonstrate synthesis strategy [2-3], in particular, new and salable water-mediated synthesis method [2]. **(ii)** I will report a systematic study on the correlations among structural evolution, Li^+ migration properties, and humidity stability resulting of the halide-based electrolytes, along with in-situ characterization for understanding of the mechanisms [4], **(iii)** Full cell battery performance will be optimized [5], **(iv)** humidity ability [6] and **(v)** other applications such as Li-O2 batteries [7]. In the end, energy densities of ASSLBs using different solid-state electrolytes in ASSLBs will be discussed.

6:25 AM F.EN04.20.10
Chemo-Mechanics of Alkali-Ion Intercalation into Iron Phosphate Composite Cathodes Bertan Ozdogru, Hannah Dykes, Darrell Gregory and Omer O. Capraz; Oklahoma State University, United States

Sodium-ion and potassium-ion batteries have attracted attention in the search for cost-effective batteries with a minimum sacrifice on the performance. Similar to Li-ion batteries, performance of these batteries depends on mechanical integrity of the cathodes and interfacial stability associated with solid-electrolyte interface formation. However, larger alkali metal-ions are expected to cause greater volumetric changes and lattice distortions in the cathode structure. Even small changes in volume upon alkali metal-ion intercalation can cause particle fracturing in brittle cathode materials. Also, diffusion of these larger alkali metal ions is slower in the electrode matrix due to their larger ionic size, compared to the Li ions. Therefore, it is expected that Na-ion and K-ion cathodes experience more mechanical instabilities at faster scan rates due to diffusion-limited ion transport. Understanding the interplay between alkali-ion chemistry, structural stability and electrochemical performance of cathode materials is crucial to develop novel cathode structures, which are suitable for Na-ion and K-ion batteries.

In this study, we investigated electrochemical strain generation in composite iron phosphate ($FePO_4$) cathode during Li^+, Na^+ and K^+ ion intercalation. Strains were monitored using *in situ*, optical, full-field digital image correlation technique. A host $FePO_4$ framework was initially formed by the electrochemical delithiation of the $LiFePO_4$ composite electrode in order to establish the identical electrodes in terms of active material loading in composite electrode, particle size, binder, and porosity of the composite electrode. $FePO_4$ composite electrodes were cycled at 1C, C/10 and C/25 in against Na and Li counter electrode, and K ions were only intercalated into $FePO_4$ at C/25 rate.

Striking differences in the physical response of $FePO_4$ were observed during the intercalation of three different alkali-metal ions. First of all, Li intercalation caused strain hysteresis at higher scan rates. Linear relationship between strains and capacity was observed during Na intercalation at any scan rate. However, the electrodes experience additional 0.05 and 0.15% more composite strains at C/10 and 1C rates compared to the electrode cycled at C/25 rate when the state of discharge was same during Na intercalation. An analytical model was developed to predict Na concentration gradients and misfit strain generation in the NFP particles. Second, only about 30 mAh/g discharge capacity was achieved at fourth cycle during the intercalation of potassium into $FePO_4$, whereas at the same scan rate, Li and Na intercalation delivered about 130 and 140 mAh/g, respectively. Despite of the size difference between Na and K ions, at the same discharge capacity, similar volumetric expansion was observed upon Na and K intercalation. Third, strain derivatives with respect to voltage were calculated using the finite difference method. Local minima in strain derivatives closely matched the current peaks during Li, Na and K insertion into the $FePO_4$ structure. Phase transformation during Li and Na intercalation, measured by ex-situ XRD, corresponds well with the current peaks observed during the cycling. Intercalation of K into $FePO_4$ was reported to cause amorphization in the crystalline $FePO_4$. Surprisingly, strain derivatives during K ion intercalation demonstrated distinct features, which aligned well with the electrochemical responses. Therefore, digital image correlation can be used to monitor electrochemical strains in other amorphous electrodes too. In conclusion, our results provide new insights about how Li, Na and K alkali ions influence the phase transitions and mechanical response of the iron phosphate cathodes.

6:35 AM F.EN04.20.11
Sulfide-Based Composite Electrolyte to Enhance the Performance of Solid-State Lithium Metal Batteries Yang Li, Thad Druffel, Mahendra Mahendra Sunkara and Hui Wang; University of Louisville, United States

Sulfide-based lithium (Li)-ion conductors represent one of the most popular solid electrolytes (SEs) for solid-state Li metal batteries (SSLMBs) with high safety. However, the practical application of sulfide-based SEs is significantly limited by their chemical instability in air and electrochemical instability with electrode materials (metallic Li anode and oxide cathodes). To address these difficulties, here, we design and demonstrate a novel sulfide-based composite electrolyte (SCE) through the combination of inorganic sulfide Li argyrodite (Li_7PS_6) with a polymer matrix. The developed SCE achieves excellent air-stability, impressive flexibility, and great chemical/electrochemical stability. Meanwhile, the presence of sulfide fillers facilitates the Li-ion transport in SCE, leading to a superior ionic conductivity at room temperature. Using the SCE enables with enhanced stability in Li symmetric cells and excellent suppression of Li dendrites. In addition, $LiFePO_4$ (LFP)/Li cells can deliver impressive specific capacity and excellent stability over long-term cycles. These features indicate this sulfide-based SCE as a promising candidate, and whose design will contribute to the practical development of SSLMBs.

6:45 AM F.EN04.20.12
Desiginig MOF-Based Nickel Cobaltite Composites for Energy Storage Ali Rashti and Tae-Sik Oh; Auburn University, United States

Metal-organic frameworks (MOFs) are considered a novel type of crystalline porous structures. These structures are composed of inorganic vertices and organic linkers coupled through the coordination bonds. MOFs have distinct purposes such as high specific surface area, controllable pore size and good thermal stability that makes them good candidates to be

used as porous templates.
In this work, the designed synthesis of $NiCo_2O_4(Co_3O_4)$ double shell nanocages (DSNCs)from zeolitic imidazolate framework-67 is studied. The DSNCs are later embedded with graphene to enhance their conductivity and electrochemical performance. The strategy includes the synthesis of zeolite imidazolate framework-67(ZIF-67)/Ni-Co layer doubled hydroxide(LDH) precursor and subsequent transformation to $NiCo_2O_4(Co_3O_4)$ DSNC by thermal annealing. The as-prepared DSNC structure is wrapped with graphene structure through a simple electrostatic self-assembly. Here, we focused on tuning the microstructure of $NiCo_2O_4(Co_3O_4)$ DSNCs by controlling the crystal size of ZIF-67 and Ni-Co LDH formation while etching the initial MOF template.
Herein, we report $NiCo_2O_4(Co_3O_4)$@rGO composite structure with a capacity of 969 $F.g^{-1}$ at current density of 1 $A.g^{-1}$ showing a remarkable stability of showing 88% of initial capacitance after 10000 cycles of charge-discharge with a high mass loading of electrodes ($mg.cm^{-2}$).
This work shows a universal process for controlled synthesis of different complex spinel structures that can be used for various applications.

6:55 AM F.EN04.20.13
Tailoring Electrode-Electrolyte Interfaces in Lithium-Ion Batteries using Molecularly Engineered Functional Polymers Laisuo Su and B. Reeja Jayan; Carnegie Mellon University, United States

Understanding and tailoring electrode-electrolyte interfaces (EEIs) is critical for enhancing the rate capability, cycling stability, and thermal safety of lithium ion batteries (LIBs). Although artificial coatings have been explored to tailor EEIs, no clear mechanisms have been identified that explain how these coatings engineer the EEIs of LIB electrodes. For the first time, we study Li^+ kinetics in different polymer-based artificial coatings and at EEIs using a combination of experimental techniques (electrochemical impedance, neutron reflectometry and depth profiling) and density functional theory (DFT) calculations. Small binding energy with Li^+ and the presence of sufficient binding sites for Li^+ allow poly(3,4-ethylenedioxythiophene) (PEDOT) based artificial coatings to enable fast charging of $LiCoO_2$. Operando synchrotron X-ray diffraction experiments suggest that the superior Li^+ transport property of the PEDOT coating further improves current homogeneity in the $LiCoO_2$ electrode during cycling, and, therefore, determines the electrochemical performance of the electrode. The $LiCoO_2$ 4.5 V cycle life tested at C/2 is increased by over 1700 % after applying the PEDOT coating. In comparison, other polymer coatings have negligible or negative effects on $LiCoO_2$ performance. Additionally, X-ray photoelectron spectroscopy and DFT calculations demonstrate that S, O present in PEDOT form chemical bonds with Co in $LiCoO_2$. These chemical bonds reduce Co dissolution and inhibit electrolyte decomposition, improving the cycling stability of $LiCoO_2$. These insights provide us practical design rules for polymer selection that will help shorten the research time and reduce the trial-and-error effort involved in tailoring EEIs for developing advanced batteries.

7:05 AM F.EN04.20.14
Advancing Lithium-ion Capacitor Energy Storage with Composite Activated Carbon Cathodes Jacob Strimaitis, Samuel Danquah, Sangram K. Pradhan and Messaoud Bahoura; Norfolk State University, United States

Hybrid supercapacitors, which exhibit the beneficial characteristics of both their battery (high energy density) and supercapacitor (high power density and durability) constituents, are in demand to meet current and future technological and infrastructural needs. While substantial efforts have already been made to modify the anode, commonly $Li_4Ti_5O_{12}$ (LTO), to increase rate performance, lesser attention has been placed on the activated carbon (AC) cathode, which has been reported as the energy density limiting electrode and is so prime for optimization. Using galvanostatic charge-discharge cycling and high-resolution imaging techniques, it was determined that systematically adding $LiMn_2O_4$ (LMO), a common battery cathode material, and Super P, a common conductive element, to the AC supercapacitor cathode changes the structure of the electrode and increases the energy density of a LTO//AC Li-ion capacitor without significantly impacting rate performance. Future work will help determine the energy storage kinetics of the composite cathode and how modifications to the LTO anode in tandem with the cathode may increase electrochemical capacity without affecting the capacitor's typical high-power density and long-term cyclability.

7:15 AM F.EN04.20.15
Inhibit of Lithium Dendrite Growth in Solid Composite Electrolyte by Phase-Field Modeling Ye Cao[1], Ren Yao[1] and Yue Zhou[2]; [1]The University of Texas at Arlington, United States; [2]South Dakota State University, United States

Lithium (Li) dendrite growth poses serious challenges for the development of Li metal batteries. Replacing liquid electrolyte with solid composite electrolyte embedded with nanofiller additives can potentially suppress the Li dendrite growth. However the underlying mechanism is still not fully understood, and most theoretical works focus on pure liquid electrolyte

and ignore the mechanical strain effects. Here we developed a phase-field model to simulate the Li dendrite growth by incorporating the microstructure of the solid composite electrolyte, and considering the mechanical effects of the electrolyte. Using aluminum oxide nanofiber embedded poly(vinylidene fluoride-co-hexafluoropropylene) (P(VDF-HFP)) as an example, we discovered two key factors, the elastic modulus and the electrolyte nanochannel width that govern the Li dendrite growth. The difference of the Young's modulus between the Li metal and solid electrolyte acts as the additional mechanical driving force, which partially offsets the electrochemical driving force to either promote or inhibit the dendrite growth. We also discovered that the introduction of the 1D nanofiber arrays could confine the Li ion transport along vertical direction, reduce the concentration gradient across the metal/electrolyte interface, and inhibit the Li dendrite growth. Finally the dependence of overall Li ion conductivity on the nanofiller is discussed. Our work provides deep understanding and designing strategy for the solid composite electrolyte for improved Li anode stability and Li ion conductivity.

7:25 AM *F.EN04.20.16
Design, Discovery and Structure-Property Relationship Investigation of Oxide, Sulfide and Halide Solid Electrolytes for All-Solid-State-Batteries Hailong Chen; Georgia Institute of Technology, United States

Solid electrolyte is the key component for all solid state batteries. Extensive research attentions are being attracted to the design and development of high performance solid electrolytes. An ideal solid electrolyte should simultaneously satisfy properties in multiple categories, including ionic and electronic conductivities, chemical stabilities against air and moisture, good mechanical properties, and good electrochemical stability and compatibility with both cathode and anode, etc. Cost and feasibility for scale production and battery fabrication are also important considerations.
Here we report our recent work on design and development of high performance novel solid electrolytes, including oxide, sulfide and halide compounds, and the comparison of their performances in batteries. These new materials are designed based on either computational prediction or empirical hypothesis. LiTaSiO5 series oxide materials show good ionic conductivity and outstanding stability. The synthesis and processing of this material will be discussed. Novel sulfide and halide solid electrolytes will also be reported. They all show very high room temperature ionic conductivities and good performance in the cycling test of all solid state batteries. High resolution synchrotron X-ray and neutron scattering techniques, solid state NMR and electron microscopy were complementarily used to reveal the structure-property relationships in these compounds. The impacts of synthesis condition, chemical composition and processing to the ionic conductivity and battery performances will be discussed.

7:40 AM F.EN04.20.17
Late News: Development of Water-Stable O3-type Transition Metal Oxide Enabling Long-Term Cyclic Stability with "Aqueous Processed" Cathodes for Na-Ion Batteries Bachu Sravan Kumar, Anagha Pradeep, Animesh Dutta and Amartya Mukhopadhyay; IIT Bombay, India

The upcoming Na-ion battery system has advantages over the Li-ion battery system in terms of the more widespread availability and lower cost of Na-precursors. Among the potential cathode material classes, O3-type layered $Na_xT_MO_2$ (T_M => transition metal ion; x~1) is important due to the inherently high Na-storage capacity. However, the O3-type $Na_xT_MO_2$ suffers from instabilities caused due to multiple structural changes during Na-extraction/insertion, T_M-dissolution into electrolyte and, more importantly, inherent sensitivity to moisture. The moisture sensitivity necessitates the usage of binders that dissolve only in toxic non-aqueous solvents like N-Methyl-2-pyrrolidone (NMP) during electrode preparation. Against this backdrop, a carefully designed composition has been developed here to address the aforementioned problems, in particular, the air/water-instability. Among other things, Ti-ion substitution for Mn-ion (partially/completely) has led to excellent air/water-stability; resulting in no phase/structural change (from the original O3 structure) even after 40 days of exposure to air and 12 h of stirring in water. By contrast, under similar conditions, O'3 and P3 phases progressively evolve for the predominantly Mn-ion containing counterparts. The excellent stability of the optimized O3-type NaT_MO_2 enables the usage of environment/health friendly and economical 'aqueous-binder' (*viz.*, Na-alginate) and water (as solvent) for electrode preparation. Furthermore, Ti-substitution also prevented the presence of Mn-ion in its +3 oxidation state; thus, addressing the Mn-dissolution problem and concomitantly supressing the increase in impedance, as well as voltage hysteresis, during electrochemical cycling. Overall, the 'aqueous-processed' cathode exhibits excellent long-term cyclic stability, with a capacity retention of ~56% after 750 cycles at C/5, including just ~4% capacity fade over the last 250 cycles investigated. Hence, this is a significant step towards the development of alkali metal-ion batteries having electrochemically stable electrodes being prepared in a health/environment friendly and cost-effective manner (by enabling the usage of water-based, as opposed to NMP-based, binder). A part of this work has been published as; Kumar *et al.*, *J. Mater. Chem. A* (2020; DOI: 10.1039/D0TA05169A).
Keywords: *Na-ion battery; layered transition metal oxide cathode; air/water-stability; aqueous processing; electrochemical behaviour*

7:50 AM F.EN04.20.18
Late News: Bi-Phase Na-Titanate Based Composite with Excellent Long-Term Electrochemical Stability and Rate Capability as Anode for Na-Ion Batteries Anagha Pradeep[1], Bachu Sravan Kumar[1], Ajay Kumar[1], Velaga Srihari[2], Himanshu Poswal[2] and Amartya Mukhopadhyay[1]; [1]IIT Bombay, India; [2]Bhabha Atomic Research Center, India

In contrast to the Li-ion battery system, graphite does not work as anode material for the upcoming Na-ion battery system. Even though hard carbon has been widely explored as anode material, it possesses safety issues since the Na-insertion potential is very low and close to that of Na-plating. In this context, the present work reports a bi-phase Na-titanate based composite anode material, which is safe, electrochemically stable, possesses very high 'rate-capability' and long-term cyclic stability, even at very high current densities. 'Bi-phase NTO', having ~66% $Na_2Ti_3O_7$ and ~34% $Na_2Ti_6O_{13}$ shows contributions from both the constituent phases, which is confirmed via *operando* synchrotron X-ray diffraction studies. 'Bi-phase NTO' is electrochemically more stable than $Na_2Ti_3O_7$ and its operating potential is well above the Na-plating potential. Furthermore, the performance of 'Bi-phase NTO' has been further improved by the addition of functionalized multi-walled carbon nanotubes (MWCNTs), which bestows the same with reversible Na-storage capacity of ~162 mAh g^{-1} at C/5 and outstanding cyclic stability. The very stable 'charge-averaged' discharge/charge potentials and only minor increment in impedance over multiple electrochemical cycles support the excellent stability of 'bi-phase NTO'/MWCNTs composites. Of special note is that the composite electrode exhibits 1st cycle reversible capacity of >140 mAh g^{-1} even at 50C, with capacity retentions of ~83% and ~58%, after 100 and 2000 cycles, respectively, including negligible capacity fade from the 300th cycle onwards. This indicates the feasibility for long-term cycling at very high current densities. Overall, this will allow the development of Na-ion cells possessing outstanding rate-capability and cyclic stability; thus addressing some of the major concerns associated with the same. A part of this work has been published as Pradeep *et al*., Electrochim. Acta (2020).

SESSION F.EN04.21: Sodium Batteries
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-EN04

5:00 AM F.EN04.21.02
Elucidating the Intergrowth of Octahedral and Prismatic Na Layers in Sodium Transition Metal Oxides Jae Chul Kim[1], Deok-Hwang Kwon[2,3], Julia Yang[2,3] and Gerbrand Ceder[2,3]; [1]Stevens Institute of Technology, United States; [2]University of California, Berkeley, United States; [3]Lawrence Berkeley National Laboratory, United States

As an alternative to Li-based technologies to develop stationary energy storage systems, Na-ion batteries have attracted substantial interest. Unlike the Li-ion, layered sodium transition metal oxide ($NaTMO_2$) cathodes can diversify their redox centers from expensive Co to cheap Mn and Fe to achieve high energy density, offering a wide variety of chemistry selection to design low-cost, high-performance batteries. These cathode materials often undergo discontinuous, yet reversible, phase transitions upon Na intercalation due to complex interatomic interactions, which result in multiple plateau-like features in their voltage profiles. However, large desodiation of Fe-containing Na-ion cathodes often leads to an unclarified, irreversible phase transition at high voltage, hindering the full use of Fe redox.

In this talk, we will discuss how transition metal selection affects the thermodynamic stability of desodiated structures of $NaTMO_2$. Specifically, our recent findings on a quaternary transition metal system, $NaTi_{0.25}Fe_{0.25}Co_{0.25}Ni_{0.25}O_2$, will be underlined. We will present structural evidence and characterization of the highly-desodiated, high-voltage phase that exhibits peculiar oxygen stacking. This phase consists of alternating octahedral and prismatic Na layers, namely OP2 stacking, in which formation is afforded by distortion-tolerant Ti and Jahn-Teller-active Fe. Moreover, we will demonstrate that this new phase participates in redox reaction reversibly, fundamentally distinct from inactive high-voltage phases in many Na-ion cathodes. Finally, a strategy to stabilize Fe-containing $NaTMO_2$ materials to create layered cathodes with high reversible Na capacity will be briefly discussed. Our results demonstrate that we can manipulate the redox reaction and associated structure change by transition metal mixing.

Understanding the Reaction Mechanism of Sodium Vanadate for an Aqueous Zn Ion Battery by Transmission Electron Microscopy Sung Joo Kim[1], Christopher Tang[2], Gurpreet Singh[2], Lisa Housel[2], Shize Yang[1], Kenneth Takeuchi[2], Amy Marschilok[2], Esther Takeuchi[2] and Yimei Zhu[1]; [1]Brookhaven National Laboratory, United States; [2]Stony Brook

University, The State University of New York, United States

Layered metal vanadate, such as sodium vanadate ($Na_{1+x}V_3O_8$ or NVO), has recently attracted immense interest as the promising aqueous Zn ion battery cathode material owing to its metal ion pillars that facilitate Zn ion diffusion within the structure. Here, reaction mechanisms of hydrated $Na_2V_6O_{16}*2H_2O$ slabs and non-hydrated $Na_{1.25}V_3O_8$ nanorods were investigated in detail by employing transmission electron microscopy. We observed the full discharge of the thin (30-50 nm) $Na_2V_6O_{16}*2H_2O$ system with successful Zn ion insertion into the bulk while detecting Zn ion insertion only at the surface for thick (120-170 nm) $Na_{1.25}V_3O_8$, demonstrating that both the hydration and the nanostructure thickness determine the reaction mechanism of NVO. Interestingly, electrochemical cycling of Zn/NVO cells induced the irreversible formation of the novel by-product phase, Na-inserted Zinc pyrovanadate ($Zn_3Na_x(OH_2)V_2O_7$ or ZNVO), which is electrochemically active. Its presence could eventually lead to a bifurcated discharge/charge process, where Zn redox reactions happen in both NVO and ZNVO contributing to the overall cell capacity. This microscopy work offers important insights into the effects of morphology and hydration on reaction mechanisms of NVO, which hold some implications on its electrochemistry for aqueous Zn ion batteries.

5:20 AM *F.EN04.21.04
Optimization of Titanate Anodes for Sodium-Ion Batteries Marca M. Doeff; Lawrence Berkeley National Laboratory, United States

Sodium-ion batteries (NIBs) are the nearest of the "Beyond Li-ion Batteries" systems to commercialization. Attractive features include the large abundance of sodium precursor materials, which reduce supply security worries and lower cost, and the ability to use Co-free cathodes and aluminum current collectors on the anode side. Further improvements require the identification of suitable replacements for the hard carbon anodes currently used, which limit energy density and present safety issues. We have recently been working with several types of sodium titanium oxides with stepped layered structures, which undergo reductive intercalation of sodium at extremely low potentials. These include "sodium nonatitanate", which can deliver up to 200 mAh/g at an average potential of about 0.3V vs. Na^+/Na, and lepidocrocite-structured titanates, whose redox properties vary depending on exact chemistry and structure. Both types of materials show excellent reversibility in sodium half-cells, making them appealing candidates for use as anode materials for NIBs. In this talk, we will discuss their structure, chemistry, and electrode optimization.

5:35 AM F.EN04.21.07
Accurately Predicting Sodium Ion Cathode Voltages from Statistical and Ab-Initio Approaches Arthur B. Youd, Daniel Davies, Christopher Savory and David O. Scanlon; University College London, United Kingdom

Na_xCoO_2 is a layered cathode material which shares many attributes with widely used $LiCoO_2$. Several geopolitical and economic factors make lithium a potentially unreliable raw material for rechargeable batteries therefore an earth abundant alternative is eagerly sought after. Sodium shares many chemical similarities with lithium however does underperform in the areas of specific energy and charge density[1]; as such understanding the electronic structure and electrochemical behaviour is an essential steppingstone to optimising said material and rationally designing new layered sodium ion cathode materials. A combination of structural dynamism, magnetic complexity and inter layer dispersion make Na_xCoO_2 a challenging material to model; thus far its electrochemical voltage profile has not been convincingly reproduced by theoretical methods.[2] The motivation of this study is to ascertain the correct level of theory necessary to robustly reproduce experimental structures and voltage profiles of Na_xCoO_2 , and thus guide the accurate simulation of other layered Na-ion cathodes.

This study simulates octahedral and prismatic structures of Na_xCoO2 within the stoichiometric range of $0 \leq x \leq 1$ using the cluster expansion approach as implemented in the CASM code[3-5] as well as high throughput ab-initio calculation management within the *atomate* program.[6] The hierarchical survey of methodology uses both generalised-gradient and hybrid functionals to examine the role of electron exchange. Our hierarchical survey examines the voltage profile of Na_xCoO_2 calculated with 6 different methodologies; these variously comprise hybrid DFT and GGA+U methods to correct for correlated d electrons, and include or exclude the effects of Van der Waals interactions to explicitly account for how each of these affects the voltage profile and thus establish the optimal ab-initio methodology to accurately reproduce such profiles in the future. This survey will inform predictions of future Na-ion cathodes, while detailed electronic structure analysis will develop our understanding of the redox processes present in $LiCoO_2$. DFT is also used to inform electronic structure analysis, specifically the composition of the valance band, with a view to ascertain the species participating in the redox process during cycling. Collectively, this approach will inform computational analyses into similar layered sodium open shell transition metal oxides for cathode applications to take the guess work out of voltage predictions.

First Principles Investigation on the Phase Stability of $Na_2Ti_3O_7$ Electrode During Hydrogenation Treatment for High Performance Na-ion Batteries Yong-Seok Choi[1,2], Sara I. Costa[3,2], Nuria Tapia-Ruiz[3,2] and David O. Scanlon[1,2,4]; [1]University College London, United Kingdom; [2]The Faraday Institution, United Kingdom; [3]Lancaster University, United Kingdom; [4]Diamond Light Source Ltd., United Kingdom

The low cost and abundance of sodium have driven the growing interest in Na-ion batteries (NIBs) as a possible alternative for Li-ion batteries. However, NIBs are still in a developmental research phase and the exploration of proper electrode materials is necessary [1]. Among the candidate electrode materials, $Na_2Ti_3O_7$ has emerged as a promising electrode material because of its low cost, nontoxicity [2,3], and high theoretical capacity of 177 $mAhg^{-1}$ [4]. Nevertheless, $Na_2Ti_3O_7$ has not been used as main electrodes owing to its low electric/ionic conductivity and poor structural stability, which causes significant capacity fading upon cycling [5]. Efforts to improve the cycling stability of sodium titanates have discovered $Na_2Ti_6O_{13}$ which has properties contradictory to $Na_2Ti_3O_7$; $Na_2Ti_6O_{13}$ exhibits high ionic conductivity and structural stability but suffers from low Na storage capacity [6]. In this regard, proper hybridization of $Na_2Ti_3O_7$ and $Na_2Ti_6O_{13}$ could break the limitations of each structure and offer a composite electrode for high performance NIBs [7].
Hydrogenation treatment, which can transform $Na_2Ti_3O_7$ into $Na_2Ti_6O_{13}$ [8,9], has recently emerged as a facile way to synthesize hybrid $Na_2Ti_3O_7/Na_2Ti_6O_{13}$ electrode [7]. From this perspective, a comprehensive understanding of the phase stability of $Na_2Ti_3O_7$ during hydrogenation treatment can enable further performance enhancements of sodium titanate electrodes. In this study, using hybrid HSE06 DFT functional implemented in VASP code, we have analyzed the phase stability of $Na_2Ti_3O_7$ during hydrogenation treatment and its effect on battery performance. The ternary phase diagram of Na-Ti-O system and subsequent Gibbs free energy calculations reveal that, as a result of the thermal energy applied during hydrogenation treatment, $Na_2Ti_3O_7$ can thermodynamically decompose into six different phases of Na_2O, Na_4TiO_4, $Na_8Ti_5O_{14}$, $Na_4Ti_5O_{12}$, $Na_2Ti_6O_{13}$, and TiO_2. The calculated band structures and their alignments show that the formation of $Na_2Ti_6O_{13}$ can reduce the band gap of initial $Na_2Ti_3O_7$ by up to 0.19 eV, which enhances electrochemical performances of the electrode. In addition to these results, the formation of defects (O vacancy and -OH group) associated with hydrogenation treatment and their effect on electrochemical performance will be also discussed. The results provided here can help designing high performance sodium titanate electrodes for future NIBs.

An Experimental and Computational Investigation of Nickel Tellurate Cathode Materials for Na-ion and Li-ion Batteries Ieuan D. Seymour[1,2], Nicholas Grundish[1], Yutao Li[1], John B. Goodenough[1] and Graeme Henkelman[1]; [1]The University of Texas at Austin, United States; [2]Imperial College London, United Kingdom

Layered transition-metal (TM) oxides have played a central role as cathodes for Na-ion and Li-ion rechargeable batteries. Alleviating the deleterious structural transitions that occur in these materials during electrochemical cycling is still a critical challenge which requires a fundamental understanding of the mechanisms taking place at the atomistic level. In this work we investigated how Te^{6+} doping into the A_xNiO_2 (A=Na and Li) family of materials leads to changes in the local structure and electrochemical performance. The Na-Ni-Te-O system provides an ideal case study into the link between local structure and electrochemical performance of Na-cathode materials. The inclusion of Te^{6+} results in the suppression of TM layer shearing during desodiation after an initial transformation from an O'3 to a P'3 structure. Using a combination of X-ray diffraction and solid-state paramagnetic NMR it can be shown that the inclusion of Na-ions into the TM layer suppresses long range Na-ordering in the P'3 structure which facilitates favorable electrochemical properties. Paramagnetic NMR measurements show that while the long-range Na ordering is suppressed in the Na-Ni-Te-O system, there is significant local ordering of the Na sites in the TM layer, with a strong preference for the formation of nearest neighbor Na-Na motifs that are distinct from analogous Li compounds.

Complimentary DFT calculations are used to understand energetics of local structural orderings and to assign the complex paramagnetic NMR spectra. The DFT calculations are coupled with an advanced basin-hopping methodology to probe the intricate relationship between structural transitions and Na-vacancy ordering as a function of sodium content in the O'3 and P'3 structures. The combined experimental and computational approach developed in this work is further extended to understand the changes in the local structure during desodiation of the isostructural Na-Ni-Fe-Sb-O family of materials.

In the analogous Li-Ni-Te-O family, two layered polymorphs and one disordered rock salt phase can be synthesized. In contrast to the Na-Ni-Te-O system, Ni^{2+} migration occurs in layered Li polymorphs which leads to rapid capacity fading. The disordered rock salt compound displayed the highest reversible capacity out of the three structures, which could be rationalized based on the presence of fast Li-transport on the partially ordered Li/Ni sublattice. The conclusions from this work have wider implications for the design of new Na-ion and Li-ion cathode materials.

Late News: "Na Ion Redistribution" in Layered Oxide Compound during Na/K Ion Exchange Haegyeom Kim; Lawrence Berkeley National Laboratory, United States

Recently, new energy storage materials for K-ion batteries (KIBs), which emerged as a low cost alterative battery system, have been developed by using Na^+/K^+ ion exchange. For example, P2-type $K_{0.5}CoO_2$ was prepared from P2-$Na_{0.84}CoO_2$ *via* electrochemical Na^+/K^+ ion exchange by Baskar *et al*.[1] P3-type K_xCrO_2 and $K_xCr_{0.9}Ru_{0.1}O_2$, both cathodes which display good cycle life, have been derived from their Na analogues through ion exchange.[2-4] There are many other examples.[5-7] In fact, ion exchange reaction has been widely used to produce metastable inorganic materials, unlike those prepared by direct chemical reactions at high temperature. New materials design for Li-ion batteries has frequently used Li^+/Na^+ ion-exchange reactions to attain structural features of Na layered oxides not directly achievable via conventional synthesis methods for Li compounds. For example, Delmas *et al.* developed O2-type $LiCoO_2$ from P2-type $Na_{0.7}CoO_2$, even though O3-type $LiCoO_2$ is the commonly observed structure.[8] Similarly, layered $LiMnO_2$ was first synthesized from α-$NaMnO_2$ via Li^+/Na^+ ion exchange by Armstrong *et al.* and Delmas *et al.*,[9, 10] whereas an orthorhombic structure (space group Pmmn) is the stable form of $LiMnO_2$ under typical synthesis conditions.[11] Nevertheless, the microscopic theory of solid-state ion-exchange is not well developed. The microscopic mechanism for Na^+/K^+ ion-exchange has been even less investigated than that of Li^+/Na^+.
In this work, we investigate how ion-exchange occurs in compounds, using electrochemical Na^+/K^+ ion exchange in $Na_3Ni_2SbO_6$ as a model system. Using *in-situ* XRD we find a surprising and remarkable sequences of phase to occur as K is inserted into a compound with Na ions remaining. We establish that the origin of this remarkable behavior upon Na/K ion exchange is the strong repulsion between the two ions. We discover that K ion insertion into the desodiated $Na_xNi_2SbO_6$ pushes the remaining Na ions away and redistributes them, thereby separating Na-rich and K-rich phases in a particle. Interestingly, this phenomenon creates a complex three-phase equilibrium during most of the de-sodiation and potassiation of $Na_xK_yNi_2SbO_6$: either one K-rich and two Na-rich phases or two K-rich and one Na-rich phase coexist, thereby perfectly satisfying the Gibbs phase rule. Our computational study further demonstrates that the phase separation originates from the large lattice mismatch along the *c*-axis between the two phases (K-rich and Na-rich phases). Our observations and interpretations demonstrate that "ion-exchange" systems may be more complex to interpret than previously understood. Our analysis should be applicable to other ion-exchange systems where the exchanged ions are not well miscible

in the host structure.

SESSION F.EN04.22: Sulfur Batteries
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-EN04

5:00 AM F.EN04.22.01

Development of Non-deteriorating Lithium-Sulfur Battery Kazuki Machida[1], Yusuke Ushioda[1], Hibiki Miyauchi[1], Kohei Inaba[1], Keitaro Takahashi[1] and Shiro Seki[2]; [1]Kougakuin University, Japan; [2]Kogakuin University, Japan

To resolve energy issues, the demand of large-scaled capacity storage batteries are increasing. Therefore, the realization of lithium-sulfur (Li-S) battery, which is one candidate of the next-generation high-performance innovative battery systems, is strongly desired. In general, lithium metal is used as the negative electrode for Li-S batteries. On the other hand, elemental sulfur (S_8) is also used as the positive electrode, and it has high theoretical reversible capacity of 1,672 $mAhg^{-1}$. However, effect of Li metal negative electrode is unclear due to their chemical properties with charge and discharge process. In this study, we applied Li-doped negative electrode for suppressing the Li-dendrite formation. Therefore, we obtained $Li_4Ti_5O_{12}$ (LTO) electrode as stable negative electrode, which is strain-free intercalation material, and high reversible characteristics of battery system are expected.
To applying LTO for Li-S batteries, electrochemical doping of Li into LTO is required owing to their deficiency of carrier ion into LTO. Therefore, at first [Li| electrolyte |LTO] cells were assembled by using disassemble cell, which can be easily taken out cell materials without short circuit into inert atmosphere (e.g., glove box). After takeoff of Li-doped LTO (Li-LTO), lithium (Li-doped) -sulfur battery was fabricated by using SPAN as sulfur positive electrode ([Li-LTO|1M-LiFSI EC/DEC=3/7|SPAN] cell). (SPAN: developed non-degraded S positive electrode). Charge and discharge performance of prepared cells were evaluated. Experimental conditions of prepared cells are weight of active material: 0.602 $mgcm^{-2}$, current density: 328 $mAcm^{-2}$, range of voltage: -0.5~1.5 V, temperature: 303K, respectively.
Although operating voltage and capacity are relatively low, charge and discharge over 2000 cycles were observed in the charge and discharge profiles. Therefore, this cell has suitable constitution in battery materials. Within 200 cycles, high coulombic efficiencies (about 99.9%) were always observed in the cycle number dependences of coulombic efficiency. Therefore, it suggests the possibility of realizing a non-degraded battery, which has high reversible characteristics by using both Li-LTO negative electrode and SPAN positive electrode.

5:10 AM F.EN04.22.02

High-loading Sulfur Cathodes in Low-electrolyte Lithium-sulfur Sheng-Heng Chung; National Cheng Kung University, Taiwan

ies is a mature and successful energy-storage technology. The continuous development of lithium-ion battery cathodes has pushed the cathode performance approaching their theoretical values, which shows a challenge for the future development. A high-capacity sulfur cathode in the lithium-sulfur battery enables a complete two-electron conversion reaction per sulfur atom and therefore provides an order of magnitude higher theoretical capacity (1,672 mA h g^{-1}) than the currently used oxide cathodes. Such a significant progress in the electrochemical characteristics let sulfur cathode getting a high attention. In

addition, sulfur is inexpensive and environmentally benign. However, as a new energy-storage technology, lithium-sulfur battery cathodes suffer from unique electrochemical challenges. The insulating nature of sulfur limits the high and reversible electrochemical utilization of the active material. The irreversible migration of polysulfides within the cells impact the cycle life and electrochemical stability of lithium-sulfur cells. These challenges further restrict the lithium-sulfur battery cathode to attain a sufficient sulfur loading and content of above 4.0 mg cm^{-2} and 65 wt.%, respectively, in a cell with a reasonable low electrolyte-to-sulfur ratio of less than 10.0 uL mg^{-1}.

In our presentation, we present innovations on electrode design enabling lithium-sulfur batteries to operate excellently with a high amount of sulfur (*i.e.*, 14.4 mg cm^{-2} and 70 wt.%) and a low electrolyte-to-sulfur ratio of 4.0 uL mg^{-1}. The cathode substrate is prepared by carbonized electrospinning nanofibers having 20 wt.%, 40 wt.%, and 100wt.% polyacrylonitrile mixing with Nafion as the sacrificial polymer. With a high content of the sacrificial Nafion, the carbonized nanofibers generate a high specific surface area of up to 640 m^2 g^{-1} with 150 m^2 g^{-1} contributed from micropores. Although a high surface area and micropores of the electrode substrate benefit the polysulfide retention, most of the electrolyte added in the cell is initially absorbed by this highly porous cathode substrate. This explains why a high amount of electrolyte that would cause a low energy density is needed in the lithium-sulfur research. This also expounds why our high-loading cathodes with a low amount of electrolyte either dry out in a short cycle life nor cannot get sufficient charges transferred *via* the electrolyte, resulting in a poor cell performance. On the other hand, the carbonized electrospinning nanofiber with no sacrificial polymer possesses a relatively low specific surface area of 130 m^2 g^{-1} and no micropores. Benefiting from a unique electrode-design criterion, the limited surface area ameliorates the fast consumption of electrolyte, while still blocking the fast polysulfide diffusion. Therefore, the cells with the 100CNF substrate output a stable discharge capacity and Coulombic efficiency of above 650 mA h g^{-1} and 98%, respectively, for 100 cycles. Such excellent electrochemical efficiency and stability demonstrate a high capacity retention of 98% with a high areal capacity and energy density of 10 mA h cm^{-2} and 20 mW h cm^{-2}, respectively, in a cell with a low electrolyte-to-sulfur ratio of only 4 uL mg^{-1}. In conclusion, the electrochemical enhancements and engineering designs of the cathode substrates with limited nanopores make them advanced cathode designs for the development of high-loading/content sulfur cathodes in high-energy-density lithium-sulfur batteries.

5:20 AM F.EN04.22.03

Performance Evaluation of Li-Ion-Sulfur Battery Using Highly Composed S_8 Positive Electrode and Li-Doped C_6 Negative Electrode

Yusuke Ushioda[1], Kohei Inaba[1], Kazuki Machida[1], Keitaro Takahashi[1], Masayoshi Watanabe[2] and Shiro Seki[1]; [1]Kogakuin University, Japan; [2]Yokohama National University, Japan

Recently, large-scaled rechargeable batteries are expected as load-leveling systems for in/output natural energy, such as solar / wind power. Thus, lithium-sulfur(Li-S) batteries are attracted attention because of sulfur-based positive electrodes have high theoretical reversible capacity (1,672 mAh/g(S_8)), low-cost of active material and so on. On the other hand, Li-S batteries still have some issues for practical use. For instance, dissolution of intermediate products (Li_2S_n) into electrolyte and deposition of Li-dendrite during charge process are serious problems for Li-S batteries. Then, we applied sulfolane (SL) based electrolyte because of their prevent properties for disolution of Li_2S_n, and prepared Li-doped graphite (Li_xC_6) negative electrodes by electrochemical process to prevent deposition of Li-dendrite. However, Li_xC_6 electrodes should be handled under inert atmosphere. Therefore, we used to disassemble-type cell, which can easily pick up Li_xC_6 electrodes. In addition, increasing for loading amount of elemental S_8 positive electrodes are required for actual high-energy-density systems. Therefore, we fabricated 3D-S_8 electrode prepared by using 3D-Al current collector, which can easily obtain electron conductive pathway. In this study, we fabricated Li-S battery using 3D-S_8 positive electrode and Li_xC_6 negative electrode (litihium-ion-sulfur battery), and evaluated by constant current charge-discharge cycle test.
S_8 and ketjen black (KB) were mixed in mortar, and mixed compound was heated at 438K into sealed bottle for compositing S_8 and KB. Slurry was prepared by the mixed compounds and binders (CMC+SBR) into H_2O. 3D-S_8 electrodes were fabricated with putting on the slurry to 3D-Al cermet current collector. Prepared 3D-S_8 electrodes were dried, punched out *f*13 mm and pressed at 0.3t. First, [Li | electrolyte | C_6] cells were prepared using disassemble-type cell, and examined with constant current charge-discharge tests. Li_xC_6 (x<1) negative electrodes were picked out by disassemble-type cell in the inert Ar-filled glove box, and washed with DMC. [Li_xC_6 | SL-based electrolyte | 3D-S_8] cells were fabricated with 2032-type coin cell, and evaluated by constant current charge-discharge cycle test.

[Li_xC_6 | SL based electrolyte | 3D-S_8] cell showed good charge-discharge behavior and high discharge capacity (*ca.* 1,000 $mAhg^{-1}$) at 1st cycle. Similar capacity and low over potential were observed comparison with normal Li-S batteries, because of low resistance derived from Li_xC_6 electrode than Li-metal electrode. In addition, reaction resistances of second plateau of discharge process and beginning charge process declined gradually as cycle passes. Those phenomena are showed frequently normal Li-S battery using Li-metal negative electrode, and regard as constitution of ionic conductive pathway on positive electrode. Furthermore, capacity fluctuations of 1st plateaus were quite lower than 2nd plateaus during discharge process at

any cycles. Also, capacity degradation of 1st plateau during discharge process for Li-S battery using SL based electrolytes was reported. From the above, we considered that low capacity fluctuation was due to the balance between capacity increasing due to constitution of conductive pathway and capacity degradation. Moreover, this cell showed high cycle performance. Quite high coulombic efficiencies (*ca.* 98.5 %) were confirmed except for 1st cycle. Also, capacity retention at 50 cycles was high (*ca*. 87.8 %). Therefore, high performance lithium-ion-sulfur battery was achieved. In addition, we will report actual energy density of litihum-ion-sulfur battery for practical application.

5:30 AM F.EN04.22.04
Transition Metal Sulfide (MS, M = Mn, Zn) Nanoparticles as Conversion Cathode Materials for Rechargeable Magnesium-Sulfur Batteries Michael Wilhelm, Tim Ludwig, Veronika Brune and Sanjay Mathur; University of Cologne, Germany

For the application in consumer electronics, magnesium metal can be used as anode material in a rechargeable magnesium batteries (RMB) which are proposed as one of the next generation batteries beyond lithium-ion batteries given their high capacity (3833 $mAh*L^{-1}$ and 2205 $mAh*g^{-1}$). More advantages beside the dendrite-free stripping/plating of Mg with high reversibility (CE close to 100 % depending on the electrolyte) are high abundance, high standard reduction potential vs. SHE (-2.37 V) and safety. While significant advantages have been achieved in RMB electrolytes, especially for Mg-S battery architectures, Mg-based cathode materials are still challenging based on their low energy density and sluggish kinetics. MnS and ZnS as cathode materials follow a conversion-type storage mechanism to form MgS. The weaker coulombic attraction between the guest Mg^{2+} and the host sulfur lattice enhances ion mobility, which is expected to enhance Mg^{2+}diffusion.
In this work, nanoparticles of MnS and ZnS were synthesized via hydrothermal synthesis and characterized by XRD, XPS, and SEM. These materials exhibited good theoretical specific densities (MnS: 569 $Wh*g^{-1}$ and ZnS: 705 $Wh*g^{-1}$) and high energy densities (MnS: 1770 $Wh*L^{-1}$ and ZnS: 2270 $Wh*L^{-1}$) in a RMB setup with a metallic Mg anode. Cyclic voltammetry and galvanostatic measurements were performed in conjunction with a non-nucleophilic $Mg(HMDS)_2$*2 $AlCl_3$ electrolyte and a salt electrolyte containing $MgCl_2$*$AlCl_3$/THF (MACC) to investigate the electrochemical performance.
To the best of our knowledge we present for the first time a MnS and a ZnS cathode material in a rechargeable magnesium battery with metallic Mg anode.

5:40 AM F.EN04.22.05
Proposal of Na Conductive New Solid Electrolyte and Their Physicochemical Properties and Na-S Battery Performance Yuji Yokomaku, Koji Hiraoka, Masaki Kato, Kohei Inaba, Hibiki Miyauchi and Shiro Seki; Kogakuin University, Japan

<Introduction>
In general, sodium-sulfur (Na-S) battery operates at high temperature (ca. 573 K) using β-Al_2O_3 ceramic as the membrane of Na-conductive electrolyte separated sodium negative electrode and sulfur positive electrode. During discharge in the Na-S battery, Na^+migrates to the S electrode through the ceramic electrolyte and products sodium polysulfide. This system by operating high temperature increases the ionic conductivity of beta-alumina and ensures to form the interface between electrode and electrolyte. However, there is a concern about the fire risk attributable to an active reaction between molten sodium and molten sulfur in case of a rupture of the b-alumina ceramic membrane. To avoid these risks, we propose low-temperature operated Na-S battery using thermally stable organic gel electrolyte with polyether-based host polymer and sulfolane (SL)-based electrolyte solution. Herein, thermal stability and ionic conductivity of proposed Na conductive gel polymer electrolyte and charge-discharge property of Na-S cells were evaluated.

<Experimental>
Liquid electrolytes were prepared by mixing SL and NaTFSA using shading bottle in Ar-filled glove box. The molar ratio was changed to *x*SL:1NaTFSA (*x*=2,3,4,5 and 6, respectively). These liquid electrolytes and polyether-based macromonomer (P(EO)/(PO), polymer) were mixed with changing weight ratio as followed formula; *y* liquid electrolyte: (10-*y*)polymer (*y*=7 and 8). After added DMPA as photo-initiator, solid gel polymer electrolytes were fabricated by photo-polymerization by UV irradiation. Prepared samples were expressed as (*x*SL)*y*El+(10-y)Po. Thermophysical properties of fabricated gel polymer electrolytes were evaluated by thermogravimetric analysis (TG) and differential scanning calorimeter analysis (DSC). In addition, ionic conductivities were measured by electrochemical impedance method. The reversibility of Na-S batteries was evaluated by charge and discharge measurements at 333 K.

<Results and discussion>
The prepared gel electrolytes were transparent film and showed high flexibility. Therefore, the P(EO/PO) polymer matrix

might maintain electrolyte solvent as the framework of SL-based liquid electrolyte. Gel electrolyte of each composition of SL and polymer showed three-steps decreasing thermogravimetry by TG measurement and it was assumed thermally decomposed in the order SL, polymer, and NaTFSA. Moreover, the gel electrolytes showed the possibility of applying to room temperature operated Na-S battery because thermogravimetry decreasing wasn't observed by less than 373K. Ionic conductivity of the gel electrolytes showed a tendency of increasing with SL composition owing to decreasing viscosity of liquid electrolytes. Na-S cells using the gel electrolyte exhibited sufficient charge and discharge operations at relatively low temperature (333 K) and exhibited a high capacity of approximately 350 mAh g^{-1}.

5:50 AM F.EN04.22.06
Sulfur and Selenium Electrodes for Rechargeable Aluminum Batteries—Investigation of Electrochemical Reaction Mechanisms by NMR Spectroscopy Rahul Jay, Ankur Jadhav and Robert J. Messinger; City College of New York, United States

Rechargeable Al metal batteries have recently garnered significant interest due to its low cost, earth abundance, inherent safety, and high volumetric and gravimetric capacities due to the trivalent nature of Al^{3+} ions. Commercialization of rechargeable aluminum battery systems has been limited, however, due to the small number of (i) electrolytes that enable reversible electrodeposition of Al metal and (ii) positive electrode materials that are compatible with the electrolytes while providing high capacity and cycle life. Sulfur (S) and selenium (Se) are promising positive electrode materials for rechargeable battery systems as they provide very high specific capacities. Although, sulfur is a very low-cost material and can provide a very high specific capacity. Battery systems with sulfur electrodes has been hindered due to its low electrical conductivity, high volume expansion during galvanostatic cycling, and deleterious polysulfide shuttle reactions during cycling. Selenium, a chalcogen like sulfur is a heavier element and consequently exhibits lower specific capacity, it possesses significantly higher electronic conductivity compared to sulfur that would be beneficial in mitigating key challenges that faces sulfur electrodes, such as low active material utilization and high charge transfer overpotentials during galvanostatic cycling. To date, there are few reports of Al-S, and Al-Se systems. There is no clear consensus on the electrochemical reaction mechanism during the charge/discharge process, while capacity fade plagues both systems during galvanostatic cycling.
Here, aluminum-sulfur (Al-S) and aluminum-selenium (Al-Se) cells were investigated with a chloroaluminate ionic liquid electrolyte, $AlCl_3$:[EMIm][Cl] (molar ratio of 1.5:1), whose electrochemical reaction mechanisms and ensuing reaction products were analyzed via a combination of bulk (XRD, NMR) and surface (XPS) analyzation techniques. Electrochemical experiments for Al-S batteries showed high initial capacities close to 1200 mAh g^{-1}. For Al-S batteries a higher capacity was observed upon charge, compared to discharge, pointing towards either an unwanted side reaction or polysulfide-shuttle-like behavior. This behavior occurred predominately at low current densities and affected the reversibility of the system. For the Al-Se batteries, the two different reaction mechanisms that have been previously reported were found to be dependent on (i) the applied current density and (ii) the crystallinity of the active material, as shown by XRD. We demonstrate that, with appropriate cycling conditions, both reaction mechanisms can occur during a single charge/discharge step, thus significantly increasing the capacity and the electrochemical window of the Al-Se cell. A significant capacity fade was also observed over a course of multiple cycles showing similar behavior compared to Al-S cells.
To understand the reaction mechanisms of Al-S and Al-Se batteries at a molecular level, solid-state magic-angle-spinning and liquid-state ^{27}Al NMR and ^{77}Se NMR measurements (on Al-Se systems) were acquired on the electrodes and electrolyte at different states-of-charge, respectively. In particular, ^{27}Al NMR measurements reveal aluminum moieties in different coordination environments and establish quantitatively their relative populations. Solid-state 2D $^{27}Al\{^{27}Al\}$ multiple-quantum MAS NMR measurements also reveal information about the local electronic environments and extents of disorder of the solid discharge products. XPS was also performed on cycled chalcogen electrodes to understand surface compositions. This work establishes the potential of conversion-type aluminum-chalcogen batteries as high-energy-density energy storage systems and highlights the importance that molecular-level analytical tools like NMR spectroscopy can have in clarifying electrochemical mechanisms in emerging electrochemical systems.

6:00 AM F.EN04.22.07
Tailoring Atomistic Interactions in Li-S Battery via a Computational Multi-Scale-Data-Driven Approach Rasha Atwi and Nav Nidhi Rajput; Tufts University, United States

A major breakthrough in battery materials is required to meet the ever-increasing proliferation of portable electronic devices, electric vehicles and their variants, as well as the need for incorporating renewable energy resources into the main energy supply [1]. In this context, lithium-sulfur (Li-S) batteries attract attention owing to their very high energy density (2,600 Wh kg^{-1}) and specific capacity (1,675 mAh g^{-1}) and significantly lower weight and cost, compared to lithium-ion batteries (LIBs) [2]. Fully packaged, it is expected that future Li-S batteries can operate at close to 500 Wh kg^{-1}, which is more than twice the

energy density of LIBs (200 Wh kg^{-1}) [3]. The problem of realizing the expected high energy density is defined by several issues including the dissolution of Li-Polysulfide (PS) species into the electrolyte, insulating properties of sulfur and Li-PS species, and volume change at the cathode [4]. Overcoming these challenges requires a fundamental understanding of the interplay between events scaling over wide spatial and temporal scales, and accurate prediction of electrode and electrolyte properties to obtain design metrics for new improved materials. In this talk, I will present how we are utilizing a multi-scale-data-driven approach to gain mechanistic insight into Li-S battery by combining density functional theory (DFT) with molecular dynamics (MD) simulations. I will describe our group's newly developed computational workflow and analysis codes for generating data with high-throughput DFT and MD simulations within the framework of the Materials Project infrastructure [5]. I will discuss usage of these tools to mitigate dissolution of LiPS species by altering the atomistic interactions between electrode and electrolyte components through functionalizing the cathode material. This approach guides and accelerates our rational selection of functional groups that exhibit strong affinity with both the cathode material and LiPS moieties from a bigger set of available candidates through fully automated DFT calculations. We use the selected candidates in detailed MD studies to understand the effect of various electrolyte variables (components, PS chain length, salt concentration) on structural and dynamical properties at the functionalized interface [6, 7]. The approach allows for creating a database of well-characterized materials to be used in machine learning-based methods as well as for testing computationally identified structures in experiments. This work provides crucial information to alleviate the dissolution of PS species during cycling, which is the main reason for rapid capacity decay in Li-S batteries.

5:00 AM F.EN04.23.01
Insights into the Design of High Energy Density MnO_2 Cathodes for Rechargeable Alkaline Batteries Andrea M. Bruck, Matthew A. Kim and Joshua Gallaway; Northeastern University, United States

Recent advances in rechargeable Zn/MnO_2 alkaline batteries have shown promise for scalable energy storage systems which provide a safe, low-cost alternative to current Li-ion technologies and have a demonstrated lifetime of thousands of cycles.[1] This cathode technology is based on a 2-electron Mn redox process where a layered birnessite-type phase has been shown to form after the first cycle with excellent reversibility between the discharge product, $Mn(OH)_2$ when Bi_2O_3 and Cu constituents were added to the electrode architecture. For this system to reach costs < $100/kWh, the complete reduction to Mn^{2+} must be reversible with high mass loading (>20 mAh/cm^2).[2] We investigate the reversible reaction between birnessite and $Mn(OH)_2$ with and without Bi_2O_3 and Cu additives using multimodal structural characterization techniques during active battery cycling to provide a fundamental understanding of the structural properties critical to reversibility. Diffraction results provide evidence of Bi^{3+} residing in the interlayer of birnessite, which prevents irreversible Mn_3O_4 formation by limiting Mn^{3+} diffusion within the crystal lattice. Also, upon charge no MnOOH intermediate phases are observed. Instead, X-ray absorption and Raman spectroscopy indicate a disordered, non-crystalline birnessite-type phase consisting of mostly neutral H_2O within the interlayer. Birnessite phases will reform without the constituents present, but Mn_3O_4 formation severely polarizes the potential they are formed at, leading to capacity fade. Also, we discuss the reversible Bi_2O_3 and Cu conversion

and their contribution to the observed capacity. We expect the results will provide crucial insight into the development of aqueous, rechargeable battery systems utilizing MnO_2.

A Nanoconfined Iron(III) Fluoride Cathode in a NaDFOB Electrolyte—Towards High-Performance Sodium-Ion Batteries Zifei Sun, Wenbin Fu, Michael Z. Liu and Peilin Lu; Georgia Institute of Technology, United States

Iron(III) fluoride (FeF_3) is considered a potential cathode for sodium-ion batteries (SIBs) due to its high capacity and low cost. However, particle pulverization upon cycling generally results in poor cycling performance. Here, we introduce a free-standing nanoconfined FeF_3 cathode and explore the effect of different salts and solvents on the improvement of its cycling performance. 1M sodium-difluoro(oxalato)borate (NaDFOB) in ternary electrolytes solvents shows the best performance compared with others in this case. The achieved high performance can be attributed to the synergic protection provided by the nanoconfined FeF_3 electrode and the NaDFOB electrolyte. Post-mortem analysis and quantum mechanics show that DFOB anions facilitated the formation of a thin cathode electrolyte interphase (CEI) on the surface of FeF_3-carbon nanofibers (CNFs) *via* oligomerization.

5:20 AM F.EN04.23.04

Designing New Cathode Materials with Unbiased Sampling of the Configuration Space Bonan Zhu and David O. Scanlon; University College London, United Kingdom

Choice of the cathode materials underpins the overall performance ceiling of battery systems. Historically, the identification of new cathode materials had led to significant advances in the battery field. To achieve truly revolutionary advances, we can employ theoretical methods that explore cathode stoichiometries beyond those seen in traditional Li-ion batteries. Database-based structure prediction methods have been developed to automate the generation of unknown materials for a given chemical composition alone. However, they can suffer from significant bias originating from the databases themselves. In the current work, we apply ab initio random structure searching (AIRSS), an unbiased structure prediction method, to search for cathode materials in the under-explored regions of the chemical space. Our tests performed over a few known systems, such as $LiFePO_4$ and $LiMnPO_4$, show that the method can rapidly rediscover the known phases and predict many previously unknown polymorphs. We will present a few newly identified promising cathode systems. The use of crystal structure prediction helps us construct fundamental structure-property relationships in cathodes, and thus will also help the field to explore and find new cathode paradigms in the future.

5:30 AM F.EN04.23.05

Let's Do It an Easier Way—Molecular Precursors for M_2S (M = Li, Na, K) as Cathode Material Veronika Brune, Christoph Bohr, Tim Ludwig and Sanjay Mathur; University of Cologne, Germany

Air stable precursors for alkali metal sulfides provide an unpredicted molecular approach to sulfur-based materials for battery applications. Theses molecular precursors facilitate a more flexible preparation of the desired material via electrospinning, based on the appropriate solubility of molecular precursors in different protic solvents like alcohol or water and DMSO compared to conventional spinning systems. We describe the design and synthesis of molecular precursors of general formula $(MSEt)_2NMe$ (M = Li, Na, K) which were characterized by NMR analysis. Provision of suitable spinning solution enable the incorporation in 3D fiber mats forming networks of 1D electrospun polymer/$(MSEt)_2NMe$ fiber hybrids. The starting material, an ethanolic PVP/$(MSEt)_2NMe$ (M = Li, Na) spinning solution was stable under air and thus enabled simple handling and an innovative preparational approach of the desired materials, compared to literature known systems. These molecular precursors allow integration of M_2S (M = Li, Na) at the cathode side of the battery, which obviate the need of additionally M_2S materials at the anode side. Air stable 3D fiber mats of homogeneous 1D electrospun PVP/$(LiSEt)_2NMe$ fibers were isolated at ambient conditions and characterized by electron microscopy. Calcination of the prepared fibers at 700°C led to homogeneous crystalline carbon based Li_2S fibers which were confirmed by XRPD, SEM and TEM analysis. These fiber mats were tested in a battery half-cell, which performed good cycle stability and efficiency comparable to literature known systems.

5:40 AM F.EN04.23.06
Stability Enhanced Li_2S Cathode Materials through Tailored 1D Electrode Design Tim Ludwig, Christoph Bohr, Arun Ichangi and Sanjay Mathur; University of Cologne, Germany

Inspired from their high theoretical capacity (1675 mAh g^{-1}) and high energy density (2600 Wh kg^{-1}) lithium-sulfur (Li-S) batteries are one of the most attractive next generation energy storage solutions to meet the emerging market requirements. Nevertheless, some challenges like the poor electrical conductivity, volume expansion during the charge-discharge process, as well as the shuttling effect of soluble polysulfides retard the commercial success of Li-S batteries. Considering these challenges for the sulfur cathode, Li_2S is an alternative
cathode material for Li–S batteries, offering several advantages like avoiding structural damages and increase the safety of the battery cell.
In this work, Li_2S/C nanofiber composites were synthesized via an electrospinning process to embed the active material in a defined, conductive 1D structure and additionally minimize the diffusion of polysulfides using metal oxides as trapping agents.
The high flexibility and mechanical stability of the fiber structure is expected to buffer the volume changes during electrochemical cycling and generates a freestanding electrode design making the use of a current collector and the preparation of a battery slurry obsolete.
Furthermore, changes in the setup of the electrospinning process allowed for the design of core/shell nanofibers, in which the active material Li_2S was completely surrounded by a carbon shell rather than just being randomly distributed in the carbon matrix. This coaxial fiber architecture facilitated handling of the materials under atmospheric conditions, slowed down the degradation of the active material by traces of water, and lowered the shuttle effect of polysulfides.

Disproving the Electrocatalytic Role of Initial Oxygen Functional Groups in Comparison to Stable Defects on Graphite Electrodes in Vanadium Redox Flow Batteries Hannes Radinger, Ahmad Ghamlouche, Frieder Scheiba and Helmut Ehrenberg; Karlsruhe Institute of Technology, Germany

For many electrochemical applications in the energy sector such as batteries, water splitting, or supercapacitors, active oxygen functional groups (OFGs) at the electrode surface are considered essential. This has sparked a lot of scientific as well as industrial activities for instance in the domain of vanadium redox flow batteries, which focus on the optimization of the carbon electrodes by various oxidation treatments. The introduced OFGs are considered to catalyze the vanadium redox reactions effectively. However, these studies often disregard that the harsh attack of the surface also leads to an increase of graphitic edge sites which may also contribute to the observed catalytic activity. In a previous study, we could demonstrate that the relative amount of OFGs is less important for the catalysis than the electrochemical stability of structural defects. Further, the initial surface composition and defect structure was altered significantly in the electrochemical cell, which complicates a prediction of the electrode performance based on OFG composition. Therefore, a more systematic approach is taken to analyze the influence of OFGs and defects on the electrocatalytic activity. To separate the effect of OFGs and defects we took the reverse approach by thermally stripping oxygen groups under inert atmosphere of two different kinds of graphitic electrodes; a pristine one with a low amount of defects and oxygen species, and a thermally activated one with a high amount, respectively. By varying the stripping temperature and saturating resulting dangling bonds with hydrogen, specific OFGs were removed prior to electrochemical cycling experiments without changing surface area or defect density of the electrode. Subsequently, the electronic and defect structure of the samples was analyzed by X-Ray photoelectron and Raman spectroscopy. Cyclic voltammetry and impedance spectroscopy were used to study the electrochemical activity. Our results suggest that the initial amount or kind of OFG has no beneficial effect on the catalysis of the vanadium redox reactions. The pristine graphite felt exhibited even higher half-cell activity after the thermal treatment, which can be attributed to an increase of graphitic edge sites by the removal of OFGs. For the activated felt no remarkable change in activity was observed after stripping, most likely due to its already initially quite high amount of defects. However, both stripped samples showed an increase of the charge-transfer resistance during cycling by the formation of oxygen species. In a second step, the evolution of OFGs on the electrode was investigated by XPS after polarization experiments at the negative and positive half-cell as

well as storage in the electrolyte without polarization. The results of our study disprove the universal opinion about the role of carbonaceous OFGs for the catalysis of the vanadium redox reactions. It is much rather the defect density that is responsible for the activity of the electrode.

5:10 AM F.EN04.24.03
Accelerating the Design of Novel Materials for Aqueous Organic Redox Flow Batteries Matthew M. Bliss and Nav Nidhi Rajput; Tufts University, United States

As more and more electricity is generated from renewable sources such as wind or solar, there is a growing demand for improved energy storage devices to mitigate the intermittent nature of these sources [1]. Of particular interest are organic redox flow batteries (RFBs) due to the organic active material's facility to undergo multiple electron transfers, its ability to be diversely sourced, and its tunability via functionalization [2]. The selection of optimal materials of such devices presents a challenge due to the sheer number of possible combinations of class of organic molecules, types and locations of functional group additions, solvents, and additives [2]. In the current work, our focus is on the selection of organic redox active materials in aqueous solvent, specifically the effect of type and position of functional groups attached to a base organic molecule on properties critical to battery performance. In particular, the effect of change in solvation structure around redox active molecules as a function of functional group and operating conditions (concentration, temperature) on the electrochemical and chemical stability, solubility, and transport properties is explored [3,4]. Such fundamental understanding allows establishing design rules to develop novel redox active molecules for flow batteries. Our approach involves using coupled high throughput ab initio and molecular dynamics simulations to estimate crucial properties of the electrolyte over a wide spatial and temporal scale and explore a large chemical and parameter space. We then develop computational databases of properties on which surrogate machine learning models can be trained to gain key insights into the effect of functional groups of the redox active species and the properties of the electrolyte, which is pivotal in the design of novel electrolytes for aqueous organic RFBs.

Bioinspired Nanoporous Ion Conducting Membranes for Next Generation Batteries Ahmet Emre, Jinchen Fan, Emine Turali-Emre, Alycia Gerber, Volkan Cecen and Nicholas Kotov; University of Michigan, United States

Bioinspired ion transport membranes have been widely investigated for energy storage applications. High theoretical specific energy density (2600Wh/kg) and high specific capacity (1675mA/g) along with natural abundance and low toxicity of sulfur have been attracting significant attention for development of an alternative battery system to replace traditional lithium ion batteries which suffer from safety and capacity/energy density limitations in various applications. However, challenges such as polysulfide dissolution and shuttling prevent mass commercialization of metal sulfur batteries. Inspired from biological ion transport mechanisms, we show a practical yet comprehensive approach for development of highperformance metal sulfur batteries. Aramid nanofiber (ANF) based composite ion transport membranes not
only prevent dendrite formation but also confine polysulfides on the cathode side. ANF composite battery separators provide diverse and opposing properties including high mechanical properties, high ionic conductivity and high thermal/chemical stability. Highly selective ion sieving properties of these biomimetic separators provide safe and high-performance batteries. Fabrication of such biocompatible, affordable,
flexible and high energy density battery is quite crucial in powering next-generation electronics including but not limited to portable, wearable and implantable biomedical devices.

5:30 AM F.EN04.24.05
1500 Wh/L and 580 W/L Lithium Cobalt Oxide Electrodes Xiujun Yue[1], Sungbong Kim[2], Ryan R. Kohlmeyer[3], Chadd T. Kiggins[3], Alissa C. Johnson[1], Arghya Patra[2], Aaron J. Blake[3], Jessica A. Grzyb[1], Akaash Padmanabha[1], Min Wang[1], John Cook[3], Paul Braun[2,2,2] and James H. Pikul[1]; [1]University of Pennsylvania, United States; [2]University of Illinois at Urbana Champaign, United States; [3]Xerion Advanced Battery Corporation, United States

New battery architectures have enabled large improvements in battery energy and power density by improving ion and electron transport through multiple solid and liquid materials as well as maximizing the volume fraction of energy storage materials. The standard battery architecture for lithium ion battery electrodes is made of small particles (to reduce solid transport distances) tightly packed together (to increase energy density and reduce interfacial resistances) with a small fraction of fillers that increase conductivity, adhesion between particles, and processability. Although effective, this slurry cast particle architecture has important limitations on energy and power. Thick electrodes increase energy density and reduce fabrication costs, however, the associated long transport distances of Li ions and electrons in thick slurry cast electrodes greatly hinder the power output. Delamination issues also limit the thickness of slurry cast electrode below ~100 μm. As a result, most electrode loadings are lower than 20 mg/cm^2, which correspond to 2−3 mAh/cm^2. Meanwhile, electrode porosity, carbon additives, and binder account for about one-third of the inactive volume in the electrode. These limitations in slurry cast particle electrodes cause significant trade-offs between energy, power, and cost for lithium and lithium-ion batteries.

Here, we demonstrate lithium cobalt oxide (LCO) based electrode architectures delivering 1516 Wh/L (over 3X higher capacity than typical slurry electrodes) electrode energy density at a loading of 52 mg/cm^2 (3X higher than typical slurry electrodes) while keeping a practical current density of 1.46 mA/cm^2, which correspond to 580 W/L power density. To achieve this performance, we electrochemically deposited hundreds of micrometer thick and up to 98% dense LCO directly onto current collectors from molten salts. Since no carbon and polymer binder was required, and the electrodes were almost completely dense, our monolithic LCO cathodes delivered close to theoretical electrode energy densities. Traditional approaches suggest that cathodes need to be ~1-10 μm thick to achieve good power density, but despite our electrode being over 100 μm thick, we extracted 63% of the electrode capacity at 1C rates (7.3 mA/cm^2) because the electrode grains were aligned so that the fastest transport directions were normal to the current collector. With a working potential of 2.5-4.7 V, our 113 μm thick (52 mg/cm^2) monolithic LCO electrode delivered 1516 Wh/L and 580 W/L at a current density of 1.46 mA/cm^2. The electrode delivered 639 Wh/L at an ultra-high 14.6 mA/cm^2 current density (5025 W/L), which is about 15% more energy than conventional electrodes discharged at low current. We realized 60% of the above energy density over the working potential range of 3-4.3 V. In addition to improved performance, these electrodes allowed for new manufacturing methods. We demonstrated this by fabricating lithium metal primary microbatteries with 400 Wh/kg and 900 Wh/L energy densities. These microbatteries had 4x larger energy density than previous size-comparable batteries.

5:40 AM F.EN04.24.06
Effect of Iron Substitution on Cobalt Oxide and Study of Its Electrochemical Performance Deepa Guragain; The University of Memphis, United States

The application of metal oxides has been increasing for energy storage device due to excellent electrochemical properties, multifunctional energy application, environmentally friendly property and lower price. Due to rapid growth of energy use, there is very high demand for new ways to store energy. It is challenged to develop efficient way to store energy without polluting environment, which is possible by using transition metal oxide. We have prepared $Fe_xCo_{3-x}O_4$ (x=0.0, 0.2,0.4,0.6,0.8,1) successfully via hydrothermal method from which we can prepared electrode to make supercapacitor device. The structural properties were investigated by X-ray diffraction (XRD) and found phase pure $Fe_xCo_{3-x}O_4$. The morphology of the series obtained from scanning electron microscopy (SEM) varies from thinner nano-plates to thicker nano-plates as the concentration of Fe increase from x=0.0 to x=1.0. Furthermore, $Fe_xCo_{3-x}O_4$ were characterized by X-ray Photoelectron spectroscopy (XPS), Fourier Transform Infrared Spectroscopy (FTIR) and Quantachrome Surface area analyzer. The maximum BET surface area obtained from Quantachrome Instrument for x=1 is 87.5 m2/g. The XPS gives elemental composition of $Fe_xCo_{3-x}O_4$ as in desired amount. The higher specific capacitance of 268 F/g at a current density of 1 A/g, 856 F/g at 2 mV/s scan rate, the energy density of 16 Wh/kg and power density of 170 W/kg in 3M KOH electrolyte was observed for x =1 sample. An increased retention capacity ~122 % measured at 5 A/g current density and Coulombic efficiency of 100%. All these results indicate Fe dope Co_3O_4 composites electrode shows promising electrocatalytic activity results in the high intrinsic electronic conductivity, can largely improve the interfacial electroactive sites, increase charge transfer rates and help to stabilize the structure of compound.

5:50 AM F.EN04.24.07

Porous Inorganic Electrode for High Perfomance Li-O_2 battery Hyunpyo Lee, Tae Young Kim, Mokwon Kim and Wonsung Choi; Samsung Advanced Institute of Technology, Korea (the Republic of)

Li-O_2 batteries with high capacity have been studied for several decades because of their superior energy density compared to Li-ion batteries. The cathode composed of carbon materials and an liquid electrolyte could play a critical role for reducing the cathode weight. However, due to the limitation of carbon based cathode, the Li-O_2 cells can't achieve both a high energy density and long cycles. It is well known that discharge product, Li_2O_2, formed during a discharge reaction with lithium ions and oxygen molecules decomposes the carbon based materials to produce Li_2CO_3.
In this study, we propose a porous inorganic electrode without an organic liquid electrolyte. The $LiNi_2O_4$ inorganic electrode is stable in saturated aqueous LiOH solution for 1 week. Porous $LiNi_2O_4$ electrode was prepared by slurry-coating by doctor-blade with sacrificial Poly(styrene-divinyl benzene) (PS-DVB) microspheres having 3 mm diameter. After thermal treatment, PS-DVB microspheres are clearly removed and introduce the pore architecture which facilitates fast oxygen transport and increases the discharge-charge reaction surface area to achieve high current density during cycles. It also acts as a storage of the discharge products, LiOH monohydrate. The reversible reaction in cathode is observed by SEM and FT-IR. With this strategy, we achieved 55 cycles at high current density (0.6 mA/cm^2) and high capacity (3 mAh/cm^2)

6:00 AM F.EN04.24.08
Incorporating a Br_3^-/Br_2-based Redox Mediator in Li–O_2/CO_2 Batteries: Performance and Mechanism Assessment Filipe Marques Mota[1], Hye Ryung Byon[2] and Dong Ha Kim[1]; [1]Ewha Womans University, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

A key step to assure the practical application of Li–air batteries involves replacing O_2 with air. The presence of CO_2 in the air (>400 ppm), however, critically alters the underlying O_2 chemistry of the Li–air battery.[1] CO_2 added to Li–O_2 cells in a tetraglyme-electrolyte was shown to swiftly shift the discharge reaction mechanism toward the formation of soluble CO_4^{2-} and $C_2O_6^{2-}$ products and solid-state Li_2CO_3. Surprisingly, CO_2 was shown to favorably act as an O_2^- scavenger during discharge, with the resulting soluble products being also correlated with enhanced full capacity and cell cyclability. Compared with the conventional Li–O_2 however, the introduced CO_2 resulted in higher recharge potentials (~4.5 V) required for the decomposition of Li_2CO_3, rendering impracticable the commercialization of these technologies.[2] In this study, we assessed the promise of incorporating a Br_3^-/Br_2-based redox mediator to suppress the overcharge potential.[3] Hindered overcharges (~0.5 V) driven by electrochemically-generated Br_2 were found to be a function of the LiBr concentration and the insulating Li_2CO_3 structure. Coupled electrochemical and spectroscopic analyses additionally discerned involved redox shuttling steps at progressive states-of-charge and, for the first time, the prominent presence of Br_2—Br_3^- loosely-bound anionic complexes in the electrolyte during the recharge step. As opposed to discrete polar Br_2 irreversibly precipitated on the CNT surface, these soluble Br_2—Br_3^- species were proposed to operate as redox mediators with advantageous facile diffusion. These findings foment the evaluation of the appropriateness of redox mediators beyond an overcharge decrease, and shed light for the development of Li–air devices.

F-EN04

5:00 AM F.EN04.25.01
A Fast Charge/Discharge And Wide-Temperature Battery With Ultra-Thin Germanium Oxide Layer On 2D TiCA3 MXene Matrix As Anode Junjie Niu; University of Wisconsin-Milwaukee, United States

In contrast to silicon, germanium shows an electrical conductivity of ~1.0 S m^{-1} that is 100 times higher than silicon, and a fast lithium ion diffusivity of 10^{-12} -10^{-8} cm^2 s^{-1} that is 400 times faster than silicon, leading to a promising potential in rapid charge/discharge batteries. Similar as silicon, the large volume expansion upon lithiation/delithiation leads to capacity decay

and thus poor cycling performance. The scalable production of complex nano-structures also pose a challenge. Recently MXene, a family of 2D transition-metal carbides, are attracting great interest in lithium-ion batteries due to their unique electrical, mechanical and electrochemical properties particularly with the high electrical conductivity. Here we present a novel 2D hybrid composite that is composed of 2D layered MXene as host covered with a thin layer of amorphous GeO_x, which showed an improved rate capability as anode electrode in lithium ion batteries (***ACS Nano 2020, 14, 3678–3686***). The battery with hybrid composite as anode maintains 90% of the initial capacity with a coulombic efficiency of 99.4 % after charging/discharging 500 cycles at 0.5 C. A high capacity retention under 10.0 C and 20.0 C and a wide temperature between -40 and 80 C was achieved. A full-cell battery paired with NMC as cathode also exhibited a high capacity.

5:10 AM F.EN04.25.02
Microstructural Evolution and Electrochimical Properties of Arachis Hypogaea Shell Derived *Ex Situ* Nitrogen-Doped Activated Carbon for Energy Storage Applications as Supercapacitor Balla D. Ngom[1], Ndeye Fatou D. Sylla[1], Ndeye Maty Ndiaye[1], Mohamed Chaker[2] and Ncholu Manyala[3]; [1]Universté Cheikh Anta Diop de Dakar, Senegal; [2]INRS, Canada; [3]University of Pretoria, South Africa

We report on the correlation of the microstructural evolution and electrochemical properties of an ex-situ N-doping KOH activated carbon derived from Arachis Hypogea Shell (NAC-AHS) and compared to the non-doped (AC-AHS). Interconnected cavities with irregular-shaped structure are reported by SEM analysis for AC-AHS. After nitrogen doping, the morphology of the NAC-AHS materials exhibited a less porous structure as compared to AC-AHS. The surface specific area (SSA) of NAC-AHS was found to be 1442 $m^2\ g^{-1}$ lower than the value of AC-AHS (1557 $m^2\ g^{-1}$), the pore volumes were also found to follow the same trend since the reported values are as follow 0.76 $cm^3\ g^{-1}$ and 0.69 $cm^3\ g^{-1}$, respectively for AC-AHS and NAC-AHS. The AC-AHS and NAC-AHS exhibited in a half cell a specific capacitance (C_s) values of 167 F g^{-1} and 216 F g^{-1}, respectively at 1 A g^{-1}, corresponding to an improvement of 30% after ex-situ N-doping, which agrees with the higher current response recorded in the CV profiles of the samples. A symmetric device fabricated from the NAC-AHS materials displayed a Cs of 251.2 F g^{-1} at 1 A g^{-1} in a wide operating voltage of 2.0 V in 2.5 M KNO_3 aqueous electrolyte. In terms of stability, it achieved 83.2% as capacity retention up to 20,000 cycles, which was, improved through the floating/ aging measurement at 5 A g^{-1}over a long period of time (~7+ days). A specific energy of 35 Wh kg^{-1} with a corresponding specific power of 1 kW kg^{-1} at 1 A g^{-1} was delivered with the device still retaining up to 22 Wh kg^{-1} and a 20 kW kg^{-1} specific power even at 20 A g^{-1}.

5:20 AM F.EN04.25.04
MXene Nanosheets as Active Materials for Nonaqueous Monovalent-Ion Battery Electrodes Davi Marcelo Soares[1], Christopher Shuck[2], Narendra Kurra[2], Yury Gogotsi[2] and Gurpreet Singh[1]; [1]Kansas State University, United States; [2]Drexel University, United States

Two-dimensional (2D) materials are deemed as more efficient players regarding ionic intercalation compared to their bulk counterparts. This property makes 2D materials attractive for applications such as energy storage. Within this ever-ascending group, 2D transition metal carbides, carbonitrides and nitrides (MXenes) are studied since 2011 due to their versatile chemistry and consequent surface terminations, which provide hydrophilic surfaces, unlike graphene, for instance. Here we study three MXene species, namely Mo_2TiC_2, $Mo_2Ti_2C_3$, and Ti_3C_2 as anode materials for lithium (LIB), sodium (SIB), and potassium-ion batteries (KIB). In terms of electrochemical results, our findings indicate reasonable cycling stability under galvanostatic charge-discharge for all alkali metal ion batteries studied. Interestingly, Ti_3C_2 potassium-ion presented the highest first cycle capacity drop; however, it also yielded the highest specific first cycle charge capacity of 305.6 mAh g^{-1}. Detailed electrochemical impedance spectroscopy (EIS) studies are also presented for better understanding of the charge storage mechanisms taking place in the MXenes studied.

5:30 AM F.EN04.25.05
WTe_2, a Semimetal Transition Metal Dichalcogenide Electrode for Potassium-Ion Batteries Davi Marcelo Soares and Gurpreet Singh; Kansas State University, United States

Potassium-ion batteries have currently been in the spotlight as an alternative to lithium- and sodium-ion batteries due to abundant availability, low reduction potential, and high theoretical energy density. Although some chemistry correlation with other monovalent-ion batteries may exist, research on potassium-ion battery chemistry is still in its infancy. Hence, a relevant research aspect of potassium-ion rechargeable batteries is the development of electrode materials that may efficiently intercalate the larger size K^+ ions in its layered structure; thus, providing reasonable capacity and reversibility. With a peculiar electronic structure, here we report the semimetal tungsten ditelluride (WTe_2) as anode material for potassium-ion batteries. This layered material presents reasonable cycling stability and specific capacity within 0 to 3 V potential range.

Results show that WTe_2 may store up to 3.3 K^+ per formula unit, at least 4 times of WS_2 KIB electrode. In sum, this work unravels the potential of WTe_2 as anode for potassium-ion batteries with respect to its physical and electrochemical properties.

5:40 AM F.EN04.25.07
On-Chip Interdigital 3D Carbon Microelectrode for High-Energy Lithium-Ion Capacitor Ebenezer Adelowo, Amin Rabiei Baboukani and Chunlei Wang; Florida International University, United States

The need for high-performance microscale energy storage units for rapidly growing microelectronic devices have continued to attract much attention. Miniaturized batteries and electrochemical capacitors (ECs) are attractive candidates for on-chip energy storage applications. Typically, ECs can give advantageous characteristics such as higher power density, faster charge/discharge properties, and ultralong cyclability than batteries. However, the limited energy density of ECs represents a significant drawback. One strategy to overcome this issue is based on the combination of the bulk and surface storage mechanisms by a battery-type and a capacitor-type electrode. Lithium-ion capacitor (LIC) is one such systems, consisting of a high energy battery-type electrode and high power capacitor-type electrode. On-chip LICs could potentially be favorable for integration along with other components in microelectronic devices to provide a good combination of high energy and power densities within a limited footprint area. Carbon microelectromechanical systems (C-MEMS) technique is one of the most interesting 3D microelectrode fabrication approaches which generally involves photolithographic patterning and pyrolyzing photoresists in an inert atmosphere to obtain glassy carbon structures. C-MEMS process is a facile route of obtaining a wide variety of ordered 3D carbon microelectrode structures with high resolution. Given the prospects of providing enhanced areal capacity, this study demonstrates a novel first-generation 3D on-chip LIC based on C-MEMS-derived interdigital carbon microelectrodes. In this work, the total developed electrode geometric surface area of each side of the interdigital microelectrode was ~0.07 cm^2. An aqueous on-chip LIC was fabricated using carbon microelectromechanical systems (C-MEMS) technique. Oxygen plasma-treated 3D carbon microelectrode arrays served as the capacitor-type electrode in the LIC, while $LiFePO_4$ integrated on the 3D carbon microelectrode arrays was used as the battery-type cathode. Among the devices, the 5 min plasma-treated sample gives the highest discharge capacity. The discharge capacities calculated from the GCD curves for 0, 1, 5, and 10 min plasma treatment durations were about 0.001, 0.041, 0.297 and 0.138, μAh cm^{-2}, respectively, based on device footprint area. The rate performance results also shows that the 5 min plasma-treated device gave the highest discharge capacities at different current densities. The discharge capacities after the tenth cycle for the 5 min plasma-treated sample at current densities of 0.24, 0.48, and 0.60 mA cm^{-2} were about 0.63, 0.18, and 0.13 μAh cm^{-2}, respectively, based on device footprint area. The decreased discharge capacities of the device upon further increasing the oxygen plasma treatment duration from 5 to 10 min may be attributed to the reduced effective surface area of the interdigital microelectrodes. Electrochemical performance evaluation shows that the aqueous on-chip LIC can deliver an areal density up to ~5.03 μWh cm^{-2}, which is ~5 times higher than the oxygen plasma-treated symmetric carbon microelectrode-based electrochemical capacitor. Our work is an initial full cell study on the application of the C-MEMS technique for the development of on-chip LIC in aqueous electrolytes. The C-MEMS approach demonstrated in this study exhibits promising potential for the facile development of on-chip LICs with 3D microelectrodes. The on-chip LIC could potentially be favorable as a high-performance compact and integrable energy storage system for practical application in microelectronic devices. The developed electrode preparation and its material and electrochemical characterizations will be discussed in detail at the conference.

SESSION F.EN04.26: New Materials Developments and Characterizations
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-EN04

5:00 AM F.EN04.26.02
Thick High Energy Density Electrode Fabrication and Active Material Synthesis Using Spark Plasma Sintering Arina Nadeina[1,2], Patrick Rozier[3,2] and Vincent Seznec[1,2]; [1]University of Picardie Jules Verne, France; [2]Réseau sur le Stockage Electrochimique de l'Energie (RS2E), CNRS FR3459, France; [3]Université de Toulouse, France

Spark Plasma Sintering (SPS) has proven to be an effective, rapid, and energy-efficient tool in the sintering of a variety of materials, such as ultrahigh temperature ceramics, composites, thermoelectric and magnetic compounds. Its main difference from the traditional sintering techniques (hot pressing, pressureless sintering, microwave sintering, etc) consists in the use of

the direct pulsed current along with a uniaxial pressure to obtain well-compacted materials. Due to the fast heating/cooling rates and internally generated heat (resistive heating), the obtained compounds experience little to no particle growth while shortened sintering times ensure the absence of the unwanted side-reactions. Recently, SPS has been demonstrated to be used not only for the sintering of materials but also for their synthesis making it an attractive technique in the fabrication of thick high energy density electrodes for Li- or Na-ion battery application as well as in the synthesis of battery's active material compounds or the fabrication of all-solid-state batteries [1-5].
High energy density electrodes could be obtained by altering the electrodes' architectures. In pursuit of increasing the energy density, some methods suggest fabrication of (ultra)thick electrodes while others concentrate on the production of electrodes with a minimum amount of inactive materials (binder-free, conductive additive-free, integrated current collectors, etc). Owing to a rapid and highly efficient sintering process, SPS offers a luxury of obtaining simultaneously binder-free and (ultra)thick electrodes which suffer no structural degradation. In 2018 Elango et. al reported a successful Spark Plasma Sintering of the $LiFePO_4$ and $Li_4Ti_5O_{12}$ electrodes with controlled porosity by hard templating method (NaCl leaching) [1]. Obtained by SPS and templating approach ultrathick electrodes (1 mm thick) showed remarkable electrochemical performance at C/20 against lithium metal delivering areal capacities 4 times higher than those of the conventional tape-casted electrodes. This study coming from our group demonstrated the proof-of-concept in the fabrication of Li-ion battery electrodes with an ultrathick design by means of SPS.
Such a fabrication technique is expected to be easily transferrable to other battery types like Na-ion batteries. However, commonly used Na-ion battery materials are not as widely produced as their Li counterparts and still require long and tedious synthesis procedures. In our work, we have recently demonstrated that SPS could be used to synthesize a common Na-ion battery cathode material – $Na_3V_2(PO_4)_2F_3$ – in under only 40 min[2] which resembles a phase-pure compound with small particle size showing slightly enhanced electrochemical performance when compared to the solid-state synthesized NVPF. SPS-synthesized NVPF requires no further treatment and could be used directly as an active material component in the production of our thick binder-free electrodes.
In this presentation, apart from the Spark Plasma Sintering-assisted synthesis of active materials for Na-ion battery application, a new generation of thick binder-free electrodes will be presented. Correlation between the electrode architecture (porosity, pore size/shape distribution, tortuosity, etc), synthesis/sintering parameters, nature of precursors, and the electrochemical performance will be discussed.

Mechanical Properties of Electrochemically Lithiated Tin Chung Su Hong and Seung Min J. Han; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Sn possesses three times higher capacity in comparison to graphite anode (372 $mAhg^{-1}$) which makes it a promising candidate for enhanced performance Li ion batteries. Contrary to Si, Sn is compliant and ductile in nature and thus is expected to readily relax the Li diffusion-induced stresses. The low melting point of Sn additionally allows for stress relaxations from time-dependent or creep deformations even at room temperature. In this study, intrinsic mechanical properties of lithiated Sn at various stages in the lithiation were evaluated using nanoindentation experiments using a special setup. In order to avoid oxidation of the highly reactive lithiated Sn, nanoindentation was performed on specimens submerged in a mineral oil bath. After careful calibration, hardness and modulus of different phases of lithiated Sn were evaluated. With increasing in the lithium content, both the hardness and modulus of the lithiated tin decreased, as expected, where the hardness and modulus are 28.6 GPa and 0.37 GPa, respectively, for fully lithiated Sn ($Li_{22}Sn_5$) and 58.0 GPa and 0.76 GPa, respectively, for unlithiated Sn. This is the first report on the mechanical properties of lithiated Sn, which is expected to be of importance in theoretical analysis of the diffusion induced stresses in Sn anodes.

Activation of Electrochemical Water-Splitting by Tuning the Polarity of Cu-Deposited Poly(vinylidene fluoride-co-hexafluropropylene) Fibrous Catalyst Shunsaku Uchiyama, Asuka Morinaga, Hiromori Tsutsumi and Yu Katayama; Yamaguchi University, Japan

Water electrolysis is an ideal method for producing hydrogen, which is expected as a next-generation energy carrier. However, the sluggish reaction kinetics of the oxygen evolution reaction (OER) limits the overall energy efficiency.[1,2]

We here present a highly-efficient water electrolyzer, consist of the metal-deposited fibrous electrode supported on a nonwoven polarized sheet, synthesized via simple and scalable electrospinning and electroless deposition methods. We selected PVdF-HFP with tunable polarity as catalyst support, to promote the diffusion of the ions in the electrolyte and optimize the reaction energetics. Cu was used as an electrocatalyst, owing to its low cost and excellent electrical conductivity. Various spectro(electro)chemical methods were performed, including infrared spectroscopy, X-ray photoelectron spectroscopy, and linear sweep voltammetry, to clarify the effect of the geometric structure of Cu and polarity of the catalyst support on the OER activity. It was found that the fibrous structure of Cu catalyst increases the active surface area as well as optimizes the mass transport and diffusion, which contributes to the improved OER activity. Furthermore, the high dipolar moment and large dielectric constant for a polarized PVdF-HFP can assist OER by its unique catalyst-support and reactant-support interaction, which can optimize the OH adsorption energetics and diffusion of the reactant (e.g., OH^-), respectively. We successfully build a prototype water electrolyzer with a nonwoven fabric-fibrous electrode assembly, which achieved the stable water electrolysis for more than 24 h at 2.5 V.
This work opens up a new avenue to fabricate a flexible and durable water electrolyzer in a scalable way, which expands the applicability of the water electrolyzer and provides a new strategy to simplify the fabrication procedure of electrocatalysts for various energy conversion/storage reactions.

Universal Utilization of Charge-Transfer Complexes for High Power- and Energy-Density Organic Rechargeable Batteries Sechan Lee[1], Jihyun Hong[2] and Kisuk Kang[1]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Organic electrode materials hold great potential due to their low cost, minimal environmental footprint, and chemical diversity. However, their electrochemical performances could not reach the level of currently used electrode materials due to the relatively low redox potential, low electrical conductivity, and high solubility in organic solvents. Those drawbacks have not been simultaneously overcome with the single moiety-based tuning such as molecular tailoring and hybridization with conductive scaffolds. Herein, we report the novel design paradigm of organic charge-transfer complexes (OCTCs), an association of two or more types of organic molecules in which a fraction of electronic charge is transferred between the molecular entities, as a new category of organic electrode material candidates.[1, 2] The OCTCs exhibit superior electrochemical performances in terms of rate capability, energy density, and cyclability, compared to the single-moiety-based organic electrode materials discovered so far. The improved performances are attributed to the high electronic conductivity and structural stability. Well-ordered stacking of the molecular layers in OCTCs creates a charge-transport path through which electrons can move freely, and the strong intermolecular interaction such as hydrogen bonding and π-π interaction secure structural stability.
We first introduce the OCTC through a combination of phenazine (PNZ) and 7,7,8,8-tetracyanoquinodimethane (TCNQ) via a room-temperature synthesis.[1] OCTC exhibited the enhancement in the electrical conductivity for 5 order magnitudes and reduction in the dissolution for 2-5 times, resulting in the high power and cycle performances that far outperform those of each single-moiety counterpart in Li-ion battery. In order to optimize the electrochemical performances in terms of energy- and power-density, two further steps were progressed in the molecular- and battery-level. First, dibenzo-1,4-dioxin (DD) is adopted due to the high redox potential of 4.1 V *vs.* Li/Li^+, and DD-TCNQ OCTC showed the increased practical energy density of 560 Wh kg^{-1}.[1] On the other hand, an aqueous electrolyte is applied to further enhance the rate performance of OCTC. Zinc aqueous batteries could achieve the ultrahigh level of active contents (80%) and loading density (10 mg cm^{-2}) with fully utilizing the specific capacity (~250 mAh g^{-1}) from both PNZ and TCNQ.[2] Surprisingly, it is observed that the redox mechanisms are different according to the electrolyte types, and we revealed that the formation of the TCNQ-electrolyte complex affects the redox reaction path. These findings demonstrate the general applicability of the OCTCs and open up an uncharted pathway toward the development of high-performance organic electrode materials via the exploration of various combinations of donor-acceptor monomers with different stoichiometry.

Understanding Length-Scale Dependence of Morphological Instability in Electrodeposition Processes Snehashis Choudhury and Lynden Archer; Cornell University, United States

Advances in the basic science and engineering principles of electrochemical energy storage is imperative for significant

progress in portable electronic devices. In this regard, metal batteries based on a reactive metal (like Li, Na) as anode have attracted remarkable attention due to their promise of improving the gravimetric energy density by at least 3-folds, compared to the current Li-ion battery that uses graphitic anode. However, a persistent challenge with metal batteries is their propensity to fail by short-circuiting due to dendrite growth, and by runaway of cell resistance because of internal side reactions. In this talk, I will discuss my research that utilizes multiscale transport modeling and experiments to fundamentally understand and thereby develop rational designs for polymer electrolytes and electrochemical interfaces to overcome these challenges. Specifically, we utilized linear stability analysis of metal electrodeposition and showed that the length-scale on which transport occurs near the electrodes can be as important as electrolyte modulus in stabilizing metal deposition. To evaluate this concept, we designed cross-linked polymer electrolytes with tunable nanostructure and quantified corresponding dendritic growth. Direct visualization of electrodeposition using optical microscopy showed remarkable agreement with the theoretical predictions.

Modeling the Amorphous Na2Ge-GeSe2 Chalcogenide System Max S. Win[1], Charles A. Sievers[1], Riccardo Dettori[1], Nir Goldman[2] and Davide Donadio[1]; [1]University of California, Davis, United States; [2]Lawrence Livermore National Laboratory, United States

Li-ion batteries with polymer-electrolytes still have several disadvantages related to costs, safety, and materials' availability. It would be desirable to develop alternative storage devices comprising solid-state electrolytes and sodium ions, which may replace current Li-ion batteries for certain applications. The Na2Ge-GeSe2 chalcogenide glass-ceramic was proposed as a promising material to be used as a solid electrolyte for Na-ion batteries. The complex chemistry and structural heterogeneity of this material are hardly described by empirical potentials, calling for first-principles modeling. However, first-principles simulations involve high computational costs and cannot scale to the size and time scales necessary to characterize the functional behavior of this material, thus requiring a multiscale approach.
Initially, we show that parameter-free ab initio molecular dynamics (AIMD) simulations reproduce the experimental properties of Ge-Se melts at different stoichiometry, and predict the structural variations induced by the inclusion of Na. In this study, we overcome the size and time scale limitations of AIMD by constructing suitable machine-learning potentials - based on the Chebyshev Polynomials paradigm (ChIMES) - with which we can simulate quenching from the melt and Na diffusion. This study will allow us to finally characterize amorphous Na-intercalated GeSe2 and predict its ionic conductivity at various conditions.

Recent Insights into Material Properties and Chemical Dynamics of the Lithium SEI Betar Gallant; Massachusetts Institute of Technology, United States

Achieving a truly stable and reversible Li metal anode would enable a step-change in today's battery energy densities if key hurdles of reactivity, insufficiently high Coulombic Efficiency, parasitic electrolyte consumption and loss of active Li can be addressed. These challenges arise invariably from reactivity at the solid electrolyte interphase (SEI) on Li. After decades of study, the native SEI, which is highly chemically nonuniform, fragile, and nanoscopically thin (< 100 nm), remains notoriously difficult to experimentally probe. To identify strategies that may rationally address these challenges by interface or electrolyte design, improved understanding of the chemistry, structure, and function of the SEI are still needed.

In this talk, I present our recent studies on dynamic processes occurring in SEI-forming reactions and also within a nominally-established SEI. First, I describe our studies on single SEI components, which we have conducted to isolate and simplify the multi-phase SEI for experimental study. We have developed synthetic approaches based on Li reactions with oxide- and fluoride-donating reactants that permit formation of a compositionally uniform SEI consisting entirely of lithium fluoride (LiF) or lithium oxide (Li_2O). The stability of LiF within the Li SEI is first examined. We find that, counter to some

assertions in literature, LiF does not fully protect Li from electrolyte reactions under even mild cycling conditions; its breakdown invites infiltration and repair from the electrolyte, causing the SEI to evolve over time to reflect the electrolyte chemistry more than the initial interphase. We compare these results to those obtained with fluorinated electrolyte, high-concentration LiFSI in FEC, and discuss our conclusions regarding the origin of improved cycling and high Coulombic Efficiency in fluorinated electrolyte systems. Next, I will discuss recent findings on transport properties of Li_2O and LiF at the interface of Li. Using impedance measurements coupled to a transport model of the interface, we have extracted conductivity, diffusion coefficients, and carrier concentrations of these phases at the chemical potential of Li for the first time. Our results indicate significant differences between Li_2O and LiF that help to identify less-resistive phases that may support more facile ion transport. Finally, I will present our emerging understanding of the chemical stability of these individual phases, Li_2O and LiF, in contact with carbonate electrolytes. Using X-ray absorption near-edge spectroscopy, we have probed the reactivity of ionic SEI phases upon exposure to electrolyte, and find evidence of varying interfacial stability as a function of SEI and electrolyte composition due to reactions at the SEI-electrolyte interface. These results help illuminate the origins of commonly-observed changes in SEI impedance over hours or days in certain electrolytes, which have lacked chemical specificity to date, and identify motifs for improved stability. The integration of this knowledge to guide design of improved SEI chemistries will be discussed.

6:15 AM F.EN04.26.12
Flexible, Biocompatible Batteries for Bioelectronics Patricia Jastrzebska-Perfect[1,2], Georgios Spyropoulos[1], Onni Rauhala[1], Jennifer Gelinas[1], Dion Khodagholy[1] and Richard Yao[1]; [1]Columbia University, United States; [2]Massachusetts Institute of Technology, United States

The wide range of operations performed by implantable bioelectronic devices mandates reliable, stable and biocompatible sources of power. Commercially available batteries, even those used in implantable devices, are predominantly based on toxic and volatile compounds that require bulky, rigid encapsulations to protect the body from exposure. Here, we introduce a battery that functions on the basis of the work-function difference between conducting polymers and inner metals, materials that are currently utilized clinically within implantable devices. To provide mechanical flexibility and high charge capacity, we developed physical processes that create dense particulate films from bulk material. Particles can slide freely within these films, ensuring flexibility that persists even when volume of material is substantially increased. We investigated how metal particle size affected anode conductivity, Young modulus, and battery discharge time. We further investigated how electrolyte membrane thickness affected metal dissolution, device capacitance, and battery cycling ability in digestive fluids. We evaluated the battery's performance and its potential application to medical devices by developing an ingestible "electronic pill" that allows wireless pH sensing and drug delivery within the gastrointestinal tract. Overall, the mechanical flexibility and biocompatibility of material used in such batteries should allow them to become a critical component of implantable bioelectronic devices.

6:25 AM F.EN04.26.15
Binder Preparation Method Influence on Silicon Anode Architecture as Probed by X-Ray Nanotomography Mary K. Burdette-Trofimov[1], Beth Armstrong[1], Johanna Weker[2], Alexander M. Rogers[1], Guang Yang[1], Ryan R. Armstrong[1], Ethan C. Self[1] and Gabriel Veith[1]; [1]Oak Ridge National Laboratory, United States; [2]SLAC National Accelerator Laboratory, United States

In this work, x-ray tomography data of silicon anodes is used to reveal the distribution of poly(acrylic acid)-based binder and silicon. This data reveals that processing conditions directly mediate the electrode (in)homogeneity. X-ray nanotomography shows poor binder and silicon intermixing resulting in segregation of silicon and binder where the binder is in the middle of the electrode. Electrode homogeneity could be improved by adding a dispersant to the slurry, which, in turn produced better cycling performance. This data may shed light on some of the reasons behind the large variability observed in the literature with respect to silicon electrode performance and proposes a way to increase electrode homogeneity.

New Chemistries for Safe and High Energy Density Lithium Primary Batteries Using Condensed Fluorinated Reactants Haining Gao and Betar Gallant; Massachusetts Institute of Technology, United States

For long-duration standalone power needs such as unmanned vehicles, space applications, and implantable/portable medical

devices, batteries need to have longer operation times and thus higher energy densities. Although today's state-of-the-art Li primary battery, Li−$SOCl_2$, has high specific energy (~500 Wh/kg), it is highly toxic if vented or leaked. Therefore, research into safer primary batteries that can achieve high energy density remains essential. Our previous work into Li-perfluorinated gas batteries, such as Li-SF_6 and Li-NF_3 batteries, demonstrated that perfluorinated compounds that are nominally chemically inert (thus have high safety) can be electrochemically activated through multi-electron transfer reduction reactions, resulting in a high theoretical energy density (*e.g.* 3922 Wh/kg for SF_6). However, the intrinsically low solubility of perfluorinated gases in typical battery electrolytes (< 5 mM) makes it necessary to have a gas reservoir present in the cell, resulting in difficulties to further optimize volumetric capacity. To overcome these issues induced by the gas phase, but still retain a multiple electron transfer reaction, we have subsequently studied new battery chemistries using liquid fluorinated reactants: an iodo-fluorocarbon series ($C_6F_{13}I$, C_4F_9I, and C_3F_7I), or 'Li-CFI'. This battery system utilizes lithium metal as the anode, and liquid CFI as both the electrolyte and active cathodic component. The Li−CFI batteries exhibit attractive electrochemical performance, with voltages up to 2.9 V and an areal capacity of > 5 mAh/cm^2 (at 0.3 mA/cm^2 on un-optimized low surface area gas diffusion layer (GDL) cathodes). The liquid nature of CFI also contributes to its outstanding rate capability: an areal capacity of ~3 mAh/cm^2 is achievable at a current density as high as 1 mA/cm^2 (on GDL). In addition to the cell configuration and performance, the discharge reaction mechanism, effect of molecular structure on the electrochemistry, and electrode/electrolyte balance strategy will be discussed. We will point to current challenges for the Li−CFI system, including relatively sluggish reduction kinetics after the first electron transfer and overpotential induced by electrode passivation. Strategies to address these issues in ongoing work will also be provided. In addition to the cathode reaction, the operation of the Li anode in these novel fluorinated electrolytes will be discussed, including the potential of using CFI to construct a stable solid electrolyte interface (SEI) on Li metal surface and improve the Li stability and cycle performance for secondary batteries.

Designing Intercalation for High-Valent Redox William C. Chueh; Stanford University, United States

Increasing the energy density of intercalation positive electrodes in Li- an Na-ion batteries necessitate high talent redox couples. Oxygen redox has emerged as a versatile and promising high-talent redox couple. However, the reversibility of this redox couple is low compared to conventional lower-valent transition metal redox couples. In this talk, I will present understandings of and design rules for high-talent redox in intercalation compounds.

7:00 AM F.EN04.26.19
Overcoming Transport Limitations in Ionic Liquid Electrolytes through an Atomistic Understanding of Ionic Correlation and Transport Nicola Molinari[1], Jonathan P. Mailoa[2] and Boris Kozinsky[1,2]; [1]Harvard University, United States; [2]Robert Bosch LLC, United States

Electrolytes comprising a Li-salt (or other alkali metal salts) dissolved in ionic liquids (ILs) are often seen as attractive candidates to replace flammable organic solvents, mainly due to their superior safety. However, relatively poor transport properties hinder their applicability. Due to high salt concentrations and long-range Coulombic interactions, these systems possess high degrees of inter-species ionic correlation, thus posing a crucial and interesting challenge to understanding their transport properties. We investigate the transport properties of IL-based electrolytes through molecular dynamics computer simulations, and report two major findings. First, by adopting rigorous concentrated multicomponent solution theory, we uncover anomalously low and even negative Li transference numbers. This is due to the strong ionic interactions resulting in significant correlations and deviations from ideal solution behavior. We show that a negative transference number is to be expected in a wide range of chemistries, suggesting a universal behavior for this class of materials. Additionally, we study the anion-cation clusters and show that lithium-containing clusters carry an overall negative charge in a remarkably wide range of compositions and concentrations. Second, we leverage the microscopic understanding developed in the previous point to suggest and test modifications to increase the cation transference number. The results have significant implications for the adoption of IL-based electrolytes as they provide a recipe for optimizing transport properties in next-generation highly concentrated and correlated electrolytes.

7:10 AM F.EN04.26.20
Computational Investigation of Earth Abundant Electrolytes of the M_3AlP_2 (M = Li, Na) System Arthur B. Youd, Daniel Davies, Christopher Savory and David O. Scanlon; University Collego London, United Kingdom

Earth abundant electrolytes are a vital paradigm in the realisation of truly sustainable solid-state rechargeable batteries. These materials must maintain a tight balancing act between chemical stability, ion mobility and earth abundance. Recent work has

shown promising Li ion mobility in phosphidoaluminates owing to the favourable alignment of AlP_4 tetrahedra.[1] The final characterisation of this as well as the exact Li migration mechanism is not fully understood. The sodium analogue (Na_3AlP_2) shares significant structural features which may make it a possible candidate for sodium ion electrolytes.[2]
In this study, we have performed ab initio Density Functional Theory calculations on M_3AlP_2 (M = Li, Na) to predict and critically assess their ion transport properties. The methodology makes use of an array of python-based tools to generate structures (pymatgen)[3], defective supercells (bsym)[4] and create workflows (atomate)[5] to perform high throughput calculations. Ab initio molecular dynamics (AIMD) and nudged elastic band (NEB) approaches are employed to examine the ion mobility and diffusion coefficients of M_3AlP_2 with a view to assessing its suitability as an electrolyte. The thermodynamic stability is window is calculated with electronic alignment relative to cathodes. Dynamic stability of these electrolytes is investigated with phonon analysis within the harmonic approximation.
While quantitative analysis of AIMD informs the extent of diffusion, qualitative directional analysis gives insights into the preferred route of diffusion as well as help propose specific mechanisms for ion diffusion. Through multiple AIMD runs we can extract temperature dependent behaviour and compare with microscopic activation barriers from NEB. These results allow us to elucidate the favourable mechanism in the phosphidoaluminates and thus draw conclusions on promising future developments for solid state electrolytes in both Li-ion and Na-ion batteries.

Metal–Organic Frameworks Encapsulated with Vanadium-Substituted Heteropoly Acid for Highly Stable Asymmetric Supercapacitors Nageh K. Allam; The American University in Cairo, Egypt

Herein, we report on a facile one-pot synthesis of polyoxometalates encapsulated zeolite imidazolate framework cages ($PMo_{10}V_2$@ZIF-67). The morphological and structural properties of the as-synthesized materials were investigated *via* FESEM, EDS, XRD and FTIR techniques. Moreover, N_2 adsorption/desorption isotherms, and XPS measurements were carried out to elucidate the textural properties and composition of the fabricated materials. Upon their use as supercapacitor electrodes, the $PMo_{10}V_2$@ZIF-67 electrode exhibited a maximum specific capacitance of 765 F/g at a scan rate of 5 mV/s. Furthermore, a supercapacitor device was assembled using activated carbon as the negative electrode and $PMo_{10}V_2$@ZIF-67 as the positive electrode, delivering a specific power of 702 W/kg and corresponding specific energy of 20.9 Wh/kg at a charging current density of 1 A/g. In addition, the device shows excellent long term stability and high Columbic efficiency over 5000 charging and discharging cycles at charging and discharging current density of 5 A/g.

7:30 AM F.EN04.26.24
Recycling of Li-Ni-Mn-Co Hydroxide from Spent Batteries to High-Performance Supercapacitors with Exceptional Stability Nageh K. Allam; American University in Cairo, Egypt

The intensive implementation of Li-ion batteries in many markets makes it increasingly urgent to address the recycling of strategic materials from spent batteries. Batteries typically contain toxic chemicals and cannot be disposed of at will. In this study, Li-Ni-Mn-Co hydroxides are successfully recycled from spent Li-ion batteries electrodeposited on nickel foam and fully characterized using different techniques such as field emission scanning electron microscopy (FESEM), x-ray diffraction (XRD), energy-dispersive X-ray spectroscopy (EDXS), inductively coupled plasma (ICP), and X-ray photoelectron spectroscopy (XPS) techniques. The recycled nanostructured films are tested in a three-electrode electrochemical system to investigate their capacitance behavior. The recycled electrodes show a high capacitance of 951 $F.g^{-1}$ (Specific capacity of 523.5 C. g^{-1}) at 1 A g^{-1}. Moreover, recycled materials are used as positive electrodes to construct asymmetric supercapacitor devices. The device shows a Coulombic efficiency of 100%, capacitance retention reaching

~90% with excellent cycling stability after 10,000 cycles as well as reasonable power and energy densities.

7:40 AM F.EN04.26.26
Structural Control of Hard Carbons Synthesized from Resorcinol-Formaldehyde Xerogels with Application as New Anode Materials Joelle Medinger, Marco Lattuada, Xavier Amantini and Pacifique Umubyeyi; University of Fribourg, Switzerland

The increase in demands of devices requiring batteries, which not only encompasses electronic devices, but also electric cars, is pushing towards the development of new materials and solutions for electrodes. Hard carbons obtained by pyrolysis of resorcinol-formaldehyde xerogels have gained in interest because of their promising properties as alternative anode materials in sodium ion batteries [1]. They are easily prepared, are non-toxic and have low production costs because a simple sol-gel process can be used to prepare them. The meso- and macroporosity and overall architecture of the xerogels can be controlled by tuning the composition of the sol mixture, and the concentration of the catalyst (pH) [2-3]. Aging and drying conditions also have a substantial effect on the final surface area and pore volume of these gels. Conversely, the microporosity is created during the pyrolysis step 800 °C for 1h under inert atmosphere, which leads to a fully carbonized porous xerogels [4]. The impact of the porosity and the pyrolysis step on the performance of the carbonized RF xerogels as electrodes have been extensively investigated.
Current synthetic methods do not permit to impart anisotropy to the macrostructure of the final material, and neither allow for a control of pores direction. By adapting a procedure developed by our group, in this work we show that the macroporous structure of carbon gels can be rendered naturally anisotropic by adding superparamagnetic colloids to the sol-gel precursor solution, and by applying a uniform magnetic field during the sol-gel transition. By ensuring that the superparamagnetic colloids are incorporated into the gel phase, the magnetic colloids will self-assemble into chain-like structures in the direction of the magnetic field and become templates for the growing gel phase [5]. The lower tortuosity brought by the structural anisotropy has known advantages [6]. As anode material, the structural control gives an optimized directional flow of the ions without interfering with the advantages brought by the well-engineered internal meso and microporous gel structure.

7:50 AM F.EN04.26.27
Controlling Charge Transport in Spinel Oxides through Manipulation of Cation Site Occupation Anuj Bhargava and Richard Robinson; Cornell University, United States

Understanding how complex oxides conduct electronic charge has relevance to a wide range of energy materials. For instance, ternary spinel oxides are actively researched for applications in electronics, sensors, catalysis, data storage, and energy storage due to their useful magnetic, catalytic, and electronic properties. It is known that the most prominent mechanism of charge transport in oxides is through hopping that follows the polaron models. But the polaron hopping models are too crude to account for the configurational differences that can occur in complex oxides, like ternary transition metal spinels, where the two different cation types can exhibit large degrees of disorder between the two cation lattice sites, possess a variety of oxidation states, and have different energy barriers. The current model, the small polaron nearest neighbor hopping model, was proposed in 1961 and has multiple limitations. Understanding the mechanisms of charge transport in ternary and higher order spinels would enable design principles for enhancing their electronic and electrochemical properties for energy applications. Here, we develop a new method to characterize the donor/acceptor pairs that form the conduction pathway for polarons: advanced synchrotron x-ray emission spectroscopy (XES) is able to accurately determine both site location and oxidation state of the cations to a higher accuracy than other common methods such as XAS and XPS. We use XES to investigate colloidal nanoparticles of the ternary $Co_xMn_{3-x}O_4$ spinel system and determine the relationship between electronic properties and cation site occupation, based on the octahedral site, donor-acceptor formalization introduced in the polaron hopping model. We find that the stochiometric volcano trend in electronic conductivity correlates well with the concentration of Mn^{4+}/Mn^{3+} hopping pairs, while the concentration of Mn^{3+}/Mn^{2+} pairs is unchanged with stoichiometry. We also find that Co does not directly contribute to conductivity, however, the Co does create configurational disorder that leads to the generation of hopping pairs for Mn at octahedral sites. From these results we conclude that Mn^{4+}/Mn^{3+} pairs are the dominant active species and the origin of the stoichiometry-dependent behavior for polaron charge transport. This work

provides a starting point for understanding and optimizing charge transport for higher order spinels to improve energy electrodes.

8:00 AM F.EN04.26.29
Molecular Dynamics Study of Ionic Conduction Mechanism in Network Glasses Mirza C. Beg and John Kieffer; University of Michigan, United States

Combining a recently developed variant of transition state theory (TST) for ionic transport in amorphous structures with molecular dynamics (MD) simulations facilitates unprecedented insights into the local and medium-range structure of glasses. Realistic structural models of network glasses are generated using MD simulations based on a reactive force field, which allows for the accommodation of dynamically variable coordination numbers for a given network former and dynamic charge transfer upon formation or breakage of covalent bonds. The TST model, which relies on mean-field statistical measures, allows us to identify the size of the spatial region affected by the activated ion hopping process. In combination with MD simulations, we can identify the specific molecular configurations that participate in the jump process and onto which the thermal energy for activation must be focused. Thus, MD simulations allow us to observe the behavior of all atoms involved in the ionic transport process, and identify the underlying mechanisms in the context of glass structure, its chemical character, and its bonding topology. Cation jumps at room temperature are a rare event, but in the supercooled liquid near Tg each cation jumps once every 1-10 ns. Since, structural relaxation comes to a halt upon cooling at Tg, we can expect meaningful results for solid state ionic conduction when studying cation mobility in this temperature range. This allows us to observe a number of jump events that is statistically significant but typically too few to rely on standard measures such as the mean squared displacements to evaluate cation mobility. We explore a potentially novel approach for estimating cation mobility that is based on the analysis of deviatory modes of motion using the construct of the velocity autocorrelation function, which can be described as an oscillatory function whose amplitude decays with time. The integral of the velocity correlation function yields the diffusion coefficient. The existence of this non-zero diffusion coefficient is a consequence of damping or decay in the velocity correlation function. Here we establish a working connection between cation mobility and the damping coefficients as a means to rapidly screen materials structures for their potential to be good ion conductors. This knowledge is used towards the development of a materials design criteria for solid-state electrolytes. (Acknowledgment: NSF DMR-1610742.)

Late News: Novel Developments in MRI Diagnostics of Commercial Batteries Stefan Benders[1], Mona Mohammadi[1], Roberta Pigliapochi[1], Christopher A. Klug[2,1] and Alexej Jerschow[1]; [1]New York University, United States; [2]U.S. Naval Research Laboratory, United States

While batteries are an essential part of modern technology, diagnostic techniques for commercial batteries are still in high demand. Magnetic Resonance Imaging (MRI) is a powerful technique with a variety of contrast options and measurable parameters, but its application to batteries in conductive enclosures poses a major challenge. Recently, the inside-out (ioMRI) technique enabled the recovery of essential information by mapping the field caused by the (changing) susceptibility of the battery associated with state-of-charge (SOC) or defects [1]. Current distributions have been measured with this technique as well [2] and the technique has been demonstrated with the simple acquisition of free induction decays (FID) paired with statistical analysis as well. A common technique in battery diagnostics is electrical impedance spectroscopy (EIS), which lacks spatial resolution in the case of commercial batteries. A novel technique has been developed, which provides the ability to measure the oscillating fields caused by alternating currents in a battery at different frequencies [3].

Although the inside-out technique provides important parameters, direct measurements of e.g. the lithium within the battery are often desirable. Due to the inability of RF radiation to penetrate through the metal casing, other ways to access the interior noninvasively are sought for. A method to incorporate the aluminum casing of a pouch cell into a resonant circuit, essentially making it a low quality rf coil was developed recently [4]. Employing this method, signals from three different characteristic environments can be observed: Metallic lithium, intercalated lithium and lithium in the electrolyte. This approach can enable deeper insights into processes within commercial batteries.

Late News: New Sulfonamide-Based Electrolytes Enable High-Energy and Long-Cycling Practical High-Voltage Lithium-Metal Batteries Weijiang Xue; Massachusetts Institute of Technology, United States

Current lithium-ion batteries (LIBs) based on a lithium transition metal oxide cathode ($LiCoO_2$, $LiMn_2O_4$, etc) and a graphite anode (372 mAh g^{-1}) are approaching their theoretical energy density (~ 300 Wh kg^{-1}) and thus are unable to satisfy the increasing demand for high-energy-density power sources for electric vehicles, electronic devices, and other promising markets. A promising and feasible approach to boost energy density > 400 Wh kg^{-1} is to turn to high-voltage rechargeable LMBs based on a Li metal anode (LMA) and a commercially-available high-Ni NMC ($LiNi_xM_{1-x}O_2$, M=Mn, Co and $x \geq 0.6$) cathode materials. However, it still remains a great challenge to for developing electrolytes that are compatible with both the Li metal anode (LMA) and the high-Ni NMC cathodes.
In order to overcome the challenge, a group of new sulfonamide-based electrolytes beyond traditional carbonate and ether-based ones are rationally designed and developed. They successfully enable a highly reversible LMA, exhibiting an excellent Coulombic efficiency with rapid ramp-up to >99% within several cycles. Furthermore, due to the excellent compatibility with high-Ni NMC cathodes, the sulfonamide-based electrolyte successfully reach a stable cycle and high energy efficiency of commercial NMC811 at an ultra-high cutoff voltage of 4.7 V vs. Li^+/Li, which is first ever reported in the literature. Benefitting from these unique performances, a full-cell energy density exceeding 400 Wh kg^{-1} has been achieved under practical conditions with industrial-level high-loading cathode, extremely low negative to positive (N/P) ratio, and lean electrolyte which demonstrates huge technological advances for practical LMBs.

8:30 AM F.EN04.26.32
Late News: Anion Chaotropicity as Indicator for Water-in-Salt Electrolyte Stability David Reber[1], Maximilian Becker[1,2], Ruben-Simon Kühnel[1] and Corsin Battaglia[1]; [1]Empa, Switzerland; [2]ETH Zürich, Switzerland

Water-in-salt electrolytes have enabled the development of novel high-voltage aqueous lithium-ion batteries due to their wide electrochemical stability window. In this study, we explore why analogous sodium electrolytes have struggled to reach the same level of electrochemical stability.[1-3] We compare solution structure and electrochemical stability for eleven sodium salts, selected among the major classes of salts proposed for highly concentrated electrolytes. We relate the water environment established for each anion to its position in the Hofmeister series and find a surprisingly strong correlation between the chaotropicity of the anion and the resulting electrochemical stability of the electrolyte. We also discuss the importance of the solid-electrolyte interphase for stable battery performance and how it relates to the anion. We further show that the search for suitable sodium salts is complicated by the fact that higher salt concentrations are needed than for their lithium equivalents.[4] Reaching such a high concentration of 25 to 30 mol/kg with one or a combination of multiple sodium salts that have the desired properties remains a major challenge. We conclude that alternative approaches such as mixed water/organic solvent or dual-cation electrolytes should be pursued to enable the development of high-voltage aqueous sodium-ion batteries. We demonstrate the potential of the mixed-solvent approach by showing that the water solubility of NaTFSI can be increased from 8 to 30 mol/kg in the presence of ionic liquids. Such a ternary electrolyte, based on highly chaotropic anions, enables stable cycling of a 2 V-class sodium-ion battery based on the $NaTi_2(PO_4)_3/Na_2Mn[Fe(CN)_6]$ electrode couple for 300 cycles at 1C with a Coulombic efficiency of >99.5%.[5]

8:40 AM F.EN04.26.33
Development of Carbon-Based Nanostrucutres for High Performance Li Metal Anodes Hansen Wang, Yuzhang Li and Yi Cui; Stanford University, United States

Development of Li metal anodes is critical to the realization of next generation high specific energy batteries.

Commercialization of Li metal anodes, however, is plagued by its poor cyclability. This is because Li metal inevitably reacts with electrolytes, forming mechanically vulnerable solid-electrolyte interphase (SEI). With the significant volume fluctuation during Li metal cycling, the SEI easily cracks, leading to dendritic growth and continuous capacity loss. Electrode structural design is one of the most promising approaches to address these issues. Various "host" frameworks have been developed to accommodate Li metal and ameliorate the volume fluctuation during cycling, enabling much improved SEI stability and Coulombic efficiency (CE). However, further optimizations of these "host" frameworks are still in demand. First, achieving completely zero volume change is still challenging. Second, most of current carbon-based structures possess decent electronic conductivity, promoting undesirable surface Li plating under high currents. Here, we report recently developed "host" frameworks that successfully address these issues, enabling further advancements in the Li metal anode cycling performance.
1. Wrinkled graphene cages (WGCs)
We report WGCs as a "host" framework for Li metal anodes. Different from previously reported amorphous carbon spheres, WGCs show highly improved mechanical stability, Li-ion conductivity and robust SEI for continuous Li metal protection. With embedded gold nucleation seeds, Li metal preferentially deposits inside the cages with minimal exposure to the electrolyte. As a result, CEs of 98.0% in a carbonate electrolyte, 99.1% in a high concentration electrolyte are realized. A Li-WGC||LFP full cell can run for ~350 cycles with minimal capacity decay.
2. Silicon (Si) nanoparticles embedded reduced graphene oxide (rGO)
A rGO "host" framework for Li metal anodes is further optimized by embedding Si nanoparticles between the graphene layers. These Si nanoparticles possess two critical functionalities. First, they serve as Li nucleation seeds to promote Li deposition within the framework even without pre-stored Li. Second, the Li_xSi alloy particles serve as supporting "pillars" between the graphene layers, enabling a negligible thickness shrinkage after full stripping of metallic Li. As a result, we achieve 99.4% Coulombic efficiency over ~600 cycles in Cu||Li half cells. Meanwhile, a Li-SirGO||NMC532 full cell runs for ~380 cycles with negligible capacity decay.

SESSION F.EN04.27: Poster Session I: Next-Generation Electrical Energy Storage—Beyond Intercalation-Type Lithium Ion

F.EN04.27.01
Structural Characterization of Solid-State Electrochemical Interfaces via Integrated Computation and Spectroscopy Deyu Lu[1], Nongnuch Artrith[2], Alexander Urban[2], Shinjae Yoo[1] and Feng Wang[1]; [1]Brookhaven National Laboratory, United States; [2]Columbia University, United States

Solid-state batteries are attracting world-wide interest for their potential to enhance safety by eliminating the need for flammable liquid electrolytes and to increase the energy density by facilitating the use of Li metal anodes and high-capacity cathodes. When incorporated into real devices, the solid electrolyte interacts with Li anodes and cathodes to form a nanometer-thick amorphous/disordered interfacial layer known as the solid electrolyte interphase (SEI), which determines the resistivity and stability of the interfaces between the electrode and electrolyte. The inherent complexity and the dynamic evolution of the SEI cannot be handled directly with first-principles methods, such as density functional theory, because of the computational hurdle associated with the large system size (e.g., more than one thousand atoms) and time scale. In order to gain insights into the structural properties and the interfacial reactions at the SEI, an integrated approach that combines high-performance computing and machine learning tools with state-of-the-art synchrotron X-ray absorption/electron energy-loss spectroscopy, is developed to tackle the complex electrochemical interfaces. The approach and some recent results from the structural modeling and spectroscopy studies of the SEI at the LiTMO2 (TM=Ni, Co, Mn) cathode/ Li7La3Zr2O12 solid electrolyte interfaces will be presented.

F.EN04.27.02
Realistic Modeling of AlCl4 Intercalation in Strained Two-Dimensional Materials Rizcky Tamarany[1], Chan-Woo Lee[1], Hana Yoon[1], Chung-Yul Yoo[2] and Kanghoon Yim[1]; [1]Korea Institute of Energy Research, Korea (the Republic of); [2]Mokpo National University, Korea (the Republic of)

Graphite-based Al-ion battery has been attracted large attention due to its extremely fast charge/discharge rate and excellent cycle stability. However, the intercalation mechanism of AlCl4 into graphite is still vague. The concern comes with the large

size of the AlCl4 molecule while the experimentally observed gallery height for graphite cathode is not large enough (~ 5.7 Å). In the past theoretical studies, the computational models mostly represent that the stable structure of intercalated AlCl4 is the tetragonal form which resulted in a large expansion of the intercalation gallery to 8~9 Å. In those studies, researchers commonly considered thermodynamically stable structures that allow free expansions of electrode structures. In this study, we suggest that a strain effect in a realistic electrode structure governs the stable form of intercalating AlCl4. We have performed first-principles calculations to show a strain-structure relation of intercalated AlCl4 in graphite and found that a planar-shape of AlCl4 molecule is more probable in realistic conditions. Using the computational results, we made model energy for AlCl4 intercalation at given structural conditions such as volume expansion rate and stage number of graphite electrode. The model energy shows good agreements with the experimental observations on the structure-engineered graphite electrodes. In addition, to examine new candidate materials for Al-ion cathode, we also conduct calculations on MoS2 and MoS2/graphene hetero-structure for AlCl4 intercalation. As a result, we believe our study provides a deeper understanding of the charging/discharging mechanism and a modeling rule to find more enhanced electrode materials in Al-ion batteries.

F.EN04.27.04
Improved Cycle Lifetime of Lithium-Sulfur Battery by Polysulfide Entrapment Using a Surface Decorated Carbon Cloth Saisaban Fahad and Akihiro Kushima; University of Central Florida, United States

Lithium sulfur batteries (LSBs) are attracting attention as a next generation energy storage device because of their high energy density, low cost, and environmental friendliness surpassing that of lithium ion batteries (LIBs). LIBs are considered insufficient for many applications such as grid energy storage and electric vehicles due to their high cost and low energy density. However, LSBs still have some problems that need to be overcome before they can be used commercially. The major problem that limits their capacity is the dissolution of long chain lithium polysulfide into the electrolyte which leads to a loss of active material and capacity decay during cycling. Here, we have developed a cost-effective method for the lithium polysulfide battery to achieve high performance by employing a nanostructured carbon black/ carbon cloth electrode that exhibits high electrical conductivity, good mechanical properties and high surface area. These benefits enable a high sulfur loading mass, capture the lithium polysulfide intermediate reaction products and avoid structural changes. As a result, this simple and novel design delivered a high specific discharge capacity exceeding 1350 mAhg-1 at 0.2 C and good capacity retention, providing a promising path towards practical lithium sulfur batteries.

F.EN04.27.07
Enhanced Polysulfide Conversion Using 2D Alloy Catalyst in Li-S Batteries Sanket D. Bhoyate[1], Junyoung Kim[1], Eunji Lee[2], Eunho Lee[1], Juhong Park[1], Jeongyong Kim[2] and Wonbong Choi[1]; [1]University of North Texas, United States; [2]SKKU, Korea (the Republic of)

The lithium sulfur battery presents unique polysulfide chemistry to exhibit high theoretical capacity of 2,600 Wh/kg. However, the life cycle of Li-S battery is greatly affected due to unwanted shuttling of soluble lithium polysulfides (LiPSs) such as Li2S8 and Li2S6, that corrodes the Li anode by forming an inactive sulfide layer. Previously, pristine 2D materials with polar surface were used as a catalyst in sulfur cathodes to overcome this issue by acting as polysulfide anchor and prevent shuttling effect. However, the concentration and weight loading of catalyst was high and lack the practical applicability in Li-S battery. To overcome this issue, we adopted novel strategy of synthesizing 2D alloys with very low concentration loading on carbon nanotube paper as a sulfur host cathode to efficiently catalyze the polysulfide reactions. The 2D alloy with mixed 2H-1T phase exhibited synergetic properties and showed high specific capacity of 1,228 mAh/g at 0.1 C and improved the cyclic stability to 400 cycles, as compared to 100 cycles for pristine cathode. The reduced shuttle effect and increased life cycle was due to accelerated transformation of the dissolved polysulfides to the insoluble LiPSs and back to sulfur. Our study shows novel approach with binder-free ultra-light weight catalytic cathodes for practical application of Li-S battery.

F.EN04.27.10
Improvement of Specific Capacitance in Lithium Batteries by Three-Dimensional Carbon Networks Valerio Dorvilien[1], Carolina Rojas[2], Neida Santacruz[3], Cid Marie Calderon Rodriguez[3], Omayra Ortiz Alicea[3], Genesis M. Ferrer[1], Frank Martinez-Henriquez[1], Daniel Fontanez[1], Frank Mendoza[1], Carolina Rojas Michea[4], Brad R. Weiner[2] and Gerardo Morell[1]; [1]University of Puerto Rico-Rio Piedras Campus, United States; [2]University of Puerto Rico, San Juan, Puerto Rico; [3]University of Puerto Rico, Rio Piedras Campus, Puerto Rico; [4]Universidad Autónoma de Chile, Chile

We propose a low cost and simple method to prepare three-dimensional (3D) carbon structures by Chemical Vapor Deposition (CVD) and characterized their structural and electrochemical properties. The 3D pore system were obtained using different zeolites (NaY, SBA-15, and ZMS-5) as solid template structures to assist in the synthesis of 3D carbon network

structures. The carbon source consisted of radicals formed from the thermal decomposition of acetone, in a relatively facile and fast chemical deposition process. The 3D carbon network structures were characterized with X-ray diffraction, Raman spectroscopy, spectroscopy, surface area measurement, scanning electron microscopy, and transmission electron microscopy. The carbon networks deposited in the pores consist of reduced graphene oxide and multiwalled carbon nanotubes; their size distribution correlates with the size of the pores of zeolites. The electrical conductivity and dispersed morphology of the 3Ds carbone network structures -based conductive electrode were examined by atomic force microscope (AFM), scanning electron microscope (SEM) and transmission electron microscope (TEM). Using the standard method we assembled the Lithium Ion Battery in the Ar-filled glove box, we used LiPF6 with EC:DMC::1:2 ratio as the electrolyte, lithium foil as the counter electrode and the 3D carbon network material. The specific capacity and cycle-life stability of the 3Ds carbon network-based lithium ion battery was investigated by cyclic voltammetry analysis.

F.EN04.27.11
3D Carbon-Coated MXene Architectures with High Capacity and Ultrafast Lithium/Sodium Storage Peng Zhang, Qizhen Zhu and Bin Xu; Beijing University of Chemical Technology, China

MXene is a promising candidate for energy storage devices owing to its versatile characteristics. However, as 2D structured material, layer restacking besides its surface oxidation is a serious issue. This re-stacking compromises significantly surface active sites, compelling the material to exhibit sluggish electro-kinetics behavior, and thus deterring the overall capacitive performance. Here, a tremella-like 3D architecture of carbon-coated Ti3C2Tx MXene (T-MXene@C) is fabricated as an efficient anode material for lithium- (LIBs) and sodium-ion batteries (SIBs), respectively. The nanohybrid is synthesized via self-polymerization of dopamine over the surface of pristine Ti3C2Tx MXene nanosheets succeeded by carbonization. The self-polymerization of dopamine in this case, facilitates the transformation of MXene sheets into 3D architectures where its post-carbonization subsequently forms a thin carbon layer over the structure, preserving the surface facets from oxidation and structural aggregation. The incursion of carbon layers within MXene not only contributes in provision of additional active area, but also enhances the structural durability of the material during charge/discharge process. Therefore, the T-MXene@C nanohybrid exhibits ultrahigh capacities, superior rate performance, and stable cyclability as anodes in both LIBs and SIBs. Moreover, the discussed strategy could be applied as general route to fabricate diverse MXene-based 3D structures with potential applications in many other areas.

F.EN04.27.12
Tin Dioxide/Graphene/Graphene Oxide as Anode Material for Lithium-Ion Batteries Valerio Dorvilien, Frank Martinez-Henriquez, Cid Marie Calderon Rodriguez, Daniel Fontanez, Genesis M. Ferrer, Omayra Ortiz Alicea, Frank Mendoza, Brad R. Weiner and Gerardo Morell; University of Puerto Rico-Rio Piedras Campus, United States

Graphene Oxide was synthesized using a Modified Hummer's Method. It is fairly known that SnO2 is used as anode material for lithium-ion batteries applications due to their high specific capacity. Hence, we use a non-conventional synthesis route to obtain a final composite, G/GO/SnO2. G/GO, with its good surface-to-volume ratio, serves as a support and matrix for SnO2 nanoparticles that buffers the huge volume changes the nanoparticles are used alone as anode for lithium ion batteries and then enhances its electrochemical properties. For the structural characterization of the synthesized material, scanning electron microscopy (SEM), energy dispersive spectroscopy (EDS) and Raman Spectroscopy were performed; showing a uniform distribution of the nanomaterial in the carbon matrix. Electrochemical analysis, such as charge/discharge profiles show that the composite can be used as anode in lithium ion batteries. In fact, at different current densities- 25, 75, 100, and 200 mA/g- the material deliver in the first cycle very high specific capacity-1808, 1253, 903, 886 mAhg-1 respectively. After repeated cycling the composite is still offering reversible capacities over 400 mAhg-1 for each current density, showing that G/GO is providing contact areas which results in more energy density at the interface electrode/electrolyte and that the SnO2 provides additional ions to the EDL and the electrochemical process.

F.EN04.27.13
Theoretical Intercalation Profiles of Layered NaMO2 (M=Co, Ni, Fe) Cathodes—Learning from the Electronic Structure of LiMO2 Christopher Savory, Arthur B. Youd and David O. Scanlon; University College London, United Kingdom

Ab initio modelling can provide valuable insights into the electronic and structure behaviour of battery materials, including the prediction of sodium, potassium and magnesium cathodes.12 Nevertheless, it is crucial that the accuracy of such ab initio calculations be established. The most common method to theoretically the strong correlation in the 3d valence electrons of transition metals is to use the addition of 'U' parameters to standard Density Functional Theory (DFT), enabling high throughput studies of Na-based materials;3 however these parameters must be tuned to experimental measurements, and are

highly sensitive to changes in oxidation state and composition - crucial properties during the intercalation of AMO2 (A=Li, Na, K) layered cathodes.4,5 Recent high-level quasiparticle self-consistent GW (QSGW) calculations performed on the layered LiMO2 (M=Co, Ni, Mn) cathodes suggest that the charge transfer transition in LiMO2 phases is underestimated, even when the inaccuracy of standard DFT at describing band gaps is accounted for, but it is well predicted by hybrid Density Functional Theory (DFT), which mixes exact exchange from Hartree-Fock theory.6 In this study, we examine how electronic correlation is described in layered sodium cathode materials with various levels of theory. We calculate the electronic structures of NaCoO2, NaNiO2 (in direct comparison to their Li counterparts) and ?-NaFeO2 - ternaries typically alloyed to form stable and efficient sodium-based cathodes7 -- using DFT+U, hybrid DFT (HSE06) and QSGW to establish a thorough comparison of the electronic properties at each level, and to establish that tuning is necessary to reproduce the valence electronic structure of such materials. We further demonstrate the practical impact of this theoretical description by calculating and comparing voltage intercalation profiles of these systems as a function of Na content, at both the DFT+U and hybrid DFT levels via a cluster expansion approach, in order to establish the most reliable comparison to experiment. We establish the necessity to use accurate, transferable methods to describe such systems, with an aim to inform ab initio studies on the future generation of first row transition metal-based cathodes. Enhancement of Ionic Conductivity of Composite Electrolytes for All-Solid-State Lithium Rechargeable Batteries by Incorporating Gold Nanorods into a Polyethylene Oxide Matrix Yifan Zhang, Nian Liu and John Zhang; Georgia Institute of Technology, United States

Solid state batteries have advantages such as safeness and high energy density. However, their conductivity at room temperature is low which limits their further commercialization. Gold nanorods can promote the Li ion transport by decreasing the crystallization of solid state electrolytes, and locally heat the electrolytes based on their photothermal conversion capability, providing a more efficient way to improve the performance of solid state batteries.

F.EN04.27.17

Large-Scale Synthesis of Uniform and Extremely Small-Sized Cobalt Ferrite Nanoparticles as High-Performance Anode Materials for Lithium-Ion Batteries Yifan Zhang, Nian Liu and John Zhang; Georgia Institute of Technology, United States

Spinel ferrites have emerged as an attracted class of materials that can find application in various fields, ranging from information storage, biomedical application to energy-related areas. As the anode in LIBs, spinel CoFe2O4 attracts much attention because of its high theoretical specific capacity (916 mAh g-1). However, some issues impede its practical application such as drastic capacity fading and poor rate capability arising from an inherent low electronic conductivity, severe aggregation, and lithiation-induced volume expansion in the cycling process. Increasing surface-to-volume ratio could provide relatively short transport distance for lithium-ion diffusion and alleviate the volume expansion, which is one of the possible strategies to solve the above-mentioned problem. In this frame, an aminolytic method is described to synthesize ultra-small (<10 nm) CoFe2O4 nanoparticles with good dispersion at a relatively low temperature without further annealing being required. Here, the 9.1 nm CoFe2O4 nanoparticles synthesized by aminolytic method delivered a reversible specific capacity of 1238 mAh g-1 after 100 cycles at a current density of 0.1C, a much better performance compared with CoFe2O4 synthesized by traditional methods in previous reports. By adjusting the reaction temperature, 3.4 nm CoFe2O4 nanoparticles could also be synthesized, delivering a slightly enhanced specific capacity (1343 mAh g-1 after 100 cycles at 0.1C). For comparison, the CoFe2O4 nanoparticles were also prepared by coprecipitation method and its electrochemical performance was studied in detail. It can be concluded that spinel CoFe2O4 synthesized by aminolytic method is a promising anode for LIBs based on its superior lithium storage performance. Further, the aminolytic method can also be used to prepare other spinel materials in different fields. The systematically studied electrochemical performance of CoFe2O4 nanoparticles is beneficial in the design of future anode materials for LIBs.

F.EN04.27.23

Li2Sx-CNT Electrode with Lean Electrolyte for High-Energy-Density Li-S Battery Yuichi Yoshie, Keisuke Hori and Suguru Noda; Waseda University, Japan

Sulfur is a promising active material because of a high theoretical capacity (1675 mA h gS?1) and low cost. Nevertheless, practical applications of S electrode have been hindered by low S fraction in a cell. Excess Li in negative electrode, auxiliary materials such as heavy current collectors of metals, and large amount of electrolyte (Electrolyte/Sulfur ratio (E/S) > 7) have been used in previous works [1], which lowers energy density of the Li-S cells based on total mass/volume (including electrodes, separator and electrolyte). We previously demonstrated the high gravimetric and volumetric energy densities based on an electrode using self-supporting sponge-like paper of few wall carbon nanotubes (FWCNTs) as current collector. The unique properties of FWCNTs with high conductivity of ~100 S cm?1 and high surface area of ~500 m2 g?1 enhanced the sulfur utilization; however, E/S ratio was still high [2]. In this work, we report the Li2Sx-CNT (4?x?8) positive electrode that works effectively even with lean electrolyte. Self-supporting paper of FWCNTs was fabricated by dispersion and filtration. Then, three types of Li2Sx (x = 4, 6, 8) in 1,2-dimethoxyethane (DME) solution were drop-casted on the papers and dried for 1 h to obtain the Li2Sx-CNT electrodes. As a reference, the S-CNT electrode was also prepared by the S vapor deposition method [2]. The Li2Sx-CNT and S-CNT (areal density of 2 mgS cm?2 and 1 mgCNT cm?2) electrodes were evaluated by assembling 2032-type coin cell with Li foil (50 µm thick) as a negative electrode, a polyethylene separator, and an electrolyte of 1 M LiTFSI + 0.2 M LiNO3 in 1:1 (v/v) DOL/DME. Although the S-CNT exhibited very small capacity, the Li2S6-CNT exhibited 1471 mA h gS?1 with lean electrolyte of E/S ratio of 3.2 µL mgS?1. Furthermore, the Li2S6-CNT achieved 526 W h kgcell?1 based on the cell including positive and negative electrodes, separator, and electrolyte at second discharge. The value is encouragingly high compared to the high-performance Li-ion battery of ~300 W h kgcell?1 [1]. [1] M. Hagen et al., Adv. Energy Mater., 5, 1401986 (2015). [2] K. Hori, et al., J. Phys. Chem. C, 123, 3951 (2019).

F.EN04.27.24

Thin Li-Metal Negative Electrode Held in Self-Supporting Paper of Carbon Nanotubes for Stable, High Energy Density Rechargeable Batteries Tomotaro Mae[1], Keisuke Hori[1], Yuki Yamada[2] and Suguru Noda[1]; [1]Waseda University, Japan; [2]The University of Tokyo, Japan

Li metal is a promising negative electrode because of its high theoretical capacity (3860 mAh gLi?1) and low potential (?3.04 V vs SHE). However, it has a serious safety problem of Li dendrite which penetrates a separator and causes short circuit [1]. Surface modification of Li foils by texture or additional layer have shown effective in suppressing the dendrite growth [2] [3], but many of such methods make the electrode too thick (several hundred µm), and excessive Li were used (5 times or more). In this work, we propose thin and light-weight electrode to achieve high gravimetric, volumetric and areal capacities. Self-supporting paper of few-wall carbon nanotubes (FWCNTs; areal mass of 0.3 mg cm?2 and thickness of ~15 µm), having high conductivity of 40 S cm?1 and large specific surface area of ~500 m2 g?1, was used as non-metal 3D current collector. Cu nanoparticles (25 nm; 0.1-0.2 mg cm?2) were held in this 3D matrix as seeds for stable Li plating/stripping. The Cu-CNT film was prepared by dispersion and filtration [4]. 2032 coin cells of symmetrical configurations (Li-CNT//Li-CNT and Li-Cu-CNT//Li-Cu-CNT) were prepared by performing electrochemical pre-cycling of the Li foil (50 µm)/CNT//CNT and Li foil (50 µm)/Cu-CNT//Cu-CNT stacks with polypropylene separator (25 µm). Charge-discharge test was performed with an areal capacity of 4 mA h cm?2 and current density of 0.4 mA cm?2. The former cell showed unstable plating/stripping behavior in several cycles due to micro-short circuits while the latter worked stably over 20 cycles with small excess (1.5-2 times of the areal capacity) in Li. The Cu nanoparticles working as the nucleation sites and mesopores in the FWCNT paper working as growth sites realized the stable operation of the cells. [1] L. A Versatile Crosslinked Solid Polymer Electrolyte for Lithium, Calcium, Aluminum and Sodium-Ion Conduction Francielli Genier, Jiayue Wang, Tianyi Yao, Saeid Biria and Ian D. Hosein; Syracuse University, United States

The development of high-performance batteries is fundamental to meeting global energy demands, while also storing energy affordably and safely. An area of intense research in the battery field has been the replacement of the liquid or gel electrolyte with a solid polymer material, namely a solid polymer electrolyte (SPE). SPEs can allow the use of metal anodes due to its suppression of dendrite formation, which could thereby double the energy density, besides further addressing concerns over the volatility and flammability of liquid electrolytes. Crosslinked polymer electrolytes are quite attractive owing to their ability to enhance conductivity, while also retaining mechanical stability.1 Studies on SPEs not only focus on different polymer systems, but also on improving the interaction of existing and new polymer networks to ions other than lithium-ion to achieve even less expensive and more efficient rechargeable batteries. Other univalent ions, in particular sodium cations, can be highlighted due to its wide availability and low cost comparing to lithium. Multivalent cations, such as Ca2+ and Al3+, are also featured in SPE studies for their high energy density and mineral abundance.2 In those studies, poly(ethylene oxide) (PEO) has been extensively employed as the electrolyte's backbone. However, polytetrahydrofuran (PTHF) has been

reported as having a looser coordination with Li+ than PEO, due to PTHF's fewer oxygen heteroatoms in its chain.3 As a result, lower activation energy for ion motion is observed, leading to higher conductivity and transference numbers. In this work, we describe the synthesis of crosslinked SPEs for lithium, sodium, aluminum, and calcium conduction using a PTHF backbone. The SPEs were crosslinked through the photo-copolymerization of PTHF and 3,4-epoxycyclohexylmethyl 3,4-epoxycyclohexanecarboxylate. The crosslinked samples were evaluated for their ionic conductivity, thermal stability, amorphousness, and mechanical properties. Ionic conductivity of the order of 10-5 - 10-4 S/cm at room temperature was achieved, which is superior to some previously reported Ca, Na, and Al dry SPEs.4,5 Thermogravimetric analysis of the electrolytes indicated that, within the operating temperature of a battery, all electrolytes were stable and showed minimal weight loss. Differential scanning calorimetry confirmed the amorphous feature of the polymer. The electrolytes also showed excellent mechanical stiffness and flexibility. Further electrochemical studies will be presented and discussed. This work represents a new route for cleaner and safer energy storage devices with the potential for a broad variety of applications. MoS2 Based High-Performance FET Devices for Memory Circuits on Flexible Platform Sayani Majumdar[1], Miika Soikkeli[1], Ioannis Zeimpekis[2], Nikolaos Aspiotis[2], Chung-Che Huang[2], Sanna Arpiainen[1] and Mika Prunnila[1]; [1]VTT Technical Research Centre, Finland; [2]University of Southampton, United Kingdom

Two-dimensional transition metal dichalcogenides (TMDs) are fertile ground for fundamental material science and emergent applications in high-performance electronics. The mechanical flexibility of 2D materials allows their incorporation in variable form factor designs such as smart wearables and foldable electronics, where their electronic and optical properties outperform conventional flexible materials such as organic polymers. In the current work, we present high-performance ALD grown MoS2 based FET devices transferred on polyimide substrates. The growth method employs ALD to grow an MoO3 layer on a 6 inch wafer which is subsequently annealed in an H2S atmosphere to convert to MoS2. The ALD allows for excellent uniformity and because the layer acts as a template the process is scalable to larger sizes. The resulting MoS2 film is 2-3 layers thick. The film was transferred on the patterned target substrate using polystyrene assisted transfer of MoS2 layer. More than 90% device yield, excellent current ON to OFF ratio of 106 and mobility values up to 32 cm2 V-1 s-1 have been measured from micron scale devices with L/W in the range of two. We will present results on the yield and homogeneity on large area memory networks aiming for low power neuromorphic circuits.

F.EN04.28.04

Infrared Permittivity of the Biaxial van der Waals Semiconductor α-MoO3 from Near- and Far-Field Correlative Studies Thomas Folland[1], Gonzalo Alvarez-Perez[2], Ion Errea[3], Javier Taboada-Gutriérrez[2], Ana I. Tresguerres-Mata[2], Joseph R. Matson[1], Andrei Bylinkin[4], Mingze He[1], Weiliang Ma[5], Qiaoliang Bao[6], Joshua D. Caldwell[1], Alexey Nikitin[4] and Pablo Alonso-Gonzalez[2]; [1]Vanderbilt University, United States; [2]University of Oviedo, Spain; [3]University of Basque Country, Spain; [4]Donostia International Physics Center, Spain; [5]Huazhong University of Science & Technology, China; [6]Soochow University, China

The natural crystal anisotropy of van der Waals materials allows them to support a range of nanophotonic phenomena not observable in other natural materials. One such example is anisotropic phonon polaritons (PhPs), which form due to polar optic phonons in materials such as hexagonal boron nitride. Such hyperbolic polaritons have been shown to enable sub-diffraction guiding of light waves, sensing of ultra-thin analytes, and hyperlensing for super resolution imaging in the mid infrared (IR). Recently, the biaxial van der Waals semiconductor α-phase molybdenum trioxide (α-MoO_3) has received

significant attention due to its ability to support PhPs which are anisotropic along all three crystal axes. These offer an unprecedented platform for controlling the flow of energy at the nanoscale, in particular for manipulating the polarization state of light. However, to fully exploit the extraordinary IR response of this material, an accurate dielectric function is required.

In this work, we report an accurate IR dielectric function of α-MoO_3 by modelling far-field, polarized IR reflectance spectra acquired on a single thick flake of this material. Unique to our work, the far-field model is refined using the experimental dispersion and damping of PhPs revealed by using scattering-type scanning near-field optical microscopy (s-SNOM) on thin flakes of α-MoO3. Through these correlative efforts, exceptional quantitative agreement is attained to both far- and near-field properties for multiple flakes, thus providing strong verification of the accuracy of our model. This also provides a novel approach to extracting dielectric functions of different 2D materials, usually too small or inhomogeneous for establishing accurate models only from standard far-field methods. Finally, by employing density functional theory (DFT), we provide insights into the various vibrational states dictating our dielectric function model and the intriguing optical properties of α-MoO_3.

F.EN04.28.05
Feedback-Controlled Electroburning of MoS_2 Monolayers Yan Qi Huan[1], Yincheng Liu[1], Choon Hwa Ken Goh[1], Kuan Eng Johnson Goh[1,2], Swee Liang Wong[1,2] and Chit Siong Lau[1]; [1]Institute of Materials Research and Engineering, Singapore; [2]National University of Singapore, Singapore

Two-dimensional materials have been identified as interesting candidates for various applications in nano-electronics, and the characterization of electrical breakdown limits is a crucial step in device development. However, methods for repeatable measurements have been scarce in two-dimensional materials, where breakdown studies have been limited to destructive methods. This lack of repeatability restricts our ability to fully account for variability in local electronic properties induced by the fabrication process and surface contaminants.

To tackle this, we implement a two-step deep-learning model to predict the breakdown mechanism and breakdown voltage of monolayer MoS_2 devices with varying channel lengths and resistances using current measured in the low-voltage regime as inputs. A deep neural network (DNN) first classifies between Joule and avalanche breakdown mechanisms with partial current traces from 0–20V. Following this, a convolutional long short-term memory network (CLSTM) predicts breakdown voltages of these classified devices based on user-defined partial current traces.

We test our model with feedback-controlled electrical measurements to achieve non-destructive electrical measurements that limit device damage and increase the amount of data collected. We show that the DNN classifier achieves an accuracy of 74% while the CLSTM model has a 14% error when requiring only 80% of the current trace as inputs. Our results indicate that information encoded in the current behavior far from the breakdown point can be used for predictions, thus enabling non-destructive and fast material characterization for 2D material device development.

F.EN04.28.06
Synthesis and Characterization of MXene-WS2 Heterostructure Devices Venkata Surya N Chava, Aruna Narayanan Nair and Sreeprasad T. Sreenivasan; The University of Texas at El Paso, United States

Atomically thin two-dimensional (2D) materials such as graphene, MoS2, WS2 show excellent material properties and therefore studied extensively for a variety of applications including electronics, optoelectronics, electrocatalysis, energy storage, etc. More recently, there has been a growing interest in 2D heterostructure devices as they offer unique opportunities to design and study possibilities for controlling and manipulating the carrier confinement and transport of charge within these device structures. Tungsten disulfide (WS2) is an excellent material for optoelectronic applications such as photodetectors as monolayer WS2 has a direct bandgap of ~ 2.05 eV. Also, recently emerged as MXenes has shown great promise in energy storage and electromagnetic shielding applications due to excellent metallic conductivity. The MXenes can show either metallic or semiconducting behavior depending on the functional groups attached to the surface during the etching process. In particular, their tunable work function property can be exploited to control the properties of the heterostructure of MXenes with other layered 2D materials. Here, we report the characterization results of one such heterostructure formed by combining MXenes with WS2. MXene is synthesized by etching the Al layer from the parent MAX phase, and WS2 is synthesized on SiO2/Si substrates using the CVD process. The electrical properties of these as-synthesized materials can be modified using different approaches such as chemical doping etc. We present results from different morphological, spectroscopic and electrical characterization techniques that are used to study the transport characteristics of these MXene-WS2 heterostructure devices.

F.EN04.28.08
Photo-Thermoelectric Effect along Waveguide-Integrated Graphene Photodetectors Jakob Muench, Hannah Watson, Osman Balci, Alfonso Ruocco and Andrea C. Ferrari; Cambridge Graphene Centre, United Kingdom

The dominating mechanism of photodetection in a single-layer graphene (SLG) based device depends on the design of the detector [1,2,3], its chosen operation [1,3], and the band diagram in the photo-active region [2,4]. Here we demonstrate, over a ?0.5eV doping range, that the photo-thermoelectric effect [5] has a long-range (exceeding the cooling length in SLG) contribution, even in uniformly doped SLG, in the absence of a Seebeck coefficient gradient, whenever non-uniform absorption creates an electronic temperature gradient. This is achieved by integrating SLG with on-chip Si waveguides to generate an heterogeneous absorption profile over tens ?m and placing electrical probes along the propagation direction of light. We show the presence of a photovoltage Vph along the waveguide. The doping-dependence of Vph suggests signal generation by hot electrons via the Seebeck effect. This has general implications for the design and optimization of optoelectronic devices based on SLG, in particular for integrated photonics, where planar integration of layered materials leads to non-uniform absorption. F.EN04.28.12
Unraveling Nonlinear Formation and Relaxation of Excitons in Atomically Thin 2D Semiconductors Matthew C. Strasbourg[1], Cory Johns[1], Thomas Darlington[2], James Hone[2], P James Schuck[2] and Nicholas Borys[1]; [1]Montana State University, United States; [2]Columbia University, United States

Transition metal dichalcogenide (TMD) semiconductors are layered van der Walls materials that exhibit exceptional optoelectronic properties in monolayer form. Their atomically thin nature and reduced long-range dielectric screening make them ideal systems in which to study many-body electronic states. Notably, excitonic many-body phenomena govern the light-matter interactions in TMD semiconductors and open up new possibilities for novel optoelectronic devices, including new classes of quantum light sources. Thus, understanding the rich suite of many-body phenomena in these systems is motivated by potential applications in on-chip optoelectronics and by the insights that can be gained into the fundamental interactions that govern TMD material properties. Here, the dynamics of several higher-order excitons including trions, biexcitons, and charged biexcitons in monolayer-WSe2 are probed using temperature-, energy-, and power-dependent time-resolved optical spectroscopy. The properties of these multiexciton states build on the unique many-body physics of the single-excitons in TMDs.These studies reveal a complex interplay between the multiexcitons and single-excitons that depends on both the density and excitation energy of the initial exciton population. In addition, the presence of defect-bound excitons is found to drastically alter the formation of multiexcitons. This competition between exciton trapping and multiexciton formation highlights the need for high-quality materials to enhance multiexciton physics. By exploring this parameter space of excitation energy, excitation density, and defect density, complex many-body interactions are revealed that suggest means to optimize multiexciton yields and thus capitalize on the emergent characteristics of multiexciton emission and exciton-multiexciton interactions that are unique to monolayer-WSe2. These observations open new doors to a number of applications such as entangle photon pair production and lasing, highlighting the importance of understanding the formation and relaxation dynamics of the rich manifold of excitons in order to leverage 2D semiconductors for advanced technologies.

F.EN04.28.13
Computational Synthesis of 2D Materials—A High-Throughput Approach to Materials Design Tara M. Boland and Arunima Singh; Arizona State University, United States

The emergence of two dimensional (2D) materials opened up many potential avenues for novel device applications such as nanoelectronics, topological insulators, field effect transistors, microwave and terahertz photonics and many more. To date there are over 1,000 theoretically predicted 2D materials. Of those theoretical materials, only 55 have been experimentally synthesized due to the difficulty in finding a suitable substrate which simultaneously stabilizes the 2D phase over of bulk phase while preserving the novel materials properties resulting from quantum confinement. One avenue to aid in the development of these novel 2D materials is to explore and predict suitable substrates which will stabilize the 2D growth using computational methods. In this work a high-throughput approach to density functional theory is used to explore the viability of various common substrates to stabilize and grow these novel theoretically predicted 2D materials. This work analyzes three key factors which determine the stability of synthesizing 2D materials via substrate assisted methods such as chemical vapor deposition. The results will provide guidance to future experimental efforts to synthesize these 2D materials.

Using various 2D materials databases and van der Waals corrected density functional theory we investigate the suitability of 12 substrates to stabilize 2D growth. First, the formation energy of the 2D material is computed relative to the most stable bulk phase. A 2D material with a high formation energy implies the material will likely only be synthesized via substrate assisted methods thus making it a good candidate material for this study. Computational synthesis can be broken down into a two-step process: the formation of the 2D flake from the bulk phase, the formation energy, and adsorption of the 2D material on a symmetry-matched and low lattice-matched substrate surface, the binding energy. When the adsorption energy, the difference between the formation from the binding energy, is less than zero the adsorption is spontaneous, exothermic, and stable. For materials which meet this criteria, the density of states is computed to characterize the electronic properties of these materials for device applications. 1. F.EN04.28.14

Surface Protection of 2D Black Phosphorus with Greatly Enhanced Photoluminescence and Stability Dongying Li and Cun-Zheng Ning; Arizona State University, United States

Black phosphorus (BP) has gained intense interests because of its tunable direct bandgap, leading to emission with photon energies from ~1.7eV for monolayer to ~0.35eV for bulk [1]. This makes few-layer BPs one of the very few 2D infrared materials, especially in communication wavelengths. Besides, BP has a strong anisotropy compared with other 2D materials due to its puckered honeycomb lattice. It leads to many interesting phenomena such as strong coupling between phonon and carriers [2]. Thus BP is an appealing 2D platform for investigating novel physics and device applications. However, few-layer BP degrades quickly in the ambient environment due to the interaction with oxygen under light excitation. Such instability causes great difficulty in investigating properties of few-layer BP and in exploring the practical applications. Although BP protection methods are reported with verified good electronic properties, there is no report on stabilized BP with enhanced photoluminescence (PL) under ambient environment. Here we report an approach to realize BP with greatly enhanced PL (by as much as 160 times) that can be stable under ambient environment for months. We adopt a three-step method to prepare BP covered by boron nitride (BN) from both sides. First, thin flakes of BP and BN are exfoliated onto PDMS layers, followed by successive transfers of the bottom BN and then BP onto SiO2 (270nm)/ Si substrate. Second, oxygen plasma is used to thin down BP to desired thickness or numbers of layers. The oxygen plasma also leaves an oxide layer on top of the thinned-down BP at the end of the process. Third, we transfer the top BN onto the oxide covered BP which is then followed by thermal annealing. This process leads to oxygen doped few-layer BP with BN binding tightly from both sides to protect BP from the environment, highly improving the stability of BP. Raman spectroscopy indicates the sandwiched BP is defective. The breathing mode shows broadening and redshift. Ag1 and Ag2 modes both split into two subpeaks. These are the signs of introduction of oxygen defects in BP. PL of oxygen doped BP shows two-order of magnitude enhancement compared with freshly etched BP, which can be explained by bound exciton luminescence. Few-layer BP produced this way shows remarkable stability. The PL line-shape and intensity of sandwiched BP are barely changed when kept in the ambient environment under room temperature. A 3-layer BP sample prepared by such method, 5 months after preparation, PL intensity is still ~80% of that measured as prepared. At an elevated temperature of 90 °C, oxygen can escape from BP, which will result in redshift of PL peak and decreased PL intensity. 7 months after preparation, the 3-layer BP sample still shows strong PL, at ~70% of the original PL intensity right before TEM measurement. TEM results show close contact between BP and BN and three BP layers can be clearly identified from side view. Quite low oxygen concentration in BP layers is consistent with the assumption that oxygen escapes from BP with time. A 4-layer BP with comparable intensity to that of the 3-layer sample made by this method shows the possible general validity of this approach. In summary, our method can produce highly stable BP with excellent PL intensity induced by oxygen defects, allowing the study of rich physics in defective BP. Furthermore, it can pave the way for research on BP-based photonic devices such as lasers, modulators, etc. [1] Li, Likai, et al. Large Voltage Generation Through Liquid Motion on Single-Layer MoS2 Adha Sukma Aji[1], Ryohei Nishi[1], Hiroki Ago[2] and Yutaka Ohno[1]; [1]Nagoya University, Japan; [2]Kyushu University, Japan

Dynamics of water is one kind of clean energy source which readily available in our surrounding environment. Recently, the direct conversion of liquid motion energy into electricity by two-dimensional (2D) materials such as graphene has gained much interest [1-3]. However, the reported output voltage values generated by liquid motion on the graphene surface are

limited to millivolts order. With these output voltage values, the graphene nanogenerators might be difficult to drive conventional silicon-based electronics. Thus, an alternative to semimetallic graphene as an active material is needed to boost the output voltage. Here we report a single-layer MoS2 nanogenerator to generate electricity from liquid movement on its surface. The centimeter-scale single-layer MoS2 sheets were prepared by using chemical vapor deposition on sapphire substrate (3 × 1 cm) with MoO3 and sulfur powder as precursors. Then, the MoS2 was transferred onto polyethylene naphthalate (PEN) substrate. The device was finalized by applying silver epoxy as electrical contact on both ends of MoS2 and a silicone film as electrode protection from liquid. To generate electricity, aqueous 1 M NaCl were dropped on the MoS2 surface on a stage inclined at 45°. Due to the high hydrophobicity of MoS2, the droplets easily slid on the MoS2 surface, generating an open-circuit voltage of ~6 V. This output voltage value is significantly higher than graphene nanogenerators previously reported [1-3]. The short-circuit current of ~5 nA was generated from liquid movement on the MoS2 surface. The power produced by droplet movement is about 1.7 nW at load resistance of 200 M?. We also show the high scalability of our MoS2 nanogenerator by arranging them in series and parallel connections. The open-circuit voltage and short-circuit current were multiplied about three times by connecting three identical MoS2 nanogenerators in series and parallel connection, respectively. In conclusion, we showed the large-area single-layer MoS2 nanogenerator, which is capable of generating output voltage more than 5 V from liquid motion. Seeing the exceptional mechanical and electrical property of single-layer MoS2, the realization of self-powering untethered wearable device based on 2D materials will soon become fulfilled. F.EN04.28.16

Greenhouse Gas Sensor Constructed with Two-Dimensional Quantum Dots Platform with Anchored Electroactive Conducting Polymer Reeba Thomas and Kalathur Santhanam; Rochester Institute of Technology, United States

Recently, there has been active interest in developing greenhouse gas sensors for understanding the influence of these gases in controlling the atmosphere and the weather (1,2). We wish to report here, a greenhouse gas sensor that has been developed using 2D graphene quantum dots (3) platform on alumina substrate containing platinum interdigitated electrodes on one side and heating resistors on the other side of the platform with an electroactive conducting polymer, as the 2D structure provides a large surface area for the active material making it more sensitive for detection and measurements. The sensor operates in two stages; in the first stage the response of the interfering gases is measured and in the second stage a thermal pulse is applied corresponding to the desorption energies of the interfering gases. The temperature on the active material was measured using an infrared thermometer. The electroactive conducting polymer was electrochemically synthesized at a graphene quantum dots electrode by a potential step electrolysis at 1.00 V vs SCE. The experiments conducted with graphene quantum dots dispersed in the electrolytic medium, shows the monomer well coupled with graphene prior to the polymerization. The polymer coupled graphene shows D and G bands arising from graphene in Raman imaging spectroscopy. The mechanistic pathways has been unraveled by Raman imaging, Fourier transform infra-red spectroscopy, UV-VIS absorption spectroscopy, and scanning electron microscope. The results suggest that 2D platform for the active material for sensing enhances the performance of the sensor with a temperature-controlled selectivity. 1. D. Edge-Contacted 2D Transition Metal Dichalcogenide (TMD) Transistors Hattan Abuzaid, Zhihui Cheng and Aaron D. Franklin; Duke University, United States

Two-dimensional (2D) transition metal dichalcogenides (TMDs) have emerged as a promising transistor channel material because of their inherent atomic thinness, which can allow further scaling of channel length. In order to miniaturize transistors in future technology nodes, not only the channel length, but also the contact length (Lc) needs to be scaled as Lc constitutes a significant portion of the device's integrated pitch/density. Researchers have suggested the use of edge contacts to enable maximum scalability; in this configuration, the channel is contacted via its side edges along the same lateral plane as the contacts. Since the injection area is practically independent of the actual Lc, the performance of edge contacts can be Lc-independent [1], thus allowing much better scalability compared to traditional top contacts. In addition, edge contacts are hypothesized to form covalent bonds with the TMD channel, which should translate to better carrier injection. Published work on edge-contacted TMD transistors has predominantly focused on MoS2 as the channel material. Since chemically dissimilar TMDs interact distinctly with different metal contacts, further research on other promising TMDs, such as MoTe2 and WSe2 is warranted. In this work, we created clean edge contacts to TMD channels utilizing our previously established method [1] using an in-situ Ar+ ion beam in an integrated electron beam evaporation chamber. We discovered that the

etching behavior of the TMDs varied, and thus the realization of clean edge contacts required custom fabrication processes. The role of contact metal is elucidated for each TMD, along with analysis of top- versus edge-contacted devices on the same TMD flake or domain. These results provide key insights on how metal selection and channel thickness influence the device performance for various edge-contacted TMD transistors. References [1] Cheng, Zhihui, et al. "Immunity to Contact Scaling in MoS2 Transistors Using in Situ Edge Contacts." Nano letters 19.8 (2019): 5077-5085.

F.EN04.28.21
Scalable and Stable Intercalation of Li+ into Multi-Layer CVD Graphene for Controlled Optical and Electronic Properties Joseph Andrade[1], Jan Folkson[1], Amanda Carr[1], Mohamed Boukhicha[2] and Matthew Eisaman[1]; [1]Stony Brook University, The State University of New York, United States; [2]Brookhaven National Laboratory, United States

While graphitic intercalant compounds (GICs) have been thoroughly studied for application in battery technologies, use of these materials for transparent conductive electrodes (TCEs) has remained fairly unexplored. Although individual layers of 2D graphene promise high intrinsic mobility and transparency, its inherent properties do not rival those of current industry-standard materials. However, with lithium-ion intercalated multi-layer graphene grown via chemical vapor deposition (CVD), we produce large-scale LiC6 films whose electrical and optical properties are expected to surpass TCE requirements. With the developed sample design, we present preliminary data suggesting a path toward scalable and stable films for TCE application.

F.EN04.28.22
Steric and Electronic Effects at Polymer-2D Materials Interfaces James Nicolas M. Pagaduan, Nicholas Hight-Huf, Avdhoot Datar, Reika Katsumata, Michael Barnes, Ashwin Ramasubramaniam and Todd Emrick; University of Massachusetts Amherst, United States

This presentation will describe the impacts of steric and electronic interactions of zwitterionic polymers in contact with two-dimensional (2D) materials. Modulation of the work function of 2D materials facilitates charge injection and improves device performance for several applications such as solar cells, electronic displays, and organic light emitting diodes. The work function of 2D materials has been tailored by gas absorption, mechanical strain, and chemical doping methods. Polymer coatings have also been applied to tune the work function of 2D materials via non-covalent adsorption, offering possibilities for designing novel hybrid organic-inorganic functional materials. However, little is known about the precise role of functional group orientation on work function modulation. Here, we select graphene as a model 2D system and systematically examine work function modulation arising from coatings of functional poly(sulfobetaine methacrylate) (PSBMA). This approach maintains the desirable structural and electronic properties of graphene while exclusively altering its surface potential via the polymer coating. Work function modulation was observed by ultraviolet photoelectron spectroscopy and Kelvin probe force microscopy. First-principles density functional theory calculations provided insights into the preferred configurations of zwitterionic SBMA pendent groups physically adsorbed on graphene sheet, resultant dipole moment, and possible range of work function shifts that are achievable. Overall, this method of work function engineering permits scalable patterning of polymer films and precise spatial control over carrier doping for fabrication of monolayer graphene-based devices.

Ni-Decorated Graphene Microchannel for Self-Activated Gas Sensors with Enhanced Response to Ethanol Taehoon Kim[1], Yeonhoo Kim[2], Seo Yun Park[1] and Ho Won Jang[1]; [1]Seoul National University, Korea (the Republic of); [2]Los Alamos National Laboratory, United States

Graphene, one of the most popular two-dimensional (2-D) materials, has been studied with high interests owing to its outstanding properties such as high thermal and electrical conductivity, easy surface decoration, and transparency with flexibility. These remarkable advantages led to the studies of graphene in varied applications including gas sensors. However, for various applications, graphene-based gas sensors have to solve various problems such as power consumption by external heaters, insufficient selectivity, and method of mass production. In this work, we report ethanol gas detection of nickel nanoparticles decorated on graphene layers which are self-activated by applied bias voltage from 1 to 5 V. The graphene is prepared by chemical vapor deposition (CVD) method and we designed a narrow graphene channel to generates heat by using a joule heating effect while working as a sensing area. Since graphene is a 2-D material, both active sensing area and electrodes composed of graphene could be easily defined by facile lithography processes. Nickel nanoparticles are deposited by the e-beam evaporator. The gas sensing properties to various gases such as NO2, H2, C2H5OH, and NH3 have been tested at room temperature while regulating the input bias voltages. Our results show superior ethanol gas detection of nickel nanoparticles decorated graphene sensors at room temperature. These results broaden the potential of graphene-based gas

sensors for real applications.

F.EN04.28.24

New Low Bandgap Graphenic Semiconductors for Solar Cells and Photocatalysts Pawan Kumar[1], Ryan Kisslinger[1], Sheng Zeng[1], Guy Bernard[1], Sergey Gusarov[2], Alexander Kobryn[2], Kazi Alam[1], Vladimir Michaelis[1] and Karthik Shankar[1]; [1]University of Alberta, Canada; [2]National Research Council Canada, Canada

Graphenic semiconductors (GSCs) are an emerging class of energy materials based on the sp2-hybridized graphene motif that either by themselves or in composites, have demonstrated excellent performance for the electrochemical reduction of CO2, the photoelectrochemical splitting of water to generate H2, and the photocatalytic reduction of CO2. GSCs have a range of astonishing properties such as high catalytic activity, strong visible light absorption, exceptional chemical stability, thermal stability until at least 350 deg. C, and facile compositional and electrical doping. GSCs are typically synthesized by low cost solvothermal and annealing processes that lend themselves to scale-up and mass production. The most prominent member of this family of compounds is g-C3N4, which has a relatively wide bandgap of 2.6 eV. Herein, we report on the synthesis, characterization and solar energy applications of a number of new GSCs [1-5]. C3N5 is a novel modified carbon nitride framework with a remarkable 3:5 C:N stoichiometry and an electronic bandgap of 1.76 eV which was formed by thermal deammoniation of a precursor consisting of melem hydrazine [1]. The two s-heptazine units in the polymeric C3N5 are bridged together with an azo linkage, which constitutes an unconventional bonding arrangement, different from g-C3N4 where three heptazine units are linked together with tertiary nitrogen. C3N5 exhibits extended conjugation due to overlap of azo nitrogens and increased electron density [1]. C3N5 was found to be an excellent electron transport layer for perovskite solar cells, and a good photocatalyst for the photoreduction of 4-nitrobenzenethiol into 4,4?-dimercaptoazobenzene. Even lower bandgap analogs of C3N5 were synthesized and characterized. We also formed highly luminescent quantum dots of g-C3N4 doped with P, F or Cl. Intimate heterojunctions of doped g-C3N4 quantum dots with BiOI and TiO2 were demonstrated to be excellent photoanodes for visible light-driven water splitting, achieving photocurrent densities as high 2.5 mA cm-2 under AM1.5G simulated sunlight [2-3]. F.EN04.28.25

Enhanced Environmental Stability Coupled with a 12.5% Power Conversion Efficiency in an Aluminum Oxide-Encapsulated n-Graphene/p-Silicon Solar Cell Serdar Yavuz, Eric Martinez Loran, David P. Fenning and Prab Bandaru; University of California, San Diego, United States

A significant improvement in the power conversion efficiency (PCE) and the environmental stability of n-Graphene/p-Si solar cells is indicated through effective n-doping of graphene, using low work function oxide capping layers. AlOx, deposited through atomic layer deposition, is particularly effective for such doping and in addition serves as an antireflection coating and a cell encapsulating layer. It is shown that the related charge transfer doping and interfacial engineering was crucial to achieve a record PCE of 12.5%. The work indicates a path forward, through work function engineering, for further efficiency gains in Gr-based solar cells

F.EN04.28.26

Electron Emission from Epitaxial Graphene Microribbons Towards Emission of Soft X-Rays Daniel Lewis and Kevin Daniels; University of Maryland, United States

X-rays have been used for decades in medical diagnostic imaging, but the presence of metal scattering interference centers can limit their effectiveness. Longer wavelength sources may mitigate this effect, but risk poor imaging from low x-ray fluence. To produce a sufficient density of low-power x-rays to allow imaging of targets with metal inclusions, the x-ray current source would require a proportionate increase in output. Graphene nanoribbons crafted by CVD[1] or arc discharge[2]

have been shown to exhibit electron emission under bias, with theoretical outputs exceeding thermionic or field emission sources of similar dimensionality and applied bias conditions. Epitaxial graphene, able to be synthesized on the wafer-scale and compatible with current fabrication techniques, can be readily processed into ribbons with superior mechanical and electrical capabilities to its CVD or arc discharge counterparts. With even low applied bias (3 - 5 V) graphene nanoribbons (0.5 - 1 um long, 10-30 nm wide) suspended in high vacuum exhibited phonon-assisted electron emission (PAEE)[1][2], resulting in emission currents being produced at internal electric fields and external pulling voltages both nearly 10^2 less than comparable thermionic or field emission sources. Emissions exhibited repeatable directionality out of the plane of the ribbons, offering a means to mechanically control the orientation of the output current; ribbons crafted from epitaxial graphene, with deposited electrodes to provide the bias, would emit out of the plane of the substrate, enabling even macro-scale directional control. Fabrication of epitaxial graphene microribbons is readily accomplished via a combination of electron beam lithography and plasma etching, while relevant metal depositions are completed with electron beam evaporation. Patterned-photoresist masks allow for precise plasma etching to isolate the ribbons and electrodes in order to craft emission arrays of arbitrary numbers, dimensions, and positions, facilitating arrangements for rapid testing of device parameters and capabilities. Metals deposited on plasma-etched surfaces allow for external ball- and wedge-bonding of gold wire, resulting in test setup and device controls being significantly cheaper, faster, easier, and more robust than those presented in referenced works. Emission currents can be measured via a straightforward setup with the devices (cathodes) and a phosphor screen (anode) positioned in a vacuum chamber with feed-through contacts for control and measurement. Results of captured currents from various dimensions, arrangements, and applied biases of the graphene microribbon emitters and arrays are provided in both absolute terms, as well as normalized to more conventional dimensions and energizing voltages of comparable thermionic and field emission electron sources. By crafting microribbon emitters in various combinations of dimensions and arrangements, and isolating control circuits from each other, it should even be possible to craft a single physical device that could alternately function as multiple different sources, either independently or in concert as need dictates. Electron sources crafted in this fashion are expected to exhibit greater output, durability, flexibility, and cost savings compared to other electron sources of comparable dimensionality and power requirements. Presented here is a treatment of the preparation, fabrication, and testing of these epitaxial graphene microribbon electron emission arrays intended as sources for low-power x-ray imaging applications. 1. F.EN04.28.27

Full Consideration of Acoustic Phonon Scatterings in Two-Dimensional Dirac Materials Yia-Chung Chang and Khoe Van Nguyen; Academia Sinica, Taiwan

The in-plane acoustic phonon scattering in graphene is solved by considering fully inelastic acoustic phonon scatterings in two-dimensional (2D) Dirac materials for large range of temperature (T) and chemical potential (?). Rigorous analytical solutions and symmetry properties of Fermionic and Bosonic functions are obtained. We illustrate how doping alters the temperature dependence of acoustic phonon scattering rates. It is shown that the quasi-elastic and ansatz equations previously derived for acoustic phonon scatterings in graphene are limiting cases of the inelastic-scattering equations derived here. For heavily-doped graphene, we found that the high-T behavior of resistivity is better described by ? (T, ?) ~T [1 - ?a ?2/3(kB T)2] rather than a linear T behavior, and in the low T regime we found ?-1 ~ (kBT)4 but with a different prefactor (i.e. ~ 3 times smaller) in comparison with the existing quasi-elastic expressions. Furthermore, we found a simple analytic "semi-inelastic" expression of the form ?-1 ~ (kBT)4 /(1 + cT 3) which matches nearly perfectly with the full inelastic results for any temperature up to 500 K and ? up to 1 eV. Our simple analytic results agree well with previous first-principles studies and available experimental data. Our analyses pave a way for investigating scatterings between electrons and other fundamental excitations with linear dispersion relation in 2D Dirac material-based heterostructures such as bogolon-mediated electron scattering in graphene-based hybrid Bose-Fermi systems.

Metal–Organic Frameworks Encapsulated with Vanadium-Substituted Heteropoly Acid for Highly Stable Asymmetric Supercapacitors Nageh K. Allam; The American University in Cairo, Egypt

Herein, we report on a facile one-pot synthesis of polyoxometalates encapsulated zeolite imidazolate framework cages ($PMo_{10}V_2$@ZIF-67). The morphological and structural properties of the as-synthesized materials were investigated *via* FESEM, EDS, XRD and FTIR techniques. Moreover, N_2 adsorption/desorption isotherms, and XPS measurements were carried out to elucidate the textural properties and composition of the fabricated materials. Upon their use as supercapacitor electrodes, the $PMo_{10}V_2$@ZIF-67 electrode exhibited a maximum specific capacitance of 765 F/g at a scan rate of 5 mV/s. Furthermore, a supercapacitor device was assembled using activated carbon as the negative electrode and $PMo_{10}V_2$@ZIF-67 as the positive electrode, delivering a specific power of 702 W/kg and corresponding specific energy of 20.9 Wh/kg at a charging current density of 1 A/g. In addition, the device shows excellent long term stability and high Columbic efficiency over 5000 charging and discharging cycles at charging and discharging current density of 5 A/g.

F.EN04.29.02
Recycling of Li-Ni-Mn-Co Hydroxide from Spent Batteries to High-Performance Supercapacitors with Exceptional Stability Nageh K. Allam; American University in Cairo, Egypt

The intensive implementation of Li-ion batteries in many markets makes it increasingly urgent to address the recycling of strategic materials from spent batteries. Batteries typically contain toxic chemicals and cannot be disposed of at will. In this study, Li-Ni-Mn-Co hydroxides are successfully recycled from spent Li-ion batteries electrodeposited on nickel foam and fully characterized using different techniques such as field emission scanning electron microscopy (FESEM), x-ray diffraction (XRD), energy-dispersive X-ray spectroscopy (EDXS), inductively coupled plasma (ICP), and X-ray photoelectron spectroscopy (XPS) techniques. The recycled nanostructured films are tested in a three-electrode electrochemical system to investigate their capacitance behavior. The recycled electrodes show a high capacitance of 951 $F.g^{-1}$ (Specific capacity of 523.5 C. g^{-1}) at 1 A g^{-1}. Moreover, recycled materials are used as positive electrodes to construct asymmetric supercapacitor devices. The device shows a Coulombic efficiency of 100%, capacitance retention reaching ~90% with excellent cycling stability after 10,000 cycles as well as reasonable power and energy densities.

F.EN04.29.03
Effect of Iron Substitution on Cobalt Oxide and Study of Its Electrochemical Performance Deepa Guragain; The University of Memphis, United States

The application of metal oxides has been increasing for energy storage device due to excellent electrochemical properties, multifunctional energy application, environmentally friendly property and lower price. Due to rapid growth of energy use, there is very high demand for new ways to store energy. It is challenged to develop efficient way to store energy without polluting environment, which is possible by using transition metal oxide. We have prepared $Fe_xCo_{3-x}O_4$ (x=0.0, 0.2,0.4,0.6,0.8,1) successfully via hydrothermal method from which we can prepared electrode to make supercapacitor device. The structural properties were investigated by X-ray diffraction (XRD) and found phase pure $Fe_xCo_{3-x}O_4$. The morphology of the series obtained from scanning electron microscopy (SEM) varies from thinner nano-plates to thicker nano-plates as the concentration of Fe increase from x=0.0 to x=1.0. Furthermore, $Fe_xCo_{3-x}O_4$ were characterized by X-ray Photoelectron spectroscopy (XPS), Fourier Transform Infrared Spectroscopy (FTIR) and Quantachrome Surface area analyzer. The maximum BET surface area obtained from Quantachrome Instrument for x=1 is 87.5 m2/g. The XPS gives elemental composition of $Fe_xCo_{3-x}O_4$ as in desired amount. The higher specific capacitance of 268 F/g at a current density of 1 A/g, 856 F/g at 2 mV/s scan rate, the energy density of 16 Wh/kg and power density of 170 W/kg in 3M KOH electrolyte was observed for x =1 sample. An increased retention capacity ~122 % measured at 5 A/g current density and Coulombic efficiency of 100%. All these results indicate Fe dope Co_3O_4 composites electrode shows promising electrocatalytic activity results in the high intrinsic electronic conductivity, can largely improve the interfacial electroactive sites, increase charge transfer rates and help to stabilize the structure of compound.

F.EN04.29.04
Microstructural Evolution and Electrochimical Properties of Arachis Hypogaea Shell Derived *Ex Situ* Nitrogen-Doped Activated Carbon for Energy Storage Applications as Supercapacitor Balla D. Ngom[1], Ndeye Fatou D. Sylla[1], Ndeye Maty Ndiaye[1], Mohamed Chaker[2] and Ncholu Manyala[3]; [1]Universté Cheikh Anta Diop de Dakar, Senegal; [2]INRS, Canada; [3]University of Pretoria, South Africa

We report on the correlation of the microstructural evolution and electrochemical properties of an ex-situ N-doping KOH

activated carbon derived from Arachis Hypogea Shell (NAC-AHS) and compared to the non-doped (AC-AHS). Interconnected cavities with irregular-shaped structure are reported by SEM analysis for AC-AHS. After nitrogen doping, the morphology of the NAC-AHS materials exhibited a less porous structure as compared to AC-AHS. The surface specific area (SSA) of NAC-AHS was found to be 1442 $m^2 g^{-1}$ lower than the value of AC-AHS (1557 $m^2 g^{-1}$), the pore volumes were also found to follow the same trend since the reported values are as follow 0.76 $cm^3 g^{-1}$ and 0.69 $cm^3 g^{-1}$, respectively for AC-AHS and NAC-AHS. The AC-AHS and NAC-AHS exhibited in a half cell a specific capacitance (C_s) values of 167 F g^{-1} and 216 F g^{-1}, respectively at 1 A g^{-1}, corresponding to an improvement of 30% after ex-situ N-doping, which agrees with the higher current response recorded in the CV profiles of the samples. A symmetric device fabricated from the NAC-AHS materials displayed a Cs of 251.2 F g^{-1} at 1 A g^{-1} in a wide operating voltage of 2.0 V in 2.5 M KNO_3 aqueous electrolyte. In terms of stability, it achieved 83.2% as capacity retention up to 20,000 cycles, which was, improved through the floating/ aging measurement at 5 A g^{-1}over a long period of time (~7+ days). A specific energy of 35 Wh kg^{-1} with a corresponding specific power of 1 kW kg^{-1} at 1 A g^{-1} was delivered with the device still retaining up to 22 Wh kg^{-1} and a 20 kW kg^{-1} specific power even at 20 A g^{-1}.

F.EN04.29.05

Electrical Transport in Coconut Shell Charcoal G. R. A. Kumara[1], Kasun J. Wimalasena[2], S. M. B. Dissanayake[2], T. M. W. J. Bandara[2], Ajith DeSilva[3,4], A. G. U. Perera[4] and K. Tennakone[1,4]; [1]National Institute of Fundamental Studies, Sri Lanka, Sri Lanka; [2]University of Peradeniya, Sri Lanka; [3]University of West Georgia, United States; [4]Georgia State University, United States

Activated coconut charcoal is unique in meso and micro pore distribution, BET surface area exceeding 2000 m^2g^{-1} and pore volume ~ 1.3 cm^3g^{-1}. It is the bio-derived carbon material of choice for supercapacitor electrodes, cryogenic gas absorption in vacuum technology and water purification. Coconut shell carbon is also the hardest biochar - hardness 3-4 in the Mohs scale. For supercapacitors, batteries and several other applications, high electrical conductivity is an advantageous parameter. Owing to large surface to volume ratio of the material, the carrier trapping sites on the surface play a crucial role in electrical transport. The DC electrical conductivity is found be greatly influenced by mode of activation, surface treatments and impurities. The most studies on electrical conductivity of activated carbons were based on measurements conducted using compacted pellets. The higher hardness of coconut shell charcoal enable use of sizable samples made from uncrushed flakes to carry out chemical treatments and conduct measurements under varying conditions. The results of measurements and interpretations will be presented, emphasizing supercapacitor applications of coconut shell charcoal.

F.EN04.29.06

Dielectric h-BN Separators for Ti_3C_2-MnO_2 Supercapacitors Alptekin Aydinli[1,2], Xuehang Wang[1], Husnu E. Unalan[2] and Yury Gogotsi[1]; [1]Drexel University, United States; [2]Middle East Technical University, Turkey

Electrochemical energy storage (EES) units are vital for mobile electronic devices that can provide high energy and power densities. Current studies mostly aim at improving the performance of the electrode active materials. Nevertheless, inert components such as electrolyte, separator and current collector occupy 70-80 wt.% of the EES devices and reducing their weight/volume can significantly improve the performance of these devices. Dielectric materials are used extensively in EES devices as separators such as ceramics in conventional capacitors. In supercapacitors, polypropylene membranes and glassy fiber films with typical thicknesses larger than 25 μm are the common separator materials. Two dimensional (2D) dielectric materials with flat and smooth surfaces at a much smaller thickness can in fact be used as efficient separators.
In this work, 2D hexagonal boron nitride (h-BN) thin films were utilized as efficient separator layers in asymmetric MXene supercapacitors. In these devices, titanium carbide (Ti_3C_2) and manganese dioxide (MnO_2) were used as the negative and positive electrodes, respectively. Electrochemical tests such as cyclic voltammetry, chronopotentiometry and electrochemical impedance spectroscopy were conducted to determine specific capacity, rate capability and cycling stability of the asymmetric supercapacitor devices. Fabricated supercapacitor devices showed promising electrochemical performance in a PVA/H_2SO_4 gel electrolyte compared to the control device with conventional Celgard separator. The reduced thickness of the h-BN separator decreased the volume of an entire supercapacitor device and significantly improved the overall capacitance.

F.EN04.29.07

Bioinspired Nanoporous Ion Conducting Membranes for Next Generation Batteries Ahmet Emre, Jinchen Fan, Emine Turali-Emre, Alycia Gerber, Volkan Cecen and Nicholas Kotov; University of Michigan, United States

Bioinspired ion transport membranes have been widely investigated for energy storage applications. High theoretical specific energy density (2600Wh/kg) and high specific capacity (1675mA/g) along with natural abundance and low toxicity of sulfur have been attracting significant attention for development of an alternative battery system to replace traditional lithium ion

batteries which suffer from safety and capacity/energy density limitations in various applications. However, challenges such as polysulfide dissolution and shuttling prevent mass commercialization of metal sulfur batteries. Inspired from biological ion transport mechanisms, we show a practical yet comprehensive approach for development of highperformance metal sulfur batteries. Aramid nanofiber (ANF) based composite ion transport membranes not
only prevent dendrite formation but also confine polysulfides on the cathode side. ANF composite battery separators provide diverse and opposing properties including high mechanical properties, high ionic conductivity and high thermal/chemical stability. Highly selective ion sieving properties of these biomimetic separators provide safe and high-performance batteries. Fabrication of such biocompatible, affordable,
flexible and high energy density battery is quite crucial in powering next-generation electronics including but not limited to portable, wearable and implantable biomedical devices.

SESSION F.LP06.01: Live Poster Session: Energy (F.EN04)
Session Chair: Han Wang
Friday Morning, December 4, 2020

F.EN04

F.EN04.28.02
MoS2 Based High-Performance FET Devices for Memory Circuits on Flexible Platform Sayani Majumdar[1], Miika Soikkeli[1], Ioannis Zeimpekis[2], Nikolaos Aspiotis[2], Chung-Che Huang[2], Sanna Arpiainen[1] and Mika Prunnila[1]; [1]VTT Technical Research Centre, Finland; [2]University of Southampton, United Kingdom

Two-dimensional transition metal dichalcogenides (TMDs) are fertile ground for fundamental material science and emergent applications in high-performance electronics. The mechanical flexibility of 2D materials allows their incorporation in variable form factor designs such as smart wearables and foldable electronics, where their electronic and optical properties outperform conventional flexible materials such as organic polymers. In the current work, we present high-performance ALD grown MoS2 based FET devices transferred on polyimide substrates. The growth method employs ALD to grow an MoO3 layer on a 6 inch wafer which is subsequently annealed in an H2S atmosphere to convert to MoS2. The ALD allows for excellent uniformity and because the layer acts as a template the process is scalable to larger sizes. The resulting MoS2 film is 2-3 layers thick. The film was transferred on the patterned target substrate using polystyrene assisted transfer of MoS2 layer. More than 90% device yield, excellent current ON to OFF ratio of 106 and mobility values up to 32 cm2 V-1 s-1 have been measured from micron scale devices with L/W in the range of two. We will present results on the yield and homogeneity on large area memory networks aiming for low power neuromorphic circuits.

F.EN04.28.04
Infrared Permittivity of the Biaxial van der Waals Semiconductor α-MoO3 from Near- and Far-Field Correlative Studies Thomas Folland[1], Gonzalo Alvarez-Perez[2], Ion Errea[3], Javier Taboada-Gutriérrez[2], Ana I. Tresguerres-Mata[2], Joseph R. Matson[1], Andrei Bylinkin[4], Mingze He[1], Weiliang Ma[5], Qiaoliang Bao[6], Joshua D. Caldwell[1], Alexey Nikitin[4] and Pablo Alonso-Gonzalez[2]; [1]Vanderbilt University, United States; [2]University of Oviedo, Spain; [3]University of Basque Country, Spain; [4]Donostia International Physics Center, Spain; [5]Huazhong University of Science & Technology, China; [6]Soochow University, China

The natural crystal anisotropy of van der Waals materials allows them to support a range of nanophotonic phenomena not observable in other natural materials. One such example is anisotropic phonon polaritons (PhPs), which form due to polar optic phonons in materials such as hexagonal boron nitride. Such hyperbolic polaritons have been shown to enable sub-diffraction guiding of light waves, sensing of ultra-thin analytes, and hyperlensing for super resolution imaging in the mid infrared (IR). Recently, the biaxial van der Waals semiconductor α-phase molybdenum trioxide (α-MoO_3) has received significant attention due to its ability to support PhPs which are anisotropic along all three crystal axes. These offer an unprecedented platform for controlling the flow of energy at the nanoscale, in particular for manipulating the polarization state of light. However, to fully exploit the extraordinary IR response of this material, an accurate dielectric function is required.

In this work, we report an accurate IR dielectric function of α-MoO_3 by modelling far-field, polarized IR reflectance spectra acquired on a single thick flake of this material. Unique to our work, the far-field model is refined using the experimental

dispersion and damping of PhPs revealed by using scattering-type scanning near-field optical microscopy (s-SNOM) on thin flakes of α-MoO3. Through these correlative efforts, exceptional quantitative agreement is attained to both far- and near-field properties for multiple flakes, thus providing strong verification of the accuracy of our model. This also provides a novel approach to extracting dielectric functions of different 2D materials, usually too small or inhomogeneous for establishing accurate models only from standard far-field methods. Finally, by employing density functional theory (DFT), we provide insights into the various vibrational states dictating our dielectric function model and the intriguing optical properties of α-MoO_3.

F.EN04.28.05

Feedback-Controlled Electroburning of MoS_2 Monolayers Yan Qi Huan[1], Yincheng Liu[1], Choon Hwa Ken Goh[1], Kuan Eng Johnson Goh[1,2], Swee Liang Wong[1,2] and Chit Siong Lau[1]; [1]Institute of Materials Research and Engineering, Singapore; [2]National University of Singapore, Singapore

Two-dimensional materials have been identified as interesting candidates for various applications in nano-electronics, and the characterization of electrical breakdown limits is a crucial step in device development. However, methods for repeatable measurements have been scarce in two-dimensional materials, where breakdown studies have been limited to destructive methods. This lack of repeatability restricts our ability to fully account for variability in local electronic properties induced by the fabrication process and surface contaminants.

To tackle this, we implement a two-step deep-learning model to predict the breakdown mechanism and breakdown voltage of monolayer MoS_2 devices with varying channel lengths and resistances using current measured in the low-voltage regime as inputs. A deep neural network (DNN) first classifies between Joule and avalanche breakdown mechanisms with partial current traces from 0–20V. Following this, a convolutional long short-term memory network (CLSTM) predicts breakdown voltages of these classified devices based on user-defined partial current traces.

We test our model with feedback-controlled electrical measurements to achieve non-destructive electrical measurements that limit device damage and increase the amount of data collected. We show that the DNN classifier achieves an accuracy of 74% while the CLSTM model has a 14% error when requiring only 80% of the current trace as inputs. Our results indicate that information encoded in the current behavior far from the breakdown point can be used for predictions, thus enabling non-destructive and fast material characterization for 2D material device development.

F.EN04.28.06

Synthesis and Characterization of MXene-WS2 Heterostructure Devices Venkata Surya N Chava, Aruna Narayanan Nair and Sreeprasad T. Sreenivasan; The University of Texas at El Paso, United States

Atomically thin two-dimensional (2D) materials such as graphene, MoS2, WS2 show excellent material properties and therefore studied extensively for a variety of applications including electronics, optoelectronics, electrocatalysis, energy storage, etc. More recently, there has been a growing interest in 2D heterostructure devices as they offer unique opportunities to design and study possibilities for controlling and manipulating the carrier confinement and transport of charge within these device structures. Tungsten disulfide (WS2) is an excellent material for optoelectronic applications such as photodetectors as monolayer WS2 has a direct bandgap of ~ 2.05 eV. Also, recently emerged as MXenes has shown great promise in energy storage and electromagnetic shielding applications due to excellent metallic conductivity. The MXenes can show either metallic or semiconducting behavior depending on the functional groups attached to the surface during the etching process. In particular, their tunable work function property can be exploited to control the properties of the heterostructure of MXenes with other layered 2D materials. Here, we report the characterization results of one such heterostructure formed by combining MXenes with WS2. MXene is synthesized by etching the Al layer from the parent MAX phase, and WS2 is synthesized on SiO2/Si substrates using the CVD process. The electrical properties of these as-synthesized materials can be modified using different approaches such as chemical doping etc. We present results from different morphological, spectroscopic and electrical characterization techniques that are used to study the transport characteristics of these MXene-WS2 heterostructure devices.

F.EN04.28.08

Photo-Thermoelectric Effect along Waveguide-Integrated Graphene Photodetectors Jakob Muench, Hannah Watson, Osman Balci, Alfonso Ruocco and Andrea C. Ferrari; Cambridge Graphene Centre, United Kingdom

The dominating mechanism of photodetection in a single-layer graphene (SLG) based device depends on the design of the detector [1,2,3], its chosen operation [1,3], and the band diagram in the photo-active region [2,4]. Here we demonstrate, over

a ?0.5eV doping range, that the photo-thermoelectric effect [5] has a long-range (exceeding the cooling length in SLG) contribution, even in uniformly doped SLG, in the absence of a Seebeck coefficient gradient, whenever non-uniform absorption creates an electronic temperature gradient. This is achieved by integrating SLG with on-chip Si waveguides to generate an heterogeneous absorption profile over tens ?m and placing electrical probes along the propagation direction of light. We show the presence of a photovoltage Vph along the waveguide. The doping-dependence of Vph suggests signal generation by hot electrons via the Seebeck effect. This has general implications for the design and optimization of optoelectronic devices based on SLG, in particular for integrated photonics, where planar integration of layered materials leads to non-uniform absorption. Shautsova et al., Nat. Comm., 9, 5190, (2018). [5] N. Gabor et al., Science, 334, 648, (2011).

F.EN04.28.12

Unraveling Nonlinear Formation and Relaxation of Excitons in Atomically Thin 2D Semiconductors Matthew C. Strasbourg[1], Cory Johns[1], Thomas Darlington[2], James Hone[2], P James Schuck[2] and Nicholas Borys[1]; [1]Montana State University, United States; [2]Columbia University, United States

Transition metal dichalcogenide (TMD) semiconductors are layered van der Walls materials that exhibit exceptional optoelectronic properties in monolayer form. Their atomically thin nature and reduced long-range dielectric screening make them ideal systems in which to study many-body electronic states. Notably, excitonic many-body phenomena govern the light-matter interactions in TMD semiconductors and open up new possibilities for novel optoelectronic devices, including new classes of quantum light sources. Thus, understanding the rich suite of many-body phenomena in these systems is motivated by potential applications in on-chip optoelectronics and by the insights that can be gained into the fundamental interactions that govern TMD material properties. Here, the dynamics of several higher-order excitons including trions, biexcitons, and charged biexcitons in monolayer-WSe2 are probed using temperature-, energy-, and power-dependent time-resolved optical spectroscopy. The properties of these multiexciton states build on the unique many-body physics of the single-excitons in TMDs.These studies reveal a complex interplay between the multiexcitons and single-excitons that depends on both the density and excitation energy of the initial exciton population. In addition, the presence of defect-bound excitons is found to drastically alter the formation of multiexcitons. This competition between exciton trapping and multiexciton formation highlights the need for high-quality materials to enhance multiexciton physics. By exploring this parameter space of excitation energy, excitation density, and defect density, complex many-body interactions are revealed that suggest means to optimize multiexciton yields and thus capitalize on the emergent characteristics of multiexciton emission and exciton-multiexciton interactions that are unique to monolayer-WSe2. These observations open new doors to a number of applications such as entangle photon pair production and lasing, highlighting the importance of understanding the formation and relaxation dynamics of the rich manifold of excitons in order to leverage 2D semiconductors for advanced technologies.

Computational Synthesis of 2D Materials—A High-Throughput Approach to Materials Design Tara M. Boland and Arunima Singh; Arizona State University, United States

The emergence of two dimensional (2D) materials opened up many potential avenues for novel device applications such as nanoelectronics, topological insulators, field effect transistors, microwave and terahertz photonics and many more. To date there are over 1,000 theoretically predicted 2D materials. Of those theoretical materials, only 55 have been experimentally synthesized due to the difficulty in finding a suitable substrate which simultaneously stabilizes the 2D phase over of bulk phase while preserving the novel materials properties resulting from quantum confinement. One avenue to aid in the development of these novel 2D materials is to explore and predict suitable substrates which will stabilize the 2D growth using computational methods. In this work a high-throughput approach to density functional theory is used to explore the viability of various common substrates to stabilize and grow these novel theoretically predicted 2D materials. This work analyzes three key factors which determine the stability of synthesizing 2D materials via substrate assisted methods such as chemical vapor deposition. The results will provide guidance to future experimental efforts to synthesize these 2D materials. Using various 2D materials databases and van der Waals corrected density functional theory we investigate the suitability of 12 substrates to stabilize 2D growth. First, the formation energy of the 2D material is computed relative to the most stable bulk phase. A 2D material with a high formation energy implies the material will likely only be synthesized via substrate assisted methods thus making it a good candidate material for this study. Computational synthesis can be broken down into a two-step process: the formation of the 2D flake from the bulk phase, the formation energy, and adsorption of the 2D material on a symmetry-matched and low lattice-matched substrate surface, the binding energy. When the adsorption energy, the difference between the formation from the binding energy, is less than zero the adsorption is spontaneous, exothermic, and

stable. For materials which meet this criteria, the density of states is computed to characterize the electronic properties of these materials for device applications. 1. We gratefully acknowledge ASU's HPC staff for support and assistance with computing resources along with the Extreme Science and Engineering Discovery Environment (XSEDE), for support by National Science Foundation grant number ACI-1548562, through award number TG-DMR-150006. F.EN04.28.14

Surface Protection of 2D Black Phosphorus with Greatly Enhanced Photoluminescence and Stability Dongying Li and Cun-Zheng Ning; Arizona State University, United States

Black phosphorus (BP) has gained intense interests because of its tunable direct bandgap, leading to emission with photon energies from ~1.7eV for monolayer to ~0.35eV for bulk [1]. This makes few-layer BPs one of the very few 2D infrared materials, especially in communication wavelengths. Besides, BP has a strong anisotropy compared with other 2D materials due to its puckered honeycomb lattice. It leads to many interesting phenomena such as strong coupling between phonon and carriers [2]. Thus BP is an appealing 2D platform for investigating novel physics and device applications. However, few-layer BP degrades quickly in the ambient environment due to the interaction with oxygen under light excitation. Such instability causes great difficulty in investigating properties of few-layer BP and in exploring the practical applications. Although BP protection methods are reported with verified good electronic properties, there is no report on stabilized BP with enhanced photoluminescence (PL) under ambient environment. Here we report an approach to realize BP with greatly enhanced PL (by as much as 160 times) that can be stable under ambient environment for months. We adopt a three-step method to prepare BP covered by boron nitride (BN) from both sides. First, thin flakes of BP and BN are exfoliated onto PDMS layers, followed by successive transfers of the bottom BN and then BP onto SiO2 (270nm)/ Si substrate. Second, oxygen plasma is used to thin down BP to desired thickness or numbers of layers. The oxygen plasma also leaves an oxide layer on top of the thinned-down BP at the end of the process. Third, we transfer the top BN onto the oxide covered BP which is then followed by thermal annealing. This process leads to oxygen doped few-layer BP with BN binding tightly from both sides to protect BP from the environment, highly improving the stability of BP. Raman spectroscopy indicates the sandwiched BP is defective. The breathing mode shows broadening and redshift. Ag1 and Ag2 modes both split into two subpeaks. These are the signs of introduction of oxygen defects in BP. PL of oxygen doped BP shows two-order of magnitude enhancement compared with freshly etched BP, which can be explained by bound exciton luminescence. Few-layer BP produced this way shows remarkable stability. The PL line-shape and intensity of sandwiched BP are barely changed when kept in the ambient environment under room temperature. A 3-layer BP sample prepared by such method, 5 months after preparation, PL intensity is still ~80% of that measured as prepared. At an elevated temperature of 90 °C, oxygen can escape from BP, which will result in redshift of PL peak and decreased PL intensity. 7 months after preparation, the 3-layer BP sample still shows strong PL, at ~70% of the original PL intensity right before TEM measurement. TEM results show close contact between BP and BN and three BP layers can be clearly identified from side view. Quite low oxygen concentration in BP layers is consistent with the assumption that oxygen escapes from BP with time. A 4-layer BP with comparable intensity to that of the 3-layer sample made by this method shows the possible general validity of this approach. In summary, our method can produce highly stable BP with excellent PL intensity induced by oxygen defects, allowing the study of rich physics in defective BP. Furthermore, it can pave the way for research on BP-based photonic devices such as lasers, modulators, etc. [1] Li, Likai, et al. Large Voltage Generation Through Liquid Motion on Single-Layer MoS2 Adha Sukma Aji[1], Ryohei Nishi[1], Hiroki Ago[2] and Yutaka Ohno[1]; [1]Nagoya University, Japan; [2]Kyushu University, Japan

Dynamics of water is one kind of clean energy source which readily available in our surrounding environment. Recently, the direct conversion of liquid motion energy into electricity by two-dimensional (2D) materials such as graphene has gained much interest [1-3]. However, the reported output voltage values generated by liquid motion on the graphene surface are limited to millivolts order. With these output voltage values, the graphene nanogenerators might be difficult to drive conventional silicon-based electronics. Thus, an alternative to semimetallic graphene as an active material is needed to boost the output voltage. Here we report a single-layer MoS2 nanogenerator to generate electricity from liquid movement on its surface. The centimeter-scale single-layer MoS2 sheets were prepared by using chemical vapor deposition on sapphire substrate (3 × 1 cm) with MoO3 and sulfur powder as precursors. Then, the MoS2 was transferred onto polyethylene naphthalate (PEN) substrate. The device was finalized by applying silver epoxy as electrical contact on both ends of MoS2 and a silicone film as electrode protection from liquid. To generate electricity, aqueous 1 M NaCl were dropped on the MoS2

surface on a stage inclined at 45°. Due to the high hydrophobicity of MoS2, the droplets easily slid on the MoS2 surface, generating an open-circuit voltage of ~6 V. This output voltage value is significantly higher than graphene nanogenerators previously reported [1-3]. The short-circuit current of ~5 nA was generated from liquid movement on the MoS2 surface. The power produced by droplet movement is about 1.7 nW at load resistance of 200 M?. We also show the high scalability of our MoS2 nanogenerator by arranging them in series and parallel connections. The open-circuit voltage and short-circuit current were multiplied about three times by connecting three identical MoS2 nanogenerators in series and parallel connection, respectively. In conclusion, we showed the large-area single-layer MoS2 nanogenerator, which is capable of generating output voltage more than 5 V from liquid motion. Seeing the exceptional mechanical and electrical property of single-layer MoS2, the realization of self-powering untethered wearable device based on 2D materials will soon become fulfilled. F.EN04.28.16

Greenhouse Gas Sensor Constructed with Two-Dimensional Quantum Dots Platform with Anchored Electroactive Conducting Polymer Reeba Thomas and Kalathur Santhanam; Rochester Institute of Technology, United States

Recently, there has been active interest in developing greenhouse gas sensors for understanding the influence of these gases in controlling the atmosphere and the weather (1,2). We wish to report here, a greenhouse gas sensor that has been developed using 2D graphene quantum dots (3) platform on alumina substrate containing platinum interdigitated electrodes on one side and heating resistors on the other side of the platform with an electroactive conducting polymer, as the 2D structure provides a large surface area for the active material making it more sensitive for detection and measurements. The sensor operates in two stages; in the first stage the response of the interfering gases is measured and in the second stage a thermal pulse is applied corresponding to the desorption energies of the interfering gases. The temperature on the active material was measured using an infrared thermometer. The electroactive conducting polymer was electrochemically synthesized at a graphene quantum dots electrode by a potential step electrolysis at 1.00 V vs SCE. The experiments conducted with graphene quantum dots dispersed in the electrolytic medium, shows the monomer well coupled with graphene prior to the polymerization. The polymer coupled graphene shows D and G bands arising from graphene in Raman imaging spectroscopy. The mechanistic pathways has been unraveled by Raman imaging, Fourier transform infra-red spectroscopy, UV-VIS absorption spectroscopy, and scanning electron microscope. The results suggest that 2D platform for the active material for sensing enhances the performance of the sensor with a temperature-controlled selectivity. 1. D. Edge-Contacted 2D Transition Metal Dichalcogenide (TMD) Transistors Hattan Abuzaid, Zhihui Cheng and Aaron D. Franklin; Duke University, United States

Two-dimensional (2D) transition metal dichalcogenides (TMDs) have emerged as a promising transistor channel material because of their inherent atomic thinness, which can allow further scaling of channel length. In order to miniaturize transistors in future technology nodes, not only the channel length, but also the contact length (Lc) needs to be scaled as Lc constitutes a significant portion of the device's integrated pitch/density. Researchers have suggested the use of edge contacts to enable maximum scalability; in this configuration, the channel is contacted via its side edges along the same lateral plane as the contacts. Since the injection area is practically independent of the actual Lc, the performance of edge contacts can be Lc-independent [1], thus allowing much better scalability compared to traditional top contacts. In addition, edge contacts are hypothesized to form covalent bonds with the TMD channel, which should translate to better carrier injection. Published work on edge-contacted TMD transistors has predominantly focused on MoS2 as the channel material. Since chemically dissimilar TMDs interact distinctly with different metal contacts, further research on other promising TMDs, such as MoTe2 and WSe2 is warranted. In this work, we created clean edge contacts to TMD channels utilizing our previously established method [1] using an in-situ Ar+ ion beam in an integrated electron beam evaporation chamber. We discovered that the etching behavior of the TMDs varied, and thus the realization of clean edge contacts required custom fabrication processes. The role of contact metal is elucidated for each TMD, along with analysis of top- versus edge-contacted devices on the same TMD flake or domain. These results provide key insights on how metal selection and channel thickness influence the device performance for various edge-contacted TMD transistors. References [1] Cheng, Zhihui, et al. Scalable and Stable Intercalation of Li+ into Multi-Layer CVD Graphene for Controlled Optical and Electronic Properties Joseph Andrade[1], Jan Folkson[1], Amanda Carr[1], Mohamed Boukhicha[2] and Matthew Eisaman[1]; [1]Stony Brook University, The State University of New York, United States; [2]Brookhaven National Laboratory, United States

While graphitic intercalant compounds (GICs) have been thoroughly studied for application in battery technologies, use of these materials for transparent conductive electrodes (TCEs) has remained fairly unexplored. Although individual layers of 2D graphene promise high intrinsic mobility and transparency, its inherent properties do not rival those of current industry-standard materials. However, with lithium-ion intercalated multi-layer graphene grown via chemical vapor deposition (CVD), we produce large-scale LiC6 films whose electrical and optical properties are expected to surpass TCE requirements. With the developed sample design, we present preliminary data suggesting a path toward scalable and stable films for TCE application.

Steric and Electronic Effects at Polymer-2D Materials Interfaces James Nicolas M. Pagaduan, Nicholas Hight-Huf, Avdhoot Datar, Reika Katsumata, Michael Barnes, Ashwin Ramasubramaniam and Todd Emrick; University of Massachusetts Amherst, United States

This presentation will describe the impacts of steric and electronic interactions of zwitterionic polymers in contact with two-dimensional (2D) materials. Modulation of the work function of 2D materials facilitates charge injection and improves device performance for several applications such as solar cells, electronic displays, and organic light emitting diodes. The work function of 2D materials has been tailored by gas absorption, mechanical strain, and chemical doping methods. Polymer coatings have also been applied to tune the work function of 2D materials via non-covalent adsorption, offering possibilities for designing novel hybrid organic-inorganic functional materials. However, little is known about the precise role of functional group orientation on work function modulation. Here, we select graphene as a model 2D system and systematically examine work function modulation arising from coatings of functional poly(sulfobetaine methacrylate) (PSBMA). This approach maintains the desirable structural and electronic properties of graphene while exclusively altering its surface potential via the polymer coating. Work function modulation was observed by ultraviolet photoelectron spectroscopy and Kelvin probe force microscopy. First-principles density functional theory calculations provided insights into the preferred configurations of zwitterionic SBMA pendent groups physically adsorbed on graphene sheet, resultant dipole moment, and possible range of work function shifts that are achievable. Overall, this method of work function engineering permits scalable patterning of polymer films and precise spatial control over carrier doping for fabrication of monolayer graphene-based devices.

Ni-Decorated Graphene Microchannel for Self-Activated Gas Sensors with Enhanced Response to Ethanol Taehoon Kim[1], Yeonhoo Kim[2], Seo Yun Park[1] and Ho Won Jang[1]; [1]Seoul National University, Korea (the Republic of); [2]Los Alamos National Laboratory, United States

Graphene, one of the most popular two-dimensional (2-D) materials, has been studied with high interests owing to its outstanding properties such as high thermal and electrical conductivity, easy surface decoration, and transparency with flexibility. These remarkable advantages led to the studies of graphene in varied applications including gas sensors. However, for various applications, graphene-based gas sensors have to solve various problems such as power consumption by external heaters, insufficient selectivity, and method of mass production. In this work, we report ethanol gas detection of nickel nanoparticles decorated on graphene layers which are self-activated by applied bias voltage from 1 to 5 V. The graphene is prepared by chemical vapor deposition (CVD) method and we designed a narrow graphene channel to generates heat by using a joule heating effect while working as a sensing area. Since graphene is a 2-D material, both active sensing area and electrodes composed of graphene could be easily defined by facile lithography processes. Nickel nanoparticles are deposited by the e-beam evaporator. The gas sensing properties to various gases such as NO2, H2, C2H5OH, and NH3 have been tested at room temperature while regulating the input bias voltages. Our results show superior ethanol gas detection of nickel nanoparticles decorated graphene sensors at room temperature. These results broaden the potential of graphene-based gas sensors for real applications.

F.EN04.28.24

New Low Bandgap Graphenic Semiconductors for Solar Cells and Photocatalysts Pawan Kumar[1], Ryan Kisslinger[1], Sheng Zeng[1], Guy Bernard[1], Sergey Gusarov[2], Alexander Kobryn[2], Kazi Alam[1], Vladimir Michaelis[1] and Karthik Shankar[1]; [1]University of Alberta, Canada; [2]National Research Council Canada, Canada

Graphenic semiconductors (GSCs) are an emerging class of energy materials based on the sp2-hybridized graphene motif that either by themselves or in composites, have demonstrated excellent performance for the electrochemical reduction of CO2, the photoelectrochemical splitting of water to generate H2, and the photocatalytic reduction of CO2. GSCs have a range of astonishing properties such as high catalytic activity, strong visible light absorption, exceptional chemical stability, thermal stability until at least 350 deg. C, and facile compositional and electrical doping. GSCs are typically synthesized by low cost solvothermal and annealing processes that lend themselves to scale-up and mass production. The most prominent member of this family of compounds is g-C3N4, which has a relatively wide bandgap of 2.6 eV. Herein, we report on the synthesis, characterization and solar energy applications of a number of new GSCs [1-5]. C3N5 is a novel modified carbon nitride framework with a remarkable 3:5 C:N stoichiometry and an electronic bandgap of 1.76 eV which was formed by thermal deammoniation of a precursor consisting of melem hydrazine [1]. The two s-heptazine units in the polymeric C3N5 are bridged together with an azo linkage, which constitutes an unconventional bonding arrangement, different from g-C3N4 where three heptazine units are linked together with tertiary nitrogen. C3N5 exhibits extended conjugation due to overlap of azo nitrogens and increased electron density [1]. C3N5 was found to be an excellent electron transport layer for perovskite solar cells, and a good photocatalyst for the photoreduction of 4-nitrobenzenethiol into 4,4?-dimercaptoazobenzene. Even lower bandgap analogs of C3N5 were synthesized and characterized. We also formed highly luminescent quantum dots of g-C3N4 doped with P, F or Cl. Intimate heterojunctions of doped g-C3N4 quantum dots with BiOI and TiO2 were demonstrated to be excellent photoanodes for visible light-driven water splitting, achieving photocurrent densities as high 2.5 mA cm-2 under AM1.5G simulated sunlight [2-3]. F.EN04.28.25

Enhanced Environmental Stability Coupled with a 12.5% Power Conversion Efficiency in an Aluminum Oxide-Encapsulated n-Graphene/p-Silicon Solar Cell Serdar Yavuz, Eric Martinez Loran, David P. Fenning and Prab Bandaru; University of California, San Diego, United States

A significant improvement in the power conversion efficiency (PCE) and the environmental stability of n-Graphene/p-Si solar cells is indicated through effective n-doping of graphene, using low work function oxide capping layers. AlOx, deposited through atomic layer deposition, is particularly effective for such doping and in addition serves as an antireflection coating and a cell encapsulating layer. It is shown that the related charge transfer doping and interfacial engineering was crucial to achieve a record PCE of 12.5%. The work indicates a path forward, through work function engineering, for further efficiency gains in Gr-based solar cells

F.EN04.28.26

Electron Emission from Epitaxial Graphene Microribbons Towards Emission of Soft X-Rays Daniel Lewis and Kevin Daniels; University of Maryland, United States

X-rays have been used for decades in medical diagnostic imaging, but the presence of metal scattering interference centers can limit their effectiveness. Longer wavelength sources may mitigate this effect, but risk poor imaging from low x-ray fluence. To produce a sufficient density of low-power x-rays to allow imaging of targets with metal inclusions, the x-ray current source would require a proportionate increase in output. Graphene nanoribbons crafted by CVD[1] or arc discharge[2] have been shown to exhibit electron emission under bias, with theoretical outputs exceeding thermionic or field emission sources of similar dimensionality and applied bias conditions. Epitaxial graphene, able to be synthesized on the wafer-scale and compatible with current fabrication techniques, can be readily processed into ribbons with superior mechanical and electrical capabilities to its CVD or arc discharge counterparts. With even low applied bias (3 - 5 V) graphene nanoribbons (0.5 - 1 um long, 10-30 nm wide) suspended in high vacuum exhibited phonon-assisted electron emission (PAEE)[1][2], resulting in emission currents being produced at internal electric fields and external pulling voltages both nearly 10^2 less than comparable thermionic or field emission sources. Emissions exhibited repeatable directionality out of the plane of the

ribbons, offering a means to mechanically control the orientation of the output current; ribbons crafted from epitaxial graphene, with deposited electrodes to provide the bias, would emit out of the plane of the substrate, enabling even macro-scale directional control. Fabrication of epitaxial graphene microribbons is readily accomplished via a combination of electron beam lithography and plasma etching, while relevant metal depositions are completed with electron beam evaporation. Patterned-photoresist masks allow for precise plasma etching to isolate the ribbons and electrodes in order to craft emission arrays of arbitrary numbers, dimensions, and positions, facilitating arrangements for rapid testing of device parameters and capabilities. Metals deposited on plasma-etched surfaces allow for external ball- and wedge-bonding of gold wire, resulting in test setup and device controls being significantly cheaper, faster, easier, and more robust than those presented in referenced works. Emission currents can be measured via a straightforward setup with the devices (cathodes) and a phosphor screen (anode) positioned in a vacuum chamber with feed-through contacts for control and measurement. Results of captured currents from various dimensions, arrangements, and applied biases of the graphene microribbon emitters and arrays are provided in both absolute terms, as well as normalized to more conventional dimensions and energizing voltages of comparable thermionic and field emission electron sources. By crafting microribbon emitters in various combinations of dimensions and arrangements, and isolating control circuits from each other, it should even be possible to craft a single physical device that could alternately function as multiple different sources, either independently or in concert as need dictates. Electron sources crafted in this fashion are expected to exhibit greater output, durability, flexibility, and cost savings compared to other electron sources of comparable dimensionality and power requirements. Presented here is a treatment of the preparation, fabrication, and testing of these epitaxial graphene microribbon electron emission arrays intended as sources for low-power x-ray imaging applications. 1. F.EN04.28.27
Full Consideration of Acoustic Phonon Scatterings in Two-Dimensional Dirac Materials Yia-Chung Chang and Khoe Van Nguyen; Academia Sinica, Taiwan

The in-plane acoustic phonon scattering in graphene is solved by considering fully inelastic acoustic phonon scatterings in two-dimensional (2D) Dirac materials for large range of temperature (T) and chemical potential (?). Rigorous analytical solutions and symmetry properties of Fermionic and Bosonic functions are obtained. We illustrate how doping alters the temperature dependence of acoustic phonon scattering rates. It is shown that the quasi-elastic and ansatz equations previously derived for acoustic phonon scatterings in graphene are limiting cases of the inelastic-scattering equations derived here. For heavily-doped graphene, we found that the high-T behavior of resistivity is better described by ? (T, ?) ~T [1 - ?a ?2/3(kB T)2] rather than a linear T behavior, and in the low T regime we found ?-1 ~ (kBT)4 but with a different prefactor (i.e. ~ 3 times smaller) in comparison with the existing quasi-elastic expressions. Furthermore, we found a simple analytic "semi-inelastic" expression of the form ?-1 ~ (kBT)4 /(1 + cT 3) which matches nearly perfectly with the full inelastic results for any temperature up to 500 K and ? up to 1 eV. Our simple analytic results agree well with previous first-principles studies and available experimental data. Our analyses pave a way for investigating scatterings between electrons and other fundamental excitations with linear dispersion relation in 2D Dirac material-based heterostructures such as bogolon-mediated electron scattering in graphene-based hybrid Bose-Fermi systems.

F.EN04.29.01
Metal–Organic Frameworks Encapsulated with Vanadium-Substituted Heteropoly Acid for Highly Stable Asymmetric Supercapacitors Nageh K. Allam; The American University in Cairo, Egypt

Herein, we report on a facile one-pot synthesis of polyoxometalates encapsulated zeolite imidazolate framework cages ($PMo_{10}V_2$@ZIF-67). The morphological and structural properties of the as-synthesized materials were investigated *via* FESEM, EDS, XRD and FTIR techniques. Moreover, N_2 adsorption/desorption isotherms, and XPS measurements were carried out to elucidate the textural properties and composition of the fabricated materials. Upon their use as supercapacitor electrodes, the $PMo_{10}V_2$@ZIF-67 electrode exhibited a maximum specific capacitance of 765 F/g at a scan rate of 5 mV/s. Furthermore, a supercapacitor device was assembled using activated carbon as the negative electrode and $PMo_{10}V_2$@ZIF-67 as the positive electrode, delivering a specific power of 702 W/kg and corresponding specific energy of 20.9 Wh/kg at a charging current density of 1 A/g. In addition, the device shows excellent long term stability and high Columbic efficiency over 5000 charging and discharging cycles at charging and discharging current density of 5 A/g.

F.EN04.29.02
Recycling of Li-Ni-Mn-Co Hydroxide from Spent Batteries to High-Performance Supercapacitors with Exceptional

Stability Nageh K. Allam; American University in Cairo, Egypt

The intensive implementation of Li-ion batteries in many markets makes it increasingly urgent to address the recycling of strategic materials from spent batteries. Batteries typically contain toxic chemicals and cannot be disposed of at will. In this study, Li-Ni-Mn-Co hydroxides are successfully recycled from spent Li-ion batteries electrodeposited on nickel foam and fully characterized using different techniques such as field emission scanning electron microscopy (FESEM), x-ray diffraction (XRD), energy-dispersive X-ray spectroscopy (EDXS), inductively coupled plasma (ICP), and X-ray photoelectron spectroscopy (XPS) techniques. The recycled nanostructured films are tested in a three-electrode electrochemical system to investigate their capacitance behavior. The recycled electrodes show a high capacitance of 951 $F.g^{-1}$ (Specific capacity of 523.5 C. g^{-1}) at 1 A g^{-1}. Moreover, recycled materials are used as positive electrodes to construct asymmetric supercapacitor devices. The device shows a Coulombic efficiency of 100%, capacitance retention reaching ~90% with excellent cycling stability after 10,000 cycles as well as reasonable power and energy densities.

Effect of Iron Substitution on Cobalt Oxide and Study of Its Electrochemical Performance Deepa Guragain; The University of Memphis, United States

The application of metal oxides has been increasing for energy storage device due to excellent electrochemical properties, multifunctional energy application, environmentally friendly property and lower price. Due to rapid growth of energy use, there is very high demand for new ways to store energy. It is challenged to develop efficient way to store energy without polluting environment, which is possible by using transition metal oxide. We have prepared $Fe_xCo_{3-x}O_4$ (x=0.0, 0.2,0.4,0.6,0.8,1) successfully via hydrothermal method from which we can prepared electrode to make supercapacitor device. The structural properties were investigated by X-ray diffraction (XRD) and found phase pure $Fe_xCo_{3-x}O_4$. The morphology of the series obtained from scanning electron microscopy (SEM) varies from thinner nano-plates to thicker nano-plates as the concentration of Fe increase from x=0.0 to x=1.0. Furthermore, $Fe_xCo_{3-x}O_4$ were characterized by X-ray Photoelectron spectroscopy (XPS), Fourier Transform Infrared Spectroscopy (FTIR) and Quantachrome Surface area analyzer. The maximum BET surface area obtained from Quantachrome Instrument for x=1 is 87.5 m2/g. The XPS gives elemental composition of $Fe_xCo_{3-x}O_4$ as in desired amount. The higher specific capacitance of 268 F/g at a current density of 1 A/g, 856 F/g at 2 mV/s scan rate, the energy density of 16 Wh/kg and power density of 170 W/kg in 3M KOH electrolyte was observed for x =1 sample. An increased retention capacity ~122 % measured at 5 A/g current density and Coulombic efficiency of 100%. All these results indicate Fe dope Co_3O_4 composites electrode shows promising electrocatalytic activity results in the high intrinsic electronic conductivity, can largely improve the interfacial electroactive sites, increase charge transfer rates and help to stabilize the structure of compound.

Microstructural Evolution and Electrochimical Properties of Arachis Hypogaea Shell Derived *Ex Situ* Nitrogen-Doped Activated Carbon for Energy Storage Applications as Supercapacitor Balla D. Ngom[1], Ndeye Fatou D. Sylla[1], Ndeye Maty Ndiaye[1], Mohamed Chaker[2] and Ncholu Manyala[3]; [1]Universté Cheikh Anta Diop de Dakar, Senegal; [2]INRS, Canada; [3]University of Pretoria, South Africa

We report on the correlation of the microstructural evolution and electrochemical properties of an ex-situ N-doping KOH activated carbon derived from Arachis Hypogea Shell (NAC-AHS) and compared to the non-doped (AC-AHS). Interconnected cavities with irregular-shaped structure are reported by SEM analysis for AC-AHS. After nitrogen doping, the morphology of the NAC-AHS materials exhibited a less porous structure as compared to AC-AHS. The surface specific area (SSA) of NAC-AHS was found to be 1442 $m^2\ g^{-1}$ lower than the value of AC-AHS (1557 $m^2\ g^{-1}$), the pore volumes were also found to follow the same trend since the reported values are as follow 0.76 $cm^3\ g^{-1}$ and 0.69 $cm^3\ g^{-1}$, respectively for AC-AHS and NAC-AHS. The AC-AHS and NAC-AHS exhibited in a half cell a specific capacitance (C_s) values of 167 F g^{-1} and 216 F g^{-1}, respectively at 1 A g^{-1}, corresponding to an improvement of 30% after ex-situ N-doping, which agrees with the higher current response recorded in the CV profiles of the samples. A symmetric device fabricated from the NAC-AHS materials displayed a Cs of 251.2 F g^{-1} at 1 A g^{-1} in a wide operating voltage of 2.0 V in 2.5 M KNO_3 aqueous electrolyte. In terms of stability, it achieved 83.2% as capacity retention up to 20,000 cycles, which was, improved through the floating/ aging measurement at 5 A g^{-1}over a long period of time (~7+ days). A specific energy of 35 Wh kg^{-1} with a corresponding specific power of 1 kW kg^{-1} at 1 A g^{-1} was delivered with the device still retaining up to 22 Wh kg^{-1} and a 20 kW kg^{-1} specific power even at 20 A g^{-1}.

F.EN04.29.05

Electrical Transport in Coconut Shell Charcoal G. R. A. Kumara[1], Kasun J. Wimalasena[2], S. M. B. Dissanayake[2], T. M. W. J. Bandara[2], Ajith DeSilva[3,4], A. G. U. Perera[4] and K. Tennakone[1,4]; [1]National Institute of Fundamental Studies, Sri Lanka, Sri Lanka; [2]University of Peradeniya, Sri Lanka; [3]University of West Georgia, United States; [4]Georgia State University, United States

Activated coconut charcoal is unique in meso and micro pore distribution, BET surface area exceeding 2000 m^2g^{-1} and pore volume ~ 1.3 cm^3g^{-1}. It is the bio-derived carbon material of choice for supercapacitor electrodes, cryogenic gas absorption in vacuum technology and water purification. Coconut shell carbon is also the hardest biochar - hardness 3-4 in the Mohs scale. For supercapacitors, batteries and several other applications, high electrical conductivity is an advantageous parameter. Owing to large surface to volume ratio of the material, the carrier trapping sites on the surface play a crucial role in electrical transport. The DC electrical conductivity is found be greatly influenced by mode of activation, surface treatments and impurities. The most studies on electrical conductivity of activated carbons were based on measurements conducted using compacted pellets. The higher hardness of coconut shell charcoal enable use of sizable samples made from uncrushed flakes to carry out chemical treatments and conduct measurements under varying conditions. The results of measurements and interpretations will be presented, emphasizing supercapacitor applications of coconut shell charcoal.

F.EN04.29.06

Dielectric h-BN Separators for Ti_3C_2-MnO_2 Supercapacitors Alptekin Aydinli[1,2], Xuehang Wang[1], Husnu E. Unalan[2] and Yury Gogotsi[1]; [1]Drexel University, United States; [2]Middle East Technical University, Turkey

Electrochemical energy storage (EES) units are vital for mobile electronic devices that can provide high energy and power densities. Current studies mostly aim at improving the performance of the electrode active materials. Nevertheless, inert components such as electrolyte, separator and current collector occupy 70-80 wt.% of the EES devices and reducing their weight/volume can significantly improve the performance of these devices. Dielectric materials are used extensively in EES devices as separators such as ceramics in conventional capacitors. In supercapacitors, polypropylene membranes and glassy fiber films with typical thicknesses larger than 25 μm are the common separator materials. Two dimensional (2D) dielectric materials with flat and smooth surfaces at a much smaller thickness can in fact be used as efficient separators.
In this work, 2D hexagonal boron nitride (h-BN) thin films were utilized as efficient separator layers in asymmetric MXene supercapacitors. In these devices, titanium carbide (Ti_3C_2) and manganese dioxide (MnO_2) were used as the negative and positive electrodes, respectively. Electrochemical tests such as cyclic voltammetry, chronopotentiometry and electrochemical impedance spectroscopy were conducted to determine specific capacity, rate capability and cycling stability of the asymmetric supercapacitor devices. Fabricated supercapacitor devices showed promising electrochemical performance in a PVA/H_2SO_4 gel electrolyte compared to the control device with conventional Celgard separator. The reduced thickness of the h-BN separator decreased the volume of an entire supercapacitor device and significantly improved the overall capacitance.

Bioinspired Nanoporous Ion Conducting Membranes for Next Generation Batteries Ahmet Emre, Jinchen Fan, Emine Turali-Emre, Alycia Gerber, Volkan Cecen and Nicholas Kotov; University of Michigan, United States

Bioinspired ion transport membranes have been widely investigated for energy storage applications. High theoretical specific energy density (2600Wh/kg) and high specific capacity (1675mA/g) along with natural abundance and low toxicity of sulfur have been attracting significant attention for development of an alternative battery system to replace traditional lithium ion batteries which suffer from safety and capacity/energy density limitations in various applications. However, challenges such as polysulfide dissolution and shuttling prevent mass commercialization of metal sulfur batteries. Inspired from biological ion transport mechanisms, we show a practical yet comprehensive approach for development of highperformance metal sulfur batteries. Aramid nanofiber (ANF) based composite ion transport membranes not
only prevent dendrite formation but also confine polysulfides on the cathode side. ANF composite battery separators provide diverse and opposing properties including high mechanical properties, high ionic conductivity and high thermal/chemical stability. Highly selective ion sieving properties of these biomimetic separators provide safe and high-performance batteries. Fabrication of such biocompatible, affordable,
flexible and high energy density battery is quite crucial in powering next-generation electronics including but not limited to portable, wearable and implantable biomedical devices.

Late News: Rational Designed Materials for Energy Storage—From the View of Semiconductor Physics Jiantao Zai; Shanghai Jiao Tong University, China

Semiconductor physics mainly discuss the energy band structures and the carrier behaviors in semiconductors. The carrier dynamics and the resulting conduction properties of semiconductors. As a semiconductor, the carrier transporting characteristics of Si has been well studied and adjusted via doping (n type, N, P; p type, B), which has been widely applied in electronics, solar cell and photocatalysis. In recent years, Si has been regarded as the most promising anode material for its highest theoretical specific capacity, and natural abundance. However, the poor conductivity of intrinsic Si still limits the rate performance of Si materials.
Previously, Yi and me found boron doping can obviously enhance the rate capability of Si–C composite. Recently, phosphorus-doped yolk-shell Si@C materials (P-doped Si@C) with balanced electron and Li+ transportation dynamics are rational designed and prepared, which deliver high specific capacities (2709 mAh g^{-1} @ 0.4 A g^{-1}), great rate capability (510 mAh g^{-1}@35 A g^{-1}) and good retention of ~95% over 800 cycles at 4 A g^{-1}. As a result, P-doped Si@C anode pairs with commercial activated carbon to assemble lithium-ion capacitor (high power density of ~61080 W kg^{-1} at 20 A g^{-1}).
Junction is also an important concept in semiconductor physics, which refers to the interface region with rectification characteristics formed by the contact of two different semiconductor phases. The formation of semiconductor junction will change the charge state of atoms near the junction interface, and then regulate the adsorption and catalytic activity of active sites in the region. Our previous research reveals the space charge of p-n junction of p-type CoP and n-type FeNi LDH can be utilized to improve the adsorption of OH^- and promote the OER process. With this in mind, The *in-situ* formed VS_x@VO_2 junctions can designed to promote the absorption of polysulfide and result high volume specific Li-S batteries. Furthermore, a n-n-type CoS_2-CoS heterojunction were designed to facilitate the electrocatalytic conversion of I^-/I_3^- and polysulfides, which can significantly improve the power density and lifetime of flow batteries. Therefore, it is possible to modulate the electronic configuration of active site by designing proper semiconductor junctions following the theories of solid physics.
In all, the semiconductor physics can offer useful theoretical guidance for rational design of high performance materials for energy storage.

Pressure-Tailored Lithium Deposition and Dissolution in Lithium Metal Batteries Chengcheng Fang and Y. Shirley Meng; University of California, San Diego, United States

Lithium (Li) metal offers high theoretical capacity, lowest negative potential and light weight, making it the ideal anode material for high-energy-density batteries. Porous electrodes resulting from unregulated Li growth is believed to be the major cause of the low Coulombic efficiency (CE) and potential safety hazards of rechargeable Li metal batteries. Strategies aiming to achieve large granular Li deposits have been extensively explored; yet, the ideal Li deposits, which consist of large Li particles seamlessly packed on the electrode and can be reversibly deposited and stripped, have never been reported. Here, by using cryo-FIB-SEM, 3D reconstruction and MD simulation, we quantitatively revealed the role of stack pressure on Li nucleation, growth and stripping, and discovered that optimal pressure for approaching 100% dense Li deposition by establishing a pressure-morphology-performance correlation. Unprecedented, a dense Li deposition (99.49% electrode density) with an ideal columnar structure has been achieved and can be reversibly plated and stripped during extended cycles at room temperature. The tailored Li deposition and stripping by optimizing stack pressure opens new opportunities to rationally mitigate inactive Li formation, improve cycle life and enable fast charging for rechargeable Li metal batteries.

Ni-Rich Layered Cathodes for All-Solid-State Li Batteries—Effects of Microstructure and Solid Electrolyte Yoon Jae Han, Sung Hoo Jung and Yoon Seok Jung; Hanyang University, Korea (the Republic of)

All-solid-state Li batteries (ASLBs) have been emerged as the enabler to achieve significantly enhanced safety and energy densities, as compared to conventional lithium-ion batteries (LIBs). Several classes of inorganic solid electrolyte (SE) materials have garnered much attention as they could be integrated with electrode active materials into ASLBs by a scalable process such as cold-pressing. Sulfides (or thiophosphates, e.g., Li_6PS_5Cl) and halides (e.g., Li_3YCl_6) satisfy critical features for scalable high-performance ASLBs; those are mechanically sinterability and high Li^+ conductivity. However, they show different comparative advantages in multiple aspects. For example, while halides are heavier than sulfides, they show superior electrochemical oxidation stability to sulfides.
As is the case for advanced LIBs based on liquid electrolytes, Ni-rich cathode materials are the key to the practical ASLB technologies. Unfortunately, they suffer from par below electrochemical performances in ASLBs, which are attributed to the interfacial instabilities in terms of both electrochemical and electrochemo-mechanical effects.
In this presentation, we report on our recent findings on the electrochemo-mechanical effects for Ni-rich layered cathode materials for ASLBs. Microstructural effects of NCM particles on the performance of ASLBs are revealed. Moreover, the performances of NCM using halide SEs are extensively compared. These results shed light on a design strategy for high-performance practical ASLBs.

Understanding for Charge/Discharge Curves of Commercial Lithium-Ion Batteries Yuhao Lu and Xiao Jie; NingDe Amperex Technology Limited, China

Lithium ion batteries (LIBs) are wildly used for portable electronics and electric vehicles due to the favorable performance compared with other rechargeable batteries. However, their degradation deteriorate their service life remarkably. Fortunately, charge/discharge curves can provide quantitative information for understanding how such degradation correlates with usage conditions and environment of LIBs.
In general, the charge/discharge curves can be divided into two parts, i.e. the open circuit voltage (OCV) and the polarization in the cell. The OCV provides a thermodynamic fingerprint of the electrode which could be roughly estimated by

charge/discharge the cell at very low C-rate. With regards to a commonly used 2430 coin cell, the difference between charge/discharge curve and theoretical OCV is less than 30mV at the full range of SOC when a 1/25C current rate is used. In this presentation, the changes in OCV during long cycles will be exhibited, which offers a quantified information on active material decay as well as the side reactions in the cell. The polarization of the cell is strongly affected by the electron and lithium ion transport inside the electrode microstructure. In this work, both the time-domain and the frequency-domain electrochemical methods ware applied to the analysis to distinguish each process onto the polarization in the cell, i.e. the contact problem between the solid phases, the mass transport through the interface and in the solid phase of the electrodes, along with the slow electrochemical reactions. Furthermore, the thermodynamic fingerprints of the positive and negative materials have strongly relation with the polarization in the cell. These relations generally becomes very complex, and thus a mathematical modeling is also used to understand and explain the charge/discharge curve for LIB in detail. Overall, it is proposed that more collaborations could be needed between the academia and industry so that the lithium ion battery degradation could be fully investigated.

Organosilicon Compounds Improve the Thermal and Electrochemical Stability of Lithium-Ion Batteries Robert Hamers[1], Sarah Guillot[2], Monica Usrey[2], Louis Morris[1] and Cesar Ortiz Ledon[1]; [1]University of Wisconsin-Madison, United States; [2]Silatronix, Inc., United States

Incorporation of organosilicon (OS) compounds in modest concentrations as low as several percent in conventional carbonate electrolytes lead to substantial improvements in the thermal and electrochemical stability of the resulting lithium ion batteries. We have been investigating the fundamental chemical degradation pathways of organosilicon compounds in an effort to understand the chemical and electrochemical origins of these remarkable properties. The combination of NMR spectroscopy, in situ FTIR, AFM, and XPS provides unique insights into how organosilicon electrolytes reduce or eliminate autocatalytic chemical pathways associated with PF6 and its degradation products. OS compounds further alter the chemical nature of SEI layers on silicon, leading to improvements in overall performance. In this talk I will summarize some of our recent work characterizing organosilicon thermal stability and electrochemical stability against different materials, including silicon-based anodes and NMC-based cathodes.

11:55 AM *
Pairing Lithium-Metal Anode with High-Nickel NMC and Sulfur Cathodes—Fundamental Understanding and Engineering Solutions Arumugam Manthiram; The University of Texas at Austin, United States

Lithium-metal anode holds tremendous potential for enabling next generation of rechargeable batteries due to their high storage capacity (3,861 mAh g^{-1}) and low reduction potential (-3.04 V vs SHE). When paired with a high-capacity cathode, such as high-nickel NMC or sulfur, lithium-metal anode can help deliver energy-dense storage systems with ~ 500 Wh kg^{-1}. However, the poor efficiency associated with lithium plating and stripping severely limits the cycle life. For realizing practical viability, reversible lithium deposition needs to be achieved by stabilizing the lithium-electrolyte interphase (SEI) layer and mitigating the extreme volume changes accompanying the cycling.

The chemistry of the lithium-electrolyte interface is rendered distinct by the choice of the cathode in a full cell, *viz*., high-nickel NMC or sulfur. This is not only due to the different electrolyte formulations used, but also due to the crossover of species between the cathode and anode. The characteristics of deposited lithium can fundamentally vary across different cathode systems, and unique strategies must be employed to stabilize lithium deposition in each case. Hence, an in-depth fundamental study is necessary to develop a thorough understanding of the lithium-electrolyte interfacial chemistry, while creative engineering solutions are necessary to achieve highly efficient lithium plating and stripping. This presentation will focus both on a fundamental understanding and offering engineering solutions.

When paired with a high-nickel NMC cathode, the lithium-metal anode is affected by transition-metal dissolution at the cathode and crossover to the anode. However, we find that during initial cycling, crossover of electrolyte decomposition products from the anode to the cathode is more severe and plays a more critical role. Not only does it alter/thicken the cathode SEI layer, it also affects the anode itself as the lithium SEI components could continually dissolve. The magnitude of this crossover is expected to depend on the nickel content in the cathode.

When paired with a sulfur cathode, the lithium-metal anode is affected by polysulfide dissolution at the cathode and crossover to the anode. We use anode-free full cells, which contain no excess lithium at the anode, to investigate the dynamics of lithium deposition. With advanced surface characterization methodologies, *e.g.*, time-of-flight secondary ion spectrometry, we find that the depletion of cyclable lithium inventory is due to the formation of "dead" metallic lithium, which itself is caused by severe electrolyte decomposition on lithium-metal surface with cycling.

The presence of polysulfide intermediates is found to have an intrinsically stabilizing effect on lithium deposition in Li-S batteries. This motivates our strategies towards engineering further improvements in cycle life. With tellurium as a cathode additive, tellurium-substituted polysulfides are formed, which reduce on lithium surface to form Li_2TeS_3 as a thin, Li^+-ion conducting SEI layer. This enables uniform deposition of lithium and mitigates electrolyte decomposition. A remarkable improvement in cyclability is achieved in energy-dense anode-free full cells and lean-electrolyte pouch cells. Similarly, using organosulfide molecules as electrolyte additives opens the possibility of favorably tuning the properties of lithium SEI layer by simply modifying the organic functional group.

The development of three-dimensional current collector matrices is also critical to achieving reversible lithium deposition. The highly conductive frameworks provide efficient electron/ion transport and guides a homogenous deposition of lithium, while the porous 3D architecture helps mitigate severe volume changes during cycling. The presentation will demonstrate various lithiophilic host materials that show considerable promise in improving the cyclability of lithium-metal anode when paired with both high-nickel NMC and sulfur cathodes.

12:15 PM *
Building Ultra-Conformal Protective Layers on Both Secondary and Primary Particles of Layered Lithium Transition Metal Oxide Cathodes Guiliang Xu and Khalil Amine; Argonne National Laboratory, United States

Nickel-rich layered lithium transition metal oxides are the most attractive cathode materials for the next generation lithium-ion batteries for automotive application. However, they suffer from crystal and interfacial structure instability under aggressive electrochemical and thermal driving force, leading to rapid performance degradation and severe safety concerns.In this talk, we reported a transformative approach by using an oxidative chemical vapour deposition technique to build a protective conductive polymer (PEDOT) skin on layered oxide cathode materials. The ultra-conformal PEDOT skin facilitates the transport of lithium ions and electrons, significantly suppresses the undesired layered to spinel/rock-salt phase transformation and the associated oxygen loss, mitigates intergranular and intragranular mechanical cracking, and effectively stabilizes cathode-electrolyte interface. This approach remarkably enhances the capacity and thermal stability under high-voltage operation. Building a protective skin at both secondary and primary particle levels of layered oxides offers a design strategy for the promising Ni-rich cathodes towards high-energy, long-life and safe lithium-ion batteries.

12:35 PM BREAK

12:50 PM *
Thermal Conduction in Li-Ion Battery Materials Ankur Jain; The University of Texas at Arlington, United States

Li-ion batteries offer excellent energy conversion rate and high energy storage density in electric vehicles, aircraft, consumer electronics and renewable energy storage. However, these batteries suffer from several safety related problems, as evidenced by recent product recalls and incidents of fires in electric cars and aircraft. Overheating due to poor thermal transport is at the heart of several of these challenges, and therefore, a fundamental understanding of heat transfer in Li-ion battery materials is critically needed. While Li-ion battery materials have been well optimized from the perspective of electrochemistry, the nature of thermal transport in these materials remains relatively less known.

This talk will summarize ongoing research on understanding and optimizing heat transfer in Li-ion battery materials through experiments and theoretical analysis. Measurement of orthotropic thermal conductivity of a Li-ion cell will be described. Measurements of thermal conductivity of the separator of a Li-ion cell will be discussed. Measurements that identify poor

thermal transport across the cathode-separator interface as the fundamental root cause of the low thermal conductivity of Li ion cells will be discussed. A molecular bridging approach that reduces this rate-limiting thermal contact resistance by 4X through improved interfacial thermal transport will be discussed. This approach is expected to significantly enhance thermal conductivity of a Li-ion cell. More recent work on enhancement of thermal transport in Gel Polymer Electrolytes (GPEs) through inclusion of BN/Al_2O_3 nano/microparticles will also be discussed. While this approach is shown to improve thermal conduction in general, a careful optimization of thermal and ionic transport in GPEs will help fully utilize this promising class of materials for next-generation solid-state batteries. Related research on developing predictive models for onset of thermal runaway based on thermal properties of battery materials and kinetics of underlying electrochemical processes will also be discussed briefly.

1:10 PM *
Performance of High Energy and High Power Commercial Li-Ion Cells for Space Missions Ratnakumar Bugga; California Institute of Technology, United States

Li-ion batteries are being widely used in planetary space missions, owing to their impressive performance characteristics, including high specific energy, long life, and the ability to operate over a wide temperature range. Historically, batteries with custom large-format Li-ion cells of 10-55 Ah have been used in various Mars missions, e.g., Mars Exploration Rovers (Spirit and Opportunity), Mars Curiosity Rover, Mars landers (Phoenix and InSight), Mars and Jupiter orbiters and the upcoming Mars 2020 Rover. However, in several other robotic and human space missions, e.g., Europa Clipper, Artemis missions to moon, and Portable Life Support System (PLSS) for Extra-Vehicular Activities, commercial 18650 Li-ion cells are being used due to their improved specific energies of ~250 Wh/kg (20-50% over custom cells), improved safety from built-in safety devices, modularity, and excellent uniformity, which obviate the need for cell-level control during charging. Several cell types with different chemistries and from different manufacturers are being evaluated at JPL. The cell chemistries differ mostly in cathodes, i.e., either lithium nickel cobalt aluminum oxide (NCA), Li-rich nickel manganese cobalt oxide (Ni-rich NMC) or blends with lithium manganese spinel oxide (LMO). Various performance tests, including cycle life at different depths of discharge, radiation tolerance and high-power characterization at different temperatures are being carried out in conjunction with Electrochemical Impedance Spectroscopy (EIS). In addition, destructive physical analysis of the cells have been performed to analyze the electrode materials, and correlate them with the performance characteristics. Finally, low temperature charge characterization studies have been carried out to ascertain the propensity of lithium plating as a function of charge current and temperature.

8:25 AM F.EN06.01.02
A Scaling Law to Determine Phase Morphologies During Ion Intercalation Dimitrios Fraggedakis, Martin Bazant and

Yang Shao-Horn; Massachusetts Institute of Technology, United States

Driven phase separation in ion intercalation materials is known to result in different non-equilibrium phase morphologies, such as intercalation waves and shrinking-core structures, but the mechanisms of pattern selection are poorly understood. Here, based on the idea that the coarsening of the slowest phase is the rate limiting step, we introduce a scaling law that quantifies the transition from quasi-equilibrium intercalation-wave to diffusion-limited shrinking-core behavior. The scaling law is validated by phase-field simulations of single Li_xCoO_2 particles, *in situ* optical imaging of single Li_xC_6 particles undergoing transitions between stage 1 ($x = 1$) and 2 ($x = 0.5$) at different rates, and all the available literature data for single-particle imaging of Li_xCoO_2, Li_xC_6 and Li_xFePO_4. The results are summarized in operational phase diagrams to guide simulations, experiments, and engineering applications of phase-separating active materials. Implications for Li-ion battery performance and degradation are discussed.

8:45 AM *F.EN06.02.01
Modeling of the Transfer Reactions at Li/SEI/Electrolyte Interface and Dendrite Free Morphology Yue Qi[1,2]; [1]Brown University, United States; [2]Michigan State University, United States

The charge transfer reaction is the fundamental reaction for rechargeable batteries. The energy landscape of this reaction depicts the equilibrium and kinetics of the electrochemical process. Typically, a Li-metal electrode is always covered by a thin layer of solid electrolyte interphase (SEI), forming a complex Li/SEI/electrolyte interface. We first introduced a new half-cell model to predict the energy landscape of the electrochemical reaction of at the complex Li/SEI/electrolyte interface, with combined density functional theory (DFT) and tight-binding (DFTB) calculations. The simulated atomic details revealed that the Li-metal surface is negatively charged at the electrochemical equilibrium condition (the experimentally defined zero voltage for Li^+/Li^0) due to the large solvation energy of Li^+ in the EC-based electrolyte. The electric field created by the negatively charged surface can reorient the electrolyte into an ordered structure, lower the Li^+ ion desolvation energy barrier, and help the Li^+ ion transport through the SEI.
Further, the calculated energy landscape can be used to describe the electrochemical reaction kinetics with a Butler-Volmer equation, enabling a multiscale modeling approach. In this study, the DFT and DFTB predicted interfacial structures, de-solvation processes, and the ion transfer energy barrier, were inputted into a non-linear phase-field model to capture the morphological evolution during the electroplating process. Specifically, this model captured the morphology difference between the dendritic Li plating in carbonate (EC)-electrolyte and faceted Mg plating in tetrahydrofuran(THF)-electrolyte under the similar current density. Furthermore, through systematical parametric analyses, we conclude that the cation desolvation-induced exchange current difference between Li and Mg is mainly responsible for their deposition morphological differences. This study provides a strategy of connecting the phase-field method and atomistic calculations and predicts that increasing the desolvation energy and lowering the equilibrium exchange current can help to achieve dendrite-free Li-metal anode.

9:05 AM BREAK

9:20 AM *F.EN06.02.04
Advances in Imaging Lithium Batteries at Different Length Scales Herman Lemmens and Zhao Liu; Thermo Fisher Scientific, Netherlands

Imaging the microstructure of a battery cell at different length scales is important to understand the degradation processes through the battery cycle life. For example, investigating the formation of defects such as dendrites at the Li anode interface requires both high resolution imaging and large field of view. Ideally, imaging techniques cover the entire electrode thickness at submicron resolution with a method that preserves the sample interface. Here, we present an approach to probe the defects at the Li-metal battery interface. A coin cell has been sliced under cryo conditions with a laser inside the vacuum of the scanning electron microscope (SEM) chamber so a pristine surface is obtained and defect formation can be observed across the entire thickness of the cell.
In another example, transport properties for a thick NMC 811 cathode were obtained from focused ion beam (FIB) milling in combination with SEM. Because of the cathode thickness, an alternative to traditional Ga FIB milling was used. With a Xenon plasma beam, it was possible to obtain a 3D data set with more than 100 µm field of view on a 70 µm thick cathode. The microstructural characteristics extracted from such representative 3D volume help the understanding of the correlation between electrode microstructural evolution and performance deterioration.

Thermal Runaway Propagation Study on Lithium-ion Cells as Packaged for Transportation Judith Jeevarajan;

Underwriters Laboratories, United States

Thermal runaway in lithium-based cells and batteries have been a significant concern during transportation. The ICAO had set temporary restrictions on transportation to limit the SOC to 30% or less. In parallel, the ICAO commissioned the Society of Aerospace Engineers (SAE) to write a standard that would have test procedures that confirmed that li-based cells in the package as shipped will not become a fire hazard. The test procedure and the verification of test protocols have been looked into in this study. The results obtained as part of this test program will be presented.

A Scaling Law to Determine Phase Morphologies During Ion Intercalation Dimitrios Fraggedakis, Martin Bazant and Yang Shao-Horn; Massachusetts Institute of Technology, United States

Driven phase separation in ion intercalation materials is known to result in different non-equilibrium phase morphologies, such as intercalation waves and shrinking-core structures, but the mechanisms of pattern selection are poorly understood. Here, based on the idea that the coarsening of the slowest phase is the rate limiting step, we introduce a scaling law that quantifies the transition from quasi-equilibrium intercalation-wave to diffusion-limited shrinking-core behavior. The scaling law is validated by phase-field simulations of single Li_xCoO_2 particles, *in situ* optical imaging of single Li_xC_6 particles undergoing transitions between stage 1 ($x = 1$) and 2 ($x = 0.5$) at different rates, and all the available literature data for single-particle imaging of Li_xCoO_2, Li_xC_6 and Li_xFePO_4. The results are summarized in operational phase diagrams to guide simulations, experiments, and engineering applications of phase-separating active materials. Implications for Li-ion battery performance and degradation are discussed.

5:25 AM F.EN06.01.03
Low Tortuous, Highly Conductive and High-Areal-Capacity Battery Electrodes Enabled by Through-Thickness Aligned Carbon Structures Kun Fu; University of Delaware, United States

Thick electrode with high-areal-capacity is a practical and promising strategy to increase the energy density of batteries, but development towards thick electrode is limited by the electrochemical performance, mechanical properties, and manufacturing approaches. In this talk, we overcome these limitations and report an ultra-thick electrode structure, called fiber-aligned thick or FAT electrode, which offers a novel electrode design and a scalable manufacturing strategy for high-areal-capacity batter electrodes. The FAT electrode uses aligned carbon fibers to construct a through-thickness fiber-aligned electrode structure, with feature of high electrode material loading, low tortuosity, high electrical and thermal conductivity, and good compression property. The low tortuosity of FAT electrode enables fast electrolyte infusion and rapid electron/ion transport, exhibiting a higher capacity retention and lower charge transfer resistance than conventional slurry-casted thick electrode design.

Late News: Kinetic Pathways of Ionic Transport in Fast Charging Lithium Titanate Tina Chen[1,2], Wei Zhang[3,4], Dong-

Hwa Seo[1], Feng Wang[4] and Gerbrand Ceder[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Nankai University, China; [4]Brookhaven National Laboratory, United States

Fast-charging batteries typically employ electrodes capable of accommodating lithium continuously via solid-solution transformation because they have few kinetic barriers apart from Li^+ diffusion.[1, 2] One exception is lithium titanate, an anode that can cycle without the Li plating observed in graphite [3] and exhibits extraordinary rate capability seemingly inconsistent with its two-phase reaction and the sluggish diffusion within its endmembers [4]. Through first-principles calculations combined with nudged-elastic band calculations, we reveal that the kinetic pathway that enables facile ionic transport in lithium titanate consists of distorted face-sharing Li polyhedra in metastable intermediate states. The importance of the face-sharing Li polyhedral is further confirmed by real-time tracking of Li^+ local environments during migration using operando electron energy-loss spectroscopy. This study highlights that the rate capability of fast-charging electrodes may be controlled not solely by the intrinsic ionic diffusivity of macroscopic phases, but also by the transport pathways available via kinetically accessible low-energy states. Findings from this study, particularly on the improved kinetics originating from the face-sharing Li motifs in intermediate lithium titanate configurations, may open new directions for designing electrode materials for fast-charging batteries.

5:45 AM F.EN06.01.07
Controlling Microstructure of Silicon-Based Anodes and Their Stress Evolution During Electrochemical Cycling Mok Yun Jin[1], Elizabeth Healy[1], Xingcheng Xiao[2] and Brian Sheldon[1]; [1]Brown University, United States; [2]General Motors, United States

Composite electrodes that incorporate oxidized silicon are a cost-effective way to accommodate stresses and extend cycle life. To obtain fundamental information about chemo-mechanical phenomena in these composite structures, several different types of materials are being investigated through tuning the microstructures of Si nanoparticles and composite SiOx particles. The evolution of internal stresses in all of these structures was monitored with precise in-situ curvature in conjunction with parallel electrochemical measurements. Ex-situ characterization with electron microscopy, x-ray diffraction, and XPS provide important complementary information about changes in the materials. The different types of materials used for this work make it possible to systematically investigate key length scales, by independently varying the microstructures such as oxide layer thicknesses and particle/nano-cluster sizes. Analysis of these results requires assessments and models of both the chemical and mechanical effects of oxide surface layers and silicon encapsulation. The implications for optimizing these composite electrode structures will also be presented.

5:55 AM F.EN06.01.08
Evaluating Temperature Dependent Capacity Fade Mechanisms of Silicon-Graphite Electrodes Yeyoung Ha[1], Donal P. Finegan[1], Andrew M. Colclasure[1], Stephen E. Trask[2] and Matthew Keyser[1]; [1]National Renewable Energy Laboratory, United States; [2]Argonne National Laboratory, United States

One of the critical factors for determining the success of lithium-ion batteries (LiBs) in electric vehicles is their resilience to a wide range of environmental conditions. As batteries with higher energy densities are being developed, ensuring that they can withstand elevated temperatures without severe capacity fade is critical. Silicon (Si), which delivers higher specific capacity compared to graphite (Gr), is a promising anode material toward increasing the energy density of LiBs. Thus, evaluating the response of Si anodes to harsh temperatures that an electric vehicle might experience is crucial to ensure the development of safe, high energy density, and long life LiBs.
In this work, the performance of Si-Gr electrode is examined in half-cell (Si-Gr/Li), full cell (Si-Gr/$LiNi_{0.5}Mn_{0.3}Co_{0.2}O_2$ and Si-Gr/$LiFePO_4$), and symmetric cell (Si-Gr/Si-Gr) configurations at varying temperatures (25, 45, and 70°C). By examining the three different cell configurations, contributions from different cell components are deconvoluted and physical mechanism for each electrode (i.e., loss of lithium inventory or active material) are evaluated. In addition, the effect of

fluoroethylene carbonate (FEC) electrolyte additive on the thermal stability of Si is examined by testing two different electrolyte compositions (Gen2 (1.2 M LiPF6 in ethylene carbonate (EC)/ethyl methyl carbonate (EMC) (3:7, w/w)) and GenF (Gen2 + 10 wt% FEC)). The degradation mechanisms in each system is further analyzed via incremental capacity analysis. As dQ/dV analysis of Si-Gr composites represent challenges not accounted for in Gr electrodes (i.e., hysteresis and path dependency), dQ/dV methods for Si-Gr electrodes are developed in this work. Detailed analyses of the electrochemical performance of Si-Gr electrodes, along with incremental capacity analysis and post-mortem analysis, provide insights into the critical factors affecting the performance of Si-Gr electrodes at elevated temperatures. Based on the results, we propose the appropriate cell configuration and protocol for testing the thermal stability of Si-based cells.

6:05 AM F.EN06.01.09
Silicon Oxycarbide as a Host Matrix of Choice to Stabilize Li-Ion Storage in Nanosized Alloying Elements Romain J. Dubey[1,2], Pradeep Vallachira Warriam Sasikumar[2], Frank Krumeich[1], Gurdial Blugan[2], Kostiantyn Kravchyk[1,2], Thomas Graule[2] and Maksym V. Kovalenko[1,2]; [1]ETH Zürich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

The ever-increased demand in energy and consumable goods have led to a high necessity for sustainable catalysts[1,2] and innovative energy storage systems[3,4,5] with high energy densities, such as Li-ion batteries (LiBs). To maximize the anodic charge storage capacity of LiBs, alloying-type anode materials such as Sn and Sb have attracted considerable interest because of their high theoretical capacity of 992 and 660 mAh g^{-1} and a suitable lithiation/delithiation voltage window of 0.01-1.5 V *vs.* Li^+/Li. Recent advances in nanostructuring of the alloying-type anodes provide an effective way of mitigating the challenges of their volume expansion upon lithiation that severely hinder the cycling stability.[6] Besides, one of the prevailing approaches toward stabilization of such electrodes is the embedding of Sn or Sb in the form of nanoparticles (NPs) in a matrix. The matrix helps to buffer the volume changes, impart better electronic connectivity, and prevent particle aggregation upon lithiation/delithiation. In this context, polymer-derived ceramics, namely, silicon oxycarbide (SiOC), is an appealing candidate for stabilizing Sn and Sb inclusions. This matrix features a high Li-ion storage capacity ranging from 600 to 700 mAh g^{-1}, low volume expansion upon lithiation of about 7%, and high electronic conductivity. In this study, we report a facile synthesis of Sn[7] and Sb[8] NPs embedded in a SiOC matrix via the pyrolysis of a cross-linked preceramic polymer. The NPs are formed *in-situ* via a carbothermal reduction during the pyrolysis. We determined that a key element to obtain a homogeneous distribution of NPs in SiOC is the employment of precursors with compatible polarities, allowing for an intimate blending of the functionalized polysiloxanes with the Sn or Sb precursors. This approach proved to be effective for buffering volume changes while retaining practical energy densities and high rate capabilities. For instance, SiOC/Sn nanocomposite exhibited a high rate capability, delivering a high capacity of 553 mAh g^{-1} at a current density of 2232 mA g^{-1} (≈ 6C for a graphite anode). Additionally, the electrochemical performance of SiOC was assessed in full cell configuration using areal capacities of 1.3 mAh cm^{-2} being relevant for high-power industrial applications. The mechanism of Sn lithiation in SiOC was evaluated by *in-situ* powder X-ray diffraction.

Late News: Rational Designed Materials for Energy Storage—From the View of Semiconductor Physics Jiantao Zai; Shanghai Jiao Tong University, China

Semiconductor physics mainly discuss the energy band structures and the carrier behaviors in semiconductors. The carrier dynamics and the resulting conduction properties of semiconductors. As a semiconductor, the carrier transporting characteristics of Si has been well studied and adjusted via doping (n type, N, P; p type, B), which has been widely applied in electronics, solar cell and photocatalysis. In recent years, Si has been regarded as the most promising anode material for its highest theoretical specific capacity, and natural abundance. However, the poor conductivity of intrinsic Si still limits the rate

performance of Si materials.
Previously, Yi and me found boron doping can obviously enhance the rate capability of Si–C composite. Recently, phosphorus-doped yolk-shell Si@C materials (P-doped Si@C) with balanced electron and Li+ transportation dynamics are rational designed and prepared, which deliver high specific capacities (2709 mAh g^{-1} @ 0.4 A g^{-1}), great rate capability (510 mAh g^{-1}@35 A g^{-1}) and good retention of ~95% over 800 cycles at 4 A g^{-1}. As a result, P-doped Si@C anode pairs with commercial activated carbon to assemble lithium-ion capacitor (high power density of ~61080 W kg^{-1} at 20 A g^{-1}).
Junction is also an important concept in semiconductor physics, which refers to the interface region with rectification characteristics formed by the contact of two different semiconductor phases. The formation of semiconductor junction will change the charge state of atoms near the junction interface, and then regulate the adsorption and catalytic activity of active sites in the region. Our previous research reveals the space charge of p-n junction of p-type CoP and n-type FeNi LDH can be utilized to improve the adsorption of OH^- and promote the OER process. With this in mind, The *in-situ* formed VS_x@VO_2 junctions can designed to promote the absorption of polysulfide and result high volume specific Li-S batteries. Furthermore, a n-n-type CoS_2-CoS heterojunction were designed to facilitate the electrocatalytic conversion of I^-/I_3^- and polysulfides, which can significantly improve the power density and lifetime of flow batteries. Therefore, it is possible to modulate the electronic configuration of active site by designing proper semiconductor junctions following the theories of solid physics.
In all, the semiconductor physics can offer useful theoretical guidance for rational design of high performance materials for energy storage.

A Novel Cryogenic Milling Route to Fabricate Nanostructured Alloy Anodes with Improved Cycling Stability Qizhang Yan[1], Shu-Ting Ko[1], Grace Whang[2], Yumin Zhao[1], Andrew Dawson[2], Sarah H. Tolbert[2], Bruce S. Dunn[2] and Jian Luo[1]; [1]University of California, San Diego, United States; [2]University of California, Los Angeles, United States

Alloys and intermetallics are of great interest as anode materials due to their high energy density, but they generally suffer from poor cycling life due to large volume expansion that leads to cracking. In this work, we demonstrate a new and facile route using cryogenic milling (cryomilling) to fabricate stable and high energy density anode materials. Because a ductile-to-brittle transition occurs for most metals at a low temperature, cryomilling can efficiently reduce the grain/particle size while adding a small amount of well-dispersed nanocarbon to stabilize the resulting nanostructures. Adding a minimum amount (1.2 wt%) of graphite during cryomilling produces SnSb anodes that demonstrate an initial coulombic efficiency of 83%, averaged efficiency >99.5%, and capacity retention of 90% over 100 cycles. Scanning electron microscopy (SEM), scanning transmission electron microscopy (STEM), and various electrochemical characterization were employed to understand this high stability. The refined grain size (~10nm) and well-dispersed carbon matrix can alleviate the volume expansion and prevent particle cracking after cycling. Cryomilling is a cost-effective manufacturing method that is widely used in the food industry, plastic powder synthesis, and fabrication of nanostructured alloys. This work demonstrates the successful application of cryomilling to battery electrode materials for the first time and shows much-improved cycle life compared with conventional ball milling.

6:40 AM F.EN06.01.12
Translating a Material Discovery into a New High-Energy-Density Lithium-Ion Battery Kent J. Griffith[1], Rogério Ribas[2], Robson Monteiro[2], Robert J. Cava[3], Robert Von Dreele[4], Anthony K. Cheetham[5], Clare Grey[6] and John B. Goodenough[7]; [1]Northwestern University, United States; [2]CBMM, Brazil; [3]Princeton University, United States; [4]Argonne National Laboratory, United States; [5]University of California Santa Barbara, United States; [6]University of Cambridge, United Kingdom; [7]The University of Texas at Austin, United States

Of the thousands of materials that have been investigated as prospective rechargeable lithium-ion battery electrodes, only a handful have successfully traversed the journey toward commercialization. Following the award of the 2019 Nobel Prize in Chemistry to Whittingham, Goodenough, and Yoshino “for the development of lithium-ion batteries”,[1] and owing to the global effort to develop advanced battery materials, we seek to chronicle a modern commercialization pathway via the tale of high-power and high-energy density titanium niobium oxide (TNO, $TiNb_2O_7$) a crystallographic shear structure.

The state-of-the-art material in the high-power and fast-charging performance space is LTO, commercialized by Toshiba as the SCiB™ battery and now used globally in applications including mild-hybrid electric passenger cars, electric buses and trolleys, electric trains, and grid energy storage systems. Relative to graphite, $Li_4Ti_5O_{12}$ provides only 50% of the gravimetric capacity and sacrifices approximately 40% of the voltage when paired with a 4.0 V cathode. Despite their limited energy density, $Li_4Ti_5O_{12}$-based cells reached commercial success because they can be cycled over 20,000 times and operated safely at current densities and temperatures that are not suitable for graphite-based batteries.

Owing to the favorable properties of niobium, $TiNb_2O_7$ is being developed as a high-energy-density alternative anode material to $Li_4Ti_5O_{12}$. It was first discovered by crystallographers in the 1950s and 1960s,[2,3] reported as a lithium-ion battery material by Bell Labs in 1983,[4] and "rediscovered" in the last decade by a team led by John Goodenough[5,6]. Since then, it has been the most studied crystallographic shear or Wadsley–Roth phase, the subject of numerous applied and fundamental studies on characteristics such as the mechanism of structure evolution,[7–9] ionic and electronic conduction,[9] and battery performance[10,11]. The lithiation reaction may proceed all the way to $Li_5Ti^{III}Nb^{III}_2O_7$ with a theoretical capacity of 387.7 $mAh \times g^{-1}$. The multielectron redox chemistry of $TiNb_2O_7$ puts it on par with the gravimetric capacity of graphite (371.9 $mAh \times g^{-1}$). It is worth mentioning that the crystal density of $TiNb_2O_7$ (4.33 $g \times cm^{-3}$) is twice that of graphite (2.22 $g \times cm^{-3}$). Thus, the volumetric energy density of this oxide anode compares even more favorably than its gravimetric energy density. The high voltage of $TiNb_2O_7$ (above 0.6 V vs. Li^+/Li) enables safe charging under high current densities even in a heterogeneous electrode with large overpotentials and may be considered a necessary feature despite the cell voltage penalty. The high operating voltage may also mitigate surface–electrolyte interphase (SEI) formation as the voltage window is largely within the stability limits of standard electrolytes.
We will present the development, the state-of-the-art, and the future of $TiNb_2O_7$ and Wadsley–Roth crystallographic shear structures as fast-charging and high-energy-density lithium-ion battery materials.

6:50 AM F.EN06.01.13
Understanding the De-/Lithiation Mechanism of Iron-Doped Zinc Oxide—From Fundamentals to Practical Considerations Jakob Asenbauer[1,2], Tobias Eisenmann[1,2], Adele Birrozzi[1,2], Alexander Hoefling[1,2], Joachim Binder[3], Sylvio Indris[1,3], Matthias Kuenzel[1,2], Jens Tuebke[1,2,4], Stefano Passerini[1,2] and Dominic Bresser[1,2]; [1]Helmholtz Institute Ulm (HIU), Germany; [2]Karlsruhe Institute of Technology (KIT), Germany; [3]Karlsruhe Institute of Technology–Institute for Applied Materials, Germany; [4]Fraunhofer Institute for Chemical Technology, Germany

The unique combination of high energy and power density made lithium-ion batteries the state-of-the-art energy storage technology to power small consumer electronics, as well as large-scale applications like electric vehicles.[1] However, especially the latter application, requires batteries that cannot only provide high energy density, but also the possibility for rapid recharging.[2] This is maybe the greatest challenge for the presently used graphite-based anodes, since the low lithiation potential (~0.1 V vs. Li/Li^+) in combination with the sluggish lithium transport within the graphite structure and across the solid electrolyte interphase (SEI) provides the risk of lithium plating and dendrite formation during fast charging, especially at low temperatures.[3]
To solve this issue, alternative anodes, following, e.g., a conversion or an alloying mechanism, are being investigated.[4] These alternatives frequently possess higher capacities and rate capabilities; however, conversion materials still suffer from low energy efficiencies, due to a significant voltage hysteresis, and the extensive volume variation of alloying materials leads to rapid capacity fading and low coulombic efficiencies. Conversion/alloying-materials (CAMs), such as $Zn_{0.9}Fe_{0.1}O$, are a relatively new material class, that combines both, the conversion and alloying mechanism in a single material.[5] During the initial lithiation of CAMs, nanograins of an alloying element and a percolating conductive network of transition metal nanoparticles are formed *in situ* by the (reversible) conversion reaction. The metallic nano-network leads to fast de-/lithiation kinetics, making them a promising candidate for high-power applications. Yet, the

achievement of sufficiently high energy efficiencies and the volume variations occurring upon cycling are still remaining obstacles and there is still a lack of knowledge about how to potentially tackle these issues.
Herein, we present our findings towards a detailed mechanistic understanding of the de-/lithiation of (carbon-coated) $Zn_{0.9}Fe_{0.1}O$. By combining *in situ* microcalorimetry, with *in situ* XRD, *ex situ* ^{7}Li NMR and *ex situ* ^{57}Fe Mössbauer spectroscopy we were able to propose a refined model for the initial de-/lithiation reaction. Furthermore, the volume variations of $Zn_{0.9}Fe_{0.1}O$ electrodes upon cycling were studied by complementary *in situ* dilatometry and *ex situ* cross-sectional SEM analysis. These measurements reveal a continuous volume variation at the electrode level in the range of 10%. This is much lower than the theoretically predicted expansion when considering bulk densities only – even though the electrodes where cycled within a 3-V potential window. On the basis of these results we highlight the favorable effect of limiting the operational voltage window. We finally confirm this for $Zn_{0.9}Fe_{0.1}O/LiNi_{0.5}Mn_{1.5}O_4$ full-cells, providing an energy and power density of 284 Wh kg^{-1} and 1105 W kg^{-1}, respectively, accompanied by an excellent energy efficiency of >93%.

Modeling of the Transfer Reactions at Li/SEI/Electrolyte Interface and Dendrite Free Morphology Yue Qi[1,2]; [1]Brown University, United States; [2]Michigan State University, United States

The charge transfer reaction is the fundamental reaction for rechargeable batteries. The energy landscape of this reaction depicts the equilibrium and kinetics of the electrochemical process. Typically, a Li-metal electrode is always covered by a thin layer of solid electrolyte interphase (SEI), forming a complex Li/SEI/electrolyte interface. We first introduced a new half-cell model to predict the energy landscape of the electrochemical reaction of at the complex Li/SEI/electrolyte interface, with combined density functional theory (DFT) and tight-binding (DFTB) calculations. The simulated atomic details revealed that the Li-metal surface is negatively charged at the electrochemical equilibrium condition (the experimentally defined zero voltage for Li^+/Li^0) due to the large solvation energy of Li^+ in the EC-based electrolyte. The electric field created by the negatively charged surface can reorient the electrolyte into an ordered structure, lower the Li^+ ion desolvation energy barrier, and help the Li^+ ion transport through the SEI.
Further, the calculated energy landscape can be used to describe the electrochemical reaction kinetics with a Butler-Volmer equation, enabling a multiscale modeling approach. In this study, the DFT and DFTB predicted interfacial structures, de-solvation processes, and the ion transfer energy barrier, were inputted into a non-linear phase-field model to capture the morphological evolution during the electroplating process. Specifically, this model captured the morphology difference between the dendritic Li plating in carbonate (EC)-electrolyte and faceted Mg plating in tetrahydrofuran(THF)-electrolyte under the similar current density. Furthermore, through systematical parametric analyses, we conclude that the cation desolvation-induced exchange current difference between Li and Mg is mainly responsible for their deposition morphological differences. This study provides a strategy of connecting the phase-field method and atomistic calculations and predicts that increasing the desolvation energy and lowering the equilibrium exchange current can help to achieve dendrite-free Li-metal anode.

5:15 AM F.EN06.02.03
Pressure-Tailored Lithium Deposition and Dissolution in Lithium Metal Batteries Chengcheng Fang and Y. Shirley Meng; University of California, San Diego, United States

Lithium (Li) metal offers high theoretical capacity, lowest negative potential and light weight, making it the ideal anode material for high-energy-density batteries. Porous electrodes resulting from unregulated Li growth is believed to be the major cause of the low Coulombic efficiency (CE) and potential safety hazards of rechargeable Li metal batteries. Strategies aiming

to achieve large granular Li deposits have been extensively explored; yet, the ideal Li deposits, which consist of large Li particles seamlessly packed on the electrode and can be reversibly deposited and stripped, have never been reported. Here, by using cryo-FIB-SEM, 3D reconstruction and MD simulation, we quantitatively revealed the role of stack pressure on Li nucleation, growth and stripping, and discovered that optimal pressure for approaching 100% dense Li deposition by establishing a pressure-morphology-performance correlation. Unprecedented, a dense Li deposition (99.49% electrode density) with an ideal columnar structure has been achieved and can be reversibly plated and stripped during extended cycles at room temperature. The tailored Li deposition and stripping by optimizing stack pressure opens new opportunities to rationally mitigate inactive Li formation, improve cycle life and enable fast charging for rechargeable Li metal batteries.

5:25 AM *F.EN06.02.04
Advances in Imaging Lithium Batteries at Different Length Scales Herman Lemmens and Zhao Liu; Thermo Fisher Scientific, Netherlands

Imaging the microstructure of a battery cell at different length scales is important to understand the degradation processes through the battery cycle life. For example, investigating the formation of defects such as dendrites at the Li anode interface requires both high resolution imaging and large field of view. Ideally, imaging techniques cover the entire electrode thickness at submicron resolution with a method that preserves the sample interface. Here, we present an approach to probe the defects at the Li-metal battery interface. A coin cell has been sliced under cryo conditions with a laser inside the vacuum of the scanning electron microscope (SEM) chamber so a pristine surface is obtained and defect formation can be observed across the entire thickness of the cell.
In another example, transport properties for a thick NMC 811 cathode were obtained from focused ion beam (FIB) milling in combination with SEM. Because of the cathode thickness, an alternative to traditional Ga FIB milling was used. With a Xenon plasma beam, it was possible to obtain a 3D data set with more than 100 µm field of view on a 70 µm thick cathode. The microstructural characteristics extracted from such representative 3D volume help the understanding of the correlation between electrode microstructural evolution and performance deterioration.

Late News: Gaining a Better Understanding of Lithium-Ion Battery Functionality Through Scanning Electron Microscopy Analytical Studies Pawel Nowakowski[1], Cecile Bonifacio[1], Jean-Marie Doux[2], Shirley Meng[2], Mary Ray[1] and Paul Fischione[1]; [1]E. A. Fischione Instruments, Inc., United States; [2]University of California, United States

All solid-state batteries (ASSB) promise high energy density, by enabling the use of Li metal anode, and safe operation, thanks to their non-flammable solid-state electrolyte. Degradation over the course of the ASSB lifecycle, however, remains a limiting issue for the technology, as the aging process constrains energy storage capabilities and performance. Better understanding of the degradation mechanisms is critical to improving ASSB functionality and performance, [1].
Scanning electron microscopy (SEM) analytical studies, such as energy dispersive X-ray spectroscopy (EDS) and electron backscatter diffraction (EBSD) analyses are important tools that give researchers the ability to characterize battery materials and understand their structures, as well as degradation. The role of the Li microstructure (grain size, crystallographic preferential orientation, etc.) on battery performance is not well understood; few reports on the microstructural characterization of lithium metal are to be found in the literature. In addition, further investigation is needed into the cathode/anode solid electrolyte interface, such as solid electrolyte decomposition, intermediate transition layer formation, and Li metal dendrite formation [2, 3].
To complete accurate and informative SEM analytical studies, the samples must be well-prepared and represent the native microstructure of study element without any oxidation, contamination and deformation or cracking induced by preparation. An artifact-free sample preparation technique is a critical key to better understand battery functionality and its ageing process. Preparing Li metal ASSB samples is particularly difficult because Li is highly sensitive to oxygen, nitrogen, water, and carbon dioxide; requiring Ar protective atmosphere. Lithium is also a very soft material and its crystallographic structure can be easily damaged by mechanical sample preparation techniques. The inherent characteristics of Li metal demand a controlled environment workflow from sample preparation through SEM analyses [4].
In this work we report on EBSD characterization of pure Li metal using a unique controlled environment workflow: argon broad ion beam milling, sample transfer to the SEM, and EBSD analyses. We present structural EBSD results on pure Li metal used as an anode in an ASSB, with special focus on texture and grain size. We will also present SEM imaging and EDS studies that document the interface layers formed during battery cycling.

Understanding the Interplay Between Li Insertion and Li Plating in Single Graphite Anode Tao Gao[1], Dimitrios Fraggedakis[1], Supratim Das[1], William C. Chueh[2], Ju Li[1] and Martin Bazant[1]; [1]Massachusetts Institute of Technology, United States; [2]Stanford University, United States

The potential safety hazards of lithium ion batteries (LIBs), as well as their capacity fade and long charging time, are major challenges that currently prevent the widespread adoption of electric vehicles. These effects are strongly correlated with lithium plating, a parasitic reaction on graphite anodes that competes with lithium intercalation when LiBs are charged at high rates or under low temperature. Li plating is known for depletion of the lithium inventory, cell shorting, and thermal runaway.

Addressing Li plating problem relies on material engineering and battery operation optimization. The efficacy of these approaches lies in the fundamental understanding of Li plating mechanism. Despite Li ion battery has been invented for 30 years, a systematic understanding on the onset and growth of Li in graphite anode is still lacking. Thermodynamics criterion requires the voltage of graphite to be negative vs. Li metal for Li plating to happen. However, in practice graphite is usually able to tolerate certain degree of negative voltage without plating. Such discrepancy necessitates the incorporation of kinetic factors. Several kinetic mechanisms have been proposed, which include electrolyte transport limitation and solid diffusion limitation. However, neither of them are validated experimentally on graphite electrode.

In this work, we test these hypotheses and elucidate the mechanism of Li plating, by investigating the interplay between Li intercalation and Li plating on a single graphite particle, using in-situ optical microscopy coupled with electrochemical test. The results show Li plating happens when the surface of graphite saturates, which shuts down the intercalation reaction. The saturation can happen much earlier than full lithiation of graphite particle due to solid diffusion limitation, resulting in severe under-utilization. The physical picture was discussed by analyzing the energy landscape of the two competing reactions and their kinetics. A theory was proposed, followed by a 1D simulation of the dynamics of Li insertion and Li plating. The discovery sheds light on directions and guidelines of materials innovation or electrode design for reducing the risk of Li plating and extreme fast charging.

Pairing Lithium-Metal Anode with High-Nickel NMC and Sulfur Cathodes—Fundamental Understanding and Engineering Solutions Arumugam Manthiram; The University of Texas at Austin, United States

Lithium-metal anode holds tremendous potential for enabling next generation of rechargeable batteries due to their high storage capacity (3,861 mAh g^{-1}) and low reduction potential (-3.04 V vs SHE). When paired with a high-capacity cathode, such as high-nickel NMC or sulfur, lithium-metal anode can help deliver energy-dense storage systems with ~ 500 Wh kg^{-1}. However, the poor efficiency associated with lithium plating and stripping severely limits the cycle life. For realizing practical viability, reversible lithium deposition needs to be achieved by stabilizing the lithium-electrolyte interphase (SEI) layer and mitigating the extreme volume changes accompanying the cycling.

The chemistry of the lithium-electrolyte interface is rendered distinct by the choice of the cathode in a full cell, *viz*., high-nickel NMC or sulfur. This is not only due to the different electrolyte formulations used, but also due to the crossover of species between the cathode and anode. The characteristics of deposited lithium can fundamentally vary across different cathode systems, and unique strategies must be employed to stabilize lithium deposition in each case. Hence, an in-depth fundamental study is necessary to develop a thorough understanding of the lithium-electrolyte interfacial chemistry, while creative engineering solutions are necessary to achieve highly efficient lithium plating and stripping. This presentation will focus both on a fundamental understanding and offering engineering solutions.

When paired with a high-nickel NMC cathode, the lithium-metal anode is affected by transition-metal dissolution at the cathode and crossover to the anode. However, we find that during initial cycling, crossover of electrolyte decomposition products from the anode to the cathode is more severe and plays a more critical role. Not only does it alter/thicken the

cathode SEI layer, it also affects the anode itself as the lithium SEI components could continually dissolve. The magnitude of this crossover is expected to depend on the nickel content in the cathode.

When paired with a sulfur cathode, the lithium-metal anode is affected by polysulfide dissolution at the cathode and crossover to the anode. We use anode-free full cells, which contain no excess lithium at the anode, to investigate the dynamics of lithium deposition. With advanced surface characterization methodologies, *e.g.*, time-of-flight secondary ion spectrometry, we find that the depletion of cyclable lithium inventory is due to the formation of "dead" metallic lithium, which itself is caused by severe electrolyte decomposition on lithium-metal surface with cycling.

The presence of polysulfide intermediates is found to have an intrinsically stabilizing effect on lithium deposition in Li-S batteries. This motivates our strategies towards engineering further improvements in cycle life. With tellurium as a cathode additive, tellurium-substituted polysulfides are formed, which reduce on lithium surface to form Li_2TeS_3 as a thin, Li^+-ion conducting SEI layer. This enables uniform deposition of lithium and mitigates electrolyte decomposition. A remarkable improvement in cyclability is achieved in energy-dense anode-free full cells and lean-electrolyte pouch cells. Similarly, using organosulfide molecules as electrolyte additives opens the possibility of favorably tuning the properties of lithium SEI layer by simply modifying the organic functional group.

The development of three-dimensional current collector matrices is also critical to achieving reversible lithium deposition. The highly conductive frameworks provide efficient electron/ion transport and guides a homogenous deposition of lithium, while the porous 3D architecture helps mitigate severe volume changes during cycling. The presentation will demonstrate various lithiophilic host materials that show considerable promise in improving the cyclability of lithium-metal anode when paired with both high-nickel NMC and sulfur cathodes.

Chemical Trends in the Lattice Thermal Conductivity of Li(Ni, Mn, Co)O_2 (NMC) Battery Cathodes Hui Yang[1,2], Christopher Savory[3,2], Benjamin J. Morgan[4,2], David O. Scanlon[3,2,5], Jonathan Skelton[6] and Aron Walsh[1,7,2]; [1]Imperial College London, United Kingdom; [2]The Faraday Institution, United Kingdom; [3]University College London, United Kingdom; [4]University of Bath, United Kingdom; [5]Diamond House, United Kingdom; [6]University of Manchester, United Kingdom; [7]Yonsei University, Korea (the Republic of)

While the transport of ions and electrons in conventional Li-ion battery cathode materials is well understood, our knowledge of the phonon (heat) transport is still in its infancy. We present a first-principles theoretical investigation of the chemical trends in the phonon frequency dispersion, mode lifetimes, and thermal conductivity in the series of layered lithium transition-metal oxides $Li(Ni_xMn_yCo_z)O_2$ (x + y + z = 1). The oxidation and spin states of the transition metal cations are found to strongly influence the structural dynamics. Calculations of the thermal conductivity show that $LiCoO_2$ has highest average conductivity of 45.9 $W.m^{-1}.K^{-1}$ at T = 300 K and the largest anisotropy, followed by $LiMnO_2$ with 8.9 $W.m^{-1}.K^{-1}$, and $LiNiO_2$ with 6.0 $W.m^{-1}.K^{-1}$. The much lower thermal conductivity of $LiMnO_2$ and $LiNiO_2$ is found to be due to 1-2 orders of magnitude shorter phonon lifetimes. We further model the properties of binary and ternary transition metal combinations and show that the thermal conductivity of NMC is suppressed with decreasing Co content and increasing Ni/Mn content. The thermal conductivity of commercial NMC622 and NMC111 compositions are substantially larger than NMC811. These results serve as a guide to ongoing work on the design of multi-component battery electrodes with more effective thermal management.

5:10 AM F.EN06.03.03
Using High Entropy to Improve Capacity and Rate Capability in Cation-Disordered Rocksalt Cathodes Zhengyan Lun[1,2], Bin Ouyang[1,2], Deok-Hwang Kwon[1,2], Huiwen Ji[2] and Gerbrand Ceder[1,2]; [1]University of California, Berkeley, United

States; [2]Lawrence Berkeley National Laboratory, United States

The recent success of Li-excess cation-disordered rocksalt (DRX) cathodes is providing an avenue to develop high energy density cathodes with abundant and low-cost metals, such as Mn, Fe and Ti. As they have high energy density, these cathode materials are currently the most viable strategy to address the resource issues of Co / Ni that will arise as conventional layered-type Li-ion cathodes are scaled towards multiple TWh of annual production. In DRX cathodes, facile Li transport relies mostly on the so-called "0-TM" 3D percolation channel, in which the intermediate tetrahedral sites are coordinated only by Li (no transition metals, TMs). The Li migration barrier along this "0-TM" channel is significantly lower compared to that of "1-TM" channel, where the intermediate tetrahedral sites are coordinated by 3 Li and 1 TM. The complexity of DRX cathodes lies in the fact that in most cases, they present various types of cation short-range order (SRO), which influences the frequency and connectivity of "0-TM" channels, thus controls the capacity and rate capability of DRX cathodes. Monte Carlo simulations have suggested that the presence of SRO in DRX cathodes generally leads to reduced Li percolation, when compared to that of a random arrangement of TM species.
Inspired by the recent observations of nearly-random cation distribution in several high-entropy metal and oxide compounds, we have found that increasing the number of TM species in DRXs will improve Li transport properties by preventing the formation of a single dominant SRO type, resulting in improved capacity and high rate capability. We show that SRO in DRX cathodes systematically decreases as more TM components are added, and as a consequence, energy density and rate capability systematically increase. A DRX cathode with six TM species achieves 307 mAh g^{-1} (955 Wh kg^{-1}) at 20 mA g^{-1} and retains more than 170 mAh g^{-1} when cycling at 2,000 mA g^{-1}. The high compositional flexibility of these materials can also enable the use of less pure precursor materials.

5:20 AM F.EN06.03.05
Enhanced Cycling Stability of Ni-Rich Cathode Material by Dry Coating Technique Tianhang Chen and Donghai Wang; The Pennsylvania State University, United States

High nickel content cathodes (Ni >90%) are promising candidates for lithium ion batteries (LIBs) due to their high energy capacity and low cost. But they are still suffering from poor cycling stability and potential thermal run away since lattice structures would become unstable upon cycling. Incorporation of Al atom by dry coating into structure has been found to be beneficial to the electrochemical and thermal stability because Al doping not only can decrease the Li/Ni mixing ratio in the Li layer but also enhance the thermal resistance to oxygen evolution due to strong Al-O bonding. The Al doping by dry coating NCM (DC_NCM_$Al(OH)_3$ and DC_NCM_Al_2O_3) reserve 87.8% and 87.1 % capacity respectively after 200 cycles while NCM only remains 70.7 %. Additionally, DC_NCM_$Al(OH)_3$ at charged state exhibits an exothermic peak at 212.4 °C which is 10 °C higher than NCM. The Al doping NCM samples reveal improved properties for high nickel content cathode, which provides a strategy for next generation LIBs.

5:30 AM F.EN06.03.06
Concurrently Approaching Volumetric and Specific Capacity Limits of Lithium Battery Cathodes via Conformal Pickering Emulsion Graphene Coatings Kyuyoung Park, Jin-Myoung Lim, Norman S. Luu, Julia R. Downing, Shay G. Wallace, Lindsay E. Chaney, Hocheon Yoo, Woo Jin Hyun, Hyeong-U Kim and Mark Hersam; Northwestern University, United States

To achieve the high energy densities demanded by emerging technologies, lithium-ion batteries (LIBs) require cathode electrodes possessing high volumetric and specific capacities[1]. While recent developments in Ni-rich cathode material composition have significantly increased the volumetric and specific capacities of cathode active materials[2, 3], the other inactive components, such as binders and carbon additives, still need to be minimized in order to approach theoretical volumetric and specific capacity limits of the entire cathode electrode. Towards this end, here we report conformal, ultrathin, and conductive graphene coatings on LIB active material particles using a scalable Pickering emulsion method[4]. Since this approach employs high-quality, liquid phase-exfoliated graphene that possesses exceptional electrical conductivity[5], only 0.5 wt% graphene is required to achieve high electrochemical performance in electrodes. Furthermore, this minimal amount of conductive additive also allows the binder loading to be reduced to 0.8 wt%, even for industrially relevant active material areal loadings (~11 mg cm^{-2}). Due to its exceptionally low inactive material loading, the resulting $LiNi_{0.8}Co_{0.15}Al_{0.05}O_2$ (NCA) electrodes achieve specific and volumetric capacities that reach ~98% of the theoretical limits for NCA. The efficient electron conduction path from the graphene coating and the shortened lithium diffusion path due to a simplified electrode structure also imply superlative rate capability, while the conformal graphene coating mitigates electrochemical degradation mechanisms and consequently enhances cycle-life. Since this Pickering emulsion coating scheme is agnostic to the cathode material composition, it can be widely applied to other active material particles, thus providing a general pathway to theoretical specific and volumetric capacities in practical LIB electrodes.

Building Ultra-Conformal Protective Layers on Both Secondary and Primary Particles of Layered Lithium Transition Metal Oxide Cathodes Guiliang Xu and Khalil Amine; Argonne National Laboratory, United States

Nickel-rich layered lithium transition metal oxides are the most attractive cathode materials for the next generation lithium-ion batteries for automotive application. However, they suffer from crystal and interfacial structure instability under aggressive electrochemical and thermal driving force, leading to rapid performance degradation and severe safety concerns.In this talk, we reported a transformative approach by using an oxidative chemical vapour deposition technique to build a protective conductive polymer (PEDOT) skin on layered oxide cathode materials. The ultra-conformal PEDOT skin facilitates the transport of lithium ions and electrons, significantly suppresses the undesired layered to spinel/rock-salt phase transformation and the associated oxygen loss, mitigates intergranular and intragranular mechanical cracking, and effectively stabilizes cathode-electrolyte interface. This approach remarkably enhances the capacity and thermal stability under high-voltage operation. Building a protective skin at both secondary and primary particle levels of layered oxides offers a design strategy for the promising Ni-rich cathodes towards high-energy, long-life and safe lithium-ion batteries.

5:55 AM F.EN06.03.09
Chemo-Mechanical Degradation in V_2O_5 Thin-Film Cathodes of Li-Ion Batteries Yuwei Zhang and Matt Pharr; Texas A&M University, United States

We have devised an approach to fabricate dense textured V_2O_5 thin films, which allows us to scrutinize the root cause of capacity fade in V_2O_5 cathodes of Li-ion batteries. Specifically, we performed in-situ measurements of stress of V_2O_5 thin films during 50 electrochemical cycles. Surprisingly, electrochemical cycling appears to induce elastic and rate-independent deformation over a voltage range relevant to battery operation (4 - 2.8 V). However, the compressive stresses gradually increase with cycle number during the first few cycles, likely due to side reactions and/or residual Li left in the V_2O_5, even after delithiation (to 4 V). Further cycling leads to accumulated mechanical (e.g., fracture, delamination) and structural changes which ultimately result in severe capacity fade.

SESSION F.EN06.04: Liquid Electrolytes

5:00 AM F.EN06.04.01
Elimination of Fluorination—The Influence of Fluorine-Free Electrolytes on the Performance of Si-Based Li-Ion Batteries Guiomar Hernández, Andrew J. Naylor, Yu-Chuan Chien, Daniel Brandell, Jonas Mindemark and Kristina Edstrom; Uppsala University, Sweden

One step towards more environmentally friendly and safer batteries is to eliminate fluorinated electrolytes, as they are susceptible to release toxic and corrosive compounds such as HF. Yet, fluorinated electrolytes are still dominating the research and market of lithium ion batteries.[1] Alternatively, replacing the state-of-the-art $LiPF_6$ with fluorine-free salt would

reduce cost, increase safety and decrease toxicity, both in the manufacturing and recycling processes.[2] In addition, additives able to form a stable solid-electrolyte interphase (SEI) are another common source of fluorine, for example fluoroethylene carbonate (FEC), which is particularly important for silicon-based electrodes as they suffer high volume changes upon cycling.[3] Despite this advantage of FEC, it has been also shown that it accelerates the degradation of the electrolyte containing $LiPF_6$ upon storage.[4]

Herein, we investigate the effects of electrolyte fluorination, from a highly fluorinated electrolyte based on the conventional $LiPF_6$ salt with FEC and vinylene carbonate (VC) as SEI-forming additives to a fluorine-free electrolyte based on lithium bis(oxalato)borate (LiBOB) salt and VC additive. These electrolytes were tested in full cells combining silicon-graphite composite electrodes with $LiNi_{1/3}Mn_{1/3}Co_{1/3}O_2$ cathodes, and characterized by means of electrochemical testing and post-mortem analysis. Our results show that the SEI composition on the anode is very different, being F-rich in the fluorinated electrolyte and O-rich in the fluorine-free electrolyte. However, both electrolyte formulations are able to stabilise silicon-based electrodes and support long cycle life in full cells. Therefore, fluorine-free alternatives are good candidates for high-energy-density full cells opening new possibilities towards safer, more sustainable and less toxic batteries.[5]

Organosilicon Compounds Improve the Thermal and Electrochemical Stability of Lithium-Ion Batteries Robert Hamers[1], Sarah Guillot[2], Monica Usrey[2], Louis Morris[1] and Cesar Ortiz Ledon[1]; [1]University of Wisconsin-Madison, United States; [2]Silatronix, Inc., United States

Incorporation of organosilicon (OS) compounds in modest concentrations as low as several percent in conventional carbonate electrolytes lead to substantial improvements in the thermal and electrochemical stability of the resulting lithium ion batteries. We have been investigating the fundamental chemical degradation pathways of organosilicon compounds in an effort to understand the chemical and electrochemical origins of these remarkable properties. The combination of NMR spectroscopy, in situ FTIR, AFM, and XPS provides unique insights into how organosilicon electrolytes reduce or eliminate autocatalytic chemical pathways associated with PF6 and its degradation products. OS compounds further alter the chemical nature of SEI layers on silicon, leading to improvements in overall performance. In this talk I will summarize some of our recent work characterizing organosilicon thermal stability and electrochemical stability against different materials, including silicon-based anodes and NMC-based cathodes.

5:25 AM F.EN06.04.03
Molecular Design for Electrolyte Solvents Enables Long-Cycling Anode-Free Lithium Metal Batteries Zhiao Yu[1], Hansen Wang[1], Yi Cui[1,2] and Zhenan Bao[1]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

Lithium (Li) ion batteries have made a great impact to society, recognized by the 2019 Nobel Prize in Chemistry. Albeit commercialized for decades, Li ion batteries are rapidly approaching their theoretical limit in energy density, thus motivating the revival of the Li metal chemistry. Nevertheless, the implementation of Li metal batteries is plagued by their poor cycle life. Uncontrollable reactions between Li metal and electrolytes form a chemically unstable and mechanically fragile solid-electrolyte interphase (SEI). The SEI easily cracks during cycling, leading to dendritic growth, “dead Li” formation and

irreversible Li inventory loss. By tuning the SEI structure and quality, electrolyte engineering is a critical and pragmatic approach. For a promising electrolyte, several key requirements are marked: (1) consistently high Coulombic efficiency (CE) to minimize Li loss, including that in the initial cycles; (2) functionality under lean electrolyte and limited-excess Li conditions for maximized energy density; (3) oxidative stability towards high-voltage cathodes; (4) rmoderate salt concentration for cost-effectiveness; (5) high boiling point and low flammability for safety and processability.

Several reports on electrolyte engineering improved the cyclability of Li metal batteries, such as additive optimization, solvent ratio modification, and liquified gas electrolytes. Particularly, the high concentration electrolytes (HCEs) and localized high concentration electrolytes (LHCEs) were acknowledged to be the most effective methods. Take the state-of-the-art version, LHCEs, as an example. The fluoro-diluents used in LHCEs were Li metal compatible yet hardly able to solvate Li^+ ions by itself. As a consequence, small amount of unstable solvents were necessary for salt dissolution, reducing but not eliminating undesirable parasitic reactions. These side reactions with the solvent molecules led to low CE in the initial cycles. Therefore a detailed methodology of rational electrolyte design is still highly demanded.

In our work, we target new solvent molecules that not only dissolve Li salt but also stay compatible when confronted with both Li metal anodes and high-voltage cathodes. Thus we design a first-time synthesized liquid molecule, fluorinated 1,4-dimethoxylbutane (FDMB), solely as the electrolyte solvent. It is paired with 1 molar lithium bis(fluorosulfonyl)imide (1 M LiFSI) in a single-salt, single-solvent formulation (1 M LiFSI/FDMB) to enable stable and high-energy-density Li metal batteries. Theoretical simulations show a unique Li^+-solvent interaction in 1 M LiFSI/FDMB and thus higher anion-solvent ratio in the Li^+ solvation structure, endowing the electrolyte with both Li metal compatibility and high-voltage tolerance. Cryogenic transmission electron microscope of Li metal plated in 1 M LiFSI/FDMB reveals an ultrathin SEI (~6 nm), accompanied by a high CE (~99.52%) and fast activation (CE ramps up to >99% within 5 cycles) for Li metal anodes. The Li|NMC full cells with limited-excess Li retain 90% capacity after 420 cycles with an average CE of 99.98%. Industrial anode-free Cu|NMC 811 pouch cells achieve ~325 Wh kg^{-1} single-cell energy density while Cu|NMC532 ones show 80% capacity retention after 100 cycles, which is one of the best performing anode-free cells. Our rational design concept for electrolyte provides a promising path to high-energy, practical Li metal batteries with high cyclability and processability.

5:35 AM F.EN06.04.05

Towards the Comprehension of Surface Species Formation in Nickel-rich Layered Materials and Their Reactivity Towards Electrolyte Ana C. Martinez Maciel[1,2,3], Sylvie Grugeon[1,2], Dominique Cailleu[4], Matthieu Courty[1,2], Pierre Tran-Van[3] and Stéphane Laruelle[1,2]; [1]Laboratoire de Réactivité et de Chimie des Solides, UMR CNRS, Université de Picardie Jules Verne, France; [2]Réseau sur le Stockage Electrochimique de l'Energie, CNRS RS2E, France; [3]Technocentre Renault, France; [4]Plate-Forme Analytique, Université de Picardie Jules Verne, France

Recently, layered oxides $LiNi_{1-x-y}Mn_xCo_yO_2$ (NMC), have found wide use in the automotive industry as positive electrode materials for lithium-ion batteries, due to their high energy density given by the nickel content[1]. Unfortunately, their surface composition is readily compromised by the chemical reactivity towards H_2O and CO_2. The instability towards H_2O limits the aqueous processing of the electrodes[2] and the surface degradation towards H_2O and CO_2 into surface species (typically Li_2CO_3 and LiOH) induces slurry gelation during the preparation of the electrodes[3], increases the cell's impedance[4], provokes early capacity fade[5] and heavier gassing is produced during battery operation[6]. Many research efforts have been devoted to demonstrating the negative consequences of Li_2CO_3 and LiOH to the electrochemical performance of the battery. Nonetheless, the whole NMC surface degradation mechanism upon storage under H_2O/CO_2 atmosphere is still controversial.

Therefore, in this work[7], the complementary acid-base titration and inductively coupled plasma techniques were implemented as accurate methods to identify and quantify the amount of soluble species in four nickel-rich NMC: 532, 622, 811 and 901; before and after exposure under a specific H_2O/CO_2 atmosphere. In addition to the typical Li_2CO_3, and LiOH, we unveiled the presence of lithium and sodium sulfate salts. Moreover, thanks to thermogravimetric analysis coupled to mass spectrometry of the as-received and exposed to H_2O/CO_2 materials, we propose a novel NMC surface degradation mechanism that involves the formation of transition metal-based surface species. Lastly, the chemical reactivity of the surface species towards a commercial $LiPF_6$-based liquid electrolyte was studied through nuclear magnetic resonance (^{19}F and ^{31}P NMR), at room and high temperature. In addition to discriminating between LiOH and Li_2O as surface species, these experiments evidenced the presence, as major decomposition product, of lithium difluorophosphate, well-known for its beneficial effect as electrolyte additive.

Ni-Rich Layered Cathodes for All-Solid-State Li Batteries—Effects of Microstructure and Solid Electrolyte Yoon Jae Han, Sung Hoo Jung and Yoon Seok Jung; Hanyang University, Korea (the Republic of)

All-solid-state Li batteries (ASLBs) have been emerged as the enabler to achieve significantly enhanced safety and energy densities, as compared to conventional lithium-ion batteries (LIBs). Several classes of inorganic solid electrolyte (SE) materials have garnered much attention as they could be integrated with electrode active materials into ASLBs by a scalable process such as cold-pressing. Sulfides (or thiophosphates, e.g., Li_6PS_5Cl) and halides (e.g., Li_3YCl_6) satisfy critical features for scalable high-performance ASLBs; those are mechanically sinterability and high Li^+ conductivity. However, they show different comparative advantages in multiple aspects. For example, while halides are heavier than sulfides, they show superior electrochemical oxidation stability to sulfides.
As is the case for advanced LIBs based on liquid electrolytes, Ni-rich cathode materials are the key to the practical ASLB technologies. Unfortunately, they suffer from par below electrochemical performances in ASLBs, which are attributed to the interfacial instabilities in terms of both electrochemical and electrochemo-mechanical effects.
In this presentation, we report on our recent findings on the electrochemo-mechanical effects for Ni-rich layered cathode materials for ASLBs. Microstructural effects of NCM particles on the performance of ASLBs are revealed. Moreover, the performances of NCM using halide SEs are extensively compared. These results shed light on a design strategy for high-performance practical ASLBs.

Advanced Polymers for High-Performance Lithium Batteries Zhen Chen[1], Cristina Iojoiu[2], Elie Paillard[3], Stefano Passerini[1] and Dominic Bresser[1]; [1]Karlsruhe Institute of Technology (KIT), Germany; [2]University Grenoble Alpes / CNRS, France; [3]Forschungszentrum Jülich GmbH, Germany

Polymers are playing already an important role for lithium batteries, serving as the main component for the separator and as binder to ensure the mechanical integrity of the electrodes. Recently, the use of polymer-based electrolytes has also gained an increasing momentum – not least due to the successful commercialization of lithium-metal polymer batteries employing poly(ethylene oxide) as ion conducting matrix.[1] Nonetheless, the need for adding a lithium salt in combination with the relatively low ionic mobility at ambient temperatures raises concerns about (reversed) charge carrier concentration gradients, rather low limiting current densities, and inhomogeneous lithium deposition at the negative electrode.[1–3] Single-ion conducting polymer electrolytes are considered beneficial in this regard – especially if the Li^+ transport occurs along well-defined conduction pathways.[2,3] The limited ionic conductivity of such systems, however, calls for alternative conduction mechanisms – e.g., employing molecular "vehicles" that facilitate Li^+ transport.[3–5]

Herein, the most recent findings in this field will be presented, covering fundamental insights about the charge transport mechanism, the potential safety of such systems, and their suitability for high-energy lithium-metal batteries incorporating Ni-rich $Li[Ni_{1-x-y}Mn_xCo_y]O_2$ as active material for the positive electrode. Moreover, it will be shown that such single-ion conducting polymers can dramatically improve the interfacial stability at the cathode – also for hybrid systems.

3D Printing of Thermally-Safe Composite Solid Polymer Electrolytes for Long Cycle Life Li Metal Batteries Md Golam Rasul, Meng Cheng, Ramin Rojaee, Tolou Shokuhfar and Reza Shahbazian-Yassar; University of Illinois at Chicago, United States

With growing demand for energy storage technologies in emerging electric vehicles and flexible electronics, a combination of research on high-performance rechargeable batteries (i.e. enhanced thermal safety and longer cycle life) and smart manufacturing techniques (i. e. additive manufacturing) is becoming increasingly crucial. In order to face the challenges, research has been going on to improve batteries from three aspects: electrochemistry, material, and device architecture. New material candidates with improved properties are being tested for different battery components: electrode, electrolyte, and separator. While conventional electrolytes suffer from high flammability and parasitic reactions due to its liquid form and result early battery failure, solid polymer electrolytes using polymer materials are gaining attention to overcome these challenges (Zhao *et al.*, 2019). However, the main challenges associated with solid polymer electrolytes (SPEs), particularly for the so called "metal battery", include finding SPEs that can: (i) offer fast Li^+ ion transport at room temperature, (ii) accommodate volume changes at the anode by reversible deformation and high flexibility, (iii) suppress the Li dendrite growth by having mechanical rigidity, and (iv) increase battery reliability by reducing thermal runaway events.
In this work, boron nitride nanosheets (BNNSs) incorporated SPEs (composite SPEs) were fabricated utilizing our lab-developed 3D printing technology. A robotic deposition system was used to extrude PVdF-based SPE inks onto electrode directly. This robotic deposition system is equipped with three-axis direction stage, control system, pneumatic extrusion dispenser, fine cylindrical nozzle, and self-designed heating block to facilitate printing of electrolytes continuously. This 3D printed composite SPE was further characterized, and performances were compared with SPE without BNNS by evaluating electrochemical, mechanical, and thermal properties. Electrochemical impedance spectroscopy study indicates 10 times improvement in ionic conductivity for composite SPE because of BNNSs addition. This increased Li^+ ion conduction was observed because of the Lewis acidic characteristic of BNNS which facilitates to trap the anions in the electrolytes (Shim *et al.*, 2017). In addition, the Young's modulus and yield strength are increased by 100 and 168 %, respectively, because of BNNS reinforcement. This improvement in mechanical properties may help to suppress Li dendrite growth as well as accommodation of volume changes (Monroe and Newman, 2005). Moreover, high thermal conductivity of BNNS is likely to enable homogenous heat distribution in composite SPEs. As a result, the hot-spot formation during parasitic thermal runaway events will be reduced, resulting in enhanced reliability of the battery. This increased mechanical robustness, homogenous heat distribution, and improved ionic conductivity will pave the way for longer battery cycle life.

5:35 AM F.EN06.05.04

Nuclear Magnetic Resonance Investigation of Lithium-Ion Transport in a Highly Conducting Solid Polymer Electrolyte Sahana Bhattacharyya[1], Mounesha Garaga[1], Matthew P. Widstrom[2], Jesse Matthews[2], Kyle Ludwig[2], Chunsheng Wang[2], Peter Kofinas[2] and Steven G. Greenbaum[1]; [1]City University of New York, United States; [2]University of Maryland, United States

Rechargeable battery technology awaits further advances to meet future demands for large scale and safe storage of energy from renewable but intermittent sources. Solid polymer electrolytes based on poly(ethylene oxide (PEO) have been under investigation for some four decades as an safer alternative to flammable organic electrolytes.[1] It still lack sufficiently high ionic conductivity for practical use at ambient temperature.[2] Recent reports of high ionic conductivity and an expanded electrochemical window of aqueous electrolytes enabled by very high salt concentration (~ 20m)[3,4] as well as earlier work on the "salt-in-polymer" concept[5] have inspired this investigation of a solid PEO-salt-water system, where the dissolved salt (LiTFSI) concentration approaches its solubility limit and in combination with water association succeeds in inhibiting

crystallization of the PEO matrix leading to higher conductivity. Room temperature ionic conductivity in these solid-like polymer electrolytes is about 2 mS-cm-^{1}, which is sufficiently high for battery application.[6] We have further characterized the ion transport process by nuclear magnetic resonance (NMR) pulsed field gradient diffusion measurements over a wide range of temperature for ^{7}Li and ^{19}F as the cation and anion, respectively. The diffusion measurements in concert with electrochemical impedance spectroscopy show that the degree of salt ion dissociation in these electrolytes is also sufficiently high. It is found that the lithium transport number, which is related to the fraction of current carried by the Li ions, exceeds 0.6 for the whole temperature range, which is unusually high for polymer electrolytes.

Understanding the Oxidative Decomposition of Polymer Electrolytes Through Electrochemical Method Zhuo LI, Yineng Zhao and Wyatt Tenhaeff; University of Rochester, United States

Anodic stability of solid-state electrolyte in full-solid-state lithium ion batteries (SSLIBs) is attracting more attention recently as SSLIB is receiving increasing attention from both industry and academia. Yet neither the definition of electrochemical stability of solid-state electrolyte nor the determination of such stability has been thoroughly investigated. The most common characterization technique for oxidative stability of solid-state materials, linear sweep voltammetry (LSV), lacks validity and reproducibility while applied on solid-state systems, as its result is greatly affected by cell configuration, sample preparation and data processing method. For example, independent research groups have reported oxidation potentials spanning from 4.0 V–5.5 V vs. Li/Li^{+} for PEO electrolytes, 3.7 V–9.0 V vs. Li/Li^{+} for LLZO electrolytes and 2.1 V–4.0 V vs. Li/Li^{+} for LGPS electrolytes using LSV methods. In practice, cycling of PEO with cathodes having charge potentials above 4 V are usually unstable.

In this work, we revisited the open question of understanding the oxidative decomposition behavior of polymer electrolyte using electrochemical, spectroscopy and chromatographical tools. A capacity-based method was developed to replace current-based LSV method. A reversibility factor (*R*), defined as the ratio between the Faradic (decomposition) charge versus non-Faradic (capacitive) charge during cycling, was established as a reliable reference for the degree of oxidative decomposition below certain cutoff potential. To reproduce the environment in solid-state cathode, a large amount of conductive additive was added into the polymer electrolyte sample and nuclear magnetic resonance (NMR) data suggests the sensitivity of the test is greatly improved. Using poly(ethylene oxide) (PEO) as sample material, the polymer was found gradually decomposing above 3.7 vs. Li/Li^{+} and reaches its practical stability limit around 4.0V vs. Li/Li^{+} with *R*-based test. The result was further confirmed with gel permeation chromatography (GPC), where the PEO sample was allowed to decompose at given voltage. Molecular weight-oxidation potential relation of the partially decomposed PEO shows good correlation with *R*-cutoff potential relation, providing direct support of the validity of the electrochemical test. The method is further verified with a nitrile-based, more oxidatively stable polymer electrolyte, hydrogenated butadiene nitrile rubber (HNBR), and the universality of such test for other polymer electrolytes was proved. HNBR was found decomposing above 3.9 V vs. Li/Li^{+} and reaches stability limit above 4.3 V vs. Li/Li^{+}.

Mixed Ionic-Electronic Conductor for All-Solid-State Lithium-Sulfur Batteries Daiwei Wang, Shiyao Zheng and Donghai Wang; The Pennsylvania State University, United States

All-solid-state Lithium-Sulfur Battery (ASSLB) is one of the protagonists for next-generation energy storage system. The high theoretical capacity of sulfur, the nonflammable characteristics of solid electrolyte and the elimination of shuttle effect endow ASSLSBs with supreme safety, high energy density and long cycle life. However, due to the insulating nature of sulfur, the utilization of active material during cycling is usually low which leads to lower capacity and practical energy density. To resolve this issue, highly efficient ionic and electronic transportation framework needs to be constructed. In all-solid-state sulfur cathode, the weight of solid electrolyte is usually above 40 wt%. While serving as lithium ion conductor,

solid electrolytes generally possess low electronic conductivity (<10^{-8} mS cm^{-1}) which may hinder electron transport in all-solid-state sulfur cathode. Therefore, to improve electronic transportation within sulfur cathode, we have prepared inorganic solid electrolytes with mixed ionic-electronic conductivity and controlled electronic conductivity for ASSLSBs. Specific capacity of the sulfur cathode could increase from below 900 mAh g^{-1} to over 1300 mAh g^{-1} (based on the weight of sulfur) at 0.1 C after employing the prepared mixed ionic-electronic conductive solid electrolyte. Besides, various aspects of the synthesized material and the fabricated sulfur cathode have also been investigated, including material structure and electrochemical evolution, cathode cycling stability, rate capability and etc.

Microstructural Heterogeneities and Interphase Effects on the Chemo-Mechanics of Thiophosphate Solid Electrolytes Marm Dixit[1], Nikhilendra Singh[2], James Horwath[3], Pavel Shevchenko[4], Eric Stach[3], Timothy Arthur[2] and Kelsey Hatzell[1]; [1]Vanderbilt University, United States; [2]Toyota Research Institute of North America, United States; [3]University of Pennsylvania, United States; [4]Argonne National Laboratory, United States

Advances in hybrid and electric vehicle technologies combined with a demand for green initiatives have motivated necessary diversification in energy storage research. To achieve customer expectations for hybrid and electric vehicles, new battery systems with higher energy densities, power densities and cycle life than the current state-of-art Lithium (Li)-ion battery are needed. Post Li-ion battery systems, especially those focused on the utilization of Li metal have recently come to the forefront of research. The ability to directly utilize Li metal anodes in rechargeable batteries presents itself as an ideal situation via the accessibility of a maximum possible theoretical specific capacity (3860 mAh/g) in comparison to commercially used anodes (e.g. graphite – 380 mAh/g). Hence, significant efforts in recent literature have targeted the development of robust Li metal anode systems.
One such system is Li-sulfur which has attracted attention due to its high theoretical capacity (1673 mAh/g) and potential low cost. However, this system is hindered by polysulfide dissolution and electrolyte decomposition at the Li metal anode. Among the various strategies which have been employed to overcome these hinderances, the use of solid-state electrolytes (inclusive of polymers, gels and conducting ceramics) stands out since the implementation of solid-state electrolytes can also serve as a mechanical barrier towards Li dendrite formation. However, solid-state electrolytes exhibit relatively lower ionic conductivities and also display poor interfacial stability towards Li metal anodes. While advances in solid-state electrolyte materials continue to improve their ionic conductivities, little is known about the interfacial interactions between sulfide-based solid-state electrolytes and Li metal. Hence, studies into understanding the interactions between Li metal and these solid-state electrolytes remains essential towards realizing all-solid-state Li battery technologies.
Here, we present a study into the chemo-mechanical transformations within lithium thiophosphates and at their solid-solid interfaces. Tandem analytical ex-situ and in-situ studies via X-ray tomography and transmission electron microcopy are used to reveal the interfacial interactions and failure modes between Li metal and lithium thiophosphates, the deposition and dissolution properties of Li metal from these electrolytes, and the effects of the deposition and dissolution properties on the bulk electrolyte structure. The presented studies allow for comparisons of Li deposition and dissolution properties below and above the critical current densities for each lithium thiophosphate electrolyte material and stand to help clarify interfacial, morphological and failure evolution mechanisms during Li cycling from them.

6:15 AM F.EN06.05.08
Designing Polymers for Stable Interphases in Lithium Metal Batteries Sanjuna Stalin and Lynden Archer; Cornell University, United States

Reactive metal anodes like lithium are known to electrodeposit in the form of irregular morphological features on planar substrates. Formed during the earliest stages of deposition, these features are thought to seed non-planar, mossy structures that proliferate in the electrode spacing, hampering electrode reversibility. A growing body of work suggests that the mechanics, structure, ion transport properties, reductive stability, and interfacial energy of interphases formed spontaneously on the metal electrode play important, but differentiated roles in regulating nucleation, growth, and reversibility of these non-planar structures. Fundamental understanding of the formation mechanisms, mechanical stability, ion transport characteristics, and interfacial properties of solid-electrolyte interphases (SEI), though in its infancy is considered a requirement for progress.
Several approaches have been investigated to mitigate or, in rarer cases completely prevent the growth of lithium dendrites. These include salt additives to improve the properties of the SEI,concentrated electrolytes that change the solvation structure of the ions and resulting SEI formation,single ion conductors that prevent concentration gradients in the bulk electrolyte phase and high modulus electrolytes that prevent dendrite formation via mechanical pressure forces. Tailoring the lithium metal/electrolyte interface with polymer coatings that serve as a protective barrier against chemical and physical instabilities has been gaining a lot of attention in the past few years.

In this talk, we elucidate design rules for elastic interphases formed on any generic metal anode and utilize experiments based on Li metal anodes to evaluate their effectiveness in arresting the various instabilities (*e.g.* morphological, chemical, mechanical/orphaning, and hydrodynamic) known to lower lifetime and reversibility of metal anodes. By combining the experiments with a theoretical stability analysis of metal electrodeposition across elastic interphases, we find that interphase thickness, mechanics, ion transport and interfacial properties all play precise, differentiated roles in setting the optimal interphase design.

6:25 AM F.EN06.05.09
Safety Considerations of Lithium Metal Anodes in Solid-State Batteries Mihir D. Upadhye[1], Alvaro Masias[2,3] and Jeff Sakamoto[1,3]; [1]Univeristy of Michigan, United States; [2]Ford Motor Company, United States; [3]University of Michigan, United States

The introduction of lithium-ion battery technology in 1991 has led to the prevalence of personal electronic devices and the burgeoning electric vehicle space. Advancements in energy density and safety of battery technology will enable further adoption of electric vehicles. Solid-state (SS) battery technology is a leading candidate for the next generation of energy storage in which the liquid electrolyte and polymer separators are replaced with a ceramic ionically conducting solid. While this technology replaces the flammable liquid electrolyte of lithium-based technology, the highly reactive lithium metal and brittle separator materials found in SS battery technology may, ostensibly, introduce other unknown considerations to safety.

Lithium metal is known to be reactive when exposed to water. With the potential application of SS battery technology in electric vehicles, an understanding of lithium metal water exposure in the context of battery architecture is necessary for the adoption of the technology. The reactivity of lithium metal in water has been assessed in various in-situ architectures in the context of existing international battery safety test standards.

Understanding for Charge/Discharge Curves of Commercial Lithium-Ion Batteries Yuhao Lu and Xiao Jie; NingDe Amperex Technology Limited, China

Lithium ion batteries (LIBs) are wildly used for portable electronics and electric vehicles due to the favorable performance compared with other rechargeable batteries. However, their degradation deteriorate their service life remarkably. Fortunately, charge/discharge curves can provide quantitative information for understanding how such degradation correlates with usage conditions and environment of LIBs.
In general, the charge/discharge curves can be divided into two parts, i.e. the open circuit voltage (OCV) and the polarization in the cell. The OCV provides a thermodynamic fingerprint of the electrode which could be roughly estimated by charge/discharge the cell at very low C-rate. With regards to a commonly used 2430 coin cell, the difference between charge/discharge curve and theoretical OCV is less than 30mV at the full range of SOC when a 1/25C current rate is used. In this presentation, the changes in OCV during long cycles will be exhibited, which offers a quantified information on active material decay as well as the side reactions in the cell. The polarization of the cell is strongly affected by the electron and lithium ion transport inside the electrode microstructure. In this work, both the time-domain and the frequency-domain electrochemical methods ware applied to the analysis to distinguish each process onto the polarization in the cell, i.e. the contact problem between the solid phases, the mass transport through the interface and in the solid phase of the electrodes, along with the slow electrochemical reactions. Furthermore, the thermodynamic fingerprints of the positive and negative materials have strongly relation with the polarization in the cell. These relations generally becomes very complex, and thus a mathematical modeling is also used to understand and explain the charge/discharge curve for LIB in detail. Overall, it is proposed that more collaborations could be needed between the academia and industry so that the lithium ion battery degradation could be fully investigated.

5:15 AM *F.EN06.06.02
Performance of High Energy and High Power Commercial Li-Ion Cells for Space Missions Ratnakumar Bugga; California Institute of Technology, United States

Li-ion batteries are being widely used in planetary space missions, owing to their impressive performance characteristics, including high specific energy, long life, and the ability to operate over a wide temperature range. Historically, batteries with custom large-format Li-ion cells of 10-55 Ah have been used in various Mars missions, e.g., Mars Exploration Rovers (Spirit and Opportunity), Mars Curiosity Rover, Mars landers (Phoenix and InSight), Mars and Jupiter orbiters and the upcoming Mars 2020 Rover. However, in several other robotic and human space missions, e.g., Europa Clipper, Artemis missions to moon, and Portable Life Support System (PLSS) for Extra-Vehicular Activities, commercial 18650 Li-ion cells are being used due to their improved specific energies of ~250 Wh/kg (20-50% over custom cells), improved safety from built-in safety devices, modularity, and excellent uniformity, which obviate the need for cell-level control during charging. Several cell types with different chemistries and from different manufacturers are being evaluated at JPL. The cell chemistries differ mostly in cathodes, i.e., either lithium nickel cobalt aluminum oxide (NCA), Li-rich nickel manganese cobalt oxide (Ni-rich NMC) or blends with lithium manganese spinel oxide (LMO). Various performance tests, including cycle life at different depths of discharge, radiation tolerance and high-power characterization at different temperatures are being carried out in conjunction with Electrochemical Impedance Spectroscopy (EIS). In addition, destructive physical analysis of the cells have been performed to analyze the electrode materials, and correlate them with the performance characteristics. Finally, low temperature charge characterization studies have been carried out to ascertain the propensity of lithium plating as a function of charge current and temperature.

5:30 AM F.EN06.06.03
Imaging Pristine Li–Ion Battery Separator Using Low Temperature SEM Luyang Han[1], Markus Boese[1], Jianliu Huang[2], Shuangwen Chen[2] and William Fadgen[3]; [1]Carl Zeiss Microscopy GmbH, Germany; [2]Carl Zeiss (Shanghai) Co., Ltd., China; [3]Carl Zeiss Microscopy, LLC, United States

Separators are an important component within a Li-ion battery cell. They need to mechanically separate anode and cathode within a cell while allowing maximum ionic conductivity of the Li-ion containing electrolyte. Commercially available separators are usually made from polyolefine membranes composed of pores in 10s to 100s of nanometers. The shape, size and distribution of porosity in the separator membrane is a key parameter influencing the performance of the Li-ion battery cell. Due to its small size, scanning electron microscopy is currently the preferred method to directly image and investigate the separators.
However, the separator membrane is highly insulating, and easily gets damaged by the electron beam. Typical SEM imaging condition usually causes significant shrinkage and melting of the porous structure, leading to the wrong measurement of pore size and distribution. In this contribution, we demonstrate a method to image the separator membrane at very low beam energy (< 1 kV) to reduce charging artifacts. Additionally, we use either a Peltier cooler or a liquid nitrogen cooled sample holder to stabilize the specimen against beam damage. The resulting images shows significantly different pore size distribution and surface morphology compared to typical SEM images obtained at room temperature. By optimizing the electron beam energy, scanning method and specimen temperature, an optimum strategy to image the separator membrane is developed to reveal its pristine surface morphology and pore structure.

5:40 AM *F.EN06.06.04
Thermal Conduction in Li-Ion Battery Materials Ankur Jain; The University of Texas at Arlington, United States

Li-ion batteries offer excellent energy conversion rate and high energy storage density in electric vehicles, aircraft, consumer electronics and renewable energy storage. However, these batteries suffer from several safety related problems, as evidenced by recent product recalls and incidents of fires in electric cars and aircraft. Overheating due to poor thermal transport is at the heart of several of these challenges, and therefore, a fundamental understanding of heat transfer in Li-ion battery materials is critically needed. While Li-ion battery materials have been well optimized from the perspective of electrochemistry, the nature of thermal transport in these materials remains relatively less known.

This talk will summarize ongoing research on understanding and optimizing heat transfer in Li-ion battery materials through experiments and theoretical analysis. Measurement of orthotropic thermal conductivity of a Li-ion cell will be described. Measurements of thermal conductivity of the separator of a Li-ion cell will be discussed. Measurements that identify poor thermal transport across the cathode-separator interface as the fundamental root cause of the low thermal conductivity of Li ion cells will be discussed. A molecular bridging approach that reduces this rate-limiting thermal contact resistance by 4X through improved interfacial thermal transport will be discussed. This approach is expected to significantly enhance thermal conductivity of a Li-ion cell. More recent work on enhancement of thermal transport in Gel Polymer Electrolytes (GPEs) through inclusion of BN/Al_2O_3 nano/microparticles will also be discussed. While this approach is shown to improve thermal

conduction in general, a careful optimization of thermal and ionic transport in GPEs will help fully utilize this promising class of materials for next-generation solid-state batteries. Related research on developing predictive models for onset of thermal runaway based on thermal properties of battery materials and kinetics of underlying electrochemical processes will also be discussed briefly.

5:55 AM F.EN06.06.05
Late News: Battery Calorimetric Analysis of Aging Effects on the Safety and Thermal Behavior of Cylindrical Lithium-Ion Cells Carlos Ziebert, Dieter Freis, Zeming Lin, Nils Uhlmann and Hans Jürgen Seifert; Karlsruhe Institute of Technology, Germany

With increasing energy density safety and thermal management of Li-ion cells is becoming more and more important because the thermal runaway can cause an ignition or even explosion with simultaneous release of toxic gases. In order to prevent such hazards, extensive research is undertaken to determine the causes of thermal runaway, as well as the influencing factors. In the last nine years, we have established battery calorimetry as a versatile characterization technique, which allows advancements for the thermal management and the safety of batteries. With six adiabatic Accelerating Rate Calorimeters (ARC) of different sizes and two sensitive Tian-Calvet calorimeters combined with cyclers we operate Europe's largest battery calorimeter center. This enables the evaluation of thermodynamic, thermal and safety data on material, cell and pack level under quasiadiabatic and isoperibolic environments for both normal and abuse conditions (thermal, electrical, mechanical).
The primary purpose of this work was to determine the correlation between cell aging and the thermal runaway of commercial Sony VTC6 18650 cells with a nominal capacity of 3 Ah, a Li-containing graphite anode and a high-Ni $LiNi_{0.9}Co_{0.075}Al_{0.025}O_2$ (NCA) cathode as determined by inductive coupled plasma optical emission spectroscopy (ICP-OES). Therefore, a comprehensive ageing study was performed with 116 cells.
First, fresh cells were stored in temperature chambers at different temperatures and states of charge and then characterized at fixed time intervals in order to study the influence.of this storage on the performance (calendar ageing). Second, cells of the same type were aged in temperature chambers at different charge/discharge rates (cyclic aging) and comprehensively characterized every 100 cycles. The ageing procedure was stopped at a state-of-health (SOH) of 80%. Information on the causes of the aging was obtained using electrochemical impedance spectrometry (EIS), X-ray diffraction and measurement of the entropy changes using the potentiometric method, where the change in the open circuit voltage is monitored against the temperature. The change in entropy showed a capacity-dependent behavior. It was found that the cathode has no signficant influence on the entropy changes and that the anode represents the dominating factor. This allows the determination of the loss of lithium inventory (LLI) in the anode and to correlate the LLI to the total capacity loss. The cathode only showed changes in the charge transfer resistance that was extracted from the EIS spectra.
After these characterizations, the cells were thermally abused using the Heat-Wait-Seek (HWS) test in an ARC. The cyclic aged cells showed increased exothermic reactions in the low temperature range. It is unclear whether these indicate lithium plating or decomposition of the SEI. The absence of these increases with calendar aging, in which plating can be ruled out, means that a larger SEI layer has a small influence on an increased temperature rate. Accordingly, it is assumed that the increase in cyclic aging in the low temperature range is due to a small amount of plating. The aged cells show a vent opening at higher temperatures than the fresh cells and minimal deviations in the temperature rates, which can be attributed to the lower capacity of the aged cells. Thus, it can be concluded that for these cells the safety level is not negatively affected when they reach a SOH of 80%.
The next step is to perform a similar analysis for cells aged until SOH 60% and 40% and to extract electrodes from the aged cells from which coin half cells can be prepared. These cells will then be studied using electrochemical impedance spectroscopy, CV measurements and both isothermal and adiabatic calorimetry.

Multi-Physics Modeling for Characterization of Latent Thermal Runaway Kirsten B. Yapp[1], Charles J. Patrissi[2], Jacob L. Moyar[2], Ryan E. Chamberlin[2], Ugur Pasaogullari[1] and Wilson K. Chiu[1]; [1]University of Connecticut, United States; [2]Naval Undersea Warfare Center Newport, United States

Thermal and electrochemical behavior of a Li-ion battery throughout thermal runaway (TR) is investigated with a goal of understanding the conditions that cause this phenomena in an effort to improve battery safety testing. TR can be caused by multiple methods, but one that is nearly impossible to detect is one triggered by an latent event such as internal short circuit (ISC). This type of initiation mechanism has a low probability, but is still a severe risk when considering the safe use of Li-ion batteries because of the likelihood of catastrophic damage. During TR, the cell temperature increases which initiates and catalyses additional exothermic chemical reactions. These reactions become self sufficient, and if heat cannot be removed quickly enough, the cell fails and can result in ignition. The danger of a single cell TR is that it can propagate through an

entire battery pack because of the close packed arrangement of the cells.
Currently, research on alternative designs to prevent propagation as well as attempts to mitigate TR are being conducted. They are based on information gathered from studies that trigger TR through the use of external heaters which can affect the kinetics of the decomposition reactions in the trigger cell and surrounding cells and exacerbate the TR event and the propagation, respectively. It is clear that in order to improve upon the fidelity of Li-ion safety research, the TR method must be further characterized. This project aims to study the trigger mechanisms relating to ISC caused by point heat source through multi-physics modeling. The results will be applied in future investigations and development of a TR trigger device to be used in Li-ion safety testing.
Initially, the focus will be on thermal modeling to identify the dimensional constraints and power requirements for a local heat source to initiate TR. Specifically regarding heat generation results due to an ISC from anode active material to the positive current collector. Previous research in the field has determined acceptable values for initiating temperatures for electrochemical reactions in the solid electrolyte interface (SEI). These conditions are used as guidelines for the thermal models. The cell and heat source is studied as 1D, 2D, and/or 3D models. Cell layers are represented with accurate material properties, cell geometries for multiple electrode configurations (pouch and cylindrical), and will be paired with realistic cell voltage and impedance. The heat source size, shape, and power conditions will be varied in order to understand where the heat transfers throughout a Li-ion cell, and how long it takes for the temperature of the various components to reach initiation temperature for their respective electrochemical reactions. Simulations are adjusted accordingly until the hot spot results in TR while mimicking real world conditions within the cell. The results will give a more detailed understanding of how an ISC is formed and how it can lead to TR. The generic heat source will later be replaced with the properties of a resistive heating element to be used in the trigger device.
Characterization through simulation is not only convenient, but it also ensures safety during initial research. Thermal modeling will be paired with future electrochemical models for a more complete and accurate representation of a Li-ion cell throughout TR. Future work also includes experiments to further validate these findings. The knowledge gained from this research is vital for understanding the effects of geometry and power on spontaneous TR. Understanding what causes this phenomenon can lead to design innovations for tools meant to identify TR or prevent propagation and the development of mitigation techniques within Li-ion batteries.

6:15 AM F.EN06.06.07
Advanced Single Cell Thermal Runaway Initiation Techniques Joshua Lamb and Loraine Torres Castro; Sandia National Laboratories, United States

The evaluation of lithium ion battery safety has traditionally focused on the performance of single cells exposed to abusive conditions. As lithium ion batteries are fielded in increasingly large and complex systems, the system level safety performance is becoming of greater concern. Testing laboratories and battery end users have begun to consider the hazards associated with a localized thermal runaway event, a single cell or small group of cells, propagating to the bulk of a large battery system. Evaluating this propagating failure requires initiating thermal runaway of a single cell or group of cells and observing how that failure affects the surrounding system.

Ultimately, testing cell to cell propagation requires a method for initiating or simulating single cell runaway while adding a minimum of excess energy into the system. Traditionally single cell failure is initiated with standard battery abuse tests, such as overcharge, thermal ramp and nail penetration tests. However, nail penetration tests can be difficult to perform in fully developed battery systems while overcharge and thermal ramp add a significant amount of excess energy into the battery system. Recent work at Sandia has looked at non-traditional thermal runaway triggers that can be applied to off-the-shelf cells. Single cells were initiated using a fiber coupled laser to create a localized failure on a cell. The ability to initiate single cell failure in both pouch and cylindrical cells is in multiple orientations is demonstrated. Limited cell to cell propagation initiated by the laser is performed as well, demonstrating the technique as a low energy initiation source for propagation testing.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

6:25 AM *F.EN06.06.08
Thermal Runaway Propagation Study on Lithium-ion Cells as Packaged for Transportation Judith Jeevarajan; Underwriters Laboratories, United States

Thermal runaway in lithium-based cells and batteries have been a significant concern during transportation. The ICAO had

set temporary restrictions on transportation to limit the SOC to 30% or less. In parallel, the ICAO commissioned the Society of Aerospace Engineers (SAE) to write a standard that would have test procedures that confirmed that li-based cells in the package as shipped will not become a fire hazard. The test procedure and the verification of test protocols have been looked into in this study. The results obtained as part of this test program will be presented.

Phosphorus-Based Anode Materials via Electrostatic Spray Deposition for High-Performance Lithium-Ion Batteries Amin Rabiei Baboukani[1], Iman Khakpour[1], Vadym Drozd[2] and Chunlei Wang[1]; [1]Florida International University, United States; [2]Center for the Study of Matter at Extreme Conditions (CeSMEC), United States

In the past few years, due to rapidly increased global demand for energy storage devices such as advanced electronics, electric vehicles (EVs), and implantable medical devices, it is essential to develop novel materials for energy storage technologies. Lithium-ion batteries (LIBs) have been the most popular and commercially available energy storage devices. However, anodes of LIBs still suffer poor theoretical capacity of graphite (372 mAh g^{-1}). Recently, phosphorus as an anode material has attained much attention owing to its high theoretical capacity (2596 mAh/g) via Li_3P alloying formation. White P (WP), black P (BP), and red P (RP) are the main three allotropes of solid phosphorus. WP is not stable in the air, flammable, and very toxic, which impose safety concerns for LIBs. BP is the most thermodynamically stable form of phosphorus with an orthorhombic crystal structure. However, the synthesis of BP via high-pressure and high-temperature process is expensive, which restricts its practical application. Compare to WP and BP, RP is non-toxic, low cost, eco-friendly, and easy to handle, making RP a promising anode for LIBs. Nevertheless, the application of RP in LIBs is obstructed by two serious issues: low electrical conductivity of RP ($\sim 10^{-14}$ S cm^{-1}), and huge volume change (more than 300 %) during lithiation and delithiation causing the pulverization of the active materials which leads to significant capacity fading, and poor cycling performance. Compositing phosphorous with carbonaceous materials and construing stable architecture are the two main methods that have been evaluated to resolve the issues and improve the electrochemical performance of P-based electrode materials. Moreover, the chemical bond of P to the conductive matrix could contribute to the integrity of the electrode during cycling In this research, for the first time we developed a binder-free P-based anode materials with sulfurized polyacrylonitrile (SPAN) as functional polymer composite fabricated through ball-milling and electrostatic spray deposition (ESD) method. SPAN-based electrodes have shown attractive electrochemical performance such as good cycling life and Coulombic efficiency due to its chemical compatibility for energy storage devices. In addition, due to the low bonding energy of S-S (265 kJ mol-1) and its high reactivity to form additional chemical bonds with RP, the conductive SPAN could be an ideal composite to increase the conductivity and control the volume expansion of RP in LIBs. The electrochemical performance of the fabricated anode materials evaluated via electrochemical impedance spectroscopy, cyclic voltammetry, and galvanostatic charge/discharge tests. The RP-SPAN hybrid electrode exhibited excellent specific capacity up to 1605 mAh g^{-1} at 0.1 A g^{-1} at 100 cycles, which is one of the best reported performances among the RP-based composite electrode in LIBs. Moreover, a specific capacity of 320 mAh g^{-1} was maintained at 3 A g^{-1}. Due to the SEM images, the hybrid electrode still maintains its microstructural integrity without obvious degradation after cycling, indicating that the volume change didn't affect the structural stability. Our results show that the ESD method is an effective approach to prepare RP-based composite with favorable morphology and composition in order to buffer mechanical stress and alleviate crack formation during cycling. The RP-SPAN hybrid delivered high specific capacity, most likely due to the synergetic effect of chemical bonding and improved kinetics. The developed anode material and its material and electrochemical characterizations will be discussed in detail at the conference.

F.EN06.07.03
Surface Modified Graphite Electrodes for Limiting Lithium Plating and Enabling Fast Charging of Li-Ion Batteries Killian Tallman[1], Bingjie Zhang[1], Shan S. Yan[2], Amy Marschilok[1,2], Kenneth Takeuchi[1], David Bock[2] and Esther Takeuchi[1,2]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

Lithium metal plating on graphite anodes has been identified as a mechanism contributing to diminished capacity retention of

Li-ion batteries under conditions of repeated fast charge. Due to mass transfer limitations, instead of lithium ion insertion in the graphite anode Li metal can deposit on the graphite anode surface when the electrode is highly polarized. The result is inactive Li metal which limits cell cycle life and raises risk of internal short-circuits due to dendrite growth. The objective of this research was to mitigate Li-plating during fast charging by increasing the overpotential of Li-deposition via interfacial surface modification. The hypothesis tested was that deposition of Cu or Ni metal on the surface of graphite electrodes can increase the Li nucleation overpotential due to crystalline mismatch and suppress Li-plating.
Thin metal films of Cu or Ni were deposited on graphite anodes. The films were characterized by a variety of methods including atomic force microscopy, scanning electron microscopy, X-ray photoelectron spectroscopy and X-ray absorption near edge structure spectroscopy. Lithium ion cells with the treated graphite anodes as well as control cells were assembled and evaluated using galvanostatic cycling. Benefit in capacity retention for the treated electrodes was demonstrated. Further, Li-plating was quantified over a series of experiments and supported the electrochemical results. The findings of this study establish that with rational design of an electrode interface, the overpotential for Li-deposition can be modulated, providing a new conceptual approach for reducing Li-plating on graphite anodes.

F.EN06.07.04
Nanocomposite of SnO_2/CeO_2 Nanostructured Electrode for Efficient Li-Ion Storage Application Samuel Danquah, Messaoud Bahoura and Sangram K. Pradhan; Norfolk State University, United States

Cerium oxide (CeO_2) nanocomposite material for Li-ion battery is synthesized using hydrothermal method. To fabricate a hybrid nanostructure electrode, CeO_2 is coated on tin oxide (SnO_2) nanorods (NR), which is grown using a vapor-liquid-solid (VLS) technique on a steel substrate. The structure of SnO_2/CeO_2 nanocomposite was confirmed by X-ray diffraction (XRD), field emission scanning electron microscopy (FESEM). The surface morphology of the hybrid nanostructure electrode confirms that, single-crystalline SnO_2 nanorods are grown vertically with spine-like structures, a few microns in length, as evident from FESEM. The electrochemical performance of SnO_2/CeO_2 shows an enhanced charge storage capability. The coin cell shows improved capacity with a higher number of charging and discharging cycles. This SnO_2/CeO_2 hybrid composite electrode shows better specific capacitance value as compared to the pristine SnO_2 electrode and pristine CeO_2 electrode.

F.EN06.07.06
Nanoscale Three-Dimensional Imaging of Degradation in Composite Si-Containing Anodes Zoey Huey[1,2], Caleb Stetson[1,2], Sang-Don Han[1], Donal P. Finegan[1], Yeyoung Ha[1], Chun-Sheng Jiang[1], Andrew Norman[1], Steven DeCaluwe[2] and Mowafak Al-Jassim[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States

The use of silicon (Si) in the anodes of next-generation lithium ion batteries (LIBs) has the potential to dramatically improve electrochemical performance over current LIBs with graphite anodes, due to the higher specific capacity of silicon.[1] However, widespread implementation of Si-containing anodes is inhibited by issues such as significant volume expansion of Si during lithiation and an unstable solid-electrolyte interphase (SEI), resulting in unreliable performance and poor cycle life. Currently, composite anodes with both Si and graphite active materials are used to increase capacity and mitigate some of the limitations associated with Si. In composite electrodes with a heterogeneous distribution of components with varying electrical properties (including Si, graphite, conductive carbon additive, and binder), it is important to understand the local distribution of each component to correlate with electrochemical processes, particularly localized degradation and heterogeneous aging, and to optimize performance. The heterogeneous distribution of these components leads to localized lithiation, nonuniform SEI formation and material degradation, and complex electron transfer pathways, which all impact anode cycling and performance.

To investigate Si-containing composite anodes in the nanoscale, we employ scanning spreading resistance microscopy (SSRM), a form of scanning probe microscopy (SPM) that probes local electronic resistivities. By examining the contrast in intrinsic electronic resistivity between the anode components, separate phases can be distinguished and understood within the composite structure. Previous work has been conducted on composite Si-graphite electrodes using SSRM, as well as with X-ray tomography, to study degradation after cycling.[2,3] SSRM is able to measure composite electrode components over a wide range of relative intrinsic resistivities with nanometer-scale resolution and a smaller sampling volume than X-ray based methods, making it ideal for distinguishing anode components and determining their spatial positions. This work studies the effects of electrochemical cycling on component distribution and aging by comparing the electrical and structural evolution of composite Si-graphite electrodes before and after charge-discharge cycling. Additionally, we compare the resistivity maps to STEM-EDS and EELS results for both pristine and cycled electrodes to understand chemical changes that occur within the observed structure. By analyzing structural and chemical changes that occur during cycling, we identify degradation mechanisms and potential design improvements to increase capacity and cycle life next-generation composite anodes.

Multiscale Modeling of Ni-Rich Cathode Materials—From Electrons, Ions, Atoms to Particles Yuqin Wu and Yue Qi; Michigan State University, United States

Ni-rich Li[Ni-Mn-Co]O_2 is a promising cathode material due to its high discharge capacity, high voltage and low cost, but its application is hindered by the poor thermal stability and low capacity retention. To guide the design of Ni-rich cathode materials, multiscale modeling analysis was used to determine its atomic structure, band structure, open-circuit voltage, and mechanical properties and to predict the critical size of Ni-rich cathode single particles that are mechanically stable. First, density functional theory (DFT) calculations were performed to identify the base structure of pure $LiNiO_2$ layered compounds based on three different space groups, namely Rm, C_2/m, and P_2/c. It was found the calculated band structures of the widely applied Rm structure of LiNiO2 is metallic, contrary to the experimentally reported insulating behavior. P_2/c structure, which allows a disproportionation of the oxidation state of Ni (Ni^{2+} and Ni^{4+}), is the most energetically stable and insulating layered structure of LiNiO2. Therefore, model structures representing Ni-rich NMC cathode materials were built by partially replacing Ni with Co or Mn in the base P_2/c $LiNiO_2$ structure. The electronic structure of model Ni-rich NMC cathode shows that Ni tends to be Ni^{3+} when neighboring with Co^{3+}, while becoming Ni^{2+} next to an Mn^{4+}. Based on the model Ni-rich cathode structures, the elastic constants and fracture energy were also computed from DFT. The information served as input to a continuum diffusion induced stress model to predict when a crack starts to propagate and leads to the fracture of a single Ni-rich NMC particle. The predicted results show good agreement with single-particle observations.

F.EN06.07.08
Enabling Lithium Metal Anode in Non-Flammable Phosphate Electrolyte with Electrochemically-Induced Chemical Reactions Haochuan Zhang, Jingru Luo, Miao Qi, Haoyi Li and Qi Dong; Boston College, United States

Lithium metal anode holds great promise in the next-generation battery but it suffers from great challenges in efficiency and safety. Previous research has developed various methods to mitigate these issues but most of them are still based on tradition flammable electrolyte systems. Here we demonstrate that reversible Li plating/striping process, which cannot be implemented in non-flammable phosphate electrolyte previously, can be realized by introducing oxygen as an additive in triethyl phosphate (TEP) electrolyte. The symmetric Li||Li cell can achieve more than 300 cycles at current density of 0.5 mA/cm^2 with O_2 existence. Mechanistic study reveals that the electrochemically induced chemical reactions between reactive O_2 species and TEP molecules alter the decomposition pathway of TEP. The possible products, Li_3PO_4/poly-phosphate thereby serve as beneficial SEI components to enable stable Li metal operation in non-flammable electrolyte. Demonstration of Li-O_2 and Li-ion battery also shows that it is promising to deploy phosphate-based electrolyte in future high-energy density batteries efficiently and safely.

Late News: A New Method for Evaluating Li-Ion Battery Anode Materials Based on Surface Compositional and Structural Characterization of Li Thermal Diffusion Jozef Ociepa, Paige Harford, Ryan Charlinski, Guenevere O'Hara and Bart Checinski; OCI Vacuum Microengineering Inc., Canada

There is a global effort to develop safer lithium-ion batteries with a high energy density and long lifetime. Material properties, their mutual interactions, and active interfaces are key factors in battery performance. Popular methods involve the mixing of different ingredients and development of a suitable fabrication process. Significant effort has been spent to understand the reaction mechanism of battery materials, but this is very challenging due to high system complexity. Different techniques have been developed to follow these reactions, and most significantly, the reactions between Li and electrode materials. Our team has developed a new method to characterize Li thermal diffusion and structural interaction on the surfaces of potential anode and cathode materials. This method is based on surface crystallographic and compositional characterization of deposited ultra-thin film of Li on potential single crystal anode material. For surface crystallography we

are using Low Energy Electron Diffraction (LEED) and for composition Auger Electron Spectroscopy (AES). This characterization monitors Li diffusion into the electrode surface and changes in surface crystalline structure and composition providing data on Li interaction with the crystalline anode material structure. This dynamic interaction of Li is monitored at the nanoscale level and gives the direct response how Li atoms interact with the substrate. The diffusion of evaporated Li on single crystals of HOPG, Si(111)-(211)-(100), SiC-6H, Diamond and LiNbO3 have been performed. The results shows that HOPG is the excellent reference substrate for this method as Li diffuses at room temperature and surface crystallography of HOPG remains unchanged. The structural reaction of Li with Si is very strong causing LEED pattern to disappear and there is no Li diffusion at room temperature. The data for SiC-6H and LiNbO3 shows better Li diffusional behavior than on Si but not as good as on HOPG. This method of using a single crystal substrate and basic surface characterization techniques is providing simple nanoscale access into the chemical reactions between Li and the substrate material that will result in better understanding of diffusional Li respond to high capacity anodes with new chemistry content.

F.EN06.07.12
Late News: Structure and Electrochemistry of Transition Metal Substituted Lithium Vanadyl Phosphate for Lithium-Ion Batteries Krystal J. Lee, Marc Francis V. Hidalgo, Yanxu Zhong, Mateusz Zuba, Natasha Chernova, Guangwen Zhou, Hao Liu and M.S. Whittingham; Binghamton University, United States

Li-ion intercalation compound enlisting multi-electron redox is a promising strategy to maximize the storage capacity of LIBs. Lithium vanadyl phosphate, $LiVOPO_4$, is one such material that can intercalate up to two Li^+ ions per vanadium ion through the change in vanadium valence from V^{5+} to V^{3+}, which translates to a theoretical capacity of 305 mAh/g and an energy density above 900 Wh/kg. However, Li-ion intercalation in the high voltage region (V^{5+}/V^{4+}) is kinetically limited by the sluggish Li-ion diffusion, and thus impedes the use of $LiVOPO_4$ in practical applications. Transition metal substitution has been a technique used to enhance the performance of battery cathodes by changing its intrinsic properties and stabilizing the crystal structure. The goal of this work is to explore experimentally if substitution with chromium and niobium can enhance the electrochemical performance of $LiVOPO_4$. X-ray diffraction and inductively coupled plasma atomic emission spectroscopy indicate the substituent is successfully incorporated into the structure. The effects of transition metal substitution on the crystal structure and the electrochemical performance of $LiVOPO_4$ will be discussed.

F.EN06.07.13
Molybdenum Disulfide Anode of Lithium-Ion Battery for High Stability and Rate Capability Chanho Park, Han S. Kang, Seung Won Lee, Hyeokjung Lee, Kyuho Lee and Cheolmin Park; Yonsei University, Korea (the Republic of)

Development of a lithium-ion battery (LIB) is of great interest with an anode based on transition metal dichalcogenide nanosheets due to their intrinsically high capacity. The stability of a LIB is, however, detrimental with the nanostructured MoS_2 anode resulting from the gradual decrease of electrical conductivity with time due to the re-stacking of the nanosheets. In this work, we present a novel MoS_2 anode with molecularly architecture graft polymer binder having functionalized groups, enabling the high stability of a LIB. The fluorinated graft polymer synthesized by one-step atomic transfer radical polymerization allows not only for exfoliating MoS_2 nanosheets in the liquid phase to guarantee the stable sheet-to-sheet separation by preventing re-aggregation but also for providing self-assembled ionic channels through which lithium ions in electrolyte readily reach close to the surface of the nanosheets. The electrochemical reduction of lithium ions efficiently occurs at the layered nanostructure of MoS_2 facilitated by the functionalized polymer binder, giving rise to a high-performance LIB with the high rate capability and stability. Our binary anode of MoS_2 nanosheets self-assembled with the graft polymer enables high cell capacity even without the requirement of conductive additives which are frequently employed for ensuring high conductivity and thus comparable cell capacity, making our approach one-step closer to commercial energy applications.

Chemical and Mechanical Stability Issues at Electrolyte/Electrode Interfaces in Solid-State Batteries Gerbrand Ceder[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Stringent chemical and mechanical constraints apply to the interfaces in solid state batteries. They have to be (electro)chemically stable against the chosen electrode materials and applied potentials. In addition, they have to be tolerant to the various mechanical issues that occur in solid state batteries such as electrode swelling/shrinking, stress concentrations at current focusing areas etc. I will present the requirements for chemically stable interfaces between various cathode and electrolyte materials and discuss to what extent coatings can address chemical incompatibility. A repeated stripping and plating of a lithium metal anode presents significant challenges. I will present results from modeling to understand the interplay between current density, stress, and lithium growth through the electrolyte. Our results indicate that in good conductors the build-up of stress to the point that it fractures the electrolyte is unlikely, indicating that other mechanisms are responsible for lithium penetration through the solid electrolyte. We also find that conductivity of the solid electrolyte plays a central role in the mechanical reliability of a solid-state battery.

12:30 PM *F.EN07.01.01
All-Solid-State Batteries—Hype vs Reality Y. Shirley Meng; University of California, San Diego, United States

All-solid-state batteries (ASSBs) have attracted enormous attention as one of the critical future technologies for safe and high energy batteries. With the emergence of many highly conductive solid electrolytes in recent years, the bottleneck is no longer Li-ion diffusion within the electrolyte. Instead, many ASSBs are limited by their low Coulombic efficiency, poor power performance, and short cycling life due to the high resistance at the interfaces within ASSBs. In this talk, I will highlight the complex characteristics of interphases, namely the composition, distribution, and electronic and ionic properties of the cathode−electrolyte and electrolyte−anode interfaces. We emphasize the significant role of chemo-mechanical behavior of the interfaces, especially when the ASSBs under constant stack pressure. Multiscale and multimodal characterization methods to explore, diagnose, and understand the dynamic and buried interfaces and interphases are essential to pave the pathway for practical high-energy ASSB.

From Bonding Interactions in Solid Electrolytes to Solvent-Influences on the Performance of Solid-State Batteries Wolfgang Zeier; University of Muenster, Germany

The advent of solid-state batteries has spawned a recent increase in interest in lithium conducting solid electrolytes, especially in the lithium thiophosphates. However, many open questions remain when trying to optimize electrolytes and understand solid state battery chemistries.

In this presentation, we explore the influence of inductive effects in superionic conductors showing that in $Li_{10}GeP_2S_{12}$, these can strongly affect the ionic transport.
We further show a better understanding of the structure-transport properties of the novel lithium and sodium rare-earth halides that show promising ionic conductivities for their use in solid state batteries.
Lastly, we show how solvent treatment of the lithium argyrodite Li_6PS_5Cl affects battery performance despite having no influence on the structural stability, suggesting stronger influences of slurry processing than previously believed.

9:00 AM *F.EN07.01.04
Towards a Fast Charging 4 V Class All-Solid-State Battery Corsin Battaglia; Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland

All-solid-state batteries combining an alkali metal anode and a high-voltage cathode have the potential to achieve high energy density. However, interface stability remains a major challenge. On the anode side, dendrite formation limits the maximum plating current density and prevents fast charging, while on the cathode side the limited oxidative stability of most solid electrolytes is a major challenge, especially when the battery is charged beyond 4 V.
Here we demonstrate that the critical current density for dendrite formation in the archetypical ceramic solid electrolyte Na-β"-alumina is ten times higher than that measured on a garnet-type $Li_7La_3Zr_2O_{12}$ electrolyte under equivalent conditions and reaches up to 12 mA/cm^2 at room temperature [1]. Further, we show that above the melting temperature of sodium, a cumulative capacity of >10 Ah of sodium can be plated and stripped at an enormous current density of 1000 mA/cm^2 without dendrite formation [2].
On the cathode side, we have been developing hydroborate solid electrolytes reaching ionic conductivities >1 mS/cm at room temperature [3]. We already demonstrated the integration of these electrolytes with a 3 V class cathode [4, 5], but recently managed to obtain stable cycling with a 4 V class cathode via a self-forming passivating interface [6]. Combined with their low gravimetric density <1.2 g/cm^3, low toxicity, high thermal and chemical stability, stability vs lithium and sodium metal anodes, soft mechanical properties enabling cold pressing [4], compatibility with solution infiltration [7], and potential for low cost [8, 9], hydroborate electrolytes represent a promising option for the cathode side of a competitive future all-solid-state battery.

Towards Solid-State Batteries for Electric Vehicles Marca M. Doeff; Lawrence Berkeley National Laboratory, United States

All solid-state batteries with lithium anodes have the potential of outperforming lithium-ion batteries with respect to energy density, safety, and reliability. However, considerable challenges exist, particularly for ceramic-based electrolytes, with regards to their design for vehicle applications. The thin film configurations that currently exist have low practical energy densities, are difficult to scale, and require expensive vacuum technologies. To overcome these difficulties, we have been using a scalable freeze tape casting method to produce porous garnet scaffolds that can be co-sintered with thin, dense components to form bilayers. The scaffold is then infiltrated with active material and other components, and lithium is attached to the other side of the bilayer to form a cell. The use of a secondary soft electrolyte obviates the need for a co-sintering step, which carries with it the risk of adverse reactions between the active material and the garnet. Batteries prepared this way may be able to achieve specific energies in excess of 400 Wh/kg. We will discuss what still needs to be done to make this a reality.

All-Solid-State Batteries—Hype vs Reality Y. Shirley Meng; University of California, San Diego, United States

All-solid-state batteries (ASSBs) have attracted enormous attention as one of the critical future technologies for safe and high energy batteries. With the emergence of many highly conductive solid electrolytes in recent years, the bottleneck is no longer Li-ion diffusion within the electrolyte. Instead, many ASSBs are limited by their low Coulombic efficiency, poor power performance, and short cycling life due to the high resistance at the interfaces within ASSBs. In this talk, I will highlight the complex characteristics of interphases, namely the composition, distribution, and electronic and ionic properties of the cathode−electrolyte and electrolyte−anode interfaces. We emphasize the significant role of chemo-mechanical behavior of the interfaces, especially when the ASSBs under constant stack pressure. Multiscale and multimodal characterization methods to explore, diagnose, and understand the dynamic and buried interfaces and interphases are essential to pave the pathway for practical high-energy ASSB.

Towards Solid-State Batteries for Electric Vehicles Marca M. Doeff; Lawrence Berkeley National Laboratory, United States

All solid-state batteries with lithium anodes have the potential of outperforming lithium-ion batteries with respect to energy density, safety, and reliability. However, considerable challenges exist, particularly for ceramic-based electrolytes, with regards to their design for vehicle applications. The thin film configurations that currently exist have low practical energy densities, are difficult to scale, and require expensive vacuum technologies. To overcome these difficulties, we have been using a scalable freeze tape casting method to produce porous garnet scaffolds that can be co-sintered with thin, dense components to form bilayers. The scaffold is then infiltrated with active material and other components, and lithium is attached to the other side of the bilayer to form a cell. The use of a secondary soft electrolyte obviates the need for a co-sintering step, which carries with it the risk of adverse reactions between the active material and the garnet. Batteries prepared this way may be able to achieve specific energies in excess of 400 Wh/kg. We will discuss what still needs to be done to make this a reality.

Solid-State Lithium-Ion Battery with Mixed 2D and 3D Electrodes David Ashby[1], Christopher Choi[2], Martin Edwards[3], A. Talin[1], Henry White[3] and Bruce S. Dunn[2]; [1]Sandia National Laboratories, United States; [2]University of California, Los Angeles, United States; [3]University of Utah, United States

It is well established that the miniaturization of batteries has not kept pace with the miniaturization of electronics. Three-dimensional (3D) batteries, which were developed with the intent of improving microbattery performance, have had limited success because of fabrication challenges and material constraints. Solid-state, 3D batteries have been particularly susceptible to these shortcomings, as conformal electrolytes for 3D configurations suffer from either having low conductivity or having interfacial reactions that lead to high electrolyte-electrode ionic resistances. In the work reported here, we overcome these solid electrolyte limitations by using an ionogel electrolyte, a subclass of solid electrolytes comprised of a room temperature ionic liquid electrolyte confined within an inorganic matrix. The high conductivity of the ionogel electrolyte (10^{-3} S cm^{-1}) ensures sufficient ion transport for high power densities.
Rather than using a 3D geometry, we selected a different platform that not only demonstrates the benefit of a non-planar electrode configuration but also enables easier fabrication using established materials and processes. Specifically, we constructed a solid-state 2.5D battery consisting of a 3D $LiFePO_4$ (LFP) post array and a planar, Li anode separated by the ionogel electrolyte, which forms around the individual LFP posts and, while in the sol state, penetrates the 3D electrode array. The ability to process the ionogel as a liquid, which then gels to a macroscopic solid phase while maintaining the liquid-like behavior at the nanoscale, satisfies the conformality and wetting issues often required for complex electrode architectures. This 2.5D battery offers high areal energy densities from the post array while the high conductivity solid electrolyte enables high power densities (4 mWh cm^{-2} at 2.8 mW cm^{-2}). These values for the 2.5D solid-state microbattery exceed the energy and power densities of any 3D solid-state system. In addition, the battery exhibited minimal capacity loss when cycled at 0.5 mA cm^{-2} over 50 cycles and complementary interfacial studies show that the 2.5D battery avoids the interface impedances which have limited other solid-state 3D battery systems. A multiphysics model derived for the 2.5D geometry provides guidance for achieving significantly higher energy and power densities.

5:45 AM *F.EN07.01.04
Towards a Fast Charging 4 V Class All-Solid-State Battery Corsin Battaglia; Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland

All-solid-state batteries combining an alkali metal anode and a high-voltage cathode have the potential to achieve high energy density. However, interface stability remains a major challenge. On the anode side, dendrite formation limits the maximum plating current density and prevents fast charging, while on the cathode side the limited oxidative stability of most solid electrolytes is a major challenge, especially when the battery is charged beyond 4 V.
Here we demonstrate that the critical current density for dendrite formation in the archetypical ceramic solid electrolyte Na-β”-alumina is ten times higher than that measured on a garnet-type $Li_7La_3Zr_2O_{12}$ electrolyte under equivalent conditions and reaches up to 12 mA/cm^2 at room temperature [1]. Further, we show that above the melting temperature of sodium, a cumulative capacity of >10 Ah of sodium can be plated and stripped at an enormous current density of 1000 mA/cm^2 without dendrite formation [2].
On the cathode side, we have been developing hydroborate solid electrolytes reaching ionic conductivities >1 mS/cm at room temperature [3]. We already demonstrated the integration of these electrolytes with a 3 V class cathode [4, 5], but recently managed to obtain stable cycling with a 4 V class cathode via a self-forming passivating interface [6]. Combined with their low gravimetric density <1.2 g/cm^3, low toxicity, high thermal and chemical stability, stability vs lithium and sodium metal anodes, soft mechanical properties enabling cold pressing [4], compatibility with solution infiltration [7], and potential for low cost [8, 9], hydroborate electrolytes represent a promising option for the cathode side of a competitive future all-solid-state battery.

Material Development and Manufacturing Strategies For Solid-State Batteries based on Sulfide Solid Electrolytes Josh Buettner-Garrett; SolidPower, United States

Solid-state batteries have emerged as the most promising contender to displace conventional Li-ion batteries in applications such as electric vehicles with their potential for greater energy density and improved safety. In order to transition from hype to true disruptor however, significant performance, manufacturing, and cost advancements must still be demonstrated. The electrolyte is the most important component of a solid-state cell, and it must combine high conductivity with anode and cathode compatibility and allow for high-throughput cell production. Oftentimes, the highest conductivity sulfide electrolytes are compatible only with graphite or higher voltage LTO anodes which limits the energy density advantages of the solid-state cell. Likewise, most inorganic solid-state cells today require production methods such as high-temperature sintering or warm isostatic pressing that are not compatible with the Li-ion production infrastructure that has been critical in driving down costs in recent years.

Solid Power is addressing each of these challenges by combining its novel sulfide electrolytes with manufacturing that closely mirrors that of Li-ion mass production today. Solid Power has a truly all-solid material set based on electrolytes that deliver 2-9 mS/cm at room temperature with stability against both Li metal anodes and Ni-rich NMC cathodes. This presentation will cover key aspects of material design for solid-state cells with an emphasis on manufacturability. Solid Power's pilot roll-to-roll production line will be introduced along with performance of cells produced on the line. Solid Power is currently producing multi-layer pouch cells up to 20 Ah in capacity with an eye toward early electric vehicle qualification. The presentation will also include a discussion of low temperature performance, quick charge capability, and abuse testing.

Chemical and Mechanical Stability Issues at Electrolyte/Electrode Interfaces in Solid-State Batteries Gerbrand Ceder[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Stringent chemical and mechanical constraints apply to the interfaces in solid state batteries. They have to be (electro)chemically stable against the chosen electrode materials and applied potentials. In addition, they have to be tolerant to the various mechanical issues that occur in solid state batteries such as electrode swelling/shrinking, stress concentrations at current focusing areas etc. I will present the requirements for chemically stable interfaces between various cathode and electrolyte materials and discuss to what extent coatings can address chemical incompatibility. A repeated stripping and plating of a lithium metal anode presents significant challenges. I will present results from modeling to understand the interplay between current density, stress, and lithium growth through the electrolyte. Our results indicate that in good conductors the build-up of stress to the point that it fractures the electrolyte is unlikely, indicating that other mechanisms are responsible for lithium penetration through the solid electrolyte. We also find that conductivity of the solid electrolyte plays a central role in the mechanical reliability of a solid-state battery.

5:15 AM *F.EN07.02.03
From Bonding Interactions in Solid Electrolytes to Solvent-Influences on the Performance of Solid-State Batteries Wolfgang Zeier; University of Muenster, Germany

The advent of solid-state batteries has spawned a recent increase in interest in lithium conducting solid electrolytes, especially in the lithium thiophosphates. However, many open questions remain when trying to optimize electrolytes and understand solid state battery chemistries.

In this presentation, we explore the influence of inductive effects in superionic conductors showing that in $Li_{10}GeP_2S_{12}$, these can strongly affect the ionic transport.
We further show a better understanding of the structure-transport properties of the novel lithium and sodium rare-earth halides that show promising ionic conductivities for their use in solid state batteries.
Lastly, we show how solvent treatment of the lithium argyrodite Li_6PS_5Cl affects battery performance despite having no

influence on the structural stability, suggesting stronger influences of slurry processing than previously believed.

5:30 AM F.EN07.02.04
Conformal Solid Electrolytes for Beyond Li-Ion Solid-State Batteries Ramsay B. Nuwayhid, Angelique J. Jarry, Alexander C. Kozen, Gary Rubloff and Keith E. Gregorczyk; University of Maryland, United States

We will discuss the development of Na-ion and K-ion conducting films using atomic layer deposition (ALD) and their progress towards nanoscale solid-state batteries (SSBs) based on more abundant alkali metals such as sodium and potassium. Building upon our achievement with 3D Li-ion SSBs[1], the enabling feature of which was the development of a lithium phosphorus oxynitride (LiPON) solid-state electrolyte (SSE)[2], we present two new solid electrolytes for Na-ion and K-ion batteries. The ALD process for these films can be generalized to involve the thermal reaction of the respective alkali *tert*-butoxide (XO^{t}Bu, X = Li, Na, K) with diethylphosphoramidate (DEPA). The NaO^{t}Bu-DEPA process produced a sodium phosphorus oxynitride (NaPON) film, analogous to its cousin LiPON. Surface analysis by X-ray photoelectron spectroscopy revealed that the NaPON (Na_4PO_3N) film closely resembled that of LiPON (Li_2PO_2N), containing similar atomic ratios (N/P = 1) and two nitrogen species (=N– and >N–), deeming their classification as phosphazenes.[3] However, the KO^{t}Bu-DEPA process resulted in a potassium phosphate (KPO) film containing ~1% nitrogen and a considerable amount of carbon incorporation. Electrochemical analysis through electrochemical impedance spectroscopy (EIS) was employed to probe the materials ionic transport behavior. NaPON displayed an ionic conductivity of 1.0×10^{-7} S/cm at 25 °C and up to 2.5×10^{-6} S/cm at 80 °C, with an activation energy of 0.53 eV. The ionic conductivity and activation energy of NaPON are in close agreement with that of ALD LiPON and other ALD-fabricated Li-ion conductors. EIS measurements of KPO displayed a lower ionic conductivity of 7.4×10^{-9} S/cm at 25 °C, which is attributed to loss of nitrogen in the obtained structure. The NaPON and KPO ALD processes represent the first ALD synthesized Na-ion and K-ion conducting films. A holistic review of LiPON, NaPON, and KPO will be presented, ranging from their reaction mechanisms to their structure and ionic transport properties. Lastly, we will focus on the aim of obtaining a 3D Na-ion SSB enabled by the NaPON SSE. This includes consideration of the conformality of NaPON in nanoporous structures, electrochemical stability, and demonstration of planar Na-ion SSBs with thin-film electrodes.

5:40 AM F.EN07.02.05
Reduction of Solid Electrolyte-Electrode Interfacial Impedance in Lithium-Ion Batteries Through a Buffer Layer Joseph Sullivan and Arijit Bose; The University of Rhode Island, United States

Lithium ion batteries (LIBs) typically utilize organic liquid electrolytes, but their flammability often places limits on their use. Solid electrolytes may alleviate concerns regarding flammability, but the interfacial resistance between a solid electrolyte and an electrode is one major hindrance for their application. The introduction of a buffer layer at the electrode-electrolyte interface may reduce this resistance and improve battery performance. In this work, an acetonitrile containing buffer layer was introduced between a graphite anode and a PEO-LiTFSI electrolyte. This electrode was examined in a half-cell configuration. Impedance spectra for cells with and without the buffer layer were obtained at assembly and after three charge/discharge cycles. At assembly, the interfacial impedance of the cells with a buffer layer was reduced by 25% when compared to unbuffered cells, and it continued to decrease as the cells were cycled. Improved contact between the active material and electrolyte is a potential reason for the lowered interfacial impedance. The addition of a buffer layer shows promise towards the goal of making an all-solid LIB with acceptable electrochemical performance.

5:50 AM F.EN07.02.06
Substrate Strain Enhances the Reversible Cycling of Thin-Film Electrodes Ananya Renuka Balakrishna and Delin Zhang; University of Southern California, United States

Solid-state batteries have a potential to enhance energy density and offer greater safety when compared with the conventional

Li-ion batteries. However, a bottleneck with using a solid-state electrolyte lies in mechanically integrating the solid-state electrolyte with the active materials (electrodes). For example, inserting and extracting Li into electrode lattices expands electrode materials upto 10% in volume. These chemo-mechanical strains in the electrode induces misfit stresses at the electrode/electrolyte interfaces, which weaken the structural integrity and electrical conductivity of the battery material composite. In today's talk, we will show how epitaxial strains in thin-film electrodes can be engineered to deter delamination. We develop a continuum model to explore the interplay between phase-transformation microstructures and substrate strains in thin-film electrodes. We apply this model to the vanadium-oxide system, and show how tensile straining of electrodes deters delamination and enhances reversible cycling of electrode materials. We plot a "phase-diagram" for thin-film electrodes as a function of battery voltage and substrate strain—this plot identifies a narrow-range of electro-mechanical boundary conditions under which a thin-film electrode can be repeatedly cycled with minimum mechanical degradation. Broadly, our work provides a battery design framework to mechanically engineer electrodes, and to enhance battery safety and lifespan.

6:00 AM F.EN07.02.07
Effect of Gas Environment on Interfacial Degradation Between Al Doped $Li_7La_3Zr_2O_{12}$ Electrolyte and $LiNi_{0.6}Mn_{0.2}Co_{0.2}O_2$ Cathode Younggyu Kim and Bilge Yildiz; Massachusetts Institute of Technology, United States

Conventional Li-ion batteries using liquid electrolytes suffer from inherent safety issues due to poor thermal stability of liquid electrolytes. Development of All-solid Li-ion Batteries by substituting liquid electrolytes to non-flammable solid electrolytes can solve this issue. $Li_7La_3Zr_2O_{12}$(LLZO) has been considered as a major candidate for making safe and high capacity cells due to its high ionic conductivity and chemical compatibility with Li anode.
However, cathode side instability still needs to be overcome. Co-sintering is needed to gain good contact between cathode and LLZO, and to reduce contact resistances. However, this process leads to formation of detrimental Li-insulating interphases. Despite the computational studies on layered oxide cathode|LLZO predicting low chemical reactivity, many experimental studies including works from our group, show formation of detrimental secondary phases at the interface during sintering. Moreover, predicted decomposed phases do not match with experimental findings.
The discrepancy comes from the effect of gas environment, which was not addressed in former computational or experimental works. Recent works from our group addressed the detrimental role of the CO_2 in the gas environment, on the interface stability of on $LiCoO_2$|LLZO, $LiNi_{0.6}Mn_{0.2}Co_{0.2}O_2$|LLZO interfacial stability. Li_2CO_3 formed in both systems because of reaction with CO_2(g) in ambient air. This is precursor to the formation of Li-deficient detrimental secondary phases such as $La_2Zr_2O_7$ and La containing perovskite phases, $LaCoO_3$, $La(Ni,Co)O_3$.
In this work, we systematically investigated effect of gas environment by annealing samples in pure O_2, humidified O_2 (O_2 with 2wt% H_2O), N_2, and CO_2 gas environments. Humidified O_2 and CO_2 environment were chosen to unravel effect of H_2O(g) and CO_2(g). We chose N_2 to investigate possibility of using it as a low-cost alternative for pure O_2 environment. We deposited thin film(~100nm) $LiNi_{0.6}Mn_{0.2}Co_{0.2}O_2$ on top of solid electrolyte by RF sputtering, and post-annealed samples to simulate the sintering process. The sample design placed interfacial region within detection depth of X-ray Absorption Spectroscopy. This thin film approach enabled us to detect the onset of interfacial degradation, even when formed secondary phases lack crystallinity. We correlated results from chemical characterization techniques (X-ray Absorption Spectroscopy, X-Ray Diffraction) with Electrochemical Impedance Spectroscopy to quantify the effect of interfacial degradation on cell performances.
The result showed that O_2 environment enables the best stability, and actually improves the interface. Interfacial resistance decreased as annealing temperature increased in O_2, and interface remained chemically stable up to 700°C. Annealing in N_2 environment also showed chemical stability up to 700°C as no secondary phases were observed. However, we could see slight reduction from the sample, showing that N_2 environment is less favorable compared to pure O_2. We found that annealing at 500°C in humidified O_2 led to hydration of the sample, causing interfacial resistance increase. However, we also observed interfacial resistance decrease along with dehydration at 700°C, showing that the detrimental effect of H_2O(g) can be avoided with sufficiently high sintering temperature. CO_2 environment was shown as most detrimental, as we observed total loss of cathode|electrolyte capacitance, together with major degradation products. This comparison concludes that avoiding CO_2 is important for maintaining a well adhered cathode-LLZO interface that transfers Li ions fast.
We acknowledge funding from U.S. Army Research Office through Institute for Solider Nanotechnologies. (Cooperative Agreement Number W911NF-18-2-0048)

6:10 AM F.EN07.02.09
Late News: Towards Enhanced Oxidative Stability for Na-Solid State Electrolytes via Halogenation—The Case of Na4(CB11H12)2B12Br12 Fabrizio Murgia[1], Marc Nierstenhöfer[2], Matteo Brighi[1], Carsten Jenne[2] and Radovan Cerny[1]; [1]Université de Genève, Switzerland; [2]Bergische Universität Wuppertal, Germany

Seeking better performing solid-state electrolytes for post-Li batteries, complex hydride-based compounds have recently drawn attention thanks to several remarkable properties. They show chemical robustness and good thermal stability, but also superior oxidative stability and lower density with respect to oxides and sulphides.[1][2] Interestingly, such class of materials displays order-disorder phase transitions that dramatically increases the ionic conductivity, achieving superionic regime ($\sigma >$ 1 mS cm^{-1}).[3] However, such rearrangement generally occurs far from room temperature (*rt*), thus limiting practical applications. Therefore, increasing the disorder in the structure to lower the phase transition towards ambient temperature is the key for further development. To do so, the combination of two different hydroborate salts can result in a new phase that decreases/suppresses the phase transition, achieving fast cation motion even at *rt*.[4]
Recently, electrochemical studies on a wide series of binary anion mixtures based on *closo*- and carba*closo*-hydroborates pointed out that their oxidative stability is limited to the decomposition voltage of the less stable anion.[5] As an example, in the $Na_4(CB_{11}H_{12})_2(B_{12}H_{12})$, which shows the highest oxidative stability of the pool, the practical voltage window corresponds to the oxidation of the $[B_{12}H_{12}]^{2-}$ cage.[6] It was already demonstrated that complete halogenation of a $[B_{12}H_{12}]^{2-}$ leads to a framework less prone to the oxidation, thus potentially enhancing the overall electrochemical stability while employed in a solid-state conductor. On this basis, the novel phase $Na_4(CB_{11}H_{12})_2B_{12}Br_{12}$ obtained by complete bromination of $Na_2[B_{12}H_{12}]$ and subsequent solid-state high-energy ball-milling with $Na[CB_{11}H_{12}]$ will be presented. DC conductivity at *rt* is found to be 0.8 mS cm^{-1}, while reaching 2.2 ms cm^{-1} at 40°C. Temperature-dependent electrochemical impedance spectroscopy reveals a non-Arrhenius behavior of the DC conductivity between – 50°C and 150 °C, although without any conductivity jump due to order/disorder phase transition. Crystal structure analysis using temperature-dependent synchrotron powder diffraction will be also presented. The electrochemical characterization of the oxidative stability by means of slow-rate scan cyclic voltammetry evidenced a wide voltage window up to 4.35 V *vs.* Na^+/Na. Such improvement opens the gate to the use of high-voltage positive electrodes, such as $Na_3V_2(PO_4)_2F_3$ (NVPF), thus achieving post-Li solid-state batteries with more competitive electrochemical performance.

6:20 AM F.EN07.02.10
Late News: Towards the Development of Air-Stable Li-La-Zirconate Based Solid Electrolyte Exhibiting Minimal Electrode/Electrolyte Interfacial Resistance for All-Solid-State Li-Ion Batteries Sushobhan Kobi, Amardeep Amardeep, Akhilesh Vyas, Parag Bhargava and Amartya Mukhopadhyay; Indian Institute of Technology Bombay, India

Despite being considered promising as a potential solid electrolyte for solid-state Li-ion batteries, Al-doped Li-La-Zirconate (LLZO) suffers from compositional/structural instability in the presence of moisture. In this regard, our prior work has indicated that the formation of $La_2Zr_2O_7$ in the bulk (in addition to Li_2CO_3 formation at surface) of Al-doped LLZO upon exposure to air leads to structural/mechanical instability and spontaneous cracking/disintegration due to the development of internal stresses [Kobi *et al.*; *J. Eur. Ceram. Soc.* 38 (2018) 4707]. This causes reduction in the Li-ion conductivity by at least ~3 orders of magnitude within 3 weeks of exposure to air. In order to address this major problem, earth abundant Mg has been attempted as a dopant, fully or partially replacing the Al-dopant [Kobi *et al.*; *J. Electrochem. Soc.* 167 (2020) 120519, Amardeep *et al.*; *Scripta Mater.* 162 (2019) 214]. As has been realized, Mg-doping also allows stabilization of the desired cubic garnet phase at room temperature, leading to almost similar Li-ion conductivity as for Al-doped LLZO. More importantly, Mg-doping supresses, in significant terms, the formation of deleterious phases and associated cracking upon long term exposure to air; thus causing no notable reduction in the Li-ion conductivity even after more than 3 weeks of air exposure. The outstanding air stability, concomitant absence of impurity phases at the surface and good Li-ion conductivity cast their influence also on the interfacial resistance at electrode/electrolyte interface. Thus, the optimized Al/Mg co-doped LLZO exhibits a very low area-specific resistance of ~18 Ω cm^2; which is also among the lowest reported to-date, sans any additional surface/interfacial engineering.

6:30 AM F.EN07.02.11
Late News: An Investigation into Failure Mechanisms for a Novel Li-Ion Solid-State Electrolyte Tofunmi Ogunfunmi[1],

Nnaemeka Ebechidi[2], Ridwan Ahmed[1], Oluwaseun K. Oyewole[1], John Obayemi[1] and Winston Soboyejo[1,2,1]; [1]Worcester Polytechnic Institute, United States; [2]African University of Science and Technology, Nigeria

Solid-state batteries are generally considered to be safer than their liquid-state counterparts due to their decreased potential for fire or short circuiting. The fabrication of solid-state batteries relies on the application of stack crimping pressure that increases the interfacial surface contacts between electrolytes and the electrodes. However, excessive compressive crimping stresses (that occur in cell assembly) can give rise to cracking phenomena that can degrade battery performance and lead to thermal runaway or failure. It is, therefore, important to develop an understanding of failure mechanisms in solid-state Li-ion electrolytes. In this paper, we use a combination of in-situ optical microscopy and Digital Imaging Correlation (strain mapping) techniques to study compressive deformation and cracking phenomena in a novel solid state Li-ion electrolyte. The stress states associated with the different stages of compressive deformation are also presented along with those due to charge-discharge cycles. The implications of the results are discussed for the material design of robust solid-state Li ion batteries.

Advancement of Low Temperature Ceramic Synthesis for Solid State Battery Components and Cells—A Personal Love Story Jennifer Rupp; Massachusetts Institute of Technology, United States

Next generation of energy storage devices may largely benefit from fast and solid Li^+ ceramic electrolyte conductors to allow for safe and efficient batteries and fast data calculation. For those applications, the ability of Li-oxides to be processed as thin film structures and with high control over Lithiation and phases at low temperature is of essence to control conductivity. Through this presentation we review the field from a new angle, not only focused on the classics such as Li-ionic transport and electrochemical stability window for Li-solid state battery electrolytes, but focusing on opportunities and challenges routes in thermal and ceramic processing of the components and their assemblies with electrodes. Also, we will carefully review and give perspectives on the role of solid state battery ceramic strategies for the electrolyte on the electrode interfaces and towards charge transfer and vs. current densities. In other words, it will be a little ceramicist (own) love story on the good and the evil we can design by smart ceramic design at the interfaces originating by the very first choices made in the electrolyte ceramic structure and material design. In the second part of the talk we will discuss new opportunities on low temperature processing of solid state electrolyte ceramics that do not technically require “classic sintering” and avoid prior particle calcination; instead demonstrating opportunities to use liquid based direct densification routes and vacuum techniques to design solid electrolytes and grafting interfaces to new hybrid and solid state battery prototypes targeted at processing below 700C for all parts. Collectively, the insights on solid state energy storage provide evidence for the functionalities that those Li-solid state material designs can have for cost and mass manufacturable solid state and hybrid battery prototypes.

10 Seconds Ultrafast High Temperature Sintering (UHS) for High Performance Solid-State Electrolytes and Batteries Liangbing Hu; University of Maryland, United States

We recently reported an ultrafast high temperature sintering (UHS) for solid state electrolytes (Science, 2020, May Cover). In this talk, I will discuss our progress in applying the UHS in the following various aspects for solid state batteries.

(1) High-performance solid-state electrolyte. The long sintering time of conventional syntheses can lead to Li loss in garnet SSEs caused by the evaporation of Li and the formation of secondary phases that lead to lower ionic conductivity. In contrast, the UHS technique enables us to tune the sintering time in units of seconds, which provides excellent control in terms of the Li content and grain growth. I will discuss our progress on applying UHS method to sintering various solid-state electrolyte, from compositions to microstructures. By programming the temperature and time (T-t), we can establish process diagrams to sinter porous vs. dense structures.

(2) Printed thin film solid-state electrolyte. I will talk about a solution-based printing process followed by rapid (~3 seconds) high-temperature (~1500 °C) reactive sintering for the fabrication of high-performance ceramic SSE films. The SSEs exhibit a dense, uniform structure and a superior ionic conductivity of up to 1 mS/cm, comparable to the bulk conductivity.

(3) Multilayer solid-state electrolyte and electrolyte-electrode co-sintering for solid state batteries. The rapid sintering also allows us to sintering multilayer solid-state electrolytes with significantly reduced interlayer diffusion.

A UMD spinoff, HighT-Tech LLC, is commercializing the above inventions (www.highT-tech.com).

5:30 AM F.EN07.03.03
Ultrafast High-Temperature Sintering (UHS) Process for Solid State Electrolytes Chengwei Wang and Liangbing Hu; University of Maryland, United States

Ceramic-based solid-state electrolytes (SSEs) are attractive materials for improving battery safety. To develop improved ceramic SSEs, computational predictions based on first principles methods can be a valuable tool in accelerating materials discovery. Experimental confirmation is essential after such predictions; however, materials screening rates are limited by the long processing time of conventional ceramic synthesis and sintering techniques, which are also prone to poor compositional control due to volatile element loss. To overcome these limitations in ceramic synthesis and processing, we report an ultrafast high-temperature sintering (UHS) process for the fabrication of ceramic materials by radiative heating that features a record-high temperature of up to 3,000 ^{o}C and an ultrafast heating rate of up to 100,000 ^{o}C/minute. The UHS method can directly sinter oxide precursors into solid, dense ceramics in seconds. Compared with previous fabrication techniques, the UHS process is >100–1000-times faster (e.g., reducing the sintering time from hours to ~10 s). As a result, we are able to achieve excellent compositional control of ceramics containing volatile components (e.g., Li in solid-state electrolytes), as well as prevent uncontrolled grain growth for outstanding material performance. Additionally, the UHS process provides excellent sintering at material interfaces with limited interdiffusion, which are essential for devices such as thin film batteries. Furthermore, this technique is compatible with 3D printing to produce novel ceramic structures and devices that are otherwise impossible to achieve by other rapid sintering methods. Finally, the UHS process is universal, allowing us to synthesize a wide range of new ceramic materials with novel composition and structure. This technique has the potential to transform and expand the discovery of ceramic compounds, with significant impacts for rapid materials screening and solid-state batteries.

High Toughness Ceramic Nanocomposite Electrolytes Christos E. Athanasiou, Mok Yun Jin, Cristina Ramirez, Nitin Padture and Brian Sheldon; Brown University, United States

The low fracture toughness of ceramic solid electrolytes can significantly limit battery performance and reliability. While small dimensions are generally needed for faster ion transport, these length scales also restrict the approaches that can be used to improve fracture resistance. Nanoscale reinforcements are thus a logical option for improving the fracture resistance of ceramic electrolytes. Reduced graphene oxide (rGO) and hexagonal boron nitride (hBN) have been successfully used to reinforce a variety of polymer and engineering ceramics, where significant changes in the elastic modulus and toughness have been obtained with relatively low volume fractions. In this talk, the reinforcement capability of small amounts of rGO and hBN added to oxide-based lithium-ion conductors will be discussed. Furthermore, a framework to assess the relevant toughening length scales and to provide guidelines for designing toughened solid electrolytes using nanomaterials will be presented.

Thin-Film Microfabrication for High Performance 3D Solid-State Batteries David M. Stewart, Haotian Wang, Victoria C. Ferrari, Keith E. Gregorczyk, Sangbok Lee and Gary Rubloff; University of Maryland, United States

Research from our Nanostructures for Electrical Energy Storage (NEES) Energy Frontier Research Center has shown that 3D architectures are key to enhanced performance in thin film batteries. As thin film processing and patterning have expanded to include battery materials, microfabrication is increasingly capable of creating high performance 3D solid state batteries (3D-SSBs). We have recently fabricated and studied two archetypal 3D-SSB designs: one employing multiple, coplanar battery layers and one using vertical channels of concentric batteries. Our experimental results validate the benefits of both 3D architectures for simultaneous high power and high energy.

Here we first summarize these results and highlight the distinctly different process sequences necessary for fabrication of the different 3D-SSBs. We then present new results from multiphysics modeling and simulation (COMSOL) that allow us to scale the energy and power metrics to different dimensions and configurations of the two designs. The electro-chemo-mechanical models also provide the basis for further examining the consequences of the 3D design. Calculations of the local stress distribution, Joule heating at high power, and transport properties at nano- and mesoscale will be shown. We find that although the physics is the same, the geometric differences play a large role in the ultimate performance of the 3D-SSBs.

These results indicate that 3D-SSBs may exceed the performance of conventional liquid electrolyte cells and also thin film solid-state batteries that use thick composite electrodes and sintered electrolytes, because thin film fabrication (1) enables designs optimized for simultaneous high power and energy and (2) minimizes excess and passive materials that do not contribute to performance. Results show that multilayer 3D thin film batteries can produce 2-3X higher energy density and 10X higher power density than conventional batteries. From these we share an emerging picture of cell design rules for further development of 3D-SSBs.

5:00 AM *F.EN07.04.01
Polymer Electrolytes for Lithium-Ion and Future Emerging Battery Technologies Julia Wellmann[1], Junli Shi[1], Tong Zhang[1], Miaomiao Liang[1], Ava Hosseinioun[1], Balasubramanyian Rajagopalan[1], Huu-Dat Nguyen[2], Zhen Chen[3], Dominik Steinle[3], Xin He[1], Jie Li[4], Jean-Yves Sanchez[5], Dominic Bresser[3], Cristina Iojoiu[2] and Elie Paillard[4]; [1]Forschungszentrum Jülich GmbH, Germany; [2]Université Grenoble Alpes, France; [3]Karlsruhe Institute of Technology, Germany; [4]Politecnico di Milano, Italy; [5]University Carlos III de Madrid, Spain

Polymer gel electrolytes have been widely used in lithium-ion batteries since 1999, where they compete with liquid electrolytes. However, they do not fully qualify as solid-state electrolytes, since they are used in combination with separators and, despite common claims concerning safety, they are mostly used to improve the cohesion between battery elements and help the wetting of the separator onto which the polymers (usually PVDF-HFP) are coated. On the other hand, commercial lithium metal batteries use solvent-free (PEO-based) solid polymer electrolytes (SPEs) without any separator, but the operation temperature for automotive application of SPEs is limited to > 70°C since the electrolyte is not sufficiently conductive at room temperature. Besides, solvent-free SPEs suffer from low anodic stability, which restricts the energy density of Li metal polymer batteries.
Research on SPEs has long been targeting single-ion conductors to prevent the establishment of concentration gradients and the resulting increase in electrolyte resistance and ultimately, the lithium depletion at metallic anodes, responsible for the fast growth of dendrites. However, until recently, these single-ion SPEs suffered from the same drawbacks as regular *salt-in-polymer* SPEs, with high operation temperatures and a limited anodic stability that prevents the use of high energy cathodes. On the other hand, studies on gel electrolytes are less clear regarding their aims, as they are often use unsubstantiated safety claims that are only fully valid for 'dry' SPEs.[1]
Thus, an overview of recent results on gel and polymer electrolytes for various types of batteries will be given. In particular, the use of non-fluorinated polymer matrixes such as crosslinked polymethacrylic acid (PMMA) to form gel electrolytes *in situ* for state-of-the-art lithium-ion batteries [2,3](or its fluorinated ionomeric version for forming crosslinked single-ion conductor gels) will be discussed. Besides, non-fluorinated and cheap ionomers such as lithium polyacrylate (LiPAA) were also proposed as *water-in-ionomer* electrolytes for high voltage aqueous lithium-ion batteries [4]. Finally, for next generation

lithium metal batteries, nanophase separated single-ion conductors membranes were easily processed from aromatic polyethersulfone block copolymers to allow high lithium plating current densities (*i.e.* 2 mA cm^{-2} at 20°C) and to enable the operation of high voltage lithium metal battery down to 0°C. Finally, since PEO presents considerable advantages in terms of cathodic stability, especially critical for divalent cation batteries (*i.e.* Ca-metal) the strategies to allow for high voltage cathode operation in combination with PEO will be discussed as well.

Acknowledgments
The research has been partially done within the VIDICAT project, funded by the European Commission under GA n°829145 within the Horizon 2020 programme.

Long-Cycle-Life Solid-State Batteries with PVDF-Based Electrolytes Liangliang Li, Xue Zhang, Chuanjiao Xue, Yang Shen and Cewen Nan; Tsinghua University, China

Solid-state lithium (Li) metal batteries based on solid polymer electrolytes are attracting a lot of interest due to good safety and high energy density. Among various polymer electrolytes, poly(vinylidene fluoride) (PVDF)-based electrolytes present higher ionic conductivity, large mechanical strength, and good electrochemical and thermal stability. In this talk, we will discuss the influence of (inorganic or organic) additives and residual solvent on the performance of the electrolytes as well as solid-state lithium metal batteries. A small amount of solvent [e.g., N,N-dimethylformamide (DMF)] is left in the electrolytes to bond with Li ions as Li-DMF complexes, not as free solvent, which could promote the Li-ion transport with the assistance of PVDF chains. Thus, by tuning the solvation effect and/or the synergistic effect with additives, the overall performance of the PVDF-based electrolytes including ionic conductivity, electrochemical stability window and stability against a Li anode can be significantly enhanced. With the fine-tuned PVDF-based electrolytes, the solid-state lithium metal batteries with a $LiFeO_4$ or $LiCoO_2$ cathode can possess a long cycle life of 1000 cycles and a high capacity retention at room temperature.

5:30 AM F.EN07.04.03
Pendent Polymer Electrolytes with Hydrocarbon Backbone and Li^+-Conducting Side Chains Yubin He, Nian Liu and Paul Kohl; Georgia Institute of Technology, United States

Solid polymer electrolytes (sPE) offer a pathway for safer, less flammable lithium batteries. However, developing a polymer that provides high Li^+ mobility as well electrochemical stability remains a challenge, because ion conductive functional units in the polymer main-chain (e.g., polycarbonate and polyether) usually suffer from poor electrochemical stability at high and low potentials. In the first part of this presentation, I will show our design and synthesis of an sPE with pendent carbonate on a hydrocarbon backbone, that has excellent conductivity and electrochemical stability simultaneously. This pendant polycarbonate is different from conventional polycarbonate electrolytes because the carbonate moiety is in the sidechain, which mitigates the stability problem of polycarbonate backbone while still providing high ionic conductivity when used with a plasticizer. Ionic conductivity as high as 1.1 mS/cm was obtained at 22°C. Stable lithium metal plating using and stripping using the sPE was observed for 1,200 hours and electrochemical stability up to 4.6 V vs Li^+/Li has been demonstrated. The low interfacial resistance (<160 ohm cm^2 at 22°C) and reasonable ionic conductivity have enabled acceptable cycling performance in a Li-$LiFePO_4$ battery at 0.98 mA/cm^2 for 2,300 cycles. In the second part of this presentation, I will show our second-generation pendent polymer electrolyte with a block co-polymer structure, to enable facile tuning of the properties. This presentation is based on our recent publications:

5:40 AM F.EN07.04.04
Ionic Conductivity Enhancement Induced by Crystallization Alignment in Polymer Electrolytes Changhao Liu, Yangyang Wang, Jong Keum and Xi C. Chen; Oak Ridge National Laboratory, United States

Solid state electrolyte is the key component to enable the successful use of solid state lithium metal batteries. Poly(ethylene oxide) (PEO)-based solid polymer electrolyte is a promising candidate with advantages including flexibility, chemical stability, and combability with large-scale manufacturing[1]. However, PEO-based electrolytes have a relatively low room temperature conductivity, between 10^{-9}-10^{-5} S/cm, which is attributed to PEO crystallization[1]. The randomly oriented, non-conductive PEO crystalline lamellae increase the tortuosity of the conduction pathway and hinder ion transport in the amorphous phase[2].
In this work, our objective is to improve the room-temperature ionic conductivity of PEO-based electrolytes by decreasing the tortuosity of the conduction pathway through alignment of the PEO crystalline phase. We use PEO/$LiCF_3SO_3$ (EO to Li molar ratio is 16:1) as our model polymer electrolyte. In order to achieve alignment of the PEO crystalline phase, a hot-draw method is implemented for the first time to achieve the desired alignment of PEO lamellae. The polymer electrolyte film is heated to above PEO's melting temperature in N_2 environment followed by hot drawing till a desired strain is reached. The sample is then cooled down to room temperature to allow for crystallization with the strain maintained during the crystallization process. The hot-draw method enables a shape-stable membrane even after the tensile stress is released. Wide angle X-ray scattering (WAXS) experiments show that as the hot draw strain increases to 200%, the orientation of PEO's (120) and (032) planes are observed. As a result, the through-plane conductivity increases by over a factor of 2. The effect of hot draw strain, temperature, and crystallization rate will be discussed.

Conditioning Hybrid Organic-Inorganic Solid Electrolytes for Improved Cation Mobility Vazrik Keshishian and John Kieffer; University of Michigan, United States

Conventional lithium ion batteries that use liquid electrolytes are not very desirable due to lack of chemical stability, safety issues and cost of production. Solid state electrolytes (SSEs) not only have the potential to correct these drawbacks, but improve performance characteristics such as energy density and power density can also be improved. To simultaneously achieve high ionic conductivity and mechanical stiffness, a composite materials design approach for creating the novel SEEs is indicated. Here we report on our development of hybrid organic-inorganic electrolytes, in which a silica backbone is formed by sol-gel synthesis routes to provide a mechanically rigid backbone. The fluid in this nano-porous structure is subsequently replaced with polymer solutions. The polymer is grafted onto the backbone through reactive groups, and thus anchored into structure to establish the ion conducting phase. This unique approach allows us to decouple the influence of mechanical properties on ionic transport properties of materials and achieve both high elastic stiffness and ionic conductivity. Recently we discovered that the network structure of a gel-cast material can be further conditioned by influencing the structural evolution during drying, such as changing sample aspect ratio. This means of processing control appears to introduce a beneficial directionality in the structure that ensues. Here we will elucidate the structural developments that take place and how they lead to improved charge carrier mobility. Acknowledgment: NSF DMR-1610742

6:00 AM F.EN07.04.06
Solvent-Mediated Synthesis of Amorphous Li_3PS_4/PEO Composite Solid Electrolytes with High Li^+ Conductivity Ethan C. Self[1], Zachary Hood[2], Teerth Brahmbhatt[3], Frank M. Delnick[1], Harry M. Meyer III[1], Guang Yang[1], Jennifer Rupp[4] and Jagjit Nanda[1]; [1]Oak Ridge National Laboratory, United States; [2]Argonne National Laboratory, United States; [3]The University of Tennessee, Knoxville, United States; [4]Massachusetts Institute of Technology, United States

A critical challenge for solid-state batteries (SSBs) is the development of solid electrolytes (SEs) with high Li^+ conductivity and good chemical/mechanical compatibility with Li metal anodes and high voltage cathodes. Crystalline β-Li_3PS_4 (LPS) represents a promising SE candidate for next-generation SSBs due to its high ionic conductivity (*e.g.*, 1.6×10^{-4} S/cm at room temperature). However, a major bottleneck for this material is the lack of scalable processing methods to produce β-LPS films, which are typically fabricated using top-down approaches such as cold pressing. Furthermore, the nano-/polycrystalline structure of many LPS-based SEs leads to nonuniform current densities across the LPS/Li interface and Li

dendrite propagation during battery operation.
This presentation will discuss the synthesis and characterization of a new class of composite LPS/poly(ethylene oxide) (LPS/PEO) solid electrolytes which are completely amorphous and exhibit Li^+ ionic conductivities up to 1×10^{-6} S/cm at room temperature. The presence of the PEO component facilities the material's processability, and synthesis conditions can be tuned to suppress crystallization of the β-LPS phase at elevated temperature (140 – 200 °C). This presentation will describe how the structure (studied using cryo-TEM, vibrational spectroscopy, and neutron scattering) and composition of LPS/PEO composites impact their Li^+ conductivity and viability for SSBs.

Data-Driven Discovery of New Materials for Solid-State Batteries Yifei Mo; University of Maryland, United States

All-solid-state Li-ion battery based on solid electrolytes is a promising next-generation battery technology with high energy density, intrinsic safety, long cycle life, and wide operational temperatures. However, the lack of solid electrolyte materials that satisfy multiple requirements, such as high ionic conductivity, good stability, and interfacial compatibility with the electrode, are impeding the development of this new battery technology. To resolve these materials challenges, we develop and leverage an array of data-driven computation techniques including machine learning to discover and design novel solid-state Li-ion conductors as solid electrolytes for all-solid-state batteries. The data-driven approach enables rapid searching over a large materials space of tens of thousands of materials with highly diverse structures and chemistries. Dozens of novel solid-state conductors are discovered through our data-driven materials search. Our data-driven analyses provide unique insights into the fundamental understanding about solid-state Li-ion conductors beyond traditional physical mechanistic studies. Our study demonstrates a new paradigm of using machine learning techniques for materials discovery that overcome the data-scarcity challenges.

5:15 AM *F.EN07.05.02
Computational Materials Design for Solid-State Li and Na Ionic Conductors Yan E. Wang[1,2,3]; [1]Samsung Research America, United States; [2]Massachusetts Institute of Technology, United States; [3]Lawrence Berkeley National Laboratory, United States

All-solid-state batteries are increasingly seen as essential for next-generation energy applications in consumer electronics and electric vehicles. Intense research effort has been devoted to designing safe, high energy density, long-life all-solid-state batteries. A major challenge has been to find solid electrolyte materials that can both support superionic conduction [1] and great interfacial stability against battery electrodes [2]. Sulfide-based solid-state electrolyte materials have demonstrated high ionic conductivity that exceeds the conductivity of liquid electrolytes. However, the stability of sulfides is rather limited and their instability and toxicity upon air or water exposure is a potential safety concern from battery industry's point of view. Oxide materials, on the other hand, have shown excellent air and electrochemical stability, but the ionic conductivity is generally lower than sulfide materials.

The ability of computational modeling based on density-functional-theory methods to accurately predict intrinsic properties of solid electrolyte materials has made modeling a critical tool for understanding the behavior of solid electrolytes and their integration in solid-state batteries [3]. Computational approaches have enabled the efficient design and discovery of new functional materials with desired properties, such as low cost, high alkali ionic conductivity, great phase and electrochemical stability, accelerating the development of all-solid-state batteries.

In this talk I will present recent findings in the physical and chemical design principles for solid-state electrolyte materials

with high ionic conductivity and stability with solid-state battery electrodes. More specifically, I will discuss crystallographic features in solid-state conductors which would enable fast ionic transport. I will also show progress of applying high-throughput screening in the computational design and discovery of lithium, sodium solid-state electrolytes and coating materials.

Solid-State Chemistries Stable with High-Energy Cathodes for Lithium-Ion Batteries Adelaide M. Nolan, Yunsheng Liu and Yifei Mo; University of Maryland, United States

The continued improvement in operating time and lifetime of electric vehicles and portable electronic devices require higher energy density in lithium ion batteries. The energy density of lithium-ion batteries can be increased by implementing high-voltage cathodes, but these cathodes are reactive and unstable during cycling with the electrolyte. To design coatings or solid electrolytes that can stabilize these cathodes, an understanding of how different chemistries interact with high-voltage cathodes is critically needed. We systematically evaluate the thermodynamic stability of a broad range of solid-state chemistries with common cathodes [1]. A materials trade-off is found in that materials stable with lithiated cathodes are often unstable with delithiated cathodes, which limits the possible choice of materials stable throughout the cycling voltage. These computational findings reaffirm previously demonstrated coating and solid electrolyte chemistries and suggest that several new chemistries, including lithium phosphates and lithium ternary fluorides, are promising solid-state chemistries stable with high-voltage cathodes. Our study provides guiding principles for designing coating and solid electrolyte materials with long-term stability with high-voltage cathodes for lithium-ion batteries.

5:40 AM F.EN07.05.04
Accurate Machine-Learning Models for the Atomic-Scale Simulation of Doped LLZO Solid Electrolytes Qian Wang[1,2], Alexander Urban[1] and Nongnuch Artrith[1]; [1]Columbia University, United States; [2]Beijing University of Posts and Telecommunications, China

Cubic garnet structure Li7La3Zr2O12 (LLZO) and doped LLZO show great promise as solid electrolytes for the next-generation solid-state Li-ion batteries due to their relatively high stabilities and bulk Li conductivities. The Li transport mechanism in the crystalline bulk structure of LLZO is well understood. However, the cell performance also depends critically on the Li transport in defected and non-crystalline LLZO phases that occur at grain boundaries or in the interphases near the electrodes. Characterizing Li transport in the narrow interphase regions is experimentally challenging, and the complex atomic structures of these phases also typically prevent first-principles modeling.
Here we develop a machine-learning (ML) model that enables the large-scale atomistic simulation of complex LLZO structures with near first-principles accuracy at a fraction of the computational cost. The model is based on an artificial neural network (ANN) potential trained on density-functional theory (DFT) reference data with an approach that we have previously developed [1-3], and it can be used to study the Li migration in crystalline and non-crystalline LLZO phases. The ANN potential has been constructed to describe defected LLZO and Al/Ga-doped LLZO compositions, since doping is needed to stabilize the cubic LLZO phase that exhibits good Li conductivity. The model is thoroughly validated by comparison with DFT calculations, confirming that our ANN potential is reliable for molecular dynamics simulations of complex LLZO structures with different Al/Ga dopant concentrations.
Our accurate and efficient LLZO ANN potential will form the basis of an extended ML approach for the modeling of grain boundaries, solid-electrolyte interphases, and cathode-electrolyte interphases in LLZO-based solid-state batteries.

5:50 AM F.EN07.05.05

Novel Solid-State Li-Ion Conductor by Computational Design and High-Throughput Screening Wonseok Jeong[1], Seungwu Han[1] and Youngho Kang[2]; [1]Seoul National University, Korea (the Republic of); [2]Incheon National University, Korea (the Republic of)

All-solid-state Li-ion batteries are receiving great attention because of various advantages such as enhanced safety, high energy density, and high durability. Up to date, several solid-state electrolytes (SSEs) including $Li_{10}GeP_2S_{12}$, $Li_7La_3Zr_2O_{12}$, and $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ have been proposed from previous experiments or computational screening from publicly available materials databases. However, none of those SSEs are fully satisfactory due to insufficient ionic conductivity, chemical or mechanical instabilities.
In this work, using DFT calculations, we take one step further. Instead of simply exploring a pre-existing materials database, we carry out a large scale high-throughput screening of potential Li-ion conductors that can display the high ionic conductivity upon aliovalent substitution. Aliovalent substitution of the non-Li cation in Li compounds is known to enhance the ionic conductivity greatly, by enabling the diffusion of Li-ions to occur in a concerted manner.[1] Starting with 15,654 ternary compounds, we identify 436 materials to meet the various preliminary chemical, topological, and bandgap criteria. For these materials, we seek potential high-energy sites for extra Li ions that are introduced to compounds when an aliovalent substitution occurs, considering structural or local potential information. Then, we explicitly add Li-ions on the confirmed high-energy sites and evaluate their vibrational frequency to assess the smoothness of the potential energy surface (PES) on which the extra Li-ions will move. Based on several materials giving rise to low vibrational frequencies, i.e., smooth PES, we create the new crystal structures by substituting non-Li elements with lower valencies and adding extra Li-ions. Finally, we examine their Li-ion conductivities using ab-initio molecular dynamics simulations. As a result of the computational design and high-throughput screening, we suggest candidate SSEs, one of them are predicted to have high Li ionic conductivity of 19 mS/cm, the large bandgap of 6.8 eV, and the energy above hull as low as 9 meV/atom, which exceeds the performance of the state-of-the-art $Li_{10}GeP_2S_{12}$.

Modeling the Electrical Double Layer at Solid-State Electrochemical Interfaces Michael W. Swift[1], James W. Swift[2] and Yue Qi[1]; [1]Michigan State University, United States; [2]Northern Arizona University, United States

Models of the electrical double-layer (EDL) at electrode/liquid-electrolyte interfaces no longer hold for all-solid-state electrochemistry. In this work, a new model for the EDL at a solid-state electrochemical interface based on the "Poisson-Fermi-Dirac equation" is formulated. By combining this model with density functional theory predictions, the interconnected electronic and ionic degrees of freedom in all-solid-state batteries, including the electronic band bending and defect concentration variation in the space-charge layer, are captured self-consistently. Along with a general mathematical solution, the EDL structure is presented in various materials that are thermodynamically stable in contact with a lithium metal anode: the solid electrolyte LLZO and the solid interlayer materials LiF, Li_2O, and Li_2CO_3. The model further predicts the optimum interlayer thicknesses to minimize the electrostatic barrier for lithium transport at relevant solid-state battery interfaces.

Strain Effect on Li-Ion Conductivity of β-Li_3PS_4 Assessed by *Ab Initio* Molecular Dynamics Study Pjotrs Zguns and Bilge Yildiz; Massachusetts Institute of Technology, United States

Electrochemo-mechanical strains are inherently present at electrode-electrolyte interfaces in solid-state Li-ion batteries. This originated from electrode expansion/contraction during battery charge/discharge, as well as volumetric changes due to interfacial reactions and electrolyte decomposition [1]. These strains reach ~3% (~10 GPa stresses) [1]. It is important to quantify how these strains affect Li-ion conduction, detrimental or beneficial, to understand their implication on battery performance. Here we investigate biaxial strain effect on Li-ion conductivity of bulk β-Li_3PS_4, sulfide solid-electrolyte, as a model system. We use Ab Initio Molecular Dynamics to quantify strain impact within elastic regime (± 2%). In response to biaxial strain, depending on the crystallographic-plane of strain (*xy*, *yz*, *zx*) and temperature (550–650 K), Li-ion diffusivity can decrease or increase up to a factor of 2. Extrapolations to room temperature indicate that up to ~5-fold conductivity increase can be anticipated. This is comparable to impact of chemical doping and Li-off-stoichiometry in this material [2]. Atomistic mechanism behind the response of Li-ion diffusivity to strain is also being assessed, based on disorder and phonon modes [3].

Correlating Structure and Dynamics in Solid Electrolytes by NMR Spectroscopy Sylvio Indris; Karlsruhe Institute of Technology, Germany

The correlation between structure and dynamics in different Li and Na solid electrolyte materials was investigated by a combination of different nuclear magnetic resonance (NMR) techniques, including magic-angle spinning NMR, temperature-dependent NMR lineshape analysis, NMR relaxometry, and field-gradient NMR. In that way, we are able to investigate the dynamics of Li or Na ions on different time scales from some nanoseconds to a few seconds, and thus we can observe the local hopping of these charge carriers as well as the long-range transport over several micrometers.
Some examples will be given for Li_3PS_4, Li_6PS_5Cl, $Li_{0.29}La_{0.57}TiO_3$, and NASICON structures for Li and Na electrolytes [1-7]. The results of these NMR experiments are compared to those obtained by impedance spectroscopy and different diffraction techniques in order to obtain information about the diffusion pathways in these crystal structures and the energy landscapes probed by the mobile ions.

LGPS-Type Sulfide Solid Electrolytes Ryoji Kanno, Satoshi Hori, Kouta Suzuki and Masaaki Hirayama; Tokyo Institute of Technology, Japan

All-solid-state is an ideal configuration of batteries. The solid electrolyte is a key technology for the development of all-solid-state batteries. Among the electrolytes proposed, the sulfide system is a candidate because of its high ionic conductivity. The LGPS ($Li_{10}GeP_2S_{12}$) electrolyte exhibits a high bulk conductivity of over 10^{-2} S cm^{-1} at room temperature and is promising for applications requiring batteries with high power and energy densities [1]. Moreover, material variations of the LGPS electrolytes provided suitable combinations of the electrodes and the electrolyte. For example, the LGPS-group materials, such as $Li_{9.54}Si_{1.74}P_{1.44}S_{11.7}Cl_{0.3}$ and $Li_{9.6}P_3S_{12}$, provided high power and high energy density to the all-solid-state cells [2]. These results derive from the intrinsic nature of the solid electrolytes, indicating the advantages of the all-solid-state devices over conventional electrochemical devices.
Systematic substitutions of the constituent elements were examined after the first report of $Li_{10}GeP_2S_{12}$. The simplest substitution system was Si and Sn analogs. Solid solutions of the Ge-Si, Ge-Sn, and Si-Sn systems were examined. Among the substitution systems, the lithium tin-silicon system with $Li_{10.35}[Sn_{0.27}Si_{1.08}]P_{1.65}S_{12}$ showed high ionic conductivity which is comparable to the original LGPS material. On the other hand, the LGPS-type structure also appeared in the L-P-S ternary

system. $Li_{9.6}P_3S_{12}$ with the LGPS-type showed high electrochemical stability which might be used for low potential ranges such as Li and carbon anode.
Partial substitution of the anion-site was studied for the halogen and oxygen systems. The oxygen and halogen substitution generally improved the electrochemical stabilities. The oxygen doped Li-P-S-O system showed higher electrochemical stability. Based on a wide composition range of the materials search, the LGPS materials were also found in the Li-A-P-S-X (A: Si, Ge, Sn, X: halogen) and Li-P-S-X (X: halogen) systems. For example, $Li_{9.54}Si_{1.74}P_{1.44}S_{11.7}Cl_{0.3}$ showed the highest conductivity of 25 $mScm^{-1}$ at room temperature. The halogen substitution systems of the L-P-S-X systems developed electrochemical stability.
The present study summarizes the materials varieties and formation ranges of the LGPS materials in these ternary and quaternary systems. In addition to the variety of the materials, the electrolyte-electrode combination which is another important parameter to achieve high battery characteristics is summarized. We also indicate the properties of the all-solid-state cells using these LGPS-type solid electrolytes with various anode and cathode systems.

Understanding How Crystallographic Defects Govern the Charging Distribution in Solid Cathode Materials Zhengrui Xu and Feng Lin; Virginia Tech, United States

Crystallographic defects exist in many redox active energy materials, e.g., battery and catalyst materials, which significantly alter their chemical properties for energy storage and conversion. In this presentation, we will address how these defects, e.g., grain boundaries and geometrically necessary dislocations, govern the charging distribution in solid layered oxide cathodes. The presentation will be divided into two sections, each addressing a specific defect type.
Architecting grain crystallographic orientation can modulate charge distribution and chemomechanical properties for enhancing the performance of polycrystalline battery materials. However, probing the interplay between charge distribution, grain crystallographic orientation, and performance remains a daunting challenge. Herein, we elucidate the spatially resolved charge distribution in lithium layered oxides with different grain crystallographic arrangements and establish a model to quantify their charge distributions. While the holistic “surface-to-bulk” charge distribution prevails in polycrystalline particles, the crystallographic orientation-guided redox reaction governs the charge distribution in the local charged nanodomains. Compared to the randomly oriented grains, the radially aligned grains exhibit a lower cell polarization and higher capacity retention upon battery cycling. The radially aligned grains create less tortuous lithium ion pathways, thus improving the charge homogeneity as statistically quantified from over 20 million nanodomains in polycrystalline particles. This study provides an improved understanding of the charge distribution and chemomechanical properties of polycrystalline battery materials.
Crystallographic defects, such as geometrically necessary dislocations, are reported to influence the redox reactions in battery particles through single-particle, multimodal, in situ synchrotron measurements. Through Laue X-ray microdiffraction, many crystallographic defects are spatially identified and statistically quantified from a large quantity of diffraction patterns in many layered oxide particles, including geometrically necessary dislocations, tilt boundaries, and mixed defects. The in situ and ex situ measurements, combining microdiffraction and X-ray spectroscopic imaging, reveal that $LiCoO_2$ particles with a higher concentration of geometrically necessary dislocations provide deeper charging reactions, indicating that dislocations may facilitate redox reactions in layered oxides during initial charging. The present study illustrates that a precise control of crystallographic defects and their distribution can potentially promote and homogenize redox reactions in battery materials.

5:45 AM F.EN07.06.05
LLZO: Al, Ta, Nb, W – Different Dopants and Their Effect on Microstructure and Lithium Diffusion Charlotte A. Fritsch[1], Anna-Lena Hansen[1], Sylvio Indris[1], Tatiana Zinkevich[1], Michael Knapp[1], Thomas Bergfeldt[2], Volodymyr Baran[3] and Helmut Ehrenberg[1]; [1]Karlsruhe Insitute of Technology, Germany; [2]Karlsruhe Institute of Technology, Germany; [3]Research Neutron Source FRM II, Germany

We investigated the influence of doping Al, Ta, Nb, W on structure and dynamics in LLZO. Using the dopants Nb or Ta yields cubic structured LLZO ($Li_7La_3Zr_2O_{12}$) with highest ionic conductivities amongst this class of solid state electrolyte. In this study, we demonstrate that these dopants can cause a symmetry reduction in LLZO leading to its crystallization in a

different space group than usually considered: I-43d instead of Ia-3d. Neutron powder diffraction and ^{6}Li-NMR are utilized to localize the Li atoms in these structures and the findings are compared to the structure of Al- and W-doped LLZO. The changes in the local structure arising from different occupations of the Li- and Zr-sites in each Al-, Nb-, Ta- or W-doped LLZO samples is evaluated with total scattering PDF analysis. The decrease of the crystal symmetry caused by Nb and Ta is supposed to have only minor influence on the bulk ionic conductivity. A 24-fold Li position splits into two 12-fold positions, so number and occupation of Li positions stays the same. To this end, impedance spectroscopic and temperature dependent ^{6}Li NMR measurements are used to determine the Li ion conductivity. We provide evidence, that the structural differences indeed can be very well distinguished by diffraction and ^{6}Li NMR. This enables us to deepen our understanding of the effect that doping / substitution has on the crystal lattice and thus the ionic conductivity.

5:55 AM F.EN07.06.06

Phase Behavior in NaSiCON Electrolytes and Electrodes Zeyu Deng[1], Sai Gautam Gopalakrishnan[2], Christian Masquelier[3] and Pieremanuele Canepa[1]; [1]National University of Singapore, Singapore; [2]Princeton University, United States; [3]Universite de Picardie Jules Verne, France

The replacement of the presently used liquid electrolytes by a non-flammable solid electrolyte is an important avenue to create safer batteries. The Natrium Superionic CONductor (NaSiCON) $Na_{1+x}Zr_2Si_xP_{3-x}O_{12}$ ($0 < x < 3$) that displays high bulk ionic conductivity and good stability towards other NaSiCON-based electrodes is a good solid electrolyte in NaSiCON-based batteries. Despite the sizeable share of research on $Na_{1+x}Zr_2Si_xP_{3-x}O_{12}$, the structural and thermodynamic properties of NaSiCON require better understanding for more efficient synthesis and optimization as a solid electrolyte, which often follows chemical intuition. Here, we analyze the thermodynamic properties of the NaSiCON electrolyte by constructing the $Na_{1+x}Zr_2Si_xP_{3-x}O_{12}$ phase diagram, based on density functional theory calculations, a cluster expansion framework, and Monte Carlo simulations. Specifically, we build the phase diagram as a function of temperature and composition ($0 < x < 3$) for the high-temperature rhombohedral structure, which has been also observed in several positive electrode materials, such as $Na_3Ti_2(PO_4)_3$, $Na_3V_2(PO_4)_3$ and $Na_3Cr_2(PO_4)_3$. Through the phase diagram, we identify the concentration domains providing the highest Na^+-ion conductivity and previously unreported phase-separation behavior across three different single-phase regions. Further, we note the similarities in the phase behavior between $Na_{1+x}Zr_2Si_xP_{3-x}O_{12}$ and other NaSiCON-based mono-transition metal electrodes and discuss the potential competition between thermodynamics and kinetics in experimentally observed phase separation. Our work is an important addition in understanding the thermodynamics of NaSiCON-based materials and in the development of inexpensive Na-ion batteries. From our results we propose that the addition of SiO_4^{4-} moieties to single-transition metal NaSiCON-phosphate-based electrodes will slow significantly the kinetics toward phase separation.

6:05 AM F.EN07.06.07

The Structure of the Amorphous Solid Electrolytes LiPON and LiSiPON Andrew S. Westover[1], Mordechai Kornbluth[2], Jue Liu[1], Nancy Dudney[1] and Andrew Kercher[1]; [1]Oak Ridge National Laboratory, United States; [2]Robert Bosch LLC., United States

The composition and structure of solid electrolytes are critical to their ability to enable the Li metal anode for high energy batteries. Perhaps the most successful solid electrolyte in terms of enabling the Li anode is the amorphous electrolyte lithium phosphorus oxynitride or LiPON. One of the most significant drawbacks of LiPON is the ionic conductivity is limited to ~3 x 10^{-6} S/cm. Developing a solid electrolyte with the advantages of LiPON, but with higher ionic conductivity, could help improve solid-state Li metal batteries. There have been a few recent reports that Si-doped LiPON, or LiSiPON, can have an ionic conductivity of 10^{-5} S/cm. In this work, we present a detailed modeling and experimental approach to characterize the structure of LiSiPON in comparison to that of LiPON. The first part of this work involves a careful look at ab-initio MD simulations of the materials. The addition of the Si increases the amount of O and N bridges between phosphate/silicate tetrahedra. These bridges have been linked to higher ionic conductivity in LiPON and could be the origin of the improved conductivity with Si doping. The second part of this work presents experimental neutron pair distribution functions. The first key result of the neutron scattering is the agreement between the experimental and simulated pair distribution functions. The neutron scattering also shows that both LiPON and LiSiPON have a pseudocrystalline repeating structure with a periodicity of ~2.3 Å.

6:15 AM F.EN07.06.11
Challenges for All-Solid-State-Batteries Based on Argyrodite-Type Solid Electrolyte Xavier Randrema[1,2], Mohamed Chakir[1], Virginie Viallet[2] and Mathieu Morcrette[2]; [1]Renault, France; [2]Laboratoire de Réactivité et Chimie des Solides, France

The rapid growth of electric mobility is characterized by a strong interest of academic and industrial research laboratories on the so-called "All-Solid-State-Batteries". Indeed, conventional commercialized batteries are based on liquid electrolyte composed by flammable compounds. The first target of solid-state technology is thus to solve concerns regarding safety issue for the more and more numerous users of electric vehicle. In addition, promising energy density ($Wh.kg^{-1}$ and $Wh.l^{-1}$) superior to conventional lithium-ion batteries are supposed thanks to the use of lithium metal as anode material (3860 $mAh.g^{-1}$). Solid electrolytes and particularly sulfide-based solid electrolyte have attracted attention because they present low temperature operation and a high ionic conductivity allowing fast charge application if lithium dendrites (1) can be solved. Among these, the Li_6PS_5Cl Argyrodite (space group) discovered in 2008 (2) is the subject of many recent studies due to its simplicity to obtain by mecano-synthesis (3) as well as a high ionic conductivity up to 3 $mS.cm^{-1}$ at room temperature (4). This material seems promising for its use in composite electrodes, but also in separator for all-solid-state-batteries made by dry or by wet process (5). Nevertheless, intrinsic chemical instabilities (6) and decomposition reactions by contact with active material lead to electrochemical performances below expectations. Moreover, an industrial lock to solid-state technology development is the difficulty to produce those batteries on current Li-ion production lines based on slurry coating processes (7).

In this work, we were first interested in the deep characterization of solid electrolyte only, to assess structure and ionic conductivity of the material. In a second time, the electrochemical stability of the phase was tested by galvanostatic cycle in order to verify the electrochemical window recently proposed by Wagemaker's team. Then, all solid-state cells were assembled by dry mix to prove solid electrolyte viability in batteries. Finally, a wet process approach will be discussed in order to match with industrial prospects. First, a protocol of active material tuned with solid electrolyte will be introduced, showing intimate contacts bewteen particles and enhanced Li^+ percolation network. Secondly, preliminary results with slurry composed of tuned active material, carbon additive and binder coated on current collector using doctor-blade method will be presented. The goal of resulting all-solid-state cells is to give a concrete and practical example about solid-state technology in order to assess its industrial development possibility.

6:25 AM F.EN07.06.15
Late News: Nido-Hydroborate Based Electrolytes for All-Solid-State Batteries Seyedhosein Payandeh[1], Ryo Asakura[1,2], Daniel Rentsch[1], Zbigniew Lodziana[3], Petroula Avramidou[1], Laurent Bigler[4], Radovan Cerny[2], Arndt Remhof[1] and Corsin Battaglia[1]; [1]Empa institute, Switzerland; [2]University of Geneva, Switzerland; [3]Polish Academy of Sciences, Poland; [4]University of Zurich, Switzerland

Closo-hydroborates and carba-*closo*-hydroborates recently emerged as a promising, yet costly class of solid electrolytes for all-solid-state batteries.[1-4] Here, we introduce *nido*-hydroborates, $MB_{11}H_{14}$ (M = Li, Na), with open cage-like structures as a new building block for solid electrolytes. We synthesized and purified $MB_{11}H_{14}$ (M = Li, Na) starting from $NaBH_4$ as a cost-effective chemical feedstock.[5] Two-dimensional (2D) nuclear magnetic resonance combined with mass spectrometry techniques were used to analyze the structure of the new building blocks. High Li/Na ionic conductivity of up to > 1 mS/cm at 25 °C is achieved by combining *nido*- with *closo/* carba-*closo*-hydroborates into cubic unit cells. Crystal structures are solved and refined using X-ray diffraction and density functional theory. Cyclic voltammetry reveals electrochemical stability of ~ 2.6 V vs Li^+/Li or Na^+/Na, respectively. Galvanostatic cycling in symmetrical cells with lithium or sodium metal electrodes shows only a small overpotential increase after > 500 cycles at 50 $\mu A/cm^2$. These results demonstrate that despite

the thermodynamic instability of *nido*-hydroborates versus metallic anodes, stable interfaces are formed and the electrolytes were successfully employed in half cells using TiS_2 as cathode active material. Finally, we discuss routes to synthesize carba-*closo*-hydroborates from *nido*-hydroborate precursors by closing the cage with a carbon atom, opening a way for the cost-efficient synthesis of hydroborate-based solid-state electrolytes for Li/Na batteries.

6:35 AM F.EN07.06.16
Late News: Charge Compensation and Ionic Conductivity in the (MgCoCuNiZn)1-xLixO1- High Entropy Oxides Nicolas Osenciat[1], David Bérardan[1], Diana Dragoe[1], Brigitte Léridon[2], Stéphane Holé[2], Arun-Kumar Meena[1], Sylvain Franger[1] and Nita Dragoe[1]; [1]Université Paris-Saclay, France; [2]École supérieure de physique et de chimie industrielles de la ville de Paris, France

A new class of materials has been discovered in 2015 [1], the high entropy oxides, which expand to ionic compounds the concept of High Entropy Alloys. The particularity of these materials is their stabilisation at high temperature by their entropy of configuration, that predominant in their total Gibbs Energy, given by Eq. (1):

(1) $\triangle_r G = \triangle_r H - T\triangle_r S$

To obtain an entropy-stabilized oxide, by maximizing their configurational entropy, we need to mix, at least, 5 binary oxides in equimolar proportions and heat them above a critical temperature (corresponding to $\triangle_r G = 0$), followed by quenching to froze the structure at room temperature. In these conditions, they form a solid metastable simple crystal structure where the cations are randomly dispersed on the cationic sublattice.

First studies, performed in our lab, have shown the large possibilities of composition by substituting cations or modulating their ratio from the initial formula (MgCoNiCuZn)O when keeping the charge balance between cations and anions (M^{2+} and O^{2-}) [2] and their very promising properties such as their colossal dielectric constant [2] and their alkali conductivity (Li^+ and Na^+) [3]. These specificities make them promising candidates for solid-state electrolytes.

With the ambition to improve the ionic conductivity of Li^+ in these compounds, currently 1 $mS.cm^{-1}$ at room temperature in $(MgCoNiCuZn)_{0.7}Li_{0.3}O$ [3], we have studied the $(MgCoNiCuZn)_{1-x}Li_xO$ series to understand the charge compensation mechanisms that occur when Li^+ substitutes a 2+ element. Thanks to X-Ray Diffraction, coupled to thermogravimetric analysis and X-ray photoelectron spectroscopy, we found out that, for low fraction of Li^+, compensation involves a partial oxidation of Co^{2+} into Co^{3+} and then, for large fractions of Li^+, a combination of cobalt oxidation and a formation of oxygen vacancies [4].

6:45 AM F.EN07.06.17
Late News: Influence of Structural Distortion and Lattice Dynamics on Li-Ion Diffusion in Li3OCl1-xBrx Superionic Conductors Ronghan Chen, Zhenming Xu and Hong Zhu; Shanghai Jiao Tong University, University of Michigan – Shanghai Jiao Tong University Joint Institute, China

The antiperovskite superionic conductors Li_3OCl and Li_3OBr show great differences in ionic conductivity. The more polarizable Li_3OBr shows a lower ionic conductivity than Li_3OCl, contradicting the idea that more polarizable framework is beneficial to achieving high ionic conductivity. In this work, we study the influence of substituting Cl with Br on the local

structure, lattice dynamics and Li ionic conductivity of $Li_3OCl_{1-x}Br_x$, based on first-principles calculations. We find that the incorporation of Br does soften the overall lattice stiffness of $Li_3OCl_{1-x}Br_x$, but the accompanied local structural distortion plays a dominant role on changing the activation energy for Li diffusion, which could increase the site energy as well as the Li ion vibration frequency. We suggest that the more distorted initial octahedral site and less distorted saddle trigonal-plane site lead to better ionic transport. In addition, the correlation between the activation energy and the pre-exponential factor of diffusivity extracted from Arrhenius plot of $Li_3OCl_{1-x}Br_x$ is found to be nonlinear, which is due to the decreasing migration entropy with increasing activation energy.

Late News: Mixed-Anion Na-Hydroborates as New Class of Solid Electrolytes Matteo Brighi, Fabrizio Murgia and Radovan Cerny; University of Geneva, Switzerland

Li- and Na-based hydroborates are known for their high ion dynamic, leading to liquid-like cation mobility after an order-disorder phase transition, suggesting their use as solid electrolytes for all-solid batteries.[1,2] However this transition takes place at elevate temperature, outside the typical operation range of a conventional battery .[3–5]
A systematic study on Na-based *closo*borates and carba-*closo*borates has been conducted by means of anion mixing, in order to stabilize room temperature Na-conducting phases, relying on increased structural disorder. The effect of such mixing is the suppression of any phase transition, leading to six novel Na-conductors with a Na-conductivity close to 1 mS cm^{-1} at room temperature.
Due to the three-dimensional aromatic nature of the boron cage, c*loso*borates are among the more robust available polyanions;[6,7] the six presented phases are indeed thermodynamically stable in the investigated temperature range $100 < T < 700$ K, while depending from the mixture the electrochemical stability window varies from 3 to 4.1 V *versus* Na^+/Na, allowing their implementation in high -voltage next generation solid-state batteries.[8]
The physical/electrochemical properties of this family will be presented, with particular remark to the non-Arrhenius conductivity behavior, arising from the ion-ion interaction. Their flexibility, in terms of operating voltage window, allowed also to check their compatibility towards different class of cathode materials such as $NaCrO_2$[9,10], $Na_2Fe_2(SO_4)_3$[11] and $Na_3V_2(PO_4)_2F_3$.

Reducing of Grain Boundary Influences by Hybridization of Polyether / $Li_{1.5}Al_{0.5}Ge_{1.5}(PO_4)_3$ for Li-Conductive Solid Electrolyte Naamo Suzuki[1], Kenta Fujii[2], Koji Ohara[3] and Shiro Seki[1]; [1]Kogakuin University, Japan; [2]Yamaguchi University, Japan; [3]Japan Synchrotron Radiation Research Institute, Japan

Introduction

Recently, rechargeable batteries are strongly desired as energy storage systems. In particular, Li-ion batteries have been realized for practical use from consumer use (e.g., smartphone, laptop computer) to large-scaled energy storage devices such as for in/output control of renewable energy and electric vehicle owing to their high-energy-density and cycle performances. However, safety will be the most important demands with the scale of batteries, and several ignition accidents have been reported. 'Solvent-free' all-solid-state batteries exhibit quite high safety and have high-energy-density due to realization of thin-film electrolyte layer without separators. Generally, solid electrolytes are mainly categorized to polymer and inorganic electrolytes. Polymer electrolyte have a sufficient self-standing property, formability of stable interface with electrode and mechanical properties. However, it exhibits relatively low ionic conductivity and Li cation transport number. On the other hand, inorganic electrolyte shows relatively high ionic conductivity, even though it have grain boundary (GB) and be easily broken by external force (e.g. dropping and expansion / contraction with charge-discharge processes). Therefore, in this study, we propose polymer / inorganic hybrid electrolyte for usage of both advantages. Hybrid electrolytes of P(EO/PO) network polymer and two-types of $Li_{1.5}Al_{0.5}Ge_{1.5}(PO_4)_3$ (LAGP) presence/absence GB resistance were investigated for developing high-performance all-solid-state Li batteries.

Experimental

All samples were prepared in a glove box under Ar atmosphere. $LiN(SO_2CF_3)_2$, rhombohedral (*r*, having GB resistances) and amorphous (*a*, not having GB resistances) LAGP (Toshima mfg.), DMPA (photo initiator) and acetonitrile (solvent) were dissolved into polyether-based macromonomer (P(EO/PO) (TA-210, Dai-ichi Kogyo Seiyaku)). Amount of hybridized LAGP((*a*) or (*r*)) were 0~200 wt% with polymer electrolytes, respectively. Mixed samples were dried in vacuum for 12h to evaporate acetonitrile. Then the slurry was casted between two glass plates separated by spacers (0.5 mm) and radical polymerized by UV irradiation at 5 min. Then, ionic conductivity were measured by non-blocking electrode cells (Li metal / electrolyte / Li metal). In addition, molecular-level structures of prepared samples were analyzed by high-energy X-ray diffraction (HEXRD) at SPring-8 (BL04B2). LAGP-free polyether electrolyte, polyether/ LAGP(*a*)150wt% hybrid electrolyte and LAGP(*a*) powder were enclosed in a sample tube and HEXRD measurements were examined.

Results and discussion

From the result of impedance measurement by blocking electrode systems, possibility of influence of GB may not appear when using an amorphous material was suggested. To compare the effects of GB, non-blocking electrode systems, clear differences between amorphous and rhombohedral were observed by the difference of frequency properties [1]. Impedance spectrum by non-blocking electrode systems of LAGP-free electrolyte and all amorphous LAGP systems showed two semicircular arcs. In both systems, high and low frequency components were assigned as bulk resistance and interfacial resistance with Li metal. On the other hand, rhombohedral LAGP systems showed ellipse behavior because GB resistance appears between the two resistance components. This result shows that amorphous LAGP obtain no GB resistance component into amorphous inorganic / polyether hybrid electrolyte. Also, the radial distribution function of three samples was calculated by HEXRD results. A periodic structure appeared in all electrolytes. Hybrid material of amorphous polymer and inorganic systems also could be measured. The results of this measurement will provide spectroscopic evidence supporting the elimination of GBs. Therefore, influence of GB by using amorphous inorganic electrolyte into polyether electrolyte were clarified.

Late News: Development of Ceramic Electrolytes for All-Solid-State Batteries Andre Borchers, Magnus Rohde and Hans Jürgen Seifert; KIT, Germany

In contrast to Lithium, Sodium is abundant worldwide. Therefore, it is reasonable to investigate its potential as a substitute for Lithium in battery cells. In addition, solid electrolytes for Sodium-ions show promising characteristics for all-solid-state batteries. If such an electrolyte is made of a Sodium-ion conducting ceramic cells are not inflammable, do not tend to decompose and offer high mechanical strengths to stop dendrite growth. The cells are much safer and are able to operate at higher temperatures, if the solid electrolytes replace the liquid electrolyte and the separator.

For the design of all-solid-state batteries, the thermal properties of the used electrolytes need to be known accurately. As a promising solid electrolyte for sodium-ion cells, $Na_3Zr_2(SiO_4)_2PO_4$-powder with NASICON structure was synthesized by Sol-Gel-method using Sodium nitrate, Nitric acid, Ammonium dihydrogen phosphate, Tetraethyl orthosilicate and Zirconium

(IV) oxynitrate hydrate as precursor materials.
Subsequently, this powder material was sintered by Field Assisted Sintering Technology (FAST) and conventional sintering.

The sintered ceramic pellets were investigated with a focus on thermal properties such as heat capacity and phase transitions using differential scanning calorimetry and thermal conductivity using laser flash analysis. The ionic conductivity was measured by impedance spectroscopy. Stoichiometry of the samples was studied by ICP-OES.

SESSION F.LP05.06: Live Poster Session: Energy (F.EN04, F.EN07 and F.EN08)
Session Chairs: Candace Chan, Jae Chul Kim, Josef Matyas and Gleb Yushin

Structural Characterization of Solid-State Electrochemical Interfaces via Integrated Computation and Spectroscopy Deyu Lu[1], Nongnuch Artrith[2], Alexander Urban[2], Shinjae Yoo[1] and Feng Wang[1]; [1]Brookhaven National Laboratory, United States; [2]Columbia University, United States

Solid-state batteries are attracting world-wide interest for their potential to enhance safety by eliminating the need for flammable liquid electrolytes and to increase the energy density by facilitating the use of Li metal anodes and high-capacity cathodes. When incorporated into real devices, the solid electrolyte interacts with Li anodes and cathodes to form a nanometer-thick amorphous/disordered interfacial layer known as the solid electrolyte interphase (SEI), which determines the resistivity and stability of the interfaces between the electrode and electrolyte. The inherent complexity and the dynamic evolution of the SEI cannot be handled directly with first-principles methods, such as density functional theory, because of the computational hurdle associated with the large system size (e.g., more than one thousand atoms) and time scale. In order to gain insights into the structural properties and the interfacial reactions at the SEI, an integrated approach that combines high-performance computing and machine learning tools with state-of-the-art synchrotron X-ray absorption/electron energy-loss spectroscopy, is developed to tackle the complex electrochemical interfaces. The approach and some recent results from the structural modeling and spectroscopy studies of the SEI at the LiTMO2 (TM=Ni, Co, Mn) cathode/ Li7La3Zr2O12 solid electrolyte interfaces will be presented.

F.EN04.27.02
Realistic Modeling of AlCl4 Intercalation in Strained Two-Dimensional Materials Rizcky Tamarany[1], Chan-Woo Lee[1], Hana Yoon[1], Chung-Yul Yoo[2] and Kanghoon Yim[1]; [1]Korea Institute of Energy Research, Korea (the Republic of); [2]Mokpo National University, Korea (the Republic of)

Graphite-based Al-ion battery has been attracted large attention due to its extremely fast charge/discharge rate and excellent cycle stability. However, the intercalation mechanism of AlCl4 into graphite is still vague. The concern comes with the large size of the AlCl4 molecule while the experimentally observed gallery height for graphite cathode is not large enough (~ 5.7 Å). In the past theoretical studies, the computational models mostly represent that the stable structure of intercalated AlCl4 is the tetragonal form which resulted in a large expansion of the intercalation gallery to 8~9 Å. In those studies, researchers commonly considered thermodynamically stable structures that allow free expansions of electrode structures. In this study, we suggest that a strain effect in a realistic electrode structure governs the stable form of intercalating AlCl4. We have performed first-principles calculations to show a strain-structure relation of intercalated AlCl4 in graphite and found that a planar-shape of AlCl4 molecule is more probable in realistic conditions. Using the computational results, we made model energy for AlCl4 intercalation at given structural conditions such as volume expansion rate and stage number of graphite electrode. The model energy shows good agreements with the experimental observations on the structure-engineered graphite electrodes. In addition, to examine new candidate materials for Al-ion cathode, we also conduct calculations on MoS2 and MoS2/graphene hetero-structure for AlCl4 intercalation. As a result, we believe our study provides a deeper understanding of the charging/discharging mechanism and a modeling rule to find more enhanced electrode materials in Al-ion batteries.

F.EN04.27.04
Improved Cycle Lifetime of Lithium-Sulfur Battery by Polysulfide Entrapment Using a Surface Decorated Carbon Cloth Saisaban Fahad and Akihiro Kushima; University of Central Florida, United States

Lithium sulfur batteries (LSBs) are attracting attention as a next generation energy storage device because of their high energy density, low cost, and environmental friendliness surpassing that of lithium ion batteries (LIBs). LIBs are considered insufficient for many applications such as grid energy storage and electric vehicles due to their high cost and low energy density. However, LSBs still have some problems that need to be overcome before they can be used commercially. The major problem that limits their capacity is the dissolution of long chain lithium polysulfide into the electrolyte which leads to a loss of active material and capacity decay during cycling. Here, we have developed a cost-effective method for the lithium polysulfide battery to achieve high performance by employing a nanostructured carbon black/ carbon cloth electrode that exhibits high electrical conductivity, good mechanical properties and high surface area. These benefits enable a high sulfur loading mass, capture the lithium polysulfide intermediate reaction products and avoid structural changes. As a result, this simple and novel design delivered a high specific discharge capacity exceeding 1350 mAhg-1 at 0.2 C and good capacity retention, providing a promising path towards practical lithium sulfur batteries.

F.EN04.27.07

Enhanced Polysulfide Conversion Using 2D Alloy Catalyst in Li-S Batteries Sanket D. Bhoyate[1], Junyoung Kim[1], Eunji Lee[2], Eunho Lee[1], Juhong Park[1], Jeongyong Kim[2] and Wonbong Choi[1]; [1]University of North Texas, United States; [2]SKKU, Korea (the Republic of)

The lithium sulfur battery presents unique polysulfide chemistry to exhibit high theoretical capacity of 2,600 Wh/kg. However, the life cycle of Li-S battery is greatly affected due to unwanted shuttling of soluble lithium polysulfides (LiPSs) such as Li2S8 and Li2S6, that corrodes the Li anode by forming an inactive sulfide layer. Previously, pristine 2D materials with polar surface were used as a catalyst in sulfur cathodes to overcome this issue by acting as polysulfide anchor and prevent shuttling effect. However, the concentration and weight loading of catalyst was high and lack the practical applicability in Li-S battery. To overcome this issue, we adopted novel strategy of synthesizing 2D alloys with very low concentration loading on carbon nanotube paper as a sulfur host cathode to efficiently catalyze the polysulfide reactions. The 2D alloy with mixed 2H-1T phase exhibited synergetic properties and showed high specific capacity of 1,228 mAh/g at 0.1 C and improved the cyclic stability to 400 cycles, as compared to 100 cycles for pristine cathode. The reduced shuttle effect and increased life cycle was due to accelerated transformation of the dissolved polysulfides to the insoluble LiPSs and back to sulfur. Our study shows novel approach with binder-free ultra-light weight catalytic cathodes for practical application of Li-S battery.

F.EN04.27.10

Improvement of Specific Capacitance in Lithium Batteries by Three-Dimensional Carbon Networks Valerio Dorvilien[1], Carolina Rojas[2], Neida Santacruz[3], Cid Marie Calderon Rodriguez[3], Omayra Ortiz Alicea[3], Genesis M. Ferrer[1], Frank Martinez-Henriquez[1], Daniel Fontanez[1], Frank Mendoza[1], Carolina Rojas Michea[4], Brad R. Weiner[2] and Gerardo Morell[1]; [1]University of Puerto Rico-Rio Piedras Campus, United States; [2]University of Puerto Rico, San Juan, Puerto Rico; [3]University of Puerto Rico, Rio Piedras Campus, Puerto Rico; [4]Universidad Autónoma de Chile, Chile

We propose a low cost and simple method to prepare three-dimensional (3D) carbon structures by Chemical Vapor Deposition (CVD) and characterized their structural and electrochemical properties. The 3D pore system were obtained using different zeolites (NaY, SBA-15, and ZMS-5) as solid template structures to assist in the synthesis of 3D carbon network structures. The carbon source consisted of radicals formed from the thermal decomposition of acetone, in a relatively facile and fast chemical deposition process. The 3D carbon network structures were characterized with X-ray diffraction, Raman spectroscopy, spectroscopy, surface area measurement, scanning electron microscopy, and transmission electron microscopy. The carbon networks deposited in the pores consist of reduced graphene oxide and multiwalled carbon nanotubes; their size distribution correlates with the size of the pores of zeolites. The electrical conductivity and dispersed morphology of the 3Ds carbone network structures -based conductive electrode were examined by atomic force microscope (AFM), scanning electron microscope (SEM) and transmission electron microscope (TEM). Using the standard method we assembled the Lithium Ion Battery in the Ar-filled glove box, we used LiPF6 with EC:DMC::1:2 ratio as the electrolyte, lithium foil as the counter electrode and the 3D carbon network material. The specific capacity and cycle-life stability of the 3Ds carbon network-based lithium ion battery was investigated by cyclic voltammetry analysis.

F.EN04.27.11

3D Carbon-Coated MXene Architectures with High Capacity and Ultrafast Lithium/Sodium Storage Peng Zhang, Qizhen Zhu and Bin Xu; Beijing University of Chemical Technology, China

MXene is a promising candidate for energy storage devices owing to its versatile characteristics. However, as 2D structured

material, layer restacking besides its surface oxidation is a serious issue. This re-stacking compromises significantly surface active sites, compelling the material to exhibit sluggish electro-kinetics behavior, and thus deterring the overall capacitive performance. Here, a tremella-like 3D architecture of carbon-coated Ti3C2Tx MXene (T-MXene@C) is fabricated as an efficient anode material for lithium- (LIBs) and sodium-ion batteries (SIBs), respectively. The nanohybrid is synthesized via self-polymerization of dopamine over the surface of pristine Ti3C2Tx MXene nanosheets succeeded by carbonization. The self-polymerization of dopamine in this case, facilitates the transformation of MXene sheets into 3D architectures where its post-carbonization subsequently forms a thin carbon layer over the structure, preserving the surface facets from oxidation and structural aggregation. The incursion of carbon layers within MXene not only contributes in provision of additional active area, but also enhances the structural durability of the material during charge/discharge process. Therefore, the T-MXene@C nanohybrid exhibits ultrahigh capacities, superior rate performance, and stable cyclability as anodes in both LIBs and SIBs. Moreover, the discussed strategy could be applied as general route to fabricate diverse MXene-based 3D structures with potential applications in many other areas.

F.EN04.27.12

Tin Dioxide/Graphene/Graphene Oxide as Anode Material for Lithium-Ion Batteries Valerio Dorvilien, Frank Martinez-Henriquez, Cid Marie Calderon Rodriguez, Daniel Fontanez, Genesis M. Ferrer, Omayra Ortiz Alicea, Frank Mendoza, Brad R. Weiner and Gerardo Morell; University of Puerto Rico-Rio Piedras Campus, United States

Graphene Oxide was synthesized using a Modified Hummer's Method. It is fairly known that SnO2 is used as anode material for lithium-ion batteries applications due to their high specific capacity. Hence, we use a non-conventional synthesis route to obtain a final composite, G/GO/SnO2. G/GO, with its good surface-to-volume ratio, serves as a support and matrix for SnO2 nanoparticles that buffers the huge volume changes the nanoparticles are used alone as anode for lithium ion batteries and then enhances its electrochemical properties. For the structural characterization of the synthesized material, scanning electron microscopy (SEM), energy dispersive spectroscopy (EDS) and Raman Spectroscopy were performed; showing a uniform distribution of the nanomaterial in the carbon matrix. Electrochemical analysis, such as charge/discharge profiles show that the composite can be used as anode in lithium ion batteries. In fact, at different current densities- 25, 75, 100, and 200 mA/g- the material deliver in the first cycle very high specific capacity-1808, 1253, 903, 886 mAhg-1 respectively. After repeated cycling the composite is still offering reversible capacities over 400 mAhg-1 for each current density, showing that G/GO is providing contact areas which results in more energy density at the interface electrode/electrolyte and that the SnO2 provides additional ions to the EDL and the electrochemical process.

F.EN04.27.13

Theoretical Intercalation Profiles of Layered NaMO2 (M=Co, Ni, Fe) Cathodes—Learning from the Electronic Structure of LiMO2 Christopher Savory, Arthur B. Youd and David O. Scanlon; University College London, United Kingdom

Ab initio modelling can provide valuable insights into the electronic and structure behaviour of battery materials, including the prediction of sodium, potassium and magnesium cathodes.12 Nevertheless, it is crucial that the accuracy of such ab initio calculations be established. The most common method to theoretically the strong correlation in the 3d valence electrons of transition metals is to use the addition of 'U' parameters to standard Density Functional Theory (DFT), enabling high throughput studies of Na-based materials;3 however these parameters must be tuned to experimental measurements, and are highly sensitive to changes in oxidation state and composition - crucial properties during the intercalation of AMO2 (A=Li, Na, K) layered cathodes.4,5 Recent high-level quasiparticle self-consistent GW (QSGW) calculations performed on the layered LiMO2 (M=Co, Ni, Mn) cathodes suggest that the charge transfer transition in LiMO2 phases is underestimated, even when the inaccuracy of standard DFT at describing band gaps is accounted for, but it is well predicted by hybrid Density Functional Theory (DFT), which mixes exact exchange from Hartree-Fock theory.6 In this study, we examine how electronic correlation is described in layered sodium cathode materials with various levels of theory. We calculate the electronic structures of NaCoO2, NaNiO2 (in direct comparison to their Li counterparts) and ?-NaFeO2 - ternaries typically alloyed to form stable and efficient sodium-based cathodes7 -- using DFT+U, hybrid DFT (HSE06) and QSGW to establish a thorough comparison of the electronic properties at each level, and to establish that tuning is necessary to reproduce the valence electronic structure of such materials. We further demonstrate the practical impact of this theoretical description by calculating and comparing voltage intercalation profiles of these systems as a function of Na content, at both the DFT+U and hybrid DFT levels via a cluster expansion approach, in order to establish the most reliable comparison to experiment. We establish the necessity to use accurate, transferable methods to describe such systems, with an aim to inform ab initio studies on the future generation of first row transition metal-based cathodes. Enhancement of Ionic Conductivity of Composite Electrolytes for All-Solid-State Lithium Rechargeable Batteries by Incorporating Gold Nanorods into a Polyethylene Oxide Matrix Yifan Zhang, Nian Liu and John Zhang; Georgia Institute of Technology, United States

Solid state batteries have advantages such as safeness and high energy density. However, their conductivity at room temperature is low which limits their further commercialization. Gold nanorods can promote the Li ion transport by decreasing the crystallization of solid state electrolytes, and locally heat the electrolytes based on their photothermal conversion capability, providing a more efficient way to improve the performance of solid state batteries.

F.EN04.27.17

Large-Scale Synthesis of Uniform and Extremely Small-Sized Cobalt Ferrite Nanoparticles as High-Performance Anode Materials for Lithium-Ion Batteries Yifan Zhang, Nian Liu and John Zhang; Georgia Institute of Technology, United States

Spinel ferrites have emerged as an attracted class of materials that can find application in various fields, ranging from information storage, biomedical application to energy-related areas. As the anode in LIBs, spinel CoFe2O4 attracts much attention because of its high theoretical specific capacity (916 mAh g-1). However, some issues impede its practical application such as drastic capacity fading and poor rate capability arising from an inherent low electronic conductivity, severe aggregation, and lithiation-induced volume expansion in the cycling process. Increasing surface-to-volume ratio could provide relatively short transport distance for lithium-ion diffusion and alleviate the volume expansion, which is one of the possible strategies to solve the above-mentioned problem. In this frame, an aminolytic method is described to synthesize ultra-small (<10 nm) CoFe2O4 nanoparticles with good dispersion at a relatively low temperature without further annealing being required. Here, the 9.1 nm CoFe2O4 nanoparticles synthesized by aminolytic method delivered a reversible specific capacity of 1238 mAh g-1 after 100 cycles at a current density of 0.1C, a much better performance compared with CoFe2O4 synthesized by traditional methods in previous reports. By adjusting the reaction temperature, 3.4 nm CoFe2O4 nanoparticles could also be synthesized, delivering a slightly enhanced specific capacity (1343 mAh g-1 after 100 cycles at 0.1C). For comparison, the CoFe2O4 nanoparticles were also prepared by coprecipitation method and its electrochemical performance was studied in detail. It can be concluded that spinel CoFe2O4 synthesized by aminolytic method is a promising anode for LIBs based on its superior lithium storage performance. Further, the aminolytic method can also be used to prepare other spinel materials in different fields. The systematically studied electrochemical performance of CoFe2O4 nanoparticles is beneficial in the design of future anode materials for LIBs.

F.EN04.27.23

Li2Sx-CNT Electrode with Lean Electrolyte for High-Energy-Density Li-S Battery Yuichi Yoshie, Keisuke Hori and Suguru Noda; Waseda University, Japan

Sulfur is a promising active material because of a high theoretical capacity (1675 mA h gS?1) and low cost. Nevertheless, practical applications of S electrode have been hindered by low S fraction in a cell. Excess Li in negative electrode, auxiliary materials such as heavy current collectors of metals, and large amount of electrolyte (Electrolyte/Sulfur ratio (E/S) > 7) have been used in previous works [1], which lowers energy density of the Li-S cells based on total mass/volume (including electrodes, separator and electrolyte). We previously demonstrated the high gravimetric and volumetric energy densities based on an electrode using self-supporting sponge-like paper of few wall carbon nanotubes (FWCNTs) as current collector. The unique properties of FWCNTs with high conductivity of ~100 S cm?1 and high surface area of ~500 m2 g?1 enhanced the sulfur utilization; however, E/S ratio was still high [2]. In this work, we report the Li2Sx-CNT (4?x?8) positive electrode that works effectively even with lean electrolyte. Self-supporting paper of FWCNTs was fabricated by dispersion and filtration. Then, three types of Li2Sx (x = 4, 6, 8) in 1,2-dimethoxyethane (DME) solution were drop-casted on the papers and dried for 1 h to obtain the Li2Sx-CNT electrodes. As a reference, the S-CNT electrode was also prepared by the S vapor deposition method [2]. The Li2Sx-CNT and S-CNT (areal density of 2 mgS cm?2 and 1 mgCNT cm?2) electrodes were evaluated by assembling 2032-type coin cell with Li foil (50 µm thick) as a negative electrode, a polyethylene separator, and an electrolyte of 1 M LiTFSI + 0.2 M LiNO3 in 1:1 (v/v) DOL/DME. Although the S-CNT exhibited very small capacity, the Li2S6-CNT exhibited 1471 mA h gS?1 with lean electrolyte of E/S ratio of 3.2 µL mgS?1. Furthermore, the Li2S6-CNT achieved 526 W h kgcell?1 based on the cell including positive and negative electrodes, separator, and electrolyte at second

discharge. The value is encouragingly high compared to the high-performance Li-ion battery of ~300 W h kgcell?1 [1]. [1] M. Hagen et al., Adv. Energy Mater., 5, 1401986 (2015). [2] K. Hori, et al., J. Phys. Chem. C, 123, 3951 (2019).

F.EN04.27.24

Thin Li-Metal Negative Electrode Held in Self-Supporting Paper of Carbon Nanotubes for Stable, High Energy Density Rechargeable Batteries Tomotaro Mae[1], Keisuke Hori[1], Yuki Yamada[2] and Suguru Noda[1]; [1]Waseda University, Japan; [2]The University of Tokyo, Japan

Li metal is a promising negative electrode because of its high theoretical capacity (3860 mAh gLi?1) and low potential (?3.04 V vs SHE). However, it has a serious safety problem of Li dendrite which penetrates a separator and causes short circuit [1]. Surface modification of Li foils by texture or additional layer have shown effective in suppressing the dendrite growth [2] [3], but many of such methods make the electrode too thick (several hundred μm), and excessive Li were used (5 times or more). In this work, we propose thin and light-weight electrode to achieve high gravimetric, volumetric and areal capacities. Self-supporting paper of few-wall carbon nanotubes (FWCNTs; areal mass of 0.3 mg cm?2 and thickness of ~15 μm), having high conductivity of 40 S cm?1 and large specific surface area of ~500 m2 g?1, was used as non-metal 3D current collector. Cu nanoparticles (25 nm; 0.1-0.2 mg cm?2) were held in this 3D matrix as seeds for stable Li plating/stripping. The Cu-CNT film was prepared by dispersion and filtration [4]. 2032 coin cells of symmetrical configurations (Li-CNT//Li-CNT and Li-Cu-CNT//Li-Cu-CNT) were prepared by performing electrochemical pre-cycling of the Li foil (50 μm)/CNT//CNT and Li foil (50 μm)/Cu-CNT//Cu-CNT stacks with polypropylene separator (25 μm). Charge-discharge test was performed with an areal capacity of 4 mA h cm?2 and current density of 0.4 mA cm?2. The former cell showed unstable plating/stripping behavior in several cycles due to micro-short circuits while the latter worked stably over 20 cycles with small excess (1.5-2 times of the areal capacity) in Li. The Cu nanoparticles working as the nucleation sites and mesopores in the FWCNT paper working as growth sites realized the stable operation of the cells. [1] L. A Versatile Crosslinked Solid Polymer Electrolyte for Lithium, Calcium, Aluminum and Sodium-Ion Conduction Francielli Genier, Jiayue Wang, Tianyi Yao, Saeid Biria and Ian D. Hosein; Syracuse University, United States

The development of high-performance batteries is fundamental to meeting global energy demands, while also storing energy affordably and safely. An area of intense research in the battery field has been the replacement of the liquid or gel electrolyte with a solid polymer material, namely a solid polymer electrolyte (SPE). SPEs can allow the use of metal anodes due to its suppression of dendrite formation, which could thereby double the energy density, besides further addressing concerns over the volatility and flammability of liquid electrolytes. Crosslinked polymer electrolytes are quite attractive owing to their ability to enhance conductivity, while also retaining mechanical stability.1 Studies on SPEs not only focus on different polymer systems, but also on improving the interaction of existing and new polymer networks to ions other than lithium-ion to achieve even less expensive and more efficient rechargeable batteries. Other univalent ions, in particular sodium cations, can be highlighted due to its wide availability and low cost comparing to lithium. Multivalent cations, such as Ca2+ and Al3+, are also featured in SPE studies for their high energy density and mineral abundance.2 In those studies, poly(ethylene oxide) (PEO) has been extensively employed as the electrolyte's backbone. However, polytetrahydrofuran (PTHF) has been reported as having a looser coordination with Li+ than PEO, due to PTHF's fewer oxygen heteroatoms in its chain.3 As a result, lower activation energy for ion motion is observed, leading to higher conductivity and transference numbers. In this work, we describe the synthesis of crosslinked SPEs for lithium, sodium, aluminum, and calcium conduction using a PTHF backbone. The SPEs were crosslinked through the photo-copolymerization of PTHF and 3,4-epoxycyclohexylmethyl 3,4-epoxycyclohexanecarboxylate. The crosslinked samples were evaluated for their ionic conductivity, thermal stability, amorphousness, and mechanical properties. Ionic conductivity of the order of 10-5 - 10-4 S/cm at room temperature was achieved, which is superior to some previously reported Ca, Na, and Al dry SPEs.4,5 Thermogravimetric analysis of the electrolytes indicated that, within the operating temperature of a battery, all electrolytes were stable and showed minimal weight loss. Differential scanning calorimetry confirmed the amorphous feature of the polymer. The electrolytes also showed excellent mechanical stiffness and flexibility. Further electrochemical studies will be presented and discussed. This work represents a new route for cleaner and safer energy storage devices with the potential for a broad variety of applications. Reducing of Grain Boundary Influences by Hybridization of Polyether / $Li_{1.5}Al_{0.5}Ge_{1.5}(PO_4)_3$ for Li-Conductive Solid Electrolyte Naamo Suzuki[1], Kenta Fujii[2], Koji Ohara[3] and Shiro Seki[1]; [1]Kogakuin University, Japan; [2]Yamaguchi University, Japan; [3]Japan Synchrotron Radiation Research Institute, Japan

Introduction

Recently, rechargeable batteries are strongly desired as energy storage systems. In particular, Li-ion batteries have been realized for practical use from consumer use (e.g., smartphone, laptop computer) to large-scaled energy storage devices such as for in/output control of renewable energy and electric vehicle owing to their high-energy-density and cycle performances. However, safety will be the most important demands with the scale of batteries, and several ignition accidents have been reported. 'Solvent-free' all-solid-state batteries exhibit quite high safety and have high-energy-density due to realization of thin-film electrolyte layer without separators. Generally, solid electrolytes are mainly categorized to polymer and inorganic electrolytes. Polymer electrolyte have a sufficient self-standing property, formability of stable interface with electrode and mechanical properties. However, it exhibits relatively low ionic conductivity and Li cation transport number. On the other hand, inorganic electrolyte shows relatively high ionic conductivity, even though it have grain boundary (GB) and be easily broken by external force (e.g. dropping and expansion / contraction with charge-discharge processes). Therefore, in this study, we propose polymer / inorganic hybrid electrolyte for usage of both advantages. Hybrid electrolytes of P(EO/PO) network polymer and two-types of $Li_{1.5}Al_{0.5}Ge_{1.5}(PO_4)_3$ (LAGP) presence/absence GB resistance were investigated for developing high-performance all-solid-state Li batteries.

Experimental

All samples were prepared in a glove box under Ar atmosphere. $LiN(SO_2CF_3)_2$, rhombohedral (*r*, having GB resistances) and amorphous (*a*, not having GB resistances) LAGP (Toshima mfg.), DMPA (photo initiator) and acetonitrile (solvent) were dissolved into polyether-based macromonomer (P(EO/PO) (TA-210, Dai-ichi Kogyo Seiyaku)). Amount of hybridized LAGP((*a*) or (*r*)) were 0~200 wt% with polymer electrolytes, respectively. Mixed samples were dried in vacuum for 12h to evaporate acetonitrile. Then the slurry was casted between two glass plates separated by spacers (0.5 mm) and radical polymerized by UV irradiation at 5 min. Then, ionic conductivity were measured by non-blocking electrode cells (Li metal / electrolyte / Li metal). In addition, molecular-level structures of prepared samples were analyzed by high-energy X-ray diffraction (HEXRD) at SPring-8 (BL04B2). LAGP-free polyether electrolyte, polyether/ LAGP(*a*)150wt% hybrid electrolyte and LAGP(*a*) powder were enclosed in a sample tube and HEXRD measurements were examined.

Results and discussion

From the result of impedance measurement by blocking electrode systems, possibility of influence of GB may not appear when using an amorphous material was suggested. To compare the effects of GB, non-blocking electrode systems, clear differences between amorphous and rhombohedral were observed by the difference of frequency properties [1]. Impedance spectrum by non-blocking electrode systems of LAGP-free electrolyte and all amorphous LAGP systems showed two semicircular arcs. In both systems, high and low frequency components were assigned as bulk resistance and interfacial resistance with Li metal. On the other hand, rhombohedral LAGP systems showed ellipse behavior because GB resistance appears between the two resistance components. This result shows that amorphous LAGP obtain no GB resistance component into amorphous inorganic / polyether hybrid electrolyte. Also, the radial distribution function of three samples was calculated by HEXRD results. A periodic structure appeared in all electrolytes. Hybrid material of amorphous polymer and inorganic systems also could be measured. The results of this measurement will provide spectroscopic evidence supporting the elimination of GBs. Therefore, influence of GB by using amorphous inorganic electrolyte into polyether electrolyte were clarified.

Late News: Development of Ceramic Electrolytes for All-Solid-State Batteries Andre Borchers, Magnus Rohde and Hans Jürgen Seifert; KIT, Germany

In contrast to Lithium, Sodium is abundant worldwide. Therefore, it is reasonable to investigate its potential as a substitute for Lithium in battery cells. In addition, solid electrolytes for Sodium-ions show promising characteristics for all-solid-state batteries. If such an electrolyte is made of a Sodium-ion conducting ceramic cells are not inflammable, do not tend to decompose and offer high mechanical strengths to stop dendrite growth. The cells are much safer and are able to operate at higher temperatures, if the solid electrolytes replace the liquid electrolyte and the separator.

For the design of all-solid-state batteries, the thermal properties of the used electrolytes need to be known accurately. As a promising solid electrolyte for sodium-ion cells, $Na_3Zr_2(SiO_4)_2PO_4$-powder with NASICON structure was synthesized by Sol-Gel-method using Sodium nitrate, Nitric acid, Ammonium dihydrogen phosphate, Tetraethyl orthosilicate and Zirconium (IV) oxynitrate hydrate as precursor materials.
Subsequently, this powder material was sintered by Field Assisted Sintering Technology (FAST) and conventional sintering.

The sintered ceramic pellets were investigated with a focus on thermal properties such as heat capacity and phase transitions using differential scanning calorimetry and thermal conductivity using laser flash analysis. The ionic conductivity was measured by impedance spectroscopy. Stoichiometry of the samples was studied by ICP-OES.

A New Disposal Method for Radioactive Waste Using Chemically Adsorbed Monolayer Teruyoshi Sasaki, Hiroto Funakoshi, Kazufumi Ogawa and Yoshifumi Suzaki; Kagawa University, Japan

Radioactive waste exists in the form of gas, liquid and solid. Among them, the disposal method of collecting radioactive waste, melted and solidifying it and burying it in the ground is common. However, in the current method, after the radioactive waste is collected, it is mixed with glass as it is to be melted and solidified, or it is mixed with cement and solidified, so that the volume of the waste becomes huge. Therefore, in this study, we investigated a process in which a chemically adsorbed monolayer having an imidazole group at the end was formed on a glass fiber, and only radioactive substances were adsorbed from a solution in which waste was dissolved, and then melted and solidified at once. As a result, we succeeded in adsorbing radioactive substances with high efficiency in solution. By using this method, if the melting point of the glass fiber is set low, the melted and solidifying process will be extremely simple, and it will be possible to manage the radioactive substances in the necessary minimum volume.

Speciation by XANES of Copper Migrated into Compacted Bentonite Using Electromigration Techniques Kazuya Idemitsu, Keisuke Yoshida, Yaohiro Inagaki and Tatsumi Arima; Kyushu University, Japan

Copper is a candidate for use as an overpack material in deep underground nuclear waste disposal. Copper, however, is susceptible to corrosion following closure of the repository and migration of the corrosion products through the buffer material may affect the migration of redox-sensitive radionuclides. Electromigration experiments were performed whereby a copper coupon, which was in contact with compacted bentonite, served as the working electrode and was held at a constant potential of +300 mV vs. Ag/AgCl electrode for up to 48 h. The chemical form of copper that migrated into the bentonite specimens were estimated by using Cu K-edge X-ray absorption near-edge structure (XANES) at Saga-Light Source, Japan. The results revealed that the oxidation state of Cu in the bentonite would be Cu(II) as shown the correlation between the amount of Cu migrated into bentonite and the corrosion current. On the other hand Cu(I) also observed on the copper coupon not in bentonite. Copper could corrode as Cu(II) then react with Cu metal and precipitate as Cu_2O on the copper metal.

Effects of Chromium and Vanadium on the Sulfate Solubility of Sodium Aluminoborosilicate Glass Natalie J. Smith-Gray[1], Jason Lonergan[2] and John S. McCloy[1,2]; [1]Washington State University, United States; [2]Pacific Northwest National Laboratory, United States

In the composition space of interest for Hanford low-activity nuclear waste glass, the waste loading of some formulations is limited by the incorporation of sulfate into the glass (i.e., its solubility). Numerous studies have been undertaken to understand the mechanism of sulfate incorporation and its affect by various other additives. In particular, the model by Vienna et al (2014, J. Amer. Ceram. Soc. 97, 3135) identified elements which tend to raise or lower sulfate solubility in borosilicate glass. In the current experimental study, we focus on representative additives that purportedly decrease (chromium) or increase (vanadium) the sulfate solubility. A baseline aluminoborosilicate composition containing Ca and Na was melted with target composition of either i) 1 wt% SO_3 and up to 2 wt% Cr_2O_3 or ii) 2 wt% SO_3 and up to 5 wt% percent V_2O_5. Thermal and physical properties were measured and structural analysis by Raman spectroscopy was performed to investigate changes in the glass structure with transition metal addition. Electron probe microanalysis was used to measure elemental compositions in melted glass for comparison with batched compositions. Increasing Cr_2O_3 concentration caused saturation of Cr concentration within the glass and formation of crystalline eskolaite (Cr_2O_3); glass transition temperature change was only dependent on the Cr which remained in glass, while measured density changes depended on both Cr in glass and eskolaite. No apparent change in sulfate solubility was observed, though not all the targeted sulfate was incorporated in

the glasses containing Cr. On the other hand, all the targeted V was incorporated into the glass, and as the concentration of V_2O_5 increased, the glass transition temperature decreased. Again, not all of the batched sulfur was incorporated into the glass, but V_2O_5 showed a weak tendency to increase the observed sulfur content in the glass. Some incorporation mechanisms to explain these trends are proposed.

Defect Evolution Measured by Raman Spectroscopy and EBSD in Rare-Earth Doped UO_2 Used Nuclear Fuel Analogues Sam Karcher[1], John S. McCloy[1], Ritesh Mohun[2] and Claire L. Corkhill[2]; [1]Washington State University, United States; [2]The University of Sheffield, United Kingdom

Uranium dioxide prepared from depleted uranium is commonly used as an analogue to study used nuclear fuels. While actual used nuclear fuel is highly complex and contains a large number of fission products, synthetic analogues are often simplified by single species doping. Previous studies involving trivalent RE doped UO_2 show reduced dissolution rates compared to undoped UO_2. When U^{IV} is replaced with a RE^{III} cation, defect clusters containing U^{V} resulting from local charge compensation form which can serve to limit ability to form U_3O_8. Uranyl ions $(UO_2)^{2+}$, which are allowed to form as a result of U^{VI} in U_3O_8, have a solubility much higher than stoichiometric UO_2. To predict the long-term stability of used nuclear fuel in oxidizing conditions it is necessary to understand the relationships between fuel chemistry, microstructure and environment.

Here, a series of UO_2 pellets doped with Ce, Nd, Yb, Zr and Th at 1 at. % and 5 at. % were prepared via uranyl nitrate + RE-nitrate co-precipitation to ensure homogenous distribution of dopant ions before pelletizing and sintering at 1700° C in H-Ar reducing atmosphere. Defect signatures in the resulting near-stoichiometric $(U,RE)O_{2+x}$ ceramic pellets were analyzed using Raman spectroscopy at multiple excitation wavelengths pre and post oxidation treatment. Through collaboration with the University of Sheffield, we have also obtained Raman data on our samples after irradiation with 1 MeV Kr ions at room temperature, fluence 5×10^{15} ions/cm^2 at the Dalton Cumbrian Facility. Deconvolution of Raman spectra reveals distinct signatures corresponding to defects such as interstitial or vacant oxygen sites or reduced lattice symmetry. The primary Raman peak observed in UO_2 at 445 cm^{-1} corresponds to the symmetric U-O stretching bond, and indicates the presence defects in the UO_2 structure by losing intensity and broadening while shifting towards higher wavenumber. Thermogravimetric analysis up to 900° C in air show a delayed transition from UO_2 to U_3O_8 in the doped samples, the effect being greatest in Yb-doped UO_2. Using Raman mapping with in-situ heating we can track the evolution of defect bands during oxidation and correlate spectral features to the orientation, size and distribution of grains and grain boundaries measured by electron backscatter diffraction (EBSD).

Radiation Damage and Thermal Aging of Nuclear Waste Forms William J. Weber; The University of Tennessee, United States

Self-radiation damage from the decay of radionuclides can affect microstructural evolution, phase stability, and thermodynamic properties in nuclear waste forms. The principal sources of radiation are beta-decay of the fission products and alpha-decay of the actinide elements. In general, beta-decay of the short-lived fission products leads to ionizing radiation that is the primary source of radiation and heat generation in high-level waste forms during the first 600 years of storage. Ionization can cause covalent and ionic bond rupture, valence changes, localized electronic excitations, and significant changes in ionic mobility; however, there is no evidence of significant long-term effects of fission product decay on the physical properties of nuclear waste forms. Because of the long half-lives of the actinides and their daughter products, alpha-decay is dominant over very long timescales. Alpha decay produces energetic alpha particles (4.5 to 5.5 MeV) and recoil nuclei (70 to 100 keV) that result in both radiation damage and the accumulation of helium. The evolution of radiation damage due to alpha-decay has been studied at ambient temperature using short-lived actinides, such as ^{238}Pu and ^{244}Cm, in many candidate glass and ceramic waste forms, and the early stages of evolution occur during the thermal period of the waste form. Ion beam irradiations of candidate ceramics are more frequently employed due to decreased costs, shorter irradiation timescales and the non-radioactive nature of the irradiated materials. Ion irradiations are performed over a wider range of irradiation conditions to implant helium, study radiation damage kinetics, understand the separate and combined effects of alpha particles and alpha recoils, and benchmark against alpha-decay damage due to short-lived actinides. At ion energies (keV to MeV) typically used to study alpha-decay damage in nuclear waste forms, the electronic and nuclear energy losses are both important, and the spatial coupling of electronic and nuclear energy loss can lead to reduced or enhanced damage production along the ion trajectory. While alpha particles are much less damaging than alpha recoils, the electronic energy loss from the alpha particles can also cause athermal annealing of alpha-recoil damage that can impact the evolution of radiation damage. Helium implantation studies have shown that helium bubbles form above a threshold helium concentration in candidate waste forms. Swift heavy ions (several hundred MeV to several GeV) have also been used to study radiation damage in nuclear waste forms; although the damage production mechanism and energy densities are substantially different from beta decay or alpha decay, large volumes are damaged.

5:21 PM OPEN DISCUSSION

5:27 PM F.EN08.04.03
Characterising the Effect of Heavy-Ion Irradiation on the Microstructure of Ce-Doped Compounds Ritesh Mohun[1], Sebastian Lawson[1], Theo Cordara[1], Hannah Smith[1], Clémence Gausse[1], Max Cole[1], John S. McCloy[2], Marc Weber[2], Sam Karcher[2], Martin Stennett[1], Neil Hyatt[1] and Claire L. Corkhill[1]; [1]The University of Sheffield, United Kingdom; [2]Washington State University, United States

In this study, we aimed to investigate the radiation effects in doped-fluorite structure ceramics. CeO_2 was chosen as the host matrix because of its fluorite crystallographic (Fm-3m) structure, which consists of a simple cubic oxygen sub-lattice with the cation ions occupying alternate cube centres, similar to UO_2, PuO_2, and ThO_2. The objective was first to quantify the defect chemistry/configurations when CeO_2 is doped with trivalent yttrium at different concentrations, and then to study the atomistic changes when the solid solutions were irradiated with 3 MeV gold ion under two different fluence, corresponding to a damage level of 6 dpa and 33 dpa values respectively.
Initial X-ray diffraction measurements of the prepared samples showed a contraction of the unit cell with Y-content attributed to a certain long-range ordering of the anion vacancies with randomly distributed Y_2O_3 micro-domains of 'C-type' structure which grows coherently within the fluorite matrix. This observation corroborates with Extended X-ray Absorption Fine Structure (EXAFs) analysis which indicated a change in the coordination number when the dopant is introduced in the CeO_2. On the other hand, Raman spectroscopy was used to quantify the presence of oxygen vacancy-type defects formed to compensate for the charge due to the substitution of Ce^{4+} with a trivalent dopant and the presence of reduced Ce^{3+}.
In regards to the irradiated samples, the excellent radiation stability of Ce-based compounds was reported and it was observed that Au-incident ions tend to reduce Ce^{4+} to Ce^{3+}. In addition, Positron annihilation spectroscopy measurements showed that the lower irradiation fluence increases considerably the concentration of lattice damages close to the disorder saturation level, where all the implanted positrons are trapped and a further increase in the irradiation dose initiates a dynamic damage recovery. Relevant defect mechanisms for the two considered irradiation fluence studies were identified and will be detailed in this presentation.

5:33 PM F.EN08.04.05
Effect of Ionizing Radiation on PuO_2 and Surrogate Oxide Materials Under Storage Condition5 Luke Jones[1], Darryl Messer[1], Robin Orr[2], Howard E. Sims[2], Andrew B. Horn[1] and Simon M. Pimblott[3]; [1]University of Manchester, United Kingdom; [2]National Nuclear Laboratory, United Kingdom; [3]Idaho National Laboratory, United States

The stockpile of plutonium separated from used nuclear fuel amounts to many 100s of tonnes. The majority of this plutonium is stored as PuO_2 powder packaged in multi-can containers. The conditions during the packaging of reprocessed PuO_2 for long term storage are closely controlled to limit water uptake as radiolytic decomposition of any adsorbed water will lead to the formation of both a potentially flammable atmosphere containing molecular hydrogen as well as reactive oxygen species which may be incorporated into the oxide phase. Consequently, the safety case for the long-term storage of PuO_2 requires a complete understanding of the fundamental physical, chemical and materials degradation processes occurring at the water-oxide interface inside the storage canisters. This study investigates the effect of ionizing radiation on PuO_2 and various surrogate oxides under atmospheres potentially encountered in storage canisters.
To elucidate the effects of adsorbed water, samples of baked oxide powder were equilibrated in humidity chambers to attain a wide range of masses of water adsorbed onto the powder surface. In the case of PuO_2, once the surface water on the oxide had equilibrated with the humid atmosphere, the samples were sealed into a glass vessel held at constant humidity with either an argon or a nitrogen over-gas and left for up to 3 months. Periodic sampling of the headspace was undertaken and the atmosphere above the oxide analyzed using gas chromatography. In the case of the surrogate oxides, once the oxides had adsorbed the maximum quantity of water, the samples were flame sealed under argon into a glass tube and Co-60 gamma irradiated. Prior to and after gamma irradiation, the oxide powders were characterized using a variety of different microscopy and spectroscopy methods. Following gamma irradiation, the headspace was analyzed using gas chromatography. For PuO_2, the rate at which H_2 was produced increased with increasing water loading. This result contrasts with the experimental data in this study and from similar experiments in the literature utilizing UO_2, CeO_2 and ZrO_2 which showed a higher rate of production for lower water coverages. There was no evidence of a steady state hydrogen concentration being reached in the PuO_2 experiments, an outcome opposite of that observed in storage canisters and in experiments performed by other groups in which the PuO_2 was not held under constant humidity. Radiolytic production of molecular oxygen was not observed. Comparison of the properties of the surrogate oxide (ZrO_2) powder prior to and post irradiation did not reveal any differences in stoichiometry, surface functionalization or the formation of oxygen-centered free radicals, so the location of the sibling oxidant to the evolved molecular hydrogen currently remains unanswered.
Parallel experimental and modeling studies considering the chemistry of PuO_2 and surrogate oxides in H_2:O_2:Ar atmospheres are ongoing. To perform the experiments, a bespoke manifold was designed and commissioned to mix various ratios of H_2-O_2 and Ar gas. Gas chromatography was used to analyse post-irradiated samples. Experiments were performed in 10 ml volume 316 stainless steel canisters (with no degradable polymeric components). Experimental data will be presented showing the extent of recombination of H_2-O_2 mixtures in Ar under ^{60}Co γ rays and accelerated He ion irradiation and the influence an oxide surface on this recombination: radiolytic reaction of H_2 with O_2 to form H_2O is enhanced over what is expected from gas phase processes suggesting significant interfacial chemistry.

5:39 PM F.EN08.04.06
Quantifying the Effects of Grain Boundary Areas on the Irradiation Behaviour of UO_2 Ritesh Mohun, Sebastian Lawson, Daniel Bailey, Shikuan Sun, Clémence Gausse, Hannah Smith, Max Cole, Martin Stennett, Neil Hyatt and Claire L. Corkhill; The University of Sheffield, United Kingdom

Complex microstructural changes occur in nuclear fuels due to the extreme environments of intense irradiation and high temperature during in-reactor operations. Several theoretical and experimental works are currently in progress to determine the effect of crystalline defects which has a major influence on the behaviour of fission products, mainly in regards to rare gases, that may impact the life-span of the rod-type uranium fuel element. For instance, the nucleation of insoluble gas bubbles is thought to act as trapping sites for migrating vacancy-type defects, and further increase in the damage levels induces significant microstructural modifications. In this study, we aimed to investigate the specific role of microstructure on the radiation stability of nuclear fuels.
For this purpose, UO_2 pellets with different microstructures were initially prepared through the wet chemistry route and sintered at different temperatures. Scanning electron microscopy and X-ray diffraction characterisations were performed to quantify the grain size/boundaries areas and crystallinity of the pristine samples. Raman spectroscopy also proved useful and

allowed to investigate the effect of sintering temperature on the concentration of intrinsic lattice defects. The samples were then implanted with 1 MeV Krypton-ions at room temperature to induce irradiation damages in the matrix of the different grain-size UO_2 pellets.
Post-irradiation measurements were carried to highlight the excellent radiation stability of fluorite-type nuclear fuels. However, it was observed that the UO_2 microstructure has an important effect on the point defects produced by the displacement cascades induced by ionic implantation. In this presentation, an attempt is made to detail the mechanisms occurring near the defect-boundary interfaces in relation to radiation damage to highlight the precise role of grain boundaries modifying the defects behaviour and their subsequent evolution in fluorite structure relevant to nuclear fuels.

5:45 PM F.EN08.04.07
Assessment of Positrons for Defect Studies in UO_2 and CeO_2 Materials Marc H. Weber[1], Ritesh Mohun[2], Sam Karcher[1], Claire L. Corkhill[2] and John S. McCloy[1]; [1]Washington State University, United States; [2]The University of Sheffield, United Kingdom

The safe disposal and long-term isolation of spent mixed oxide nuclear fuel poses significant challenges. Uranium and plutonium oxides enriched with rare earth and lanthanide fission products and under constant irradiation with alpha particles and neutrons must be stored in geologic formations for thousands of years. A detailed understanding of the microstructure and chemistry is required to optimize processing designed to recover fissionable products from used fuel and to improve the safety and volume of radioactive waste. Cerium oxide (ceria) has been identified as a suitable non-radioactive substitute to study the microstructure and its evolution under long term irradiation.
A number of techniques have been applied to uranium and cerium oxides to investigate basic properties and point defects. These include neutron scattering, X-ray diffraction and Raman spectroscopy of as produced, irradiated and annealed materials. These are sensitive to structural properties (XRD, neutrons) and oxygen vacancies (Raman). Positron annihilation spectroscopies (PAS) are sensitive to neutral and negatively charged vacancy-like point defects and impurity-vacancy complexes. Positrons can provide depth resolved information about uranium or cerium vacancies to complement Raman data. PAS has been applied previously to UO_{2+x} to investigate the properties of nuclear fuels.[1,2,3] Virtually no PAS work exists on CeO_2, doped or undoped. Currently, PAS are being used to investigate rare earth and lanthanide doped cerium oxide. The work on uranium oxide by the group of MF Barthe[1,2] demonstrated the presence of significant concentrations of uranium vacancies or Schottky defects as well as the presence of negatively charged interstitial oxygen atoms in oxygen rich. They also investigated the effect of 1 MeV helium implantation and the interaction of the implanted helium with the formed vacancies during annealing. Xe bubbles and their thermal evolution could also be observed.[4]
In this presentation, the basics of positron annihilation spectroscopy will be presented. PAS work on undoped and doped cerium oxide will be shown and compared to results from uranium oxides. To simulate spent nuclear fuels, the samples were doped at different concentration with rare earth elements or yttrium, zirconium. Select samples were irradiated with heavy ions at different doses. Differences were observed depending on what simulated fission products are present. Preliminary results and literature searches show some correlation with Raman data.

Secondary Phase Derived Uranium Oxy-Hydroxides as Potential Host Matrices for Anionic Fission Daughters Gabriel Murphy, Philip Kegler, Andreas Wilden, Martina Klinkenberg and Evgeny Alekseev; Forschungszentrum Jülich GmbH,

Germany

Layered uranium oxyhydroxide (LUOH) phases are important minerals which occur as weathering products of uraninite deposits and also importantly, are encountered during the paragenetic sequence of secondary phases that form during an accident scenario involving spent nuclear fuel (SNF) in the near-field (1). Understanding the structural-chemistry of these phases is of importance as via interaction mechanisms, they can potentially retard the transport of harmful fission daughters from SNF towards groundwater and the biosphere. Particularly it has been previously shown that the secondary LUOH phases, such as metaschoepite, uranophane and studite, can act to impede and retard the transport of fission daughters and SNF products such as NpO_2^+, Cs^+ and Sr^+ (2,3). Chemically, the origin of these favourable interactions is predominantly due to favourable intercalation chemistry between cationic SNF species with that of anionic lattices of encountered phases. However in the case of anionic fission daughters, such as ^{131}I and ^{79}Se, these present considerable concern during release from SNF as the overwhelming majority of near-field SNF secondary phases and minerals possess anionic lattices, including LUOH phases, which are typically not expected to react and intercalate well with. Although some evidence is present for partial intercalation of anionic iodine into layered mineral structures through ionic exchange mechanisms in model system studies (4-6) the current consensus is the retention of anionic SNF release products in the near field is not proven and best considered in the far-field of SNF repository performance and accident scenario assessment. Layered double hydroxide (LDH) phases are considered prime candidate materials and minerals for the retention of these anionic phases and received considerable attention (7), however in the context of an accident scenario with SNF their occurrence is not certain. We have recently undertaken a comprehensive systematic investigation of actinide solid state systems relevant to SNF and nuclear waste management. In the course of our investigations we have examined the chemical interactions that may occur between the anionic fission daughter species, I and Se in different chemical forms with some potential LUOH phases associated with SNF. Using a combination of batch synthesis experiments and *in situ* exchange experiments, we provide evidence for the inclusion and retention of these anionic species in LUOH phases. Importantly, using single crystal X-ray diffraction we show the ability for anionic species to be incorporated into certain LUOH phases is a consequence of their respective topological arrangement of uranyl and hydroxyl groups. Furthermore, by considering the topology and structural chemistry of LUOH phases, it can allow for a predictive basis to be established towards which the relative interaction affinity between certain anionic fission daughter species and specific LUOH phases can be understood. The systematic experimental studies used in this investigation will be discussed in detail w.r.t potential interactions that occur between anionic fission daughters and LUOH derived secondary phases that occur during an accident scenario involving SNF.

An Investigation into the Local Structure of Ln_2TiO_5 Stuffed Pyrochlores Through XAS Analysis Daniel A. Austin[1], Martin Stennett[1], Shikuan Sun[1], Bruce Ravel[2] and Neil Hyatt[1]; [1]University of Sheffield, United Kingdom; [2]National Institute of Standards and Technology, United States

Stuffed pyrochlore ceramics, with the general stoichiometry Ln_2TiO_5, have received significant interest for application within the nuclear industry due to their high radiation tolerance, good thermal stability, and structural flexibility. These ceramics have been proposed as a potential wasteform for actinide wastes, for incorporation into inert matrix fuels (IMF), and as inclusion in oxide dispersion strengthened (ODS) steels. These materials can be viewed as derivatives of pyrochlore structured $Ln_2Ti_2O_7$ phases and are often more conveniently written in the form $Ln_2(Ln_{0.67}Ti_{1.33})O_{6.67}$, where the pyrochlore B-site now contains mixed occupancy. These materials can adopt a variety of different crystal structures depending on the size of the lanthanide cation, and the temperature and pressure used during synthesis. The three reported crystal structures are orthorhombic (*Pnma*), hexagonal (*P6₃/mmc*) and cubic defect-fluorite (*Fm-3m*). Compounds that are nominally assigned as defect-fluorite by X-ray diffraction have been probed by neutron diffraction (ND) and transmission electron microscopy (TEM) revealing features consistent with the presence of short range ordered regions with the (*Fd-3m*) cubic pyrochlore structure.

In this contribution we present a study probing the local structure of a series of Ln_2TiO_5 (Ln = La, Gd, Dy, Yb, Y) compounds. They were synthesised via a solid state synthesis route under different cooling regimes to prepare samples of identical chemistry but different short range ordering. Fabrication of high quality sintered specimens of Ln_2TiO_5 phases is a particular challenge due to their refractory nature. Therefore, a systematic study of sintering parameters was undertaken to optimise the fabrication of sintered ceramic specimen. Characterisation of these materials was performed using techniques including XRD, SEM/EDX and XAS. Initial XAS results show that some of these materials do have a cubic pyrochlore-like local structure but show a deviation from the ideal coordination environment of cubic pyrochlore.

6:12 PM F.EN08.06.04
Chemical Bond Complexity in $A^{III}_6B^{VI}O_{12}$ Fluorite-Related Ternary Oxides Maulik K. Patel[1], Kurt E. Sickafus[2] and Gianguido Baldinozzi[3]; [1]University of Liverpool, United Kingdom; [2]The University of Tennessee, Knoxville, United States; [3]Université Paris-Saclay, France

Oxides with generic stoichiometry A_7O_{12} occupy, in a generic phase diagram, an intermediate place between fluorite and bixbyite structure types. Their structure is derived from the ideal fluorite structure, and it is characterized by a more or less pronounced ordering of the O vacancies within the average fluorite sublattice. We believe that ternary oxides with this generic formula display some structural flexibility relevant to fission product stabilization in nuclear fuels and to the understanding of actinide waste forms as well. We would like to discuss the structural characteristics of the chemical bonds in these ternary systems consisting of trivalent and hexavalent cations studying the electron density using the tools of the quantum theory of atoms in molecules (Bader's AIM theory and ELF). Eventually, in these compounds with generic formula $A^{III}_6B^{VI}O_{12}$, the A cation can be either an actinide or a rare earth element, whereas the B cation can be either a transition metal (W, Mo) or hexavalent uranium. We believe that studying the characteristics of the polyhedron of the sevenfold coordinated A ion is particularly interesting: it is often described in the literature as a mono-capped trigonal prism, with bond lengths exhibiting an extremely large dispersion, ranging for instance from 2.19 to 2.70 Å in Y_6WO_{12}. We would discuss the implications of this large dispersion of distances on the chemical bond characteristics, compare DFT models with experiments on pristine and irradiated specimens, and discuss the competitive metastability of the oxygen deficient cubic fluorite phase that can be observed in some of these systems, as for instance Y_6MoO_{12}.

SESSION F.EN08.10: Live Lightning/Flash III: In Memory of Lou Vance and His Contribution to Development of Nuclear Waste
Session Chairs: Daniel Gregg and Josef Matyas

F.EN08

11:30 AM F.EN08.01.01
Remembering Eric (Lou) Vance (1942-2019)—A Pioneer in Nuclear Wasteforms Daniel Gregg, Rifat Farzana, Pranesh Dayal, Rohan Holmes and Gerry Triani; Australian Nuclear Science and Technology Organisation, Australia

Dr Eric (Lou) Vance was a trailblazer in developing novel treatment solutions for intractable nuclear wastes, who spent 32 years at the Australian Nuclear Science & Technology Organisation (ANSTO) in Sydney. Largely known for his contributions to Synroc technology, Lou's experience spans multiple continents including time at Pennsylvania State University with McCarthy and Roy as well as time at the Atomic Energy of Canada Limited where he studied sphene glass-ceramics. In 1987 he was recruited to ANSTO to progress Synroc technology. Under Lou's leadership, the original Synroc titanate full ceramic formulations invented by Ringwood evolved into a waste treatment technology platform. This platform can be applied to produce glass, glass-ceramic and ceramic wasteforms via hot-isostatic pressing.
Lou's seminal contributions to the science of nuclear waste management are evident in his ~400 scientific articles in international journals/refereed conference proceedings and his co-authorship of 3 patents relating to Synroc. An entertaining and highly popular speaker, Lou was committed to attending two to three international conferences a year to showcase the Synroc technology and his innovative nuclear wasteform research. Lou was a steadfast member of the Scientific Basis for Nuclear Waste Management symposium for several decades and a highly enthusiastic mentor. In this paper, we celebrate the research career of the late Dr Vance and his substantial and essential contributions to the field of nuclear wasteform development and to the development of Synroc technology.

11:36 AM F.EN08.01.02

Iodine Waste Forms—Review and Contributions of Dr. Lou Vance John S. McCloy[1,2], Brian Riley[2,1] and Saehwa Chong[2,1]; [1]Washington State University, United States; [2]Pacific Northwest National Laboratory, United States

The capture and immobilization of long-lived radioactive iodine I-129 must be a priority for future nuclear fuel cycles involving reprocessing. This review summarizes work on waste forms for radioiodine, emphasizing the contributions of Dr. Lou Vance as well as recent work in other groups. As early as the 1980s, Dr. Vance recognized the need for iodine waste forms and was a leader in innovative waste form solutions for iodine and other volatile halides. His studies included immobilization in silicate minerals including zeolites and sodalite, encapsulation in metallic tin, partitioning in synroc mixed-phase ceramics, and consolidation of copper iodide. Here, we recognize his particular contributions to the understanding of iodosodalite, and note some recent work by others following in his footsteps.

11:42 AM F.EN08.01.03
Hot-Isostatic Pressing of Synroc-C—The Effect of Ti-Metal Additions Daniel Gregg, Rifat Farzana, Pranesh Dayal, Zaynab Aly, Rohan Holmes and Gerry Triani; Australian Nuclear Science and Technology Organisation, Australia

Synroc-C, a multiphase ceramic wasteform based on stable and leach resistant titanate minerals, was invented by Australian scientists in the late 1970s. The formulation was directed toward the immobilization of PUREX wastes from the reprocessing of nuclear fuels and was originally to be produced *via* hot-uniaxial pressing (HUPing). Although glass was chosen as the preferred technology during the "Atlanta shoot-out" in the US in 1981, this was ultimately because Synroc lacked the technical maturity of vitrification. However, given the enhanced performance properties of Synroc-C as a wasteform, significant interest has been sustained in this Synroc formulation. The vast majority of work on Synroc-C has been undertaken following consolidation by HUP processing. There is very little reported on hot-isostatically pressed (HIPed) Synroc-C, where HIP canisters are filled with the calcined wasteform material (waste + additives), evacuated and sealed. The HIP canister is then loaded into the HIP chamber and processed through the desired time-temperature-pressure profile to achieve a dense and consolidated wasteform. The appropriate redox conditions within the HIP canister are vital to the formation of the correct phase composition and ultimately attaining a stable and leach resistant wasteform.
In this study, we investigate the effect of Ti-metal addition on the phase formation, microstructural characteristics and durability of HIPed Synroc-C. Dense Synroc-C samples containing 20 wt.% simulated high level waste and with varying Ti-metal additions (0%, 2%, 4% and 8 wt.%) were prepared by HIPing in stainless steel HIP canisters. An investigation of microstructure, mineral phases and elemental distribution in the samples was carried out using quantitative X-ray diffraction and electron microscopic analyses. Results from durability tests are also discussed.

11:48 AM F.EN08.01.04
Immobilisation Options for the Disposition of UK Plutonium Neil Hyatt, Lewis Blackburn, Laura Gardner, Shikuan Sun, Martin Stennett and Claire L. Corkhill; University of Sheffield, United Kingdom

The UK holds the world's largest inventory of separated plutonium under civil safeguards, projected to reach 140 tons at the end of reprocessing options. A significant fraction of this material requires immobilisation for disposal since it is unsuitable for reuse in MOX fuel, which is HM Government's preferred policy for disposition. Additionally, should it not prove possible to implement the policy for plutonium reuse in MOX fuel an alternative immobilisation and disposal option will be required for the greater inventory. This presentation will review the current status of wasteform engineering and process development for manufacture of zirconolite ceramic and glass-ceramic wasteforms for immobilisation of waste and inventory plutonium. We will demonstrate the development of Ce and U surrogate formulations, validated by targeted plutonium studies, with regard to phase assemblage and Pu / surrogate incorporation mechanism. The development of a novel containment system to enable hot isostatic pressing studies utilising U and Th surrogates will be presented, together with operational experience. The application of new, and potentially disruptive, wasteform manufacture technology will also be discussed.

11:54 AM F.EN08.01.05
Immobilization of Cesium and Iodine into $Cs_3Bi_2I_9$ Perovskite-Silica Composites and Core-Shell Waste Forms Kun Yang and Jie Lian; Rensselaer Polytechnic Institute, United States

$Cs_3Bi_2I_9$, a defect perovskite derivative, is a potential host phase to immobilize iodine and cesium with high waste loadings. In this work, two strategies are explored to form $Cs_3Bi_2I_9$-silica composites and core-shell structures in order to improve chemical durability of waste form materials meanwhile maintaining high waste loadings. $Cs_3Bi_2I_9$ loadings as high as 70 wt.% were incorporated into a silica matrix to form silica-ceramic composites, and 20 wt.% $Cs_3Bi_2I_9$ was encapsulated into silica to form a core–shell structure at low temperatures and high pressure. Semi-dynamic leaching experiments indicated Cs

and I were incongruently released from waste form matrices depends on the bonding environment and surface passivating effect. A BiOI alteration layer formed during the surface reorganization, acting as a passivation layer to reduce the release of radionuclides. The long-term iodine release rate was low (30 mg m^{-2} day^{-1}) for 70 wt.% $Cs_3Bi_2I_9$–silica composites leached in deionized water at 90 °C, which can be further reduced to 5×10^{-3} mg m^{-2} day^{-1} for the 20 wt.% core-shell structure. This work highlights a robust way to immobilize the highly mobile radioactive nuclides and surface passivating mechanism through elemental transport across the liquid-solid interface for $Cs_3Bi_2I_9$.

12:00 PM F.EN08.01.06
Incorporation Mechanism of Sr and Ca in Geopolymer Cement Wasteforms Brant Walkley[1,1], Xinyuan Ke[2,1], Ben Griffith[3], Oday Hussein[1], Susan Bernal[4], John Hanna[3] and John Provis[1]; [1]The University of Sheffield, United Kingdom; [2]University of Bath, United Kingdom; [3]University of Warwick, United Kingdom; [4]University of Leeds, United Kingdom

Radioactive waste streams containing ^{90}Sr, from nuclear power generation and environmental cleanup operations, are immobilised in the UK in blended Portland cement (PC) grouts to limit radionuclide leaching. Due to poor compatibility of certain wastes with PC, alternatives such as alkali aluminosilicate 'geopolymer' binders are being investigated. Here, we used multinuclear solid-state nuclear magnetic resonance (NMR) spectroscopy probing ^{23}Na, ^{27}Al, ^{29}Si and ^{39}K nuclei, including high-field (20.0 T) and cross polarisation experiments, along with X-ray diffraction experiments, to investigate the incorporation mechanism of Sr^{2+} and Ca^{2+} in geopolymer wasteforms formed by alkali-activation of metakaolin. The main reaction product identified in gels cured at both 20°C and 80°C is a fully polymerised Al-rich alkali aluminosilicate hydrate ((N,K)-A-S-H) gel comprising Al and Si in tetrahedral coordination, with Si in $Q^4(4Al)$ and $Q^4(3Al)$ sites, and Na^+ and K^+ balancing the negative charge resulting from Al^{3+} in tetrahedral coordination. Faujasite-Na and partially Sr-substituted zeolite Na-A form within the gels cured at 80°C. Incorporation of Sr^{2+} or Ca^{2+} displaces some Na^+ and K^+ from the charge-balancing sites, with a slight decrease in the Si/Al ratio of the (N,K)-A-S-H gel. Ca^{2+} and Sr^{2+} induce essentially the same structural changes in the gels. It was concluded that the disordered geopolymers can readily accommodate Sr^{2+} and Ca^{2+} into their aluminosilicate framework structure via substitution of the divalent alkaline earth cations for monovalent alkali cations in charge balancing sites. This indicates that geopolymer gels are excellent candidates for immobilisation of radioactive waste containing ^{90}Sr and other alkaline earth radionuclides.

12:06 PM *F.EN08.01.07
Development and Application of Colloidal Silica-Based Grouts for Waste Containment Rebecca Lunn, M. Pedrotti, P. Bots, G. El Mountassir, A. Pegano and J. Renshaw; University of Strathclyde, United Kingdom

The UK's nuclear sites contain stored wastes in ponds and silos as well as large volumes of contaminated concrete and soil. During storage decommissioning and deconstruction operations, there are significant risks of radionuclide transport via groundwater and airborne particulate releases. Colloidal silica grout is a nano-particulate material that has the potential to reduce these risks very significantly. In order to utilize such nanoparticulate material as a barrier, we require a detailed understanding of the grout properties. These include its injectability, mechanical behaiour, hydrauclic properties, durability and its impact on the geochemistry of radionuclides in the environment (e.g. fission products such as Sr and Cs). Over the past 5 years, experiments at Strathclyde have progressivley investigated colloidal silica grout properties. Colloidal silica-grouted sand shows an increased stiffness and an enhanced peak friction angle, while still having a very low hydraulic conductivity (~ 10-10 m/s), typical of intact clay. Even under drained conditions, the grout provides mechanical improvement to the soil and retains a very low hydraulic conductivity. The impact on radionuclide geochemistry has been investigated through combining leaching experiments with XAS analyses. These show that colloidal silica induces several competing effects on the mobility of Sr and Cs. First, cations within the colloidal silica gel compete with Sr and Cs for surface complexation sites. Second, an increased number of surface complexation sites is provided by the silica nanoparticles and finally, the elevated pH within the colloidal silica increases the surface complexation to clay minerals and the silica nanoparticles. Finally, experiments to investigate injectability and monitorability show that colloidal silica grout can be successfully injected in silty-sands, its gelling time can be accurately predicted in a full range of environmental conditions and the location of the subsurface barrier created can be accurately identified using Electrical Resistivity Tomography. Potential applications of colloidal silica on nuclear sites include inhibiting radionuclide migration from recently decommissioned structures during care and maintenance (e.g. silos and ponds from which wastes have already been retrieved); the development of primary or secondary barriers around existing radionuclide (or other) contaminated areas; and stabilisation of underground structures. Research work is continuing to improve the mechanical and chemical properties of colloidal silica grouts, such that they can be tailored to suit for indivdual nuclear site-based applications.

12:12 PM F.EN08.01.08

Utilizing Machine Learning in Nuclear Waste Management Natalie J. Smith-Gray, Irmak Sargin, Scott Beckman and John S. McCloy; Washington State University, United States

Machine learning (ML) is a valuable tool that can be used, in combination with domain expertise, to provide insight into nuclear waste vitrification processes. This talk summarizes our preliminary efforts in using ML methods to address important problems facing the nuclear waste vitrification mission at the Hanford site in Washington State. Three case studies using ML modeling will be described: nepheline crystallization, refractory corrosion, and sulfate solubility. In Hanford high-level waste, nepheline crystallization can occur in melt compositions containing high Na and Al contents when glass cools slowly in the canister, partitioning radioactive components to a less-durable residual glass fraction. In low-activity waste compositions, which are generally higher in alkali and volatile components like sulfur and halides, different critical issues present. Firstly, the low solubility of sulfate in borosilicate glass has led to many studies to predict glass composition dependence of this property, such that excess sulfur is not volatilized or partitioned to an alkali molten salt phase during processing. Second, these glass compositions tend to be harsh on refractories, leading to concerns over corrosion and general degradation of melter ceramic components and premature failure. For these three cases, existing datasets were used along with ML techniques to investigate the datasets and create predictive models for the output properties of interest. For all these studies, data science was used to identify underlying trends and correlations which were then applied to create supervised learning models. As a result, it has become evident that ML is a powerful tool that can be utilized to provide insight into complex issues in nuclear waste management, here specifically focused on immobilization by vitrification.

12:18 PM F.EN08.01.09
Machine Learning for Glass Wasteforms' Design and Performance Mathieu Bauchy; University of California, Los Angeles, United States

Vitrification is a key process to turn high-level nuclear waste into durable glasses. However, the virtually infinite compositional envelope accessible to glass wasteforms renders traditional design methods based on empirical knowledge and trial-and-error poorly efficient. In addition, the complex, disordered atomic structure of glasses makes it challenging to develop some mechanistic models relating their composition to their properties and performance. Here, I will discuss how machine learning offers a promising alternative route to predict the properties of glass wasteforms and guide/accelerate the design of novel glasses with enhanced performance for nuclear waste immobilization applications.

12:24 PM F.EN08.01.10
Developing High-Throughput Computational Methods to Discover Hierarchical Waste Forms Matthew Christian, Vladislav Klepov, Kristen Pace, Gregory Morrison, Theodore Besmann and Hans-Conrad zur Loye; University of South Carolina, United States

The development of stable actinide and other radionuclide hierarchical waste-form materials offer potential advantages of greater efficiency/loading, lower leach rates, ease of processing for so-called legacy nuclear wastes. Current waste-form discovery relies heavily on experiments that may or may not be successful in producing a viable product. Computational crystal discovery has aided in the search for new materials for different applications through use of high-throughput algorithms. However, these approaches have not been adapted to actinide and lanthanide compounds due to additional corrections required to properly handle *f*-orbital-containing elements. This presentation will consider the challenges and possible solutions to creating high-throughput computational methods to aide in the experimental discovery of novel hierarchical waste forms and offer tangible examples.

12:30 PM F.EN08.01.11
Thermodynamic Modelling of the Pd-Ru-Te-O for Nuclear High-Level Waste Immobilization Stéphane Gosse[1,2], C. Laurin[3], E. Régnier[3], A. Laplace[3] and S. Schuller[3]; [1]CEA, France; [2]Université Paris-Saclay, France; [3]Commissariat à l'Energie Atomique – Centre de Marcoule, France

Pd and Ru are the main platinoid fission products formed during burnup of nuclear fuels. During fuel reprocessing, these element partly dissolve in nitric acid and they exhibit very low solubility into borosilicate glasses during the vitrification process. Due to their affinity towards tellurium from the fission product solution, palladium mainly precipitates under (Pd-Te) intermetallics [1] and ruthenium is likely to form hcp solid solutions [2]. The composition and microstructures of these phases are also sensitive to oxygen potential [3]; oxydation of ruthenium can lead to needle-shaped or polyhedral $(Rh,Ru)O_2$ oxide phases [4]. These precipitates can affect significantly the physico-chemical properties of the glass melt during melting in hot or cold crucible.
For decades, many studies were undertaken at CEA [5] to point out the high temperature interactions of the platinum group

metals (PGM) issuing from the calcinated waste. In parallel to these studies, a Calphad database is being developed to address the thermodynamics of such systems to provide an assessment of the PGMs in nuclear waste.
This study presents the assessed binary systems. Some calculations are also performed to highlight how this flexible tool makes is used to predict the stability between metallic and oxide phases as a function of temperature and oxygen potential mainly driven by the glass.

12:36 PM F.EN08.01.12
Thermodynamic Assessment of Zn-Containing Hollandite as a Robust Waste Form Juliano Schorne-Pinto[1], Kyle Brinkman[2], Jake Amoroso[3], Scott Misture[4] and Theodore Besmann[1]; [1]University of South Carolina, United States; [2]Clemson University, United States; [3]Savannah River National Laboratory, United States; [4]Alfred University, United States

The hollandite phase is a potential nuclear waste form for alkaline-earth metals such as Cs and Ba by chemical incorporation into the crystalline lattice. The general hollandite formula is $A_xB_8O_{16}$ with the A-site habitually occupied by large mono- or divalent cations (e.g., Ba, Sr, Na, K, Rb, Cs, Pb), and the B-site by small di-, tri-, or tetravalent cations (e.g., Ti, Al, Fe, Cr, Sc) and it crystallizes in a tetragonal or monoclinic structure depending on the composition. Recently, our group has developed a thermodynamic database to describe the BaO-Cs_2O-TiO_2-Cr_2O_3-Al_2O_3-Fe_2O_3-FeO-Ga_2O_3 system based on the Calphad method, where the hollandite solid-solution was modeled using the Compound Energy Formalism (CEF). Recent findings show the impact of varying A-site Cs stoichiometry of Zn-containing hollandite compositions and related thermodynamic stability. This consequently improved the limited performance of the hollandite phase in a multi-phase composite called SYNROC. We here report on our efforts to include the Zn in our waste form thermodynamic database, modeling the phase equilibria of the complex hollandite-forming oxide waste system.

Multi-Column Evaluations for the Capture and Separation of Krypton and Xenon Using Mordenite Based Sorbents Mitchell Greenhalgh, Amy Welty and Troy Garn; Idaho National Laboratory, United States

A multi-column adsorption system has been designed and installed to evaluate the independent capture and separation of xenon and krypton utilizing solid phase sorbents being developed by the DOE-NE Offgas Sigma team. The xenon and krypton are present in the offgas stream resulting from a used nuclear fuel reprocessing plant. The system is intended to provide greater operating flexibility and testing at a wide range of flow rates while maintaining desired pressure conditions. This system also allows for continuous analysis of effluent gas from each column. The system was set up by packing the first column with AgZ-PAN which has demonstrated a high selectivity for xenon over krypton at ambient temperatures. A second column was packed with HZ-PAN to capture the krypton. The AgZ-PAN column was maintained at ambient temperatures whereas the HZ-PAN column was maintained at 191K. A simulated offgas stream consisting of 1000 ppmv xenon and 150 ppmv krypton in a balance of air was introduced to the first column to capture the xenon and the resulting xenon free effluent was then routed into the second column for krypton capture. Flowrates of the feed stream were varied from 50-2000 sccm. The results of the multi-column testing demonstrated successful separation of xenon from krypton and indicated that increasing superficial velocity does not significantly impact sorbent capacity or initial breakthrough of the columns. This procedure, while not optimized, may be used to reduce the final waste volume of captured radioactive gas species emitted from a reprocessing facility.

1:06 PM OPEN SLOT

1:12 PM F.EN08.03.03
The State-of-the-art Development of Mechanically and Chemically Robust Sorbent for Management of Iodine Josef Matyas, James Amonette and Michael Sinnewell; Pacific Northwest National Laboratory, United States

New generation sorbents are being investigated for the removal and immobilization of radioiodine from the gas streams in a used nuclear fuel reprocessing facility. Silver-functionalized silica aerogel (Ag^0-aerogel) exhibits high selectivity and sorption capacity for iodine. Moreover, a feasible consolidation of iodine-loaded Ag^0-aerogel to a durable SiO_2-based waste form is an attractive choice for sequestering radioiodine. Extended-duration testing of Ag^0-aerogel in highly oxidizing reprocessing off-gas streams indicated fragmentation of granules into small particles. These particles were held up in the column without being carried-over into the off-gas system. However, production of small particles during sorption can lead to compaction of the sorbent, restricting the flow of gas through the column. Our study targeted development of mechanically and chemically stable Ag^0-aerogel through optimized synthesis process, which included using a patent-pending technology treatment to strengthen the granules. The reinforced Ag^0-aerogel with bulk density ~ 0.5 g/cm^3 went through rigorous testing at different off-gas streams followed by attrition testing with a vibratory sieve shaker. There were no fines generated even after 60 min exposure to shaking speeds of ~1800 revolutions per minute, with ~3 mm orbital shaker movement. The mechanically/chemically robust Ag^0-aerogel retained high iodine sorption capacity of 400.5 ± 2.2 mg/g. The presentation will focus on various strategies that have been developed to improve the mechanical/chemical properties of Ag^0-aerogel and conclude with a summary of highlights and a prognosis for future developments.

1:18 PM *F.EN08.03.04
On-Line Monitoring of Molten Salts to Characterize Chemical Composition Amanda Lines, Shirmir Branch, Heather Felmy, Adan Medina, Hope Lackey, Gregg Lumetta and Samuel Bryan; Pacific Northwest National Laboratory, United States

Molten salt systems provide highly efficient heat transfer options without pressurization, making them a potentially valuable tool throughout the energy sector, including solar power and nuclear energy. Molten salt reactors are of particular interest due to the advancements they can offer to the nuclear field, such as improved safety. However, the chemical behavior of key species anticipated in molten salt reactors is not well understood. Tools are needed to monitor and characterize the chemical composition of molten salts to better understand the behavior of actinides, fission products, and corrosion products. Furthermore, these tools are needed to allow for molten salt process control and to support the maintenance of materials accountancy. Of the options available, optical spectroscopy enables powerful routes to characterize these systems *in situ*. Utilization of these tools allows for the fast and robust identification and quantification of many chemical species of interest to molten salt processing, reactor control, and corrosion characterization. Most importantly, optical spectroscopy can enable the analysis of oxidation state ratios and species complexation, which can significantly impact system performance and corrosion behavior. Optical spectroscopy-based monitoring can be leveraged in fundamental and applied research. For example, optical spectroscopy can be paired with electrochemistry in spectroelectrochemistry to provide a powerful route to fundamental characterization of redox behavior, speciation, and chemical behavior dependence on temperature. Optical spectroscopy can also be paired with chemometric analysis to enable real-time quantification of target analytes within salt melts. Complex salt systems containing many chemical species will exhibit complex spectral data, presenting signal interferences and band overlap, which can hinder accurate analysis. However, the application of chemometric analysis can enable accurate characterization of multicomponent streams to provide real-time, automated monitoring of a process stream or batch. Optical spectroscopy-based on-line monitoring enables fast and robust identification and quantification of many actinides, fission products, and corrosion products. Here we demonstrate the application of optical monitoring approaches to the characterization of chloride-based salt melts containing lanthanides and actinides.

SESSION F.EN08.12: Live Lightning/Flash V: Spent Nuclear Fuel and Glass Corrosion Research
Session Chairs: Dirk Bosbach and Lena Evins

Overview of the SKB Spent Fuel Research Program over the Years—Knowledge Gained and Remaining Open Questions Lena Z. Evins; Swedish Nuclear Fuel and Waste Management Co, Sweden

The Swedish strategy for spent nuclear fuel has, since around 1980, been direct geological disposal. Research about the properties and dissolution of spent fuel has been going on since then. An overview of this research program is given here with a focus on questions posed and answered along the way, ending with remaining open questions. At the beginning, some basic studies were performed to gain information about spent fuel as wasteform. Dissolution studies were at first mainly performed in contact with air, and often with aqueous solutions that mimicked the expected groundwater chemistry. However, complexities relating to precipitation of secondary phases indicated that simplified water compositions were preferred. Knowing that the radioactivity of the fuel caused radiolytic oxidation of uranium and thus controlled the dissolution rate, there were also attempts to achieve reducing conditions via bubbling a hydrogen/argon mixture in presence of a palladium-catalyst. The first attempts resulted in variable results, but notably, a reduction in apparent leach rate was observed for some experiments [1]. Later, possibilities to perform the leaching experiments in autoclaves, with controlled hydrogen atmosphere, allowed experimental conditions closer to the expected repository conditions. These experiments showed that hydrogen, during this type of experimental set-up, could suppress oxidative dissolution caused by radiolysis [2,3]. A new phase of research was thus started where the mechanistic explanation for the observed behaviour was sought. Experimental work, both with spent nuclear fuel and with analogue materials, was coupled with modelling efforts. At the time of the SR-Site safety assessment [4], which was a part of the license application submitted in 2011, a certain understanding had been reached, based on the effect of metallic particles in fuel. Still, questions remained and studies performed during the last decade (see for example [5]) can now be summarised to illustrate the knowledge gained, and remaining open questions. This summary is utilized in the next step in the licensing process: the application to start building the spent fuel repository, which is expected to be submitted within the next couple of years. In the coming decade the SKB research program will continue, with the goal to support the development of the safety assessment report, SAR, which will be submitted to the authorities as a part of the license application connected to start of trial operations.
During all these years, international collaboration has been a cornerstone of the SKB research program. This international collaboration has been carried out via European projects or bilateral agreements, and triggered the start-up of the Spent Fuel Workshops [6]. The research program has also been presented at this MRS symposium since the early 1980's.

Understanding the Dissolution of Advanced Doped Nuclear Fuels for Geological Disposal Hannah Smith, Theo Cordara, Ritesh Mohun, Clémence Gausse, Max Cole, Martin Stennett, Neil Hyatt and Claire L. Corkhill; The University of Sheffield, United Kingdom

The addition of dopants, including chromium and aluminium, to uranium dioxide fuel results in the formation of larger grained microstructures, capable of higher fission gas retention and reduced swelling during operation within nuclear reactors. Despite their growing use by nuclear power plant operators, the long-term dissolution behaviour of spent doped fuels, when compared to typical spent fuel, is not yet well constrained. In a geological disposal facility, the release of radionuclides is known to be controlled by the oxidation of the UO_2 matrix and the subsequent dissolution of UO_2^{2+} species, therefore any changes to the matrix from the addition of dopants could be expected to influence the dissolution kinetics and/or mechanisms.

We here present the results of an investigation of how the addition of Cr_2O_3 to UO_2 fuel influences the crystal chemistry of UO_2 and its dissolution kinetics. Initial results, from experiments performed in air and a bicarbonate solution, show that the addition of Cr_2O_3 reduces the normalised mass loss of uranium. The potential influencing factors that give rise to increased durability with Cr addition, e.g. defect concentration, Cr-oxidation state etc. are discussed.

The “back end” of the nuclear fuel cycle corresponds to the direct disposal or reprocessing of the spent nuclear fuel (SNF), and to the conditioning and disposal in an appropriate repository of the nuclear wastes. In most of these processes, the behavior of actinides and fission products is governed by dissolution reactions at solid/ liquid interface. The design of reprocessing process and of nuclear waste disposal strategy requires the determination of well constrained kinetic and thermodynamic data. The acquisition of reliable kinetic and thermodynamic data is a tough issue considering on the one hand, the complexity of SNF in terms of chemical composition and microstructure and on the other hand, the challenge posed by the manipulation of highly radioactive samples.

For several years, we developed and improved a methodology that aims to determine dissolution rates of uranium-based oxide materials and thermodynamic data of phases of interest for final disposal of spent fuel in deep-mined geological repositories. This methodology is based on the synthesis of model compounds with well defined composition and microstructure, on the measurement of macroscopic dissolution rates in controlled chemical and hydrodynamic conditions, and on the monitoring of the properties of the solid/ liquid interface at the microscopic scale. For that purpose, several surface characterization techniques were used and developed, such as 3D reconstruction of Environmental SEM images, AFM or Grazing Incidence-XRD. To illustrate the progress made beyond the state of the art by using this methodology, several examples have been selected among the studies that we reported in the literature. The selected examples deal either with the reprocessing of uranium based oxides in nitric acid conditions, or with the behavior of UO_2 in SNF under the weathering conditions of geologic disposal.

The mechanisms that control the kinetics of dissolution of U-based oxides in nitric acid solutions are illustrated through the study of samples showing different compositions and microstructures. The use of oriented UO_2 single crystals allowed to evidence the enhanced reactivity of the surface at defect sites during a first kinetic regime. The second kinetic step was attributed to a catalyzed dissolution mechanism involving species produced at the solid/ liquid interface during the first step. The key role of catalytic species in the strong increase of dissolution rate was demonstrated not only for UO_2 single crystals, but also for sintered pellets of (U, Th) mixed oxides and UO_2-doped with platinum group metals. The monitoring of solid/ liquid interface by 3D-ESEM during uncatalyzed and catalyzed regimes revealed specific dissolution sites of enhanced reactivity and specific dissolution features related to UO_2 crystallographic orientation, which traduced a structural control of the topographic evolution of the material.

Most of the geologic sites under investigation for underground repositories are located in undisturbed clay-rich rock or granite, with silica-rich groundwaters, deep enough to have reducing conditions. Understanding the interaction of used fuel with the silicate-rich groundwaters is critical to evaluate the safety of different disposal strategies. For several years, we investigated the role of silicates in the mechanisms of UO_2 weathering. For the first time, we were able to show the formation of coffinite ($USiO_4$) from UO_2 in the presence of solution saturated with respect to SiO_2(am) under conditions typical of deep-mined geologic repositories for SNF. Through dedicated experiments, we have constrained the conditions of formation of coffinite in an Eh-pH diagram. Finally, we showed that coffinite precipitation could lower the uranium release from the UO_2 matrix of SNF through oxidative weathering in the presence of oxygen in the geological repository.

Evaluating Diavlent Cation (Zn, Ca, Mg) Behaviour During the Dissolution of Simulant UK High Level Waste Glass Adam J. Fisher, Russell J. Hand and Claire L. Corkhill; University of Sheffield, United Kingdom

In an effort to incorporate high levels of Mo associated with the post-operational clean-out of high active liqor storage tanks at the Sellafield reprocessing facility in the UK, a modified version of the "MW" sodium aluminoborosilicate base glass has been adopted. The addition of Ca favours the formation of $CaMoO_4$, while Zn infers improved viscosity. This new Ca/Zn MW base glass is currently being used to immobilise reprocessing wastes from oxide fuels and also magnox fuels, which contain a significant proportion of Mg. The divalent cations Ca^{2+}, Zn^{2+} and Mg^{2+} are known to exert an influence on the durability of vitrified wastes, however the nature of their additive, or competitive effects are yet to be fully understood.

We here describe the results of a range of experiments that aim to elucidate the influence of divalent cations on the mechanims and kinetics of glass dissolution. The addition of Zn to the glass was found to enhance durability in dilute, Si-undersaturated conditions, due to an increase in glass polymerisation with increasing Zn content, as determined by ^{29}Si MAS NMR. However, under conditions of Si-saturation, the presence of Zn prevented the formation of a passivating silica gel

layer, and promoted the formation of Zn-containing smectite clays, significantly enhancing the dissolution rate with increasing Zn content. Mg had a similar effect to Zn, which was additive, however glasses containing Ca generally showed lower dissolution rates, in agreement with other studies. The formation of Zn- and Mg-bearing silicates was concurrent with a significant increase in the dissolution rate, similar to Stage III "rate resumption" behaviour, which has previously only been associated with the formation of zeolites.

Fabrication of Unirradiated Advanced Fuel for Dissolution Studies Under Repository Conditions M Nieves Rodríguez-Villagra[1], Sergio Fernández[1], Laura J. Bonales[2], Abel Milena-Pérez[1], Ana Nuñez[1], Sofía Durán[1], Laureano Anta[1], Luis Gutierrez[1] and Joaquín Cobos[3]; [1]CIEMAT, Spain; [2]CSIC-INTA, Spain; [3]EBD-CSIC, Spain

Safety assessment of Spent Nuclear Fuel (SNF) disposal in a Deep Geological Repository (DGR) requires evidences of radionuclides release after groundwater eventually gets into a breached container and contacts the fuel. Within the frame of EU H2020 program into the DISCO project, the impact of additives (Cr, Cr/Al and Gd) is being investigated on the long term DGR dissolution performance and compared to conventional UO_2. In particular, the effect of these dopants is studied on the long term matrix dissolution rate of the SNF, the so-called Advanced Tolerant Fuels (ATF), such as Cr_2O_3-doped UO_2, and Cr_2O_3-Al_2O_3-doped UO_2 fuels.
ATF have demonstrated to reach higher burn-up than conventional UO_2 fuels because dopants provide enhanced safety against Pellet-Clad Interaction failure (PCI), higher density, enlarged grain size, lower fission gas release and higher creep rate. Besides, the difference between those ATF and standard UO_2 in thermo-physical properties is almost negligible [1-4]. However, the dopants influence upon the matrix leaching performance at long term under DGR conditions is still largely unknown when compared to traditional UO_2 SNF.
The combinatory effects of two uncertain parameters (dopants influence and H_2) on UO_2 matrix leaching resistance are investigated. In the context of WP2 and WP4 of the DISCO project, UO_2-based pellets doped with a nominal concentration of $0.06^{w}/_{o}Cr_2O_3$, $0.05^{w}/_{o}Cr_2O_3$-$0.02^{w}/_{o}Al_2O_3$ and $4.5^{w}/_{o}Gd_2O_3$, were systematically produced by homogenizing stoichiometric proportions of UO_2 and dopants, and carefully characterized in order to understand the effects of the addition of Cr- and/or Al-oxide into the fuel matrix dissolution behaviour. Gd-doped UO_2 was also included, as a burnable poison and a trivalent rare-earth dopants (RE^{III}). The results are the basis for potential more complex systems which would correspond to irradiated doped fuels.
Previous studies suggest that RE^{III} play an important role on the UO_2 oxidation, revealing that they prevent the fuel from a complete oxidation to U_3O_8 [5], so in order to better understand the effect of trivalent RE^{III}, a set of dissolution experiments is carried out. The presence of reducing species, such as H_2 (produced by anaerobic iron corrosion and radiolytically), affects the reactivity of UO_2; hence, it must be considered in a long-term safety assessment. On the other hand, it is well known that HCO_3^- (one of the key complexing constituents in the groundwater) is highly likely to influence fuel dissolution by enhancing the solubility of U^{VI} thus preventing the secondary phase formation [6].
To experimentally evaluate the effect of additives (doped fuels) together with H_2(g) and different leachants on UO_2 matrix dissolution rate, leaching experiments were performed under different representative aqueous systems. Prepared pellet/disks were characterized by means of XRD, Raman spectroscopy and SEM-EDX. In order to understand the effect of the presence/absence of HCO_3- that could be considered as relevant to those coming from the interaction of water between natural barriers (groundwater) and EBS (Engineering Barrier System), specific synthetic groundwater was used in the dissolution tests. Static leaching experiments of doped-UO_2 pellets were run in stainless steel autoclaves with reaction vessels made of PEEK autoclaves under a N_2/4.7%H_2 atmosphere. The U and dopants concentration released into the aqueous solution was quantified by ICP-MS. pH and redox measurements were also tracked during the experiments.

Investigation of Secondary Phases Formed During Long Term Aqueous Leaching of Spent Nuclear Fuel Charlotta Askeljung[1], Anders Puranen[2], Olivia Roth[1], Kyle Johnson[1], Alexandre Barreiro Fidalgo[1], Lena Z. Evins[3] and Kastriot Spahiu[3]; [1]Studsvik Nuclear AB, Sweden; [2]AB SVAFO, Sweden; [3]Swedish Nuclear Fuel and Waste Management Co, Sweden

For a future deep repository for spent nuclear fuel, the rate and mechanism for dissolution of fission products and actinides from spent fuel is a key parameter for the safety assessment of the disposal concept. Although the majority of the fuel to be

placed in the deep repository is expected to be intact at the time of disposal, some failed fuel rods will also be present. In a failed fuel rod, the uranium matrix may have been exposed to water in the reactor and during interim storage for several years or decades prior to disposal. This exposure can lead to oxidation of the matrix and the formation of secondary phases under conditions of low uranium solubility. Upon barrier failure and ground water exposure of the spent fuel in the deep repository, these pre-oxidized layers are expected to dissolve at a higher rate compared to unaffected UO_2 and hence increase the rate of radionuclide release. For this reason, knowledge about the characteristics of failed fuel and its behavior under deep repository conditions is required for the evaluation of the long-term safety of geological repositories. The present work aims to add to this knowledge.

Although the behavior of spent nuclear fuel under deep repository conditions has been studied extensively, studies of failed fuel are, in this context, relatively scarce, in particular studies of failed fuel that has been exposed to water during decades of wet interim storage. However, at the Studsvik laboratory in Sweden, leaching tests of spent fuel have been performed since the 1980s. This provides an opportunity to investigate the effects of long term contact with water under aerated conditions, such as those occurring in a wet interim storage.

In this study, XRD investigations have been performed on the surfaces of two fuel pellet samples which have been exposed to leaching solutions (synthetic ground water and deionized water, respectively) for over 30 years. Furthermore, the fuel surfaces have been exposed to carbonate solutions in an effort to dissolve the oxidized phases formed during the extended leaching time. The aim is to characterize the fuel matrix alteration.

Preliminary Results of Dissolution Experiments with Cr-(Pu) Doped UO_2 in Reducing Conditions at SCK CEN Christelle Cachoir, Thierry Mennecart and Karel Lemmens; SCK CEN, Belgium

The development of robust safety cases for geological disposal of spent fuel requires a solid understanding of its dissolution over very long time scale (up to a million years). While the dissolution of standard spent fuel has reached a good level of comprehension, the development of modern LWR fuels (Cr/Al-doped UO_2 or MOX fuels) raises the question whether these fuels will behave similarly to standard fuels in geological repository conditions. Within the EU-DisCo project, systematic dissolution studies have been initiated with carefully prepared and characterized, simplified UO_2-based model materials to understand the matrix dissolution of these modern LWR fuels under geological repository relevant conditions. As DisCo partner SCK CEN has performed such dissolution tests to study the effect of Cr-doping on the UO_2 matrix dissolution rate in reducing conditions. Tests were started on four model materials : UO_2, Cr-UO_2, Pu-UO_2 and Pu/Cr-UO_2 with a density close to 94% of the theoretical density and average grain size around 10 µm for UO_2 and Pu-UO_2 , 35 µm for Cr-UO_2 and 25 µm for Pu/Cr-UO_2 . The Cr doped pellets contain 1600 µg Cr_2O_3 per gram of UO_2, and the alpha doping level of the Pu-doped pellets (~ 18 MBq/gUO_2) is representative for a fuel age of 10,000 years. Static dissolution experiments with these model materials have been performed in autoclaves in two reference waters (synthetic young cementitious water at pH 13.5 and bicarbonate water at pH 9) under 10 bar H_2 pressure and in presence of Pt/Pd catalyst. After a predissolution in 0.01 M NaCl solution for 3 weeks to remove the pre-oxidized UOX layer, samples were taken from the solution over a period up to 2 months. For the materials UO_2 and Cr-UO_2, the Cr-doping leads to lower uranium concentrations in solution, both in synthetic cementitious and in bicarbonate water. In the synthetic cementitious water, this effect is constant over the entire experiment, but the concentrations, increasing immediately after the replacement of the NaCl solution by the cementitious solution, remain high at ~10^{-7} M for UO_2 and ~10^{-8} M for Cr-UO_2. In bicarbonate water, the initial uranium concentrations (after replacement of the NaCl solution by the bicarbonate solution) are the same as for the cementitious water, but after 2 months, all concentrations are ~10^{-9} M. These preliminary results suggest that the Cr doping decreases the U release in solution, but the long-term effect depends on the leaching solution. Experiments with the Pu doped materials (Pu-UO_2 and Pu/Cr-UO_2) are now carried on to study the Cr-effect in combination with alpha-radiolysis of the solution.

8:42 AM F.EN08.05.09
Aqueous Leaching of Chromia-Doped UO_2 Spent Nuclear Fuel Under Oxidizing Conditions Alexandre Barreiro Fidalgo[1], Olivia Roth[1], Lena Z. Evins[2] and Kastriot Spahiu[2]; [1]Studsvik Nuclear AB, Sweden; [2]SKB, Sweden

Programs for deep geological repositories are being developed in many countries to safely dispose of spent nuclear fuel. Therefore, understanding the behavior of spent nuclear fuel under relevant conditions is crucial for the safety assessment of these facilities. During the last decades, new types of nuclear fuel are being introduced in commercial reactors. To allow these new fuels in the spent fuel repository, it must be shown that they do not dissolve at a higher rate than standard fuel. Fuel additives such as chromium oxide (Cr_2O_3) have an impact on the UO_2 microstructure and therefore might affect properties

relevant to the safety assessment.

The main goal of this investigation is to understand the effects of Cr-doping on the instant release fraction of fission products and the matrix dissolution under oxidative conditions. A sample consisting of fuel fragments and separated cladding is leached in simplified groundwater under aerated conditions at Studsvik's Hot Cell Laboratory. The fuel used in this study was manufactured by AREVA and has been irradiated in a Swedish commercial pressurized water reactor (PWR) to a local burnup at the sampling position of ~59 MWd/kgU.

Data from the leaching experiments are presented and compared to other commercial fuels' leaching performance: Cr-doped fuel with lower doping levels (Advanced DOped Pellet Technology, ADOPT) and standard UO_2 fuel.

8:48 AM F.EN08.05.10
UO_2-Based Model Systems—Model Materials for Studying the Matrix Corrosion of Spent Modern Nuclear Fuels Philip Kegler, Martina Klinkenberg, Andrey Bukaemskiy, Felix Brandt, Guido Deissmann and Dirk Bosbach; Forschungszentrum Jülich GmbH, Germany

The direct disposal of spent modern nuclear fuel (SNF) in a deep geological repository (DGR) requires an in-depth understanding of the long-term corrosion behavior of the SNF and the associated radionuclide source term. These are indispensable requirements for demonstrating the long-term safety of the DGR. Today's modern Cr- and Al-doped light water reactor (LWR) fuels have already successfully demonstrated their improved in-reactor performance, but it is still not known, whether the corrosion behavior of such fuels in a DGR is similar to conventional spent LWR-fuels. Due to the chemical and structural complexity of SNF and its high beta and gamma radiation field, experiments with SNF cannot unravel all of the various concurring dissolution mechanisms entirely. Thus within the EU-DisCo project single-effect dissolution studies are carried out with systematically produced and carefully characterized UO_2-based model materials, to provide additional insights into the behavior of modern doped LWR-fuels under the post-closure conditions expected in a DGR, complementary to dedicated dissolution experiments with SNF.
Here, we present recent results on the dissolution behavior of tailor made UO_2 model materials in accelerated static batch experiments using H_2O_2 as simulant for radiolytic oxidants, present in long-term disposal scenarios for SNF in failed container conditions due to the alpha-irradiation of water. In these dissolution experiments pure UO_2 reference pellets exhibiting different densities and grain sizes, as well as Cr-doped UO_2 pellets with various Cr-doping levels, produced using different doping methods having different grain sizes, were used. In addition, Nd-doped and industrially produced Cr- and Cr/ Nd-doped UO_2 pellets were used to determine the influence of these parameters on the dissolution rates. The dissolution experiments were performed under strictly controlled conditions with respect to exclusion of oxygen, temperature control, and exclusion of light. During the dissolution experiments, solutions were systematically sampled and the H_2O_2 (UV-Vis) and the uranium (ICP-MS) concentrations were determined.
The initial dissolution rates of all materials were determined from the concentrations of dissolved U(VI) obtained within the first 24 hours of the experiments. In experiments with pure UO_2 reference pellets a clear linear dependence of the initial dissolutions rates from the density of the pellets was observed, with higher initial dissolution rates at lower densities. No dependence on grain size was found. The initial dissolution rates of pure, Cr-doped, and Nd-doped UO_2 pellets fall into three groups: i) pure UO_2 pellets with the fastest dissolution rates, independent of the oxygen potential during sintering (and therefore the grain size), ii) Cr-doped UO_2 pellets, independent of doping method, doping level, and oxygen potential during sintering (grain size), and iii) Nd-doped UO_2 pellets with the lowest dissolution rates. The following initial dissolution rates were calculated for the different materials:
pure UO_2: 1.3 +/- 0.1 * 10^{-6} mol/m^2*s
Cr-doped UO_2: 0.65 +/- 0.2 * 10^{-6} mol/m^2*s
Nd-doped UO_2: 1.63 +/- 0.7 * 10^{-7} mol/m^2*s
The slight difference between the dissolution rates of pure UO_2 and Cr-doped UO_2 pellets (i.e. factor 2) can partly be explained by the slightly lower density of pure UO_2 pellets compared to Cr-doped UO_2 pellets. A very strong influence of Nd, representative of fission lanthanides in SNF, on the dissolution rates in this type of experiments is clearly visible. Although the density of the Nd-doped UO_2 pellets is similar to the Cr-doped pellets (i.e. 96-98% relative density), the initial dissolution rate is more than half an order of magnitude lower than for Cr-doped pellets. Overall, the results of this study indicate that the Cr-doping of modern nuclear fuels seems to have no significant effect on the corrosion behavior of UO_2-based SNF.
.

Dissolution Kinetics of Metaluminous and Peralkaline Calcium Aluminosilicate Glass at 75°C, pH = 7.5: Rate Control

by Si-Content of Glass Jon P. Icenhower, Hugh McMahon, Misty Riesbeck, Elzbieta Bakowska, Randall Youngman and Nicholas Smith; Corning, United States

The dissolution rates of six calcium aluminosilicate glasses were determined experimentally at pH(25 °C) = 7.5 and a temperature of 75 °C in a Single-Pass Flow-Through (SPFT) system. Glasses studied in this work can be categorized into two sets of three compositions each. In the first (metaluminous) set, the molar proportion of CaO to Al_2O_3 remained the same (1:1), while SiO_2 increased (40, 50 and 60 mol.%). The second (peralkaline) set was characterized by constant Al_2O_3 (10 mol.%), with decreasing CaO and increasing SiO_2 (40, 50 and 60 mol.%). Measurements of ^{27}Al by MAS-NMR indicated a slight increase in $Al^{[5]}$ at the expense of $Al^{[4]}$ with decreasing Si concentration. One to four grams of powdered glass (300 to 425 mm diameter) were placed into 10 mL volume reactors with solution input through the bottom and effluent solution output through the top. Solutions were buffered by 0.05 M *TRIS* and flow-rates varied between ~38 and 500 mL/d. A plot of the dissolution rate vs. flow-rate (q) to surface area (S) showed that all dissolution rates were maximized at $q/S \approx 45 \times 10^8$ m/s. Dissolution rates were from 4.2, 1.5 and 0.62×10^{-7} mol/(m^2 sec) for the metaluminous and 1.0, 0.65 and 0.50×10^{-7} mol/(m^2 sec) in the peralkaline glasses, respectively. Interestingly, the data indicate that rates for the metaluminous trio are generally faster than those of the peralkaline set, which runs contrary to expectations. As a set of glasses, the $\log_{10}$ rates [mol/(m^2 sec)] are inversely proportional to the fraction of Si in the glasses, forming a single array of values. These data indicate that rates are strongly tied to the Si content of glasses, and that other glass composition parameters— including Ca/Al (molar) ratio—exert a much weaker effect on dissolution rate in this medium.

9:00 AM F.EN08.05.13
Adsorption and Diffusion of Boron Isotopes in Aqueous Glass Dissolution Thomas L. Goût[1], Rui Guo[1,2], Sambuddha Misra[1,3], Aleksey Sadekov[4], Edward Tipper[1], Madeleine Bohlin[5] and Ian Farnan[1]; [1]University of Cambridge, United Kingdom; [2]Tsinghua University, China; [3]Indian Institute of Science, India; [4]The University of Western Australia, Australia; [5]Uppsala University, Sweden

Predicting the release rates of radionuclides from nuclear waste glasses during aqueous dissolution within a disposal facility over geological timescales requires robust models of dissolution built upon an extensive understanding of glass dissolution mechanisms. However, many of the dissolution models presented in the past decade conflict regarding the mechanisms predicted to control dissolution. Whilst nanoscale post-process analyses of altered glasses have afforded insights into altered layer structures, these results highlight the need for an additional dimension to understand the mechanisms of glass dissolution beyond the conventionally employed techniques presented in the literature.
In a previous study, lithium isotope fingerprinting techniques were applied to the leachates of a simplified Magnox waste glass leached at 90 °C. It was shown that whilst dissolution was initially congruent, lithium isotopes leached incongruently through diffusive processes across a passivating altered layer component at longer durations. However, further evidence was required to rank the dissolution models presented in the literature. Here, boron isotope fingerprinting techniques were applied to the same Magnox glass to further understand its dissolution processes, understand how lithium and boron were leached and distinguish between dissolution models. Additionally, the same isotopic techniques were applied to leachates of an international benchmark glass composition to compare the dissolution processes of the two compositions and allow for interdiffusion models to be fitted to the results. Solution renewal experiments took place to further investigate the passivating nature of the altered layers and their role as a diffusive barrier to dissolution at long durations.
Boron isotopes leached from the Magnox glass were consistent with congruent models of dissolution in the initial stages of dissolution, but at later stages were consistent with diffusive isotopic fractionation across a passivating altered layer component about an incongruent dissolution front. Whilst boron isotopes in the leachates of International Simple Glass were consistent with diffusive, incongruent dissolution models throughout dissolution, boron isotopes in its solution renewal experiment were most consistent with congruent models of dissolution. As such, these isotopic methodologies demonstrate that no single dissolution model may be correct for all glass compositions and experimental conditions; providing an improved understanding of the mechanisms governing aqueous glass dissolution and supporting the idea of a model which unifies the mechanisms presented in the literature.

Chemical and Structural Investigations on Uranium Oxide Based Microparticles as Reference Materials for Analytical Measurements Stefan Neumeier[1], Philip Kegler[1], Fabien Pointurier[2], Anne-Laure Faure[2], Kathy Dardenne[3], Jörg Rothe[3], Tonya Vitova[3], Martina Klinkenberg[1], Fabian Kreft[1], Dirk Bosbach[1] and Irmgard Niemeyer[1]; [1]Forschungszentrum Jülich GmbH, Germany; [2]CEA, France; [3]Karlsruhe Institute of Technology, Germany

The analysis of individual micrometre- and submicrometre-sized particles collected by IAEA safeguards inspectors on swipe samples during in-field verification activities requires the implementation of a sustainable quality control system. This system

needs to be further advanced by developing mass spectrometric analytical measurements and of suitable reference materials. In this context pure and compound reference materials in microparticulate form such as U, *Ln*/U, Th/U and Pu/U microparticles are of special interest. For the design of these microparticulate reference materials, according to their required properties, the understanding of morphology, chemistry, and structure is essential.
To this end, the production of pure and neodymium doped uranium-oxide based microparticles utilising an aerosol-based particle production process which has been developed and established in the laboratories of Forschungszentrum Juelich since 2012 will be presented. This method allows for the generation of microparticles with monodisperse particle size distribution. SEM/EDX measurements confirmed the monodispersity of the produced microspheres as well as the incorporation of 15 mol% Nd into the compound particles. Additionally, results from *In-SEM* μ-Raman (CEA, DAM) and U L_3-edge XAFS measurements in U L_α fluorescence yield detection mode (INE-Beamline @ KIT synchrotron radiation source) will be discussed pointing to the formation of U_3O_8 microparticles for both compounds. The position and shape of the X-ray absorption spectrum is insignificantly affected by the incorporation of 15 mol% Nd, indicating the structural flexibility and stability of the U_3O_8 microparticles. Additionally, a minor fraction of schoepite phase was identified by Raman measurements, which is most probably caused by ageing processes during storage under laboratory conditions.
The first batch of U_3O_8 microparticles produced in Juelich was successfully applied in an international laboratory exercise NUSIMEP9 organised by JRC-Geel and finally certified regarding the isotopic composition and the U amount per particle. These results demonstrate that the process established in Juelich allows for a very flexible and reliable preparation of reference materials for particle analysis methods applied in safeguards.

Nanostructured Uranium Oxide Thin Films Developed by Molecular Precursors Using Chemical Vapor Deposition Dennis Grödler, Lasse Jurgensen, Aida Raauf, Markus Zegke and Sanjay Mathur; Institute of Inorganic Chemistry, Germany

Advanced materials have been made using a variety of elements, however, uranium has not seen much impact. The common fear of working with “nuclear material” has prevented its chemical use, even though it has been known since 1911 to be an efficient catalyst in the widely applied Haber-Bosch process. A possible strategy to synthesize advanced materials based on uranium is the chemical vapor deposition (CVD). To date, only a few suitable uranium precursors have been reported.
Here we report new volatile uranium(IV) complexes based on β-ketoenamine ligands, which have been structurally characterized and which can be synthesized via a simple salt metathesis. Functionalization of the N atom of the chelating ligand changes the coordination motif, and subsequent NMR studies offer a deeper insight into the coordination chemistry. Sterically demanding ligands (L) selectively lead to heteroleptic complexes of the form UCl_2L_2 while an additional degree of freedom in the substituent allows for the isolation of homoleptic complex of the form UL_4 with significantly increased volatility. These are suitable candidates for CVD towards uranium oxide thin films. Uranium oxides with band-gap energies in a range of 1.8 – 2.7 eV coupled with their good electrical and catalytic properties mostly driven by facile valence dynamics of the uranium cations are promising electrode materials in photoelectrochemical water splitting reactions.
We have been able to synthesize a variety of such ligands and present four novel uranium complexes which we are currently investigating with respect to the formation of novel uranium based thin film materials. Furthermore, using β-heteroarylthioketamine ligands leads to similar complexes that may be used as precursors for uranium sulfide thin films.

SESSION F.EN08.01: In Memory of Lou Vance and His Contribution to Development of Nuclear Waste Forms
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-EN08

5:00 AM F.EN08.01.01
Remembering Eric (Lou) Vance (1942-2019)—A Pioneer in Nuclear Wasteforms Daniel Gregg, Rifat Farzana, Pranesh Dayal, Rohan Holmes and Gerry Triani; Australian Nuclear Science and Technology Organisation, Australia

Dr Eric (Lou) Vance was a trailblazer in developing novel treatment solutions for intractable nuclear wastes, who spent 32 years at the Australian Nuclear Science & Technology Organisation (ANSTO) in Sydney. Largely known for his contributions to Synroc technology, Lou’s experience spans multiple continents including time at Pennsylvania State University with McCarthy and Roy as well as time at the Atomic Energy of Canada Limited where he studied sphene glass-ceramics. In 1987 he was recruited to ANSTO to progress Synroc technology. Under Lou’s leadership, the original Synroc titanate full ceramic formulations invented by Ringwood evolved into a waste treatment technology platform. This platform

can be applied to produce glass, glass-ceramic and ceramic wasteforms via hot-isostatic pressing.
Lou's seminal contributions to the science of nuclear waste management are evident in his ~400 scientific articles in international journals/refereed conference proceedings and his co-authorship of 3 patents relating to Synroc. An entertaining and highly popular speaker, Lou was committed to attending two to three international conferences a year to showcase the Synroc technology and his innovative nuclear wasteform research. Lou was a steadfast member of the Scientific Basis for Nuclear Waste Management symposium for several decades and a highly enthusiastic mentor. In this paper, we celebrate the research career of the late Dr Vance and his substantial and essential contributions to the field of nuclear wasteform development and to the development of Synroc technology.

5:10 AM F.EN08.01.02
Iodine Waste Forms—Review and Contributions of Dr. Lou Vance John S. McCloy[1,2], Brian Riley[2,1] and Saehwa Chong[2,1]; [1]Washington State University, United States; [2]Pacific Northwest National Laboratory, United States

The capture and immobilization of long-lived radioactive iodine I-129 must be a priority for future nuclear fuel cycles involving reprocessing. This review summarizes work on waste forms for radioiodine, emphasizing the contributions of Dr. Lou Vance as well as recent work in other groups. As early as the 1980s, Dr. Vance recognized the need for iodine waste forms and was a leader in innovative waste form solutions for iodine and other volatile halides. His studies included immobilization in silicate minerals including zeolites and sodalite, encapsulation in metallic tin, partitioning in synroc mixed-phase ceramics, and consolidation of copper iodide. Here, we recognize his particular contributions to the understanding of iodosodalite, and note some recent work by others following in his footsteps.

5:20 AM F.EN08.01.03
Hot-Isostatic Pressing of Synroc-C—The Effect of Ti-Metal Additions Daniel Gregg, Rifat Farzana, Pranesh Dayal, Zaynab Aly, Rohan Holmes and Gerry Triani; Australian Nuclear Science and Technology Organisation, Australia

Synroc-C, a multiphase ceramic wasteform based on stable and leach resistant titanate minerals, was invented by Australian scientists in the late 1970s. The formulation was directed toward the immobilization of PUREX wastes from the reprocessing of nuclear fuels and was originally to be produced *via* hot-uniaxial pressing (HUPing). Although glass was chosen as the preferred technology during the "Atlanta shoot-out" in the US in 1981, this was ultimately because Synroc lacked the technical maturity of vitrification. However, given the enhanced performance properties of Synroc-C as a wasteform, significant interest has been sustained in this Synroc formulation. The vast majority of work on Synroc-C has been undertaken following consolidation by HUP processing. There is very little reported on hot-isostatically pressed (HIPed) Synroc-C, where HIP canisters are filled with the calcined wasteform material (waste + additives), evacuated and sealed. The HIP canister is then loaded into the HIP chamber and processed through the desired time-temperature-pressure profile to achieve a dense and consolidated wasteform. The appropriate redox conditions within the HIP canister are vital to the formation of the correct phase composition and ultimately attaining a stable and leach resistant wasteform.
In this study, we investigate the effect of Ti-metal addition on the phase formation, microstructural characteristics and durability of HIPed Synroc-C. Dense Synroc-C samples containing 20 wt.% simulated high level waste and with varying Ti-metal additions (0%, 2%, 4% and 8 wt.%) were prepared by HIPing in stainless steel HIP canisters. An investigation of microstructure, mineral phases and elemental distribution in the samples was carried out using quantitative X-ray diffraction and electron microscopic analyses. Results from durability tests are also discussed.

5:30 AM F.EN08.01.04
Immobilisation Options for the Disposition of UK Plutonium Neil Hyatt, Lewis Blackburn, Laura Gardner, Shikuan Sun, Martin Stennett and Claire L. Corkhill; University of Sheffield, United Kingdom

The UK holds the world's largest inventory of separated plutonium under civil safeguards, projected to reach 140 tons at the end of reprocessing options. A significant fraction of this material requires immobilisation for disposal since it is unsuitable for reuse in MOX fuel, which is HM Government's preferred policy for disposition. Additionally, should it not prove possible to implement the policy for plutonium reuse in MOX fuel an alternative immobilisation and disposal option will be required for the greater inventory. This presentation will review the current status of wasteform engineering and process development for manufacture of zirconolite ceramic and glass-ceramic wasteforms for immobilisation of waste and inventory plutonium. We will demonstrate the development of Ce and U surrogate formulations, validated by targeted plutonium studies, with regard to phase assemblage and Pu / surrogate incorporation mechanism. The development of a novel containment system to enable hot isostatic pressing studies utilising U and Th surrogates will be presented, together with operational experience. The application of new, and potentially disruptive, wasteform manufacture technology will also be discussed.

5:40 AM F.EN08.01.06
Immobilization of Cesium and Iodine into $Cs_3Bi_2I_9$ Perovskite-Silica Composites and Core-Shell Waste Forms Kun Yang and Jie Lian; Rensselaer Polytechnic Institute, United States

$Cs_3Bi_2I_9$, a defect perovskite derivative, is a potential host phase to immobilize iodine and cesium with high waste loadings. In this work, two strategies are explored to form $Cs_3Bi_2I_9$-silica composites and core-shell structures in order to improve chemical durability of waste form materials meanwhile maintaining high waste loadings. $Cs_3Bi_2I_9$ loadings as high as 70 wt.% were incorporated into a silica matrix to form silica-ceramic composites, and 20 wt.% $Cs_3Bi_2I_9$ was encapsulated into silica to form a core–shell structure at low temperatures and high pressure. Semi-dynamic leaching experiments indicated Cs and I were incongruently released from waste form matrices depends on the bonding environment and surface passivating effect. A BiOI alteration layer formed during the surface reorganization, acting as a passivation layer to reduce the release of radionuclides. The long-term iodine release rate was low (30 mg m^{-2} day^{-1}) for 70 wt.% $Cs_3Bi_2I_9$–silica composites leached in deionized water at 90 °C, which can be further reduced to 5×10^{-3} mg m^{-2} day^{-1} for the 20 wt.% core-shell structure. This work highlights a robust way to immobilize the highly mobile radioactive nuclides and surface passivating mechanism through elemental transport across the liquid-solid interface for $Cs_3Bi_2I_9$.

5:50 AM F.EN08.01.07
Incorporation Mechanism of Sr and Ca in Geopolymer Cement Wasteforms Brant Walkley[1,1], Xinyuan Ke[2,1], Ben Griffith[3], Oday Hussein[1], Susan Bernal[4], John Hanna[3] and John Provis[1]; [1]The University of Sheffield, United Kingdom; [2]University of Bath, United Kingdom; [3]University of Warwick, United Kingdom; [4]University of Leeds, United Kingdom

Radioactive waste streams containing ^{90}Sr, from nuclear power generation and environmental cleanup operations, are immobilised in the UK in blended Portland cement (PC) grouts to limit radionuclide leaching. Due to poor compatibility of certain wastes with PC, alternatives such as alkali aluminosilicate 'geopolymer' binders are being investigated. Here, we used multinuclear solid-state nuclear magnetic resonance (NMR) spectroscopy probing ^{23}Na, ^{27}Al, ^{29}Si and ^{39}K nuclei, including high-field (20.0 T) and cross polarisation experiments, along with X-ray diffraction experiments, to investigate the incorporation mechanism of Sr^{2+} and Ca^{2+} in geopolymer wasteforms formed by alkali-activation of metakaolin. The main reaction product identified in gels cured at both 20°C and 80°C is a fully polymerised Al-rich alkali aluminosilicate hydrate ((N,K)-A-S-H) gel comprising Al and Si in tetrahedral coordination, with Si in $Q^4(4Al)$ and $Q^4(3Al)$ sites, and Na^+ and K^+ balancing the negative charge resulting from Al^{3+} in tetrahedral coordination. Faujasite-Na and partially Sr-substituted zeolite Na-A form within the gels cured at 80°C. Incorporation of Sr^{2+} or Ca^{2+} displaces some Na^+ and K^+ from the charge-balancing sites, with a slight decrease in the Si/Al ratio of the (N,K)-A-S-H gel. Ca^{2+} and Sr^{2+} induce essentially the same structural changes in the gels. It was concluded that the disordered geopolymers can readily accommodate Sr^{2+} and Ca^{2+} into their aluminosilicate framework structure via substitution of the divalent alkaline earth cations for monovalent alkali cations in charge balancing sites. This indicates that geopolymer gels are excellent candidates for immobilisation of radioactive waste containing ^{90}Sr and other alkaline earth radionuclides.

6:00 AM *F.EN08.01.08
Development and Application of Colloidal Silica-Based Grouts for Waste Containment Rebecca Lunn, M. Pedrotti, P. Bots, G. El Mountassir, A. Pegano and J. Renshaw; University of Strathclyde, United Kingdom

The UK's nuclear sites contain stored wastes in ponds and silos as well as large volumes of contaminated concrete and soil. During storage decommissioning and deconstruction operations, there are significant risks of radionuclide transport via groundwater and airborne particulate releases. Colloidal silica grout is a nano-particulate material that has the potential to reduce these risks very significantly. In order to utilize such nanoparticulate material as a barrier, we require a detailed understanding of the grout properties. These include its injectability, mechanical behaiour, hydrauclic properties, durability and its impact on the geochemistry of radionuclides in the environment (e.g. fission products such as Sr and Cs). Over the past 5 years, experiments at Strathclyde have progressivley investigated colloidal silica grout properties. Colloidal silica-grouted sand shows an increased stiffness and an enhanced peak friction angle, while still having a very low hydraulic conductivity (~ 10-10 m/s), typical of intact clay. Even under drained conditions, the grout provides mechanical improvement to the soil and retains a very low hydraulic conductivity. The impact on radionuclide geochemistry has been investigated through combining leaching experiments with XAS analyses. These show that colloidal silica induces several competing effects on the mobility of Sr and Cs. First, cations within the colloidal silica gel compete with Sr and Cs for surface complexation sites. Second, an increased number of surface complexation sites is provided by the silica nanoparticles and finally, the elevated pH within the colloidal silica increases the surface complexation to clay minerals and the silica

nanoparticles. Finally, experiments to investigate injectability and monitorability show that colloidal silica grout can be successfully injected in silty-sands, its gelling time can be accurately predicted in a full range of environmental conditions and the location of the subsurface barrier created can be accurately identified using Electrical Resistivity Tomography. Potential applications of colloidal silica on nuclear sites include inhibiting radionuclide migration from recently decommissioned structures during care and maintenance (e.g. silos and ponds from which wastes have already been retrieved); the development of primary or secondary barriers around existing radionuclide (or other) contaminated areas; and stabilisation of underground structures. Research work is continuing to improve the mechanical and chemical properties of colloidal silica grouts, such that they can be tailored to suit for indivdual nuclear site-based applications.

6:15 AM F.EN08.01.09
Utilizing Machine Learning in Nuclear Waste Management Natalie J. Smith-Gray, Irmak Sargin, Scott Beckman and John S. McCloy; Washington State University, United States

Machine learning (ML) is a valuable tool that can be used, in combination with domain expertise, to provide insight into nuclear waste vitrification processes. This talk summarizes our preliminary efforts in using ML methods to address important problems facing the nuclear waste vitrification mission at the Hanford site in Washington State. Three case studies using ML modeling will be described: nepheline crystallization, refractory corrosion, and sulfate solubility. In Hanford high-level waste, nepheline crystallization can occur in melt compositions containing high Na and Al contents when glass cools slowly in the canister, partitioning radioactive components to a less-durable residual glass fraction. In low-activity waste compositions, which are generally higher in alkali and volatile components like sulfur and halides, different critical issues present. Firstly, the low solubility of sulfate in borosilicate glass has led to many studies to predict glass composition dependence of this property, such that excess sulfur is not volatilized or partitioned to an alkali molten salt phase during processing. Second, these glass compositions tend to be harsh on refractories, leading to concerns over corrosion and general degradation of melter ceramic components and premature failure. For these three cases, existing datasets were used along with ML techniques to investigate the datasets and create predictive models for the output properties of interest. For all these studies, data science was used to identify underlying trends and correlations which were then applied to create supervised learning models. As a result, it has become evident that ML is a powerful tool that can be utilized to provide insight into complex issues in nuclear waste management, here specifically focused on immobilization by vitrification.

6:25 AM F.EN08.01.10
Machine Learning for Glass Wasteforms' Design and Performance Mathieu Bauchy; University of California, Los Angeles, United States

Vitrification is a key process to turn high-level nuclear waste into durable glasses. However, the virtually infinite compositional envelope accessible to glass wasteforms renders traditional design methods based on empirical knowledge and trial-and-error poorly efficient. In addition, the complex, disordered atomic structure of glasses makes it challenging to develop some mechanistic models relating their composition to their properties and performance. Here, I will discuss how machine learning offers a promising alternative route to predict the properties of glass wasteforms and guide/accelerate the design of novel glasses with enhanced performance for nuclear waste immobilization applications.

6:35 AM F.EN08.01.11
Developing High-Throughput Computational Methods to Discover Hierarchical Waste Forms Matthew Christian, Vladislav Klepov, Kristen Pace, Gregory Morrison, Theodore Besmann and Hans-Conrad zur Loye; University of South Carolina, United States

The development of stable actinide and other radionuclide hierarchical waste-form materials offer potential advantages of greater efficiency/loading, lower leach rates, ease of processing for so-called legacy nuclear wastes. Current waste-form discovery relies heavily on experiments that may or may not be successful in producing a viable product. Computational crystal discovery has aided in the search for new materials for different applications through use of high-throughput algorithms. However, these approaches have not been adapted to actinide and lanthanide compounds due to additional corrections required to properly handle *f*-orbital-containing elements. This presentation will consider the challenges and possible solutions to creating high-throughput computational methods to aide in the experimental discovery of novel hierarchical waste forms and offer tangible examples.

6:45 AM F.EN08.01.12
Thermodynamic Modelling of the Pd-Ru-Te-O for Nuclear High-Level Waste Immobilization Stéphane Gosse[1,2], C. Laurin[3], E. Régnier[3], A. Laplace[3] and S. Schuller[3]; [1]CEA, France; [2]Université Paris-Saclay, France; [3]Commissariat à

l'Energie Atomique – Centre de Marcoule, France

Pd and Ru are the main platinoid fission products formed during burnup of nuclear fuels. During fuel reprocessing, these element partly dissolve in nitric acid and they exhibit very low solubility into borosilicate glasses during the vitrification process. Due to their affinity towards tellurium from the fission product solution, palladium mainly precipitates under (Pd-Te) intermetallics [1] and ruthenium is likely to form hcp solid solutions [2]. The composition and microstructures of these phases are also sensitive to oxygen potential [3]; oxydation of ruthenium can lead to needle-shaped or polyhedral $(Rh,Ru)O_2$ oxide phases [4]. These precipitates can affect significantly the physico-chemical properties of the glass melt during melting in hot or cold crucible.
For decades, many studies were undertaken at CEA [5] to point out the high temperature interactions of the platinum group metals (PGM) issuing from the calcinated waste. In parallel to these studies, a Calphad database is being developed to address the thermodynamics of such systems to provide an assessment of the PGMs in nuclear waste.
This study presents the assessed binary systems. Some calculations are also performed to highlight how this flexible tool makes is used to predict the stability between metallic and oxide phases as a function of temperature and oxygen potential mainly driven by the glass.

6:55 AM F.EN08.01.13
Thermodynamic Assessment of Zn-Containing Hollandite as a Robust Waste Form Juliano Schorne-Pinto[1], Kyle Brinkman[2], Jake Amoroso[3], Scott Misture[4] and Theodore Besmann[1]; [1]University of South Carolina, United States; [2]Clemson University, United States; [3]Savannah River National Laboratory, United States; [4]Alfred University, United States

The hollandite phase is a potential nuclear waste form for alkaline-earth metals such as Cs and Ba by chemical incorporation into the crystalline lattice. The general hollandite formula is $A_xB_8O_{16}$ with the A-site habitually occupied by large mono- or divalent cations (e.g., Ba, Sr, Na, K, Rb, Cs, Pb), and the B-site by small di-, tri-, or tetravalent cations (e.g., Ti, Al, Fe, Cr, Sc) and it crystallizes in a tetragonal or monoclinic structure depending on the composition. Recently, our group has developed a thermodynamic database to describe the BaO-Cs_2O-TiO_2-Cr_2O_3-Al_2O_3-Fe_2O_3-FeO-Ga_2O_3 system based on the Calphad method, where the hollandite solid-solution was modeled using the Compound Energy Formalism (CEF). Recent findings show the impact of varying A-site Cs stoichiometry of Zn-containing hollandite compositions and related thermodynamic stability. This consequently improved the limited performance of the hollandite phase in a multi-phase composite called SYNROC. We here report on our efforts to include the Zn in our waste form thermodynamic database, modeling the phase equilibria of the complex hollandite-forming oxide waste system.

SESSION F.EN08.02: Corrosion of Nuclear Fuel and Waste Containers
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-EN08

5:00 AM *F.EN08.02.01
An Overview of Corrosion Research on the Canadian Nuclear Waste Container Peter G. Keech[1], Wilfred J. Binns[1], Mehran Behazin[1] and James J. Noel[2]; [1]NWMO, Canada; [2]University of Western Ontario, Canada

Canada's plan for the permanent storage of high level nuclear waste is to construct a Deep Geological Repository (DGR) at a depth of at least 500 m in a suitable host rock. The waste, which is composed almost entirely of CANDU fuel bundles, will be seal-welded into copper-coated steel "used fuel containers" (UFCs), which will be placed in bentonite clay within the DGR. Concurrent with site selection activities to find an informed, willing host community, the Nuclear Waste Management Organization (NWMO) is developing the UFC within a large technical and engineering program. The service life for the UFC is on the order of 1 million years, so research into container degradation, primarily via corrosion, is paramount to the success of the UFC development program. Research is done in partnership with many international waste management organizations, as well as through collaborations with national laboratories and academic research teams.

Overall, four types of corrosion comprise the total expected corrosion: oxic corrosion as a result of trapped oxygen during emplacement; radiation influenced corrosion owing to fuel decay; anoxic corrosion of copper and microbiologically-influenced corrosion. From these processes, some consideration must be made for non-uniform corrosion effects, and the service life must be supported by extensive modeling/simulation. This paper will provide experimental and modeling evidence for prediction of the long-term container corrosion performance, as well as outlining a path forward with respect to corrosion research as the Canadian program transitions through licensing activities and toward construction and operation.

5:15 AM *F.EN08.02.02
Long-Term Atmospheric Corrosion and Stress Corrosion Cracking of 304 Stainless Steel Used in Spent Nuclear Fuel Dry Storage Containers Jenifer Locke[1], Jay Srinivasan[1], Alana Parey[1,2], Gabriella Marino[1], Benjamin Sutton[1], Jianxiong Li[1], Glenn Daehn[1], Anupam Vivek[1], Thodla Ramgopal[3], Alexander Shapiro[1,4], James Greigo[2], Philip Noell[2], Jason Taylor[2], Charles Bryan[2], Rebecca F. Schaller[2], Eric Schindelholz[1] and Antonio Ramirez[1]; [1]The Ohio State University, United States; [2]Sandia National Laboratories, United States; [3]DNV-GL, United States; [4]Titanium Brazing Inc, United States

Welded austenitic stainless steels (SS) are used to construct canisters for the dry storage of spent nuclear fuel. Exposure to ambient marine environments can lead to salt deposition and brine deliquescence, which, at long storage times, may lead to localized corrosion and stress corrosion cracking (SCC). Studies on the effects of atmospheric relative humidity (RH), which determines electrolyte concentration and chemistry, on corrosion and SCC and the effectiveness of several SCC repair strategies are being conducted on SS304, a common material for canister construction.

Studies examining the effects of RH quantify the effect of electrolyte composition and exposure time (1 w to 2 y) on pitting corrosion. RH was found to play an influential role in determining pit density and morphology. Specifically, pit density is increased at the 40% RH compared to 76% RH, reaching a limiting pit density of roughly 6X higher. Additionally, at 76 % RH, pits displayed an ellipsoidal surface geometry with smooth facets at the pit base, whereas, at 40 % pits showed evidence of attack along distinct features that appear to be slip bands. Moreover, surface micro-cracks were found to emanate from pits at 40 % RH alone for all exposure times with no applied external load. As such, a hypothesis is presented for the effects of pit morphology and surface cracking at 40% RH based on synergistic electrochemical and microstructural causes. At low RH, high [Cl^-], mass transport restriction due to precipitated salts at the surface, and preferential dissolution along slip bands results in a fissure-like pit geometry that serves as a stress concentrator. Together with residual stresses from surface grinding possibly forming strain-induced martensite, hydrogen embrittlement is possible to due to cathodic hydrogen generation. Studies are ongoing to confirm this theory. Furthermore, the effect of electrolyte chemistry and electrolyte droplet size are being conducted to determine the cause of the unique pit morphology produced under 40 % RH exposure.

A companion study to investigate the effect of pit morphology on SCC initiation under atmospheric exposure is examining tension samples printed with ASTM sea salt, pre-exposed at 40 and 76 % RH, producing pre-corrosion that will serve as crack initiation sites once loaded. After pre-exposure from 1 w to 2 y, samples are mechanically loaded (at 1.2 X the nominal yield strength) under the same atmospheric conditions. A preliminary investigation for 40 % RH (after 6 months of pre-exposure) show surface cracks after 6 months of mechanical loading. Finite element models are being developed to understand 3D stress concentration profiles around each pit morphology (i.e. 40 % vs 76 %).

A study is also underway to identify which of several candidate repair strategies are effective at repairing already present SCC and maintaining future atmospheric and SCC resistance. ASTM G-36 boiling $MgCl_2$ testing will be used to downselect between tungsten-arc welding, friction stir welding, vaporizing foil actuator welding, cold spray, and soldering for further research.

5:30 AM F.EN08.02.03
Effect of Bentonite Dry Density on Corrosion of Embedded Copper Claire Tully[1], Dmitrij Zagidulin[1], James J. Noel[1,2] and Wilfred J. Binns[3]; [1]The University of Western Ontario, Canada; [2]Surface Science Western, Canada; [3]Nuclear

Waste Management Organization, Canada

The Nuclear Waste Management Organization plans to manage Canada's used nuclear fuel by isolating it underground within a multiple-barrier system, in a deep geological repository (DGR), in keeping with internationally accepted best practice.[1] In the proposed design, used fuel bundles will be sealed in copper-coated carbon steel used fuel containers (UFC), encased in blocks of highly compacted bentonite clay, and emplaced ~500 m below ground in the DGR. Any gaps between the rock walls and the bentonite blocks will then be filled with a bentonite gapfill material (GFM). Due to its physical and chemical properties, the bentonite will significantly limit the transport of reactive species to the UFCs. The high swelling pressure of bentonite can suppress the action of sulphate reducing bacteria (SRB) by decreasing the clay pore space and lowering water activity, which then limits microbially influenced corrosion of the UFC.[2]
The goal of this work is to investigate the effects of bentonite dry density, the presence of oxygen, and the evolution of environmental conditions on the corrosion of copper in contact with bentonite, and on SRB viability. We are conducting a series of experiments in bentonite-filled vessels exposed to ocean conditions (ocean modules, OM) and more controlled laboratory-based conditions (pressure cells, PC). The OM are porous vessels containing copper coupons embedded in GFM that has been compacted to various dry densities. The modules are then placed in the Pacific Ocean at depths of up to 2.6 km for months-to-years at a time, exposed to seawater, with hydrostatic pressures representative of potential DGR pressures. PC experiments contain copper coupons embedded in GFM and are pressurized to 100 bar with Type-1 water for varying durations up to 1 year. After exposure, copper coupons are analyzed by SEM, XPS, FIB, and AES, the water activity of the bentonite is assessed, and 16s RNA analysis used to determine the presence of SRB.
Two OMs, both with cold-spray (Cu_{cs}) and wrought (Cu_w) copper coupons, with GFM (dry density of 1.25 or 1.45 g/cm^3) were exposed to seawater at a depth of 90 meters for 6 months. The surfaces of the copper coupons experienced non-uniform corrosion, possibly due to non-uniform wetting and subsequent swelling of the clay. The copper speciation in the surface corrosion products consisted of ~85 % Cu_2O, ~ 5 % Cu_2S, ~3 % CuCl, and ~ 3 % CuO. Cu_w had higher amounts of Cu_2O and lower amounts of Cu_2S at both GFM dry densities. Both the Cu_w and Cu_{cs} exposed to the higher density GFM had lower amounts of Cu_2S and higher amounts of Cu_2O on the surface. This may be the result of non-uniform swelling, decreased mobility of the sulphide or a decrease in the number of metabolically active SRBs, or a combination of those factors.[2] Mass loss measurements determined that Cu_{cs} had a higher corrosion rate than Cu_w; however, Cu_w corrosion rates were less affected by the GFM density. Overall, the increase in bentonite dry density resulted in a decrease in copper corrosion rates, with the Cu_{cs} corrosion rate being decreased more significantly than that of Cu_w.
The experiments performed in PCs for 1 month duration provided similar results. Cross-sections of the film formed at the copper surface revealed the presence of copper, oxygen, and sulphur, unevenly distributed across the copper surface, accounting for the non-uniform corrosion observed. The corrosion rates were significantly higher than those in the OM experiments due to the higher oxygen concentration.

Investigating the Corrosion of Natural Uranium Dioxide by Hydrogen Peroxide and Hydrogen Martin Badley[1], James J. Noel[1,2] and David W. Shoesmith[1,2]; [1]The University of Western Ontario, Canada; [2]Surface Science Western, Canada

The proposed plan for the long-term management of used nuclear fuel in Canada is to seal it in copper-coated steel containers (UFC) and emplace them in a deep geologic repository using a multi-barrier containment concept. While there is extensive literature providing confidence that UFCs will remain intact until fuel radiation levels decay to insignificant levels, it is judicious to investigate the consequences of container failure, when groundwater could come into contact with the fuel. The goal of this project is to investigate the effect of radiolytically produced oxidants on the corrosion/dissolution rates, and the influence of oxidant scavengers on the respective rates for fuel specimens that represent fuel used in Canada.
Within a failed UFC, water radiolysis could lead to the production of localized oxidizing conditions at the surface of the fuel, potentially leading to fuel corrosion and radionuclide release to the groundwater. The rate of such a process would be determined by the radiation dose rate from the fuel, and the reactivity of the fuel, which will be determined by its composition, in particular by the degree of non-stoichiometry and the concentration of fission products.[1, 2] The corrosion rate at the fuel surface can be suppressed in the presence of oxidant scavengers produced at the steel-groundwater interface. These scavenging ions will consume radiolytically produced oxidants, largely through a catalytic reaction on noble metal particles.[3] For undoped UO_2 (i.e., in the absence of fission products) the reactivity has been shown to be very dependent on the degree of non-stoichiometry (x in UO_{2+x}), which can be estimated by electrical conductivity measurements.[4] Overall, specimen

conductivities are being measured by electrical impedance measurements. The reactivity of characterized specimens is subsequently being determined using either electrochemical measurements or analytical measurements of the amounts of H_2O_2 consumed and U dissolved. Further, measurements of the oxidant scavenging properties of H_2 are being investigated in the absence of noble metal particles to observe the influence of localized non-stoichiometry. This research will work towards expanding the established model for the α-radiolytic corrosion of used nuclear fuel.[5]

Numerical Implementation of a Copper Corrosion Model for Used Fuel Containers Used in a Deep Geological Repository Scott Briggs[1] and Fraser King[2]; [1]Nuclear Waste Management Organization, Canada; [2]Integrity Corrosion Consulting Ltd., Canada

The Nuclear Waste Management Organization is responsible for the implementation of Adaptive Phased Management (APM), Canada's plan for the long-term management of used nuclear fuel in a deep geological repository (DGR). Currently in the site selection process, NWMO is seeking partnership with an informed and willing community to host the DGR while technical research is on-going in support of APM. An integral part of isolating and containing the used nuclear fuel is the engineered barrier system which consists of the bentonite clay, a long-lived steel container (with copper coating) and a durable waste form (zircaloy cladding and high-density ceramic fuel pellet). The copper coating consists of a 3 mm copper layer on a steel container and in this current work, a copper corrosion model was developed to predict the long-term uniform corrosion behaviour. The current model builds on the work by King and Kolar (2006) by extending the previous 1D model to include 3D geometry effects. The model was developed in COMSOL Multiphysics using a finite-element approach including 1D and 3D implementations. A step-wise approach was used in the development of the model, starting with a simple reaction scheme and increasing mechanistic detail while ensuring numerical stability and careful validation against experimental results. The developed copper corrosion model predicts the corrosion potential along with environmental parameters (ex. [Cl^-], [O_2]), copper species concentrations and mass transfer rates which can be used to determine, mechanistically, the rate-controlling processes for both the anodic and cathodic reactions. Corrosion potentials can also be used to determine the likelihood of pitting corrosion in the DGR environment and the corrosion current density can be used to predict the rate of uniform corrosion.

Multi-Column Evaluations for the Capture and Separation of Krypton and Xenon Using Mordenite Based Sorbents Mitchell Greenhalgh, Amy Welty and Troy Garn; Idaho National Laboratory, United States

A multi-column adsorption system has been designed and installed to evaluate the independent capture and separation of xenon and krypton utilizing solid phase sorbents being developed by the DOE-NE Offgas Sigma team. The xenon and

krypton are present in the offgas stream resulting from a used nuclear fuel reprocessing plant. The system is intended to provide greater operating flexibility and testing at a wide range of flow rates while maintaining desired pressure conditions. This system also allows for continuous analysis of effluent gas from each column. The system was set up by packing the first column with AgZ-PAN which has demonstrated a high selectivity for xenon over krypton at ambient temperatures. A second column was packed with HZ-PAN to capture the krypton. The AgZ-PAN column was maintained at ambient temperatures whereas the HZ-PAN column was maintained at 191K. A simulated offgas stream consisting of 1000 ppmv xenon and 150 ppmv krypton in a balance of air was introduced to the first column to capture the xenon and the resulting xenon free effluent was then routed into the second column for krypton capture. Flowrates of the feed stream were varied from 50-2000 sccm. The results of the multi-column testing demonstrated successful separation of xenon from krypton and indicated that increasing superficial velocity does not significantly impact sorbent capacity or initial breakthrough of the columns. This procedure, while not optimized, may be used to reduce the final waste volume of captured radioactive gas species emitted from a reprocessing facility.

5:15 AM F.EN08.03.03
The State-of-the-art Development of Mechanically and Chemically Robust Sorbent for Management of Iodine Josef Matyas, James Amonette and Michael Sinnewell; Pacific Northwest National Laboratory, United States

New generation sorbents are being investigated for the removal and immobilization of radioiodine from the gas streams in a used nuclear fuel reprocessing facility. Silver-functionalized silica aerogel (Ag^0-aerogel) exhibits high selectivity and sorption capacity for iodine. Moreover, a feasible consolidation of iodine-loaded Ag^0-aerogel to a durable SiO_2-based waste form is an attractive choice for sequestering radioiodine. Extended-duration testing of Ag^0-aerogel in highly oxidizing reprocessing off-gas streams indicated fragmentation of granules into small particles. These particles were held up in the column without being carried-over into the off-gas system. However, production of small particles during sorption can lead to compaction of the sorbent, restricting the flow of gas through the column. Our study targeted development of mechanically and chemically stable Ag^0-aerogel through optimized synthesis process, which included using a patent-pending technology treatment to strengthen the granules. The reinforced Ag^0-aerogel with bulk density ~ 0.5 g/cm^3 went through rigorous testing at different off-gas streams followed by attrition testing with a vibratory sieve shaker. There were no fines generated even after 60 min exposure to shaking speeds of ~1800 revolutions per minute, with ~3 mm orbital shaker movement. The mechanically/chemically robust Ag^0-aerogel retained high iodine sorption capacity of 400.5 ± 2.2 mg/g. The presentation will focus on various strategies that have been developed to improve the mechanical/chemical properties of Ag^0-aerogel and conclude with a summary of highlights and a prognosis for future developments.

5:25 AM *F.EN08.03.04
On-Line Monitoring of Molten Salts to Characterize Chemical Composition Amanda Lines, Shirmir Branch, Heather Felmy, Adan Medina, Hope Lackey, Gregg Lumetta and Samuel Bryan; Pacific Northwest National Laboratory, United States

Molten salt systems provide highly efficient heat transfer options without pressurization, making them a potentially valuable tool throughout the energy sector, including solar power and nuclear energy. Molten salt reactors are of particular interest due to the advancements they can offer to the nuclear field, such as improved safety. However, the chemical behavior of key species anticipated in molten salt reactors is not well understood. Tools are needed to monitor and characterize the chemical composition of molten salts to better understand the behavior of actinides, fission products, and corrosion products. Furthermore, these tools are needed to allow for molten salt process control and to support the maintenance of materials accountancy. Of the options available, optical spectroscopy enables powerful routes to characterize these systems *in situ*. Utilization of these tools allows for the fast and robust identification and quantification of many chemical species of interest to molten salt processing, reactor control, and corrosion characterization. Most importantly, optical spectroscopy can enable the analysis of oxidation state ratios and species complexation, which can significantly impact system performance and corrosion behavior. Optical spectroscopy-based monitoring can be leveraged in fundamental and applied research. For example, optical spectroscopy can be paired with electrochemistry in spectroelectrochemistry to provide a powerful route to fundamental characterization of redox behavior, speciation, and chemical behavior dependence on temperature. Optical spectroscopy can also be paired with chemometric analysis to enable real-time quantification of target analytes within salt melts. Complex salt systems containing many chemical species will exhibit complex spectral data, presenting signal interferences and band overlap, which can hinder accurate analysis. However, the application of chemometric analysis can enable accurate characterization of multicomponent streams to provide real-time, automated monitoring of a process stream or batch. Optical spectroscopy-based on-line monitoring enables fast and robust identification and quantification of many actinides, fission products, and corrosion products. Here we demonstrate the application of optical monitoring approaches to

the characterization of chloride-based salt melts containing lanthanides and actinides.

SESSION F.EN08.04: Effects in Nuclear Waste Forms

F-EN08

5:00 AM *F.EN08.04.01
Radiation Damage and Thermal Aging of Nuclear Waste Forms William J. Weber; The University of Tennessee, United States

Self-radiation damage from the decay of radionuclides can affect microstructural evolution, phase stability, and thermodynamic properties in nuclear waste forms. The principal sources of radiation are beta-decay of the fission products and alpha-decay of the actinide elements. In general, beta-decay of the short-lived fission products leads to ionizing radiation that is the primary source of radiation and heat generation in high-level waste forms during the first 600 years of storage. Ionization can cause covalent and ionic bond rupture, valence changes, localized electronic excitations, and significant changes in ionic mobility; however, there is no evidence of significant long-term effects of fission product decay on the physical properties of nuclear waste forms. Because of the long half-lives of the actinides and their daughter products, alpha-decay is dominant over very long timescales. Alpha decay produces energetic alpha particles (4.5 to 5.5 MeV) and recoil nuclei (70 to 100 keV) that result in both radiation damage and the accumulation of helium. The evolution of radiation damage due to alpha-decay has been studied at ambient temperature using short-lived actinides, such as ^{238}Pu and ^{244}Cm, in many candidate glass and ceramic waste forms, and the early stages of evolution occur during the thermal period of the waste form. Ion beam irradiations of candidate ceramics are more frequently employed due to decreased costs, shorter irradiation timescales and the non-radioactive nature of the irradiated materials. Ion irradiations are performed over a wider range of irradiation conditions to implant helium, study radiation damage kinetics, understand the separate and combined effects of alpha particles and alpha recoils, and benchmark against alpha-decay damage due to short-lived actinides. At ion energies (keV to MeV) typically used to study alpha-decay damage in nuclear waste forms, the electronic and nuclear energy losses are both important, and the spatial coupling of electronic and nuclear energy loss can lead to reduced or enhanced damage production along the ion trajectory. While alpha particles are much less damaging than alpha recoils, the electronic energy loss from the alpha particles can also cause athermal annealing of alpha-recoil damage that can impact the evolution of radiation damage. Helium implantation studies have shown that helium bubbles form above a threshold helium concentration in candidate waste forms. Swift heavy ions (several hundred MeV to several GeV) have also been used to study radiation damage in nuclear waste forms; although the damage production mechanism and energy densities are substantially different from beta decay or alpha decay, large volumes are damaged.

5:15 AM F.EN08.04.03
Characterising the Effect of Heavy-Ion Irradiation on the Microstructure of Ce-Doped Compounds Ritesh Mohun[1], Sebastian Lawson[1], Theo Cordara[1], Hannah Smith[1], Clémence Gausse[1], Max Cole[1], John S. McCloy[2], Marc Weber[2], Sam Karcher[2], Martin Stennett[1], Neil Hyatt[1] and Claire L. Corkhill[1]; [1]The University of Sheffield, United Kingdom; [2]Washington State University, United States

In this study, we aimed to investigate the radiation effects in doped-fluorite structure ceramics. CeO_2 was chosen as the host matrix because of its fluorite crystallographic (Fm-3m) structure, which consists of a simple cubic oxygen sub-lattice with the cation ions occupying alternate cube centres, similar to UO_2, PuO_2, and ThO_2. The objective was first to quantify the defect chemistry/configurations when CeO_2 is doped with trivalent yttrium at different concentrations, and then to study the atomistic changes when the solid solutions were irradiated with 3 MeV gold ion under two different fluence, corresponding to a damage level of 6 dpa and 33 dpa values respectively.
Initial X-ray diffraction measurements of the prepared samples showed a contraction of the unit cell with Y-content attributed to a certain long-range ordering of the anion vacancies with randomly distributed Y_2O_3 micro-domains of 'C-type' structure which grows coherently within the fluorite matrix. This observation corroborates with Extended X-ray Absorption Fine Structure (EXAFs) analysis which indicated a change in the coordination number when the dopant is introduced in the CeO_2. On the other hand, Raman spectroscopy was used to quantify the presence of oxygen vacancy-type defects formed to compensate for the charge due to the substitution of Ce^{4+} with a trivalent dopant and the presence of reduced Ce^{3+}.
In regards to the irradiated samples, the excellent radiation stability of Ce-based compounds was reported and it was observed that Au-incident ions tend to reduce Ce^{4+} to Ce^{3+}. In addition, Positron annihilation spectroscopy measurements

showed that the lower irradiation fluence increases considerably the concentration of lattice damages close to the disorder saturation level, where all the implanted positrons are trapped and a further increase in the irradiation dose initiates a dynamic damage recovery. Relevant defect mechanisms for the two considered irradiation fluence studies were identified and will be detailed in this presentation.

5:25 AM F.EN08.04.04
Structural Behavior of Ordered Mesoporous Silica Under Swift Heavy Ions and Electrons Irradiation Jun Lin[1], Xavier Deschanels[1], Clara Grygiel[2], Guillaume Toquer[1] and Sandrine Dourdain[1]; [1]ICSM, CEA, CNRS, ENSCM, Univ Montpellier, France; [2]CIMAP, CEA-CNRS, France

Ordered mesoporous silica still attracts considerable attention because of a myriad of industrial potential applications, such as catalysis, gas adsorption, electronics, optics, drug delivery and nuclear waste storage. More precisely concerning the latter example, alternative processes for the treatment of radioactive effluents containing actinides and fission products are developing. In this way, a precise knowledge of the damage induced in those materials, due to the radiation, is then required. Apart from radiation tolerance of mesoporous metallic foam already reported by Bringa *et al.*[1], other studies[2] have highlighted the collapse of the mesoporous network of silica-based materials induced by the ballistic radiation damage for an energy deposited close to a few 10^{21} keV/cm^3.
In this work, two kinds of samples have been irradiated to evaluate their dimensional effect in electronic regime. In one hand, thin films (~100 nm) of mesoporous silica deposited by dip-coating onto silicon wafer were irradiated at IRRSUD (GANIL) with ions having a stopping power in the 1-10 keV/nm range. In the second hand, pellets obtained by compaction of powders were irradiated at lower stopping power from 10^{-3} keV/nm (2 MeV electrons, LSI) to 1 keV/nm (proton ~20 MeV, CEMHTI). These samples were analyzed before and after irradiation by X-ray reflectometry (thin films), nitrogen adsorption isotherm and small angle X-ray scattering measurements (pellets), electron microscopy (Scanning, Transmission) to investigate the evolution of the porous structure and also by spectroscopy (nuclear magnetic resonance, infra-red) to evaluate the evolution of the silica network. A mechanism is proposed to explain and describe the evolution of the mesoporous structure under irradiation.

5:35 AM F.EN08.04.05
Effect of Ionizing Radiation on PuO_2 and Surrogate Oxide Materials Under Storage Condition5 Luke Jones[1], Darryl Messer[1], Robin Orr[2], Howard E. Sims[2], Andrew B. Horn[1] and Simon M. Pimblott[3]; [1]University of Manchester, United Kingdom; [2]National Nuclear Laboratory, United Kingdom; [3]Idaho National Laboratory, United States

The stockpile of plutonium separated from used nuclear fuel amounts to many 100s of tonnes. The majority of this plutonium is stored as PuO_2 powder packaged in multi-can containers. The conditions during the packaging of reprocessed PuO_2 for long term storage are closely controlled to limit water uptake as radiolytic decomposition of any adsorbed water will lead to the formation of both a potentially flammable atmosphere containing molecular hydrogen as well as reactive oxygen species which may be incorporated into the oxide phase. Consequently, the safety case for the long-term storage of PuO_2 requires a complete understanding of the fundamental physical, chemical and materials degradation processes occurring at the water-oxide interface inside the storage canisters. This study investigates the effect of ionizing radiation on PuO_2 and various surrogate oxides under atmospheres potentially encountered in storage canisters.
To elucidate the effects of adsorbed water, samples of baked oxide powder were equilibrated in humidity chambers to attain a wide range of masses of water adsorbed onto the powder surface. In the case of PuO_2, once the surface water on the oxide had equilibrated with the humid atmosphere, the samples were sealed into a glass vessel held at constant humidity with either an argon or a nitrogen over-gas and left for up to 3 months. Periodic sampling of the headspace was undertaken and the atmosphere above the oxide analyzed using gas chromatography. In the case of the surrogate oxides, once the oxides had adsorbed the maximum quantity of water, the samples were flame sealed under argon into a glass tube and Co-60 gamma irradiated. Prior to and after gamma irradiation, the oxide powders were characterized using a variety of different microscopy and spectroscopy methods. Following gamma irradiation, the headspace was analyzed using gas chromatography. For PuO_2, the rate at which H_2 was produced increased with increasing water loading. This result contrasts with the experimental data in this study and from similar experiments in the literature utilizing UO_2, CeO_2 and ZrO_2 which showed a higher rate of production for lower water coverages. There was no evidence of a steady state hydrogen concentration being reached in the

PuO_2 experiments, an outcome opposite of that observed in storage canisters and in experiments performed by other groups in which the PuO_2 was not held under constant humidity. Radiolytic production of molecular oxygen was not observed. Comparison of the properties of the surrogate oxide (ZrO_2) powder prior to and post irradiation did not reveal any differences in stoichiometry, surface functionalization or the formation of oxygen-centered free radicals, so the location of the sibling oxidant to the evolved molecular hydrogen currently remains unanswered.
Parallel experimental and modeling studies considering the chemistry of PuO_2 and surrogate oxides in H_2:O_2:Ar atmospheres are ongoing. To perform the experiments, a bespoke manifold was designed and commissioned to mix various ratios of H_2-O_2 and Ar gas. Gas chromatography was used to analyse post-irradiated samples. Experiments were performed in 10 ml volume 316 stainless steel canisters (with no degradable polymeric components). Experimental data will be presented showing the extent of recombination of H_2-O_2 mixtures in Ar under ^{60}Co γ rays and accelerated He ion irradiation and the influence an oxide surface on this recombination: radiolytic reaction of H_2 with O_2 to form H_2O is enhanced over what is expected from gas phase processes suggesting significant interfacial chemistry.

5:45 AM F.EN08.04.06
Quantifying the Effects of Grain Boundary Areas on the Irradiation Behaviour of UO_2 Ritesh Mohun, Sebastian Lawson, Daniel Bailey, Shikuan Sun, Clémence Gausse, Hannah Smith, Max Cole, Martin Stennett, Neil Hyatt and Claire L. Corkhill; The University of Sheffield, United Kingdom

Complex microstructural changes occur in nuclear fuels due to the extreme environments of intense irradiation and high temperature during in-reactor operations. Several theoretical and experimental works are currently in progress to determine the effect of crystalline defects which has a major influence on the behaviour of fission products, mainly in regards to rare gases, that may impact the life-span of the rod-type uranium fuel element. For instance, the nucleation of insoluble gas bubbles is thought to act as trapping sites for migrating vacancy-type defects, and further increase in the damage levels induces significant microstructural modifications. In this study, we aimed to investigate the specific role of microstructure on the radiation stability of nuclear fuels.
For this purpose, UO_2 pellets with different microstructures were initially prepared through the wet chemistry route and sintered at different temperatures. Scanning electron microscopy and X-ray diffraction characterisations were performed to quantify the grain size/boundaries areas and crystallinity of the pristine samples. Raman spectroscopy also proved useful and allowed to investigate the effect of sintering temperature on the concentration of intrinsic lattice defects. The samples were then implanted with 1 MeV Krypton-ions at room temperature to induce irradiation damages in the matrix of the different grain-size UO_2 pellets.
Post-irradiation measurements were carried to highlight the excellent radiation stability of fluorite-type nuclear fuels. However, it was observed that the UO_2 microstructure has an important effect on the point defects produced by the displacement cascades induced by ionic implantation. In this presentation, an attempt is made to detail the mechanisms occurring near the defect-boundary interfaces in relation to radiation damage to highlight the precise role of grain boundaries modifying the defects behaviour and their subsequent evolution in fluorite structure relevant to nuclear fuels.

5:55 AM F.EN08.04.07
Assessment of Positrons for Defect Studies in UO_2 and CeO_2 Materials Marc H. Weber[1], Ritesh Mohun[2], Sam Karcher[1], Claire L. Corkhill[2] and John S. McCloy[1]; [1]Washington State University, United States; [2]The University of Sheffield, United Kingdom

The safe disposal and long-term isolation of spent mixed oxide nuclear fuel poses significant challenges. Uranium and plutonium oxides enriched with rare earth and lanthanide fission products and under constant irradiation with alpha particles and neutrons must be stored in geologic formations for thousands of years. A detailed understanding of the microstructure and chemistry is required to optimize processing designed to recover fissionable products from used fuel and to improve the safety and volume of radioactive waste. Cerium oxide (ceria) has been identified as a suitable non-radioactive substitute to study the microstructure and its evolution under long term irradiation.
A number of techniques have been applied to uranium and cerium oxides to investigate basic properties and point defects. These include neutron scattering, X-ray diffraction and Raman spectroscopy of as produced, irradiated and annealed materials. These are sensitive to structural properties (XRD, neutrons) and oxygen vacancies (Raman). Positron annihilation spectroscopies (PAS) are sensitive to neutral and negatively charged vacancy-like point defects and impurity-vacancy complexes. Positrons can provide depth resolved information about uranium or cerium vacancies to complement Raman data. PAS has been applied previously to UO_{2+x} to investigate the properties of nuclear fuels.[1,2,3] Virtually no PAS work exists

on CeO_2, doped or undoped. Currently, PAS are being used to investigate rare earth and lanthanide doped cerium oxide. The work on uranium oxide by the group of MF Barthe[1,2] demonstrated the presence of significant concentrations of uranium vacancies or Schottky defects as well as the presence of negatively charged interstitial oxygen atoms in oxygen rich. They also investigated the effect of 1 MeV helium implantation and the interaction of the implanted helium with the formed vacancies during annealing. Xe bubbles and their thermal evolution could also be observed.[4]
In this presentation, the basics of positron annihilation spectroscopy will be presented. PAS work on undoped and doped cerium oxide will be shown and compared to results from uranium oxides. To simulate spent nuclear fuels, the samples were doped at different concentration with rare earth elements or yttrium, zirconium. Select samples were irradiated with heavy ions at different doses. Differences were observed depending on what simulated fission products are present. Preliminary results and literature searches show some correlation with Raman data.

5:00 AM *F.EN08.05.01
Overview of the SKB Spent Fuel Research Program over the Years—Knowledge Gained and Remaining Open Questions Lena Z. Evins; Swedish Nuclear Fuel and Waste Management Co, Sweden

The Swedish strategy for spent nuclear fuel has, since around 1980, been direct geological disposal. Research about the properties and dissolution of spent fuel has been going on since then. An overview of this research program is given here with a focus on questions posed and answered along the way, ending with remaining open questions. At the beginning, some basic studies were performed to gain information about spent fuel as wasteform. Dissolution studies were at first mainly performed in contact with air, and often with aqueous solutions that mimicked the expected groundwater chemistry. However, complexities relating to precipitation of secondary phases indicated that simplified water compositions were preferred. Knowing that the radioactivity of the fuel caused radiolytic oxidation of uranium and thus controlled the dissolution rate, there were also attempts to achieve reducing conditions via bubbling a hydrogen/argon mixture in presence of a palladium-catalyst. The first attempts resulted in variable results, but notably, a reduction in apparent leach rate was observed for some experiments [1]. Later, possibilities to perform the leaching experiments in autoclaves, with controlled hydrogen atmosphere, allowed experimental conditions closer to the expected repository conditions. These experiments showed that hydrogen, during this type of experimental set-up, could suppress oxidative dissolution caused by radiolysis [2,3]. A new phase of research was thus started where the mechanistic explanation for the observed behaviour was sought. Experimental work, both with spent nuclear fuel and with analogue materials, was coupled with modelling efforts. At the time of the SR-Site safety assessment [4], which was a part of the license application submitted in 2011, a certain understanding had been reached, based on the effect of metallic particles in fuel. Still, questions remained and studies performed during the last decade (see for example [5]) can now be summarised to illustrate the knowledge gained, and remaining open questions. This summary is utilized in the next step in the licensing process: the application to start building the spent fuel repository, which is expected to be submitted within the next couple of years. In the coming decade the SKB research program will continue, with the goal to support the development of the safety assessment report, SAR, which will be submitted to the authorities as a part of the license application connected to start of trial operations.
During all these years, international collaboration has been a cornerstone of the SKB research program. This international collaboration has been carried out via European projects or bilateral agreements, and triggered the start-up of the Spent Fuel Workshops [6]. The research program has also been presented at this MRS symposium since the early 1980's.

Understanding the Dissolution of Advanced Doped Nuclear Fuels for Geological Disposal Hannah Smith, Theo Cordara, Ritesh Mohun, Clémence Gausse, Max Cole, Martin Stennett, Neil Hyatt and Claire L. Corkhill; The University of Sheffield, United Kingdom

The addition of dopants, including chromium and aluminium, to uranium dioxide fuel results in the formation of larger grained microstructures, capable of higher fission gas retention and reduced swelling during operation within nuclear reactors. Despite their growing use by nuclear power plant operators, the long-term dissolution behaviour of spent doped fuels, when compared to typical spent fuel, is not yet well constrained. In a geological disposal facility, the release of radionuclides is known to be controlled by the oxidation of the UO_2 matrix and the subsequent dissolution of UO_2^{2+} species, therefore any changes to the matrix from the addition of dopants could be expected to influence the dissolution kinetics and/or mechanisms.

We here present the results of an investigation of how the addition of Cr_2O_3 to UO_2 fuel influences the crystal chemistry of UO_2 and its dissolution kinetics. Initial results, from experiments performed in air and a bicarbonate solution, show that the addition of Cr_2O_3 reduces the normalised mass loss of uranium. The potential influencing factors that give rise to increased durability with Cr addition, e.g. defect concentration, Cr-oxidation state etc. are discussed.

Physico-Chemical Phenomena Located at the Solid/Liquid Interface of Uranium-Based Oxide Materials Stephanie Szenknect[1], Laurent Claparede[2], Adel Mesbah[3], Theo Cordara[1], Thomas Dalger[1], Solène Bertolotto[4], Nicolas Clavier[3], Renaud Podor[3] and Nicolas Dacheux[2]; [1]ICSM, CEA, France; [2]ICSM, UM, France; [3]ICSM, CNRS, France; [4]CEA, DEN, DMRC, France

The “back end” of the nuclear fuel cycle corresponds to the direct disposal or reprocessing of the spent nuclear fuel (SNF), and to the conditioning and disposal in an appropriate repository of the nuclear wastes. In most of these processes, the behavior of actinides and fission products is governed by dissolution reactions at solid/ liquid interface. The design of reprocessing process and of nuclear waste disposal strategy requires the determination of well constrained kinetic and thermodynamic data. The acquisition of reliable kinetic and thermodynamic data is a tough issue considering on the one hand, the complexity of SNF in terms of chemical composition and microstructure and on the other hand, the challenge posed by the manipulation of highly radioactive samples.

For several years, we developed and improved a methodology that aims to determine dissolution rates of uranium-based oxide materials and thermodynamic data of phases of interest for final disposal of spent fuel in deep-mined geological repositories. This methodology is based on the synthesis of model compounds with well defined composition and microstructure, on the measurement of macroscopic dissolution rates in controlled chemical and hydrodynamic conditions, and on the monitoring of the properties of the solid/ liquid interface at the microscopic scale. For that purpose, several surface characterization techniques were used and developed, such as 3D reconstruction of Environmental SEM images, AFM or Grazing Incidence-XRD. To illustrate the progress made beyond the state of the art by using this methodology, several examples have been selected among the studies that we reported in the literature. The selected examples deal either with the reprocessing of uranium based oxides in nitric acid conditions, or with the behavior of UO_2 in SNF under the weathering conditions of geologic disposal.

The mechanisms that control the kinetics of dissolution of U-based oxides in nitric acid solutions are illustrated through the study of samples showing different compositions and microstructures. The use of oriented UO_2 single crystals allowed to evidence the enhanced reactivity of the surface at defect sites during a first kinetic regime. The second kinetic step was attributed to a catalyzed dissolution mechanism involving species produced at the solid/ liquid interface during the first step.

The key role of catalytic species in the strong increase of dissolution rate was demonstrated not only for UO_2 single crystals, but also for sintered pellets of (U, Th) mixed oxides and UO_2-doped with platinum group metals. The monitoring of solid/ liquid interface by 3D-ESEM during uncatalyzed and catalyzed regimes revealed specific dissolution sites of enhanced reactivity and specific dissolution features related to UO_2 crystallographic orientation, which traduced a structural control of the topographic evolution of the material.

Most of the geologic sites under investigation for underground repositories are located in undisturbed clay-rich rock or granite, with silica-rich groundwaters, deep enough to have reducing conditions. Understanding the interaction of used fuel with the silicate-rich groundwaters is critical to evaluate the safety of different disposal strategies. For several years, we investigated the role of silicates in the mechanisms of UO_2 weathering. For the first time, we were able to show the formation of coffinite ($USiO_4$) from UO_2 in the presence of solution saturated with respect to SiO_2(am) under conditions typical of deep-mined geologic repositories for SNF. Through dedicated experiments, we have constrained the conditions of formation of coffinite in an Eh-pH diagram. Finally, we showed that coffinite precipitation could lower the uranium release from the UO_2 matrix of SNF through oxidative weathering in the presence of oxygen in the geological repository.

Evaluating Diavlent Cation (Zn, Ca, Mg) Behaviour During the Dissolution of Simulant UK High Level Waste Glass Adam J. Fisher, Russell J. Hand and Claire L. Corkhill; University of Sheffield, United Kingdom

In an effort to incorporate high levels of Mo associated with the post-operational clean-out of high active liqor storage tanks at the Sellafield reprocessing facility in the UK, a modified version of the "MW" sodium aluminoborosilicate base glass has been adopted. The addition of Ca favours the formation of $CaMoO_4$, while Zn infers improved viscosity. This new Ca/Zn MW base glass is currently being used to immobilise reprocessing wastes from oxide fuels and also magnox fuels, which contain a significant proportion of Mg. The divalent cations Ca^{2+}, Zn^{2+} and Mg^{2+} are known to exert an influence on the durability of vitrified wastes, however the nature of their additive, or competitive effects are yet to be fully understood.

We here describe the results of a range of experiments that aim to elucidate the influence of divalent cations on the mechanims and kinetics of glass dissolution. The addition of Zn to the glass was found to enhance durability in dilute, Si-undersaturated conditions, due to an increase in glass polymerisation with increasing Zn content, as determined by ^{29}Si MAS NMR. However, under conditions of Si-saturation, the presence of Zn prevented the formation of a passivating silica gel layer, and promoted the formation of Zn-containing smectite clays, significantly enhancing the dissolution rate with increasing Zn content. Mg had a similar effect to Zn, which was additive, however glasses containing Ca generally showed lower dissolution rates, in agreement with other studies. The formation of Zn- and Mg-bearing silicates was concurrent with a significant increase in the dissolution rate, similar to Stage III "rate resumption" behaviour, which has previously only been associated with the formation of zeolites.

Fabrication of Unirradiated Advanced Fuel for Dissolution Studies Under Repository Conditions M Nieves Rodríguez-Villagra[1], Sergio Fernández[1], Laura J. Bonales[2], Abel Milena-Pérez[1], Ana Nuñez[1], Sofía Durán[1], Laureano Anta[1], Luis Gutierrez[1] and Joaquín Cobos[3]; [1]CIEMAT, Spain; [2]CSIC-INTA, Spain; [3]EBD-CSIC, Spain

Safety assessment of Spent Nuclear Fuel (SNF) disposal in a Deep Geological Repository (DGR) requires evidences of radionuclides release after groundwater eventually gets into a breached container and contacts the fuel. Within the frame of EU H2020 program into the DISCO project, the impact of additives (Cr, Cr/Al and Gd) is being investigated on the long term DGR dissolution performance and compared to conventional UO_2. In particular, the effect of these dopants is studied on the long term matrix dissolution rate of the SNF, the so-called Advanced Tolerant Fuels (ATF), such as Cr_2O_3-doped UO_2, and Cr_2O_3-Al_2O_3-doped UO_2 fuels.
ATF have demonstrated to reach higher burn-up than conventional UO_2 fuels because dopants provide enhanced safety against Pellet-Clad Interaction failure (PCI), higher density, enlarged grain size, lower fission gas release and higher creep rate. Besides, the difference between those ATF and standard UO_2 in thermo-physical properties is almost negligible [1-4]. However, the dopants influence upon the matrix leaching performance at long term under DGR conditions is still largely unknown when compared to traditional UO_2 SNF.
The combinatory effects of two uncertain parameters (dopants influence and H_2) on UO_2 matrix leaching resistance are investigated. In the context of WP2 and WP4 of the DISCO project, UO_2-based pellets doped with a nominal concentration of $0.06^{w}/_{o}Cr_2O_3$, $0.05^{w}/_{o}Cr_2O_3$-$0.02^{w}/_{o}Al_2O_3$ and $4.5^{w}/_{o}Gd_2O_3$, were systematically produced by homogenizing stoichiometric proportions of UO_2 and dopants, and carefully characterized in order to understand the effects of the addition of Cr- and/or Al-oxide into the fuel matrix dissolution behaviour. Gd-doped UO_2 was also included, as a burnable poison and a trivalent

rare-earth dopants (RE^{III}). The results are the basis for potential more complex systems which would correspond to irradiated doped fuels.
Previous studies suggest that RE^{III} play an important role on the UO_2 oxidation, revealing that they prevent the fuel from a complete oxidation to U_3O_8 [5], so in order to better understand the effect of trivalent RE^{III}, a set of dissolution experiments is carried out. The presence of reducing species, such as H_2 (produced by anaerobic iron corrosion and radiolytically), affects the reactivity of UO_2; hence, it must be considered in a long-term safety assessment. On the other hand, it is well known that HCO_3^- (one of the key complexing constituents in the groundwater) is highly likely to influence fuel dissolution by enhancing the solubility of U^{VI} thus preventing the secondary phase formation [6].
To experimentally evaluate the effect of additives (doped fuels) together with $H_2(g)$ and different leachants on UO_2 matrix dissolution rate, leaching experiments were performed under different representative aqueous systems. Prepared pellet/disks were characterized by means of XRD, Raman spectroscopy and SEM-EDX. In order to understand the effect of the presence/absence of HCO_3- that could be considered as relevant to those coming from the interaction of water between natural barriers (groundwater) and EBS (Engineering Barrier System), specific synthetic groundwater was used in the dissolution tests. Static leaching experiments of doped-UO_2 pellets were run in stainless steel autoclaves with reaction vessels made of PEEK autoclaves under a N_2/4.7%H_2 atmosphere. The U and dopants concentration released into the aqueous solution was quantified by ICP-MS. pH and redox measurements were also tracked during the experiments.

Investigation of Secondary Phases Formed During Long Term Aqueous Leaching of Spent Nuclear Fuel Charlotta Askeljung[1], Anders Puranen[2], Olivia Roth[1], Kyle Johnson[1], Alexandre Barreiro Fidalgo[1], Lena Z. Evins[3] and Kastriot Spahiu[3]; [1]Studsvik Nuclear AB, Sweden; [2]AB SVAFO, Sweden; [3]Swedish Nuclear Fuel and Waste Management Co, Sweden

For a future deep repository for spent nuclear fuel, the rate and mechanism for dissolution of fission products and actinides from spent fuel is a key parameter for the safety assessment of the disposal concept. Although the majority of the fuel to be placed in the deep repository is expected to be intact at the time of disposal, some failed fuel rods will also be present. In a failed fuel rod, the uranium matrix may have been exposed to water in the reactor and during interim storage for several years or decades prior to disposal. This exposure can lead to oxidation of the matrix and the formation of secondary phases under conditions of low uranium solubility. Upon barrier failure and ground water exposure of the spent fuel in the deep repository, these pre-oxidized layers are expected to dissolve at a higher rate compared to unaffected UO_2 and hence increase the rate of radionuclide release. For this reason, knowledge about the characteristics of failed fuel and its behavior under deep repository conditions is required for the evaluation of the long-term safety of geological repositories. The present work aims to add to this knowledge.

Although the behavior of spent nuclear fuel under deep repository conditions has been studied extensively, studies of failed fuel are, in this context, relatively scarce, in particular studies of failed fuel that has been exposed to water during decades of wet interim storage. However, at the Studsvik laboratory in Sweden, leaching tests of spent fuel have been performed since the 1980s. This provides an opportunity to investigate the effects of long term contact with water under aerated conditions, such as those occurring in a wet interim storage.

In this study, XRD investigations have been performed on the surfaces of two fuel pellet samples which have been exposed to leaching solutions (synthetic ground water and deionized water, respectively) for over 30 years. Furthermore, the fuel surfaces have been exposed to carbonate solutions in an effort to dissolve the oxidized phases formed during the extended leaching time. The aim is to characterize the fuel matrix alteration.

Preliminary Results of Dissolution Experiments with Cr-(Pu) Doped UO_2 in Reducing Conditions at SCK CEN Christelle Cachoir, Thierry Mennecart and Karel Lemmens; SCK CEN, Belgium

The development of robust safety cases for geological disposal of spent fuel requires a solid understanding of its dissolution over very long time scale (up to a million years). While the dissolution of standard spent fuel has reached a good level of

comprehension, the development of modern LWR fuels (Cr/Al-doped UO_2 or MOX fuels) raises the question whether these fuels will behave similarly to standard fuels in geological repository conditions. Within the EU-DisCo project, systematic dissolution studies have been initiated with carefully prepared and characterized, simplified UO_2-based model materials to understand the matrix dissolution of these modern LWR fuels under geological repository relevant conditions. As DisCo partner SCK CEN has performed such dissolution tests to study the effect of Cr-doping on the UO_2 matrix dissolution rate in reducing conditions. Tests were started on four model materials : UO_2, Cr-UO_2, Pu-UO_2 and Pu/Cr-UO_2 with a density close to 94% of the theoretical density and average grain size around 10 µm for UO_2 and Pu-UO_2 , 35 µm for Cr-UO_2 and 25 µm for Pu/Cr-UO_2 . The Cr doped pellets contain 1600 µg Cr_2O_3 per gram of UO_2, and the alpha doping level of the Pu-doped pellets (~ 18 MBq/gUO_2) is representative for a fuel age of 10,000 years. Static dissolution experiments with these model materials have been performed in autoclaves in two reference waters (synthetic young cementitious water at pH 13.5 and bicarbonate water at pH 9) under 10 bar H_2 pressure and in presence of Pt/Pd catalyst. After a predissolution in 0.01 M NaCl solution for 3 weeks to remove the pre-oxidized UOX layer, samples were taken from the solution over a period up to 2 months. For the materials UO_2 and Cr-UO_2, the Cr-doping leads to lower uranium concentrations in solution, both in synthetic cementitious and in bicarbonate water. In the synthetic cementitious water, this effect is constant over the entire experiment, but the concentrations, increasing immediately after the replacement of the NaCl solution by the cementitious solution, remain high at ~10^{-7} M for UO_2 and ~10^{-8} M for Cr-UO_2. In bicarbonate water, the initial uranium concentrations (after replacement of the NaCl solution by the bicarbonate solution) are the same as for the cementitious water, but after 2 months, all concentrations are ~10^{-9} M. These preliminary results suggest that the Cr doping decreases the U release in solution, but the long-term effect depends on the leaching solution. Experiments with the Pu doped materials (Pu-UO_2 and Pu/Cr-UO_2) are now carried on to study the Cr-effect in combination with alpha-radiolysis of the solution.

6:25 AM F.EN08.05.09
Aqueous Leaching of Chromia-Doped UO_2 Spent Nuclear Fuel Under Oxidizing Conditions Alexandre Barreiro Fidalgo[1], Olivia Roth[1], Lena Z. Evins[2] and Kastriot Spahiu[2]; [1]Studsvik Nuclear AB, Sweden; [2]SKB, Sweden

Programs for deep geological repositories are being developed in many countries to safely dispose of spent nuclear fuel. Therefore, understanding the behavior of spent nuclear fuel under relevant conditions is crucial for the safety assessment of these facilities. During the last decades, new types of nuclear fuel are being introduced in commercial reactors. To allow these new fuels in the spent fuel repository, it must be shown that they do not dissolve at a higher rate than standard fuel. Fuel additives such as chromium oxide (Cr_2O_3) have an impact on the UO_2 microstructure and therefore might affect properties relevant to the safety assessment.

The main goal of this investigation is to understand the effects of Cr-doping on the instant release fraction of fission products and the matrix dissolution under oxidative conditions. A sample consisting of fuel fragments and separated cladding is leached in simplified groundwater under aerated conditions at Studsvik's Hot Cell Laboratory. The fuel used in this study was manufactured by AREVA and has been irradiated in a Swedish commercial pressurized water reactor (PWR) to a local burnup at the sampling position of ~59 MWd/kgU.

Data from the leaching experiments are presented and compared to other commercial fuels' leaching performance: Cr-doped fuel with lower doping levels (Advanced DOped Pellet Technology, ADOPT) and standard UO_2 fuel.

6:35 AM F.EN08.05.10
UO_2-Based Model Systems—Model Materials for Studying the Matrix Corrosion of Spent Modern Nuclear Fuels Philip Kegler, Martina Klinkenberg, Andrey Bukaemskiy, Felix Brandt, Guido Deissmann and Dirk Bosbach; Forschungszentrum Jülich GmbH, Germany

The direct disposal of spent modern nuclear fuel (SNF) in a deep geological repository (DGR) requires an in-depth understanding of the long-term corrosion behavior of the SNF and the associated radionuclide source term. These are indispensable requirements for demonstrating the long-term safety of the DGR. Today's modern Cr- and Al-doped light water reactor (LWR) fuels have already successfully demonstrated their improved in-reactor performance, but it is still not known, whether the corrosion behavior of such fuels in a DGR is similar to conventional spent LWR-fuels. Due to the chemical and structural complexity of SNF and its high beta and gamma radiation field, experiments with SNF cannot unravel all of the various concurring dissolution mechanisms entirely. Thus within the EU-DisCo project single-effect dissolution studies are carried out with systematically produced and carefully characterized UO_2-based model materials, to provide additional insights into the behavior of modern doped LWR-fuels under the post-closure conditions expected in a DGR, complementary to dedicated dissolution experiments with SNF.
Here, we present recent results on the dissolution behavior of tailor made UO_2 model materials in accelerated static batch

experiments using H_2O_2 as simulant for radiolytic oxidants, present in long-term disposal scenarios for SNF in failed container conditions due to the alpha-irradiation of water. In these dissolution experiments pure UO_2 reference pellets exhibiting different densities and grain sizes, as well as Cr-doped UO_2 pellets with various Cr-doping levels, produced using different doping methods having different grain sizes, were used. In addition, Nd-doped and industrially produced Cr- and Cr/ Nd-doped UO_2 pellets were used to determine the influence of these parameters on the dissolution rates. The dissolution experiments were performed under strictly controlled conditions with respect to exclusion of oxygen, temperature control, and exclusion of light. During the dissolution experiments, solutions were systematically sampled and the H_2O_2 (UV-Vis) and the uranium (ICP-MS) concentrations were determined.
The initial dissolution rates of all materials were determined from the concentrations of dissolved U(VI) obtained within the first 24 hours of the experiments. In experiments with pure UO_2 reference pellets a clear linear dependence of the initial dissolutions rates from the density of the pellets was observed, with higher initial dissolution rates at lower densities. No dependence on grain size was found. The initial dissolution rates of pure, Cr-doped, and Nd-doped UO_2 pellets fall into three groups: i) pure UO_2 pellets with the fastest dissolution rates, independent of the oxygen potential during sintering (and therefore the grain size), ii) Cr-doped UO_2 pellets, independent of doping method, doping level, and oxygen potential during sintering (grain size), and iii) Nd-doped UO_2 pellets with the lowest dissolution rates. The following initial dissolution rates were calculated for the different materials:
pure UO_2: 1.3 +/- 0.1 * 10^{-6} mol/m^2*s
Cr-doped UO_2: 0.65 +/- 0.2 * 10^{-6} mol/m^2*s
Nd-doped UO_2: 1.63 +/- 0.7 * 10^{-7} mol/m^2*s
The slight difference between the dissolution rates of pure UO_2 and Cr-doped UO_2 pellets (i.e. factor 2) can partly be explained by the slightly lower density of pure UO_2 pellets compared to Cr-doped UO_2 pellets. A very strong influence of Nd, representative of fission lanthanides in SNF, on the dissolution rates in this type of experiments is clearly visible. Although the density of the Nd-doped UO_2 pellets is similar to the Cr-doped pellets (i.e. 96-98% relative density), the initial dissolution rate is more than half an order of magnitude lower than for Cr-doped pellets. Overall, the results of this study indicate that the Cr-doping of modern nuclear fuels seems to have no significant effect on the corrosion behavior of UO_2-based SNF.
.

Dissolution Kinetics of Metaluminous and Peralkaline Calcium Aluminosilicate Glass at 75°C, pH = 7.5: Rate Control by Si-Content of Glass Jon P. Icenhower, Hugh McMahon, Misty Riesbeck, Elzbieta Bakowska, Randall Youngman and Nicholas Smith; Corning, United States

The dissolution rates of six calcium aluminosilicate glasses were determined experimentally at pH(25 °C) = 7.5 and a temperature of 75 °C in a Single-Pass Flow-Through (SPFT) system. Glasses studied in this work can be categorized into two sets of three compositions each. In the first (metaluminous) set, the molar proportion of CaO to Al_2O_3 remained the same (1:1), while SiO_2 increased (40, 50 and 60 mol.%). The second (peralkaline) set was characterized by constant Al_2O_3 (10 mol.%), with decreasing CaO and increasing SiO_2 (40, 50 and 60 mol.%). Measurements of ^{27}Al by MAS-NMR indicated a slight increase in $Al^{[5]}$ at the expense of $Al^{[4]}$ with decreasing Si concentration. One to four grams of powdered glass (300 to 425 mm diameter) were placed into 10 mL volume reactors with solution input through the bottom and effluent solution output through the top. Solutions were buffered by 0.05 M *TRIS* and flow-rates varied between ~38 and 500 mL/d. A plot of the dissolution rate vs. flow-rate (q) to surface area (S) showed that all dissolution rates were maximized at $q/S \approx 45 \times 10^8$ m/s. Dissolution rates were from 4.2, 1.5 and 0.62×10^{-7} mol/(m^2 sec) for the metaluminous and 1.0, 0.65 and 0.50×10^{-7} mol/(m^2 sec) in the peralkaline glasses, respectively. Interestingly, the data indicate that rates for the metaluminous trio are generally faster than those of the peralkaline set, which runs contrary to expectations. As a set of glasses, the $\log_{10}$ rates [mol/(m^2 sec)] are inversely proportional to the fraction of Si in the glasses, forming a single array of values. These data indicate that rates are strongly tied to the Si content of glasses, and that other glass composition parameters— including Ca/Al (molar) ratio—exert a much weaker effect on dissolution rate in this medium.

7:00 AM F.EN08.05.12
Assessing the Effect of Radioactive Waste Glass Dissolution in an Updated Geological Disposal Facility Radionuclide Migration Model Joseph Lillington[1], Thomas L. Goût[1], Tajudeen Iwalewa[2] and Ian Farnan[1]; [1]University of Cambridge, United Kingdom; [2]Harvard University, United States

The UK intends to ultimately dispose of its nuclear waste by storing it deep underground within a geological disposal facility (GDF). The planned setup is to vitrify high-level waste (HLW) within glass, encase this in a metal canister, and store this using a buffer within the host rock. Currently, there is no agreed site for a UK GDF, and therefore, accurate modelling is

required despite significant uncertainties in the modelling parameters. This study aims to build upon previous work that simulated HLW radionuclide migration within both clay and granite host rocks. Significant updates have been made to the original GoldSim Monte-Carlo models, including updating the HLW inventory, radionuclide sorption, diffusion, and solubility coefficients, canister degradation failure rates, number of waste canisters, granite/clay density, sensitivity analysis, and Monte-Carlo parameters. In addition, the effect of HLW dissolution has been examined by varying the source-terms used (initial dissolution, residual, and resumption rates) through variation on the original simplistic source-terms, and by coupling GoldSim with the analytical GRAAL model (via MATLAB). Results demonstrate that radionuclide migration behaviour is similar between the original and updated GoldSim models, despite cumulative activities being approximately one to two orders of magnitude lower in the upper part (crown) of the GDF. Variation on the original simplistic glass dissolution source terms has an understand but insignificant effect on GDF performance, with there being no substantial difference having used the original model glass dissolution rates versus those applied by the UK nuclear industry. Finally, radionuclide activities are strongly correlated with systematic modifications in analytical GRAAL model parameters through changes in glass degradation rates.

7:10 AM F.EN08.05.13
Adsorption and Diffusion of Boron Isotopes in Aqueous Glass Dissolution Thomas L. Goût[1], Rui Guo[1,2], Sambuddha Misra[1,3], Aleksey Sadekov[4], Edward Tipper[1], Madeleine Bohlin[5] and Ian Farnan[1]; [1]University of Cambridge, United Kingdom; [2]Tsinghua University, China; [3]Indian Institute of Science, India; [4]The University of Western Australia, Australia; [5]Uppsala University, Sweden

Predicting the release rates of radionuclides from nuclear waste glasses during aqueous dissolution within a disposal facility over geological timescales requires robust models of dissolution built upon an extensive understanding of glass dissolution mechanisms. However, many of the dissolution models presented in the past decade conflict regarding the mechanisms predicted to control dissolution. Whilst nanoscale post-process analyses of altered glasses have afforded insights into altered layer structures, these results highlight the need for an additional dimension to understand the mechanisms of glass dissolution beyond the conventionally employed techniques presented in the literature.
In a previous study, lithium isotope fingerprinting techniques were applied to the leachates of a simplified Magnox waste glass leached at 90 °C. It was shown that whilst dissolution was initially congruent, lithium isotopes leached incongruently through diffusive processes across a passivating altered layer component at longer durations. However, further evidence was required to rank the dissolution models presented in the literature. Here, boron isotope fingerprinting techniques were applied to the same Magnox glass to further understand its dissolution processes, understand how lithium and boron were leached and distinguish between dissolution models. Additionally, the same isotopic techniques were applied to leachates of an international benchmark glass composition to compare the dissolution processes of the two compositions and allow for interdiffusion models to be fitted to the results. Solution renewal experiments took place to further investigate the passivating nature of the altered layers and their role as a diffusive barrier to dissolution at long durations.
Boron isotopes leached from the Magnox glass were consistent with congruent models of dissolution in the initial stages of dissolution, but at later stages were consistent with diffusive isotopic fractionation across a passivating altered layer component about an incongruent dissolution front. Whilst boron isotopes in the leachates of International Simple Glass were consistent with diffusive, incongruent dissolution models throughout dissolution, boron isotopes in its solution renewal experiment were most consistent with congruent models of dissolution. As such, these isotopic methodologies demonstrate that no single dissolution model may be correct for all glass compositions and experimental conditions; providing an improved understanding of the mechanisms governing aqueous glass dissolution and supporting the idea of a model which unifies the mechanisms presented in the literature.

7:20 AM F.EN08.05.15
Late News: Using Data Analytics in Glass Property Prediction Joseph Lillington[1], Thomas L. Goût[1], Mike Harrison[2] and Ian Farnan[1]; [1]University of Cambridge, United Kingdom; [2]National Nuclear Laboratory, United Kingdom

The rates of aqueous dissolution and radionuclide release from glasses used to immobilise high-level waste that will be disposed of within a geological disposal facility are strongly dependent on composition. Glasses are challenging to reliably fabricate because after liquid cooling, they are considered to be in non-thermodynamic equilibrium, and therefore their state variable, for example volume, cannot be predicted solely from temperature and composition, but also requires consideration of factors such as thermal history. Other material properties therefore prove valuable as descriptors of glass state, for example, glass viscosity or density. In addition, phase separation can occur depending on the glass composition, particularly with increased waste loadings. This study uses machine learning to predict glass viscosity, viscosity model fitting parameters, density, and phase separation, aiming to both predict glass properties and extract relevant compositional dependencies from the analytics. A series of algorithms have been applied both in isolation and in combination, for example, via voting or

stacking. Data has been provided by the nuclear industry or by making use of large-scale international datasets. Overall, results indicate that machine learning can be valuable either in accurately predicting the properties of nuclear waste glasses (viscosity, viscosity model fitting parameters, density, phase separation) or can be used to analyse the importance of different features either for determining particular properties directly or indirectly by correlating features and prediction errors.

Secondary Phase Derived Uranium Oxy-Hydroxides as Potential Host Matrices for Anionic Fission Daughters Gabriel Murphy, Philip Kegler, Andreas Wilden, Martina Klinkenberg and Evgeny Alekseev; Forschungszentrum Jülich GmbH, Germany

Layered uranium oxyhydroxide (LUOH) phases are important minerals which occur as weathering products of uraninite deposits and also importantly, are encountered during the paragenetic sequence of secondary phases that form during an accident scenario involving spent nuclear fuel (SNF) in the near-field (1). Understanding the structural-chemistry of these phases is of importance as via interaction mechanisms, they can potentially retard the transport of harmful fission daughters from SNF towards groundwater and the biosphere. Particularly it has been previously shown that the secondary LUOH phases, such as metaschoepite, uranophane and studite, can act to impede and retard the transport of fission daughters and SNF products such as NpO_2^+, Cs^+ and Sr^+ (2,3). Chemically, the origin of these favourable interactions is predominantly due to favourable intercalation chemistry between cationic SNF species with that of anionic lattices of encountered phases. However in the case of anionic fission daughters, such as ^{131}I and ^{79}Se, these present considerable concern during release from SNF as the overwhelming majority of near-field SNF secondary phases and minerals possess anionic lattices, including LUOH phases, which are typically not expected to react and intercalate well with. Although some evidence is present for partial intercalation of anionic iodine into layered mineral structures through ionic exchange mechanisms in model system studies (4-6) the current consensus is the retention of anionic SNF release products in the near field is not proven and best considered in the far-field of SNF repository performance and accident scenario assessment. Layered double hydroxide (LDH) phases are considered prime candidate materials and minerals for the retention of these anionic phases and received considerable attention (7), however in the context of an accident scenario with SNF their occurrence is not certain. We have recently undertaken a comprehensive systematic investigation of actinide solid state systems relevant to SNF and nuclear waste management. In the course of our investigations we have examined the chemical interactions that may occur between the anionic fission daughter species, I and Se in different chemical forms with some potential LUOH phases associated with SNF. Using a combination of batch synthesis experiments and *in situ* exchange experiments, we provide evidence for the inclusion and retention of these anionic species in LUOH phases. Importantly, using single crystal X-ray diffraction we show the ability for anionic species to be incorporated into certain LUOH phases is a consequence of their respective topological arrangement of uranyl and hydroxyl groups. Furthermore, by considering the topology and structural chemistry of LUOH phases, it can allow for a predictive basis to be established towards which the relative interaction affinity between certain anionic fission daughter species and specific LUOH phases can be understood. The systematic experimental studies used in this investigation will be discussed in detail w.r.t potential interactions that occur between anionic fission daughters and LUOH derived secondary phases that occur during an accident scenario involving SNF.

An Investigation into the Local Structure of Ln_2TiO_5 Stuffed Pyrochlores Through XAS Analysis Daniel A. Austin[1], Martin Stennett[1], Shikuan Sun[1], Bruce Ravel[2] and Neil Hyatt[1]; [1]University of Sheffield, United Kingdom; [2]National Institute of Standards and Technology, United States

Stuffed pyrochlore ceramics, with the general stoichiometry Ln_2TiO_5, have received significant interest for application within the nuclear industry due to their high radiation tolerance, good thermal stability, and structural flexibility. These ceramics have been proposed as a potential wasteform for actinide wastes, for incorporation into inert matrix fuels (IMF), and as inclusion in oxide dispersion strengthened (ODS) steels. These materials can be viewed as derivatives of pyrochlore structured $Ln_2Ti_2O_7$ phases and are often more conveniently written in the form $Ln_2(Ln_{0.67}Ti_{1.33})O_{6.67}$, where the pyrochlore B-site now contains mixed occupancy. These materials can adopt a variety of different crystal structures depending on the size of the lanthanide cation, and the temperature and pressure used during synthesis. The three reported crystal structures are orthorhombic (*Pnma*), hexagonal (*P6$_3$/mmc*) and cubic defect-fluorite (*Fm-3m*). Compounds that are nominally assigned as defect-fluorite by X-ray diffraction have been probed by neutron diffraction (ND) and transmission electron microscopy (TEM) revealing features consistent with the presence of short range ordered regions with the (*Fd-3m*) cubic pyrochlore structure.

In this contribution we present a study probing the local structure of a series of Ln_2TiO_5 (Ln = La, Gd, Dy, Yb, Y) compounds. They were synthesised via a solid state synthesis route under different cooling regimes to prepare samples of identical chemistry but different short range ordering. Fabrication of high quality sintered specimens of Ln_2TiO_5 phases is a particular challenge due to their refractory nature. Therefore, a systematic study of sintering parameters was undertaken to optimise the fabrication of sintered ceramic specimen. Characterisation of these materials was performed using techniques including XRD, SEM/EDX and XAS. Initial XAS results show that some of these materials do have a cubic pyrochlore-like local structure but show a deviation from the ideal coordination environment of cubic pyrochlore.

Chemical Bond Complexity in $A^{III}_6B^{VI}O_{12}$ Fluorite-Related Ternary Oxides Maulik K. Patel[1], Kurt E. Sickafus[2] and Gianguido Baldinozzi[3]; [1]University of Liverpool, United Kingdom; [2]The University of Tennessee, Knoxville, United States; [3]Université Paris-Saclay, France

Oxides with generic stoichiometry A_7O_{12} occupy, in a generic phase diagram, an intermediate place between fluorite and bixbyite structure types. Their structure is derived from the ideal fluorite structure, and it is characterized by a more or less pronounced ordering of the O vacancies within the average fluorite sublattice. We believe that ternary oxides with this generic formula display some structural flexibility relevant to fission product stabilization in nuclear fuels and to the understanding of actinide waste forms as well. We would like to discuss the structural characteristics of the chemical bonds in these ternary systems consisting of trivalent and hexavalent cations studying the electron density using the tools of the quantum theory of atoms in molecules (Bader's AIM theory and ELF). Eventually, in these compounds with generic formula $A^{III}_6B^{VI}O_{12}$, the A cation can be either an actinide or a rare earth element, whereas the B cation can be either a transition metal (W, Mo) or hexavalent uranium. We believe that studying the characteristics of the polyhedron of the sevenfold coordinated A ion is particularly interesting: it is often described in the literature as a mono-capped trigonal prism, with bond lengths exhibiting an extremely large dispersion, ranging for instance from 2.19 to 2.70 Å in Y_6WO_{12}. We would discuss the implications of this large dispersion of distances on the chemical bond characteristics, compare DFT models with experiments on pristine and irradiated specimens, and discuss the competitive metastability of the oxygen deficient cubic fluorite phase that can be observed in some of these systems, as for instance Y_6MoO_{12}.

Chemical and Structural Investigations on Uranium Oxide Based Microparticles as Reference Materials for Analytical Measurements Stefan Neumeier[1], Philip Kegler[1], Fabien Pointurier[2], Anne-Laure Faure[2], Kathy Dardenne[3], Jörg Rothe[3], Tonya Vitova[3], Martina Klinkenberg[1], Fabian Kreft[1], Dirk Bosbach[1] and Irmgard Niemeyer[1]; [1]Forschungszentrum Jülich GmbH, Germany; [2]CEA, France; [3]Karlsruhe Institute of Technology, Germany

The analysis of individual micrometre- and submicrometre-sized particles collected by IAEA safeguards inspectors on swipe samples during in-field verification activities requires the implementation of a sustainable quality control system. This system needs to be further advanced by developing mass spectrometric analytical measurements and of suitable reference materials. In this context pure and compound reference materials in microparticulate form such as U, *Ln*/U, Th/U and Pu/U microparticles are of special interest. For the design of these microparticulate reference materials, according to their required properties, the understanding of morphology, chemistry, and structure is essential.
To this end, the production of pure and neodymium doped uranium-oxide based microparticles utilising an aerosol-based

particle production process which has been developed and established in the laboratories of Forschungszentrum Juelich since 2012 will be presented. This method allows for the generation of microparticles with monodisperse particle size distribution. SEM/EDX measurements confirmed the monodispersity of the produced microspheres as well as the incorporation of 15 mol% Nd into the compound particles. Additionally, results from *In-SEM* μ-Raman (CEA, DAM) and U L_3-edge XAFS measurements in U L_α fluorescence yield detection mode (INE-Beamline @ KIT synchrotron radiation source) will be discussed pointing to the formation of U_3O_8 microparticles for both compounds. The position and shape of the X-ray absorption spectrum is insignificantly affected by the incorporation of 15 mol% Nd, indicating the structural flexibility and stability of the U_3O_8 microparticles. Additionally, a minor fraction of schoepite phase was identified by Raman measurements, which is most probably caused by ageing processes during storage under laboratory conditions.
The first batch of U_3O_8 microparticles produced in Juelich was successfully applied in an international laboratory exercise NUSIMEP9 organised by JRC-Geel and finally certified regarding the isotopic composition and the U amount per particle. These results demonstrate that the process established in Juelich allows for a very flexible and reliable preparation of reference materials for particle analysis methods applied in safeguards.

Nanostructured Uranium Oxide Thin Films Developed by Molecular Precursors Using Chemical Vapor Deposition Dennis Grödler, Lasse Jurgensen, Aida Raauf, Markus Zegke and Sanjay Mathur; Institute of Inorganic Chemistry, Germany

Advanced materials have been made using a variety of elements, however, uranium has not seen much impact. The common fear of working with “nuclear material” has prevented its chemical use, even though it has been known since 1911 to be an efficient catalyst in the widely applied Haber-Bosch process. A possible strategy to synthesize advanced materials based on uranium is the chemical vapor deposition (CVD). To date, only a few suitable uranium precursors have been reported.
Here we report new volatile uranium(IV) complexes based on β-ketoenamine ligands, which have been structurally characterized and which can be synthesized via a simple salt metathesis. Functionalization of the N atom of the chelating ligand changes the coordination motif, and subsequent NMR studies offer a deeper insight into the coordination chemistry. Sterically demanding ligands (L) selectively lead to heteroleptic complexes of the form UCl_2L_2 while an additional degree of freedom in the substituent allows for the isolation of homoleptic complex of the form UL_4 with significantly increased volatility. These are suitable candidates for CVD towards uranium oxide thin films. Uranium oxides with band-gap energies in a range of 1.8 – 2.7 eV coupled with their good electrical and catalytic properties mostly driven by facile valence dynamics of the uranium cations are promising electrode materials in photoelectrochemical water splitting reactions.
We have been able to synthesize a variety of such ligands and present four novel uranium complexes which we are currently investigating with respect to the formation of novel uranium based thin film materials. Furthermore, using β-heteroarylthioketamine ligands leads to similar complexes that may be used as precursors for uranium sulfide thin films.

SESSION F.EN08.07: Poster Session: Scientific Basis for Nuclear Waste Management
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020

A New Disposal Method for Radioactive Waste Using Chemically Adsorbed Monolayer Teruyoshi Sasaki, Hiroto Funakoshi, Kazufumi Ogawa and Yoshifumi Suzaki; Kagawa University, Japan

Radioactive waste exists in the form of gas, liquid and solid. Among them, the disposal method of collecting radioactive waste, melted and solidifying it and burying it in the ground is common. However, in the current method, after the radioactive waste is collected, it is mixed with glass as it is to be melted and solidified, or it is mixed with cement and solidified, so that the volume of the waste becomes huge. Therefore, in this study, we investigated a process in which a chemically adsorbed monolayer having an imidazole group at the end was formed on a glass fiber, and only radioactive substances were adsorbed from a solution in which waste was dissolved, and then melted and solidified at once. As a result, we succeeded in adsorbing radioactive substances with high efficiency in solution. By using this method, if the melting point of the glass fiber is set low, the melted and solidifying process will be extremely simple, and it will be possible to manage the radioactive substances in the necessary minimum volume.

Speciation by XANES of Copper Migrated into Compacted Bentonite Using Electromigration Techniques Kazuya Idemitsu, Keisuke Yoshida, Yaohiro Inagaki and Tatsumi Arima; Kyushu University, Japan

Copper is a candidate for use as an overpack material in deep underground nuclear waste disposal. Copper, however, is susceptible to corrosion following closure of the repository and migration of the corrosion products through the buffer material may affect the migration of redox-sensitive radionuclides. Electromigration experiments were performed whereby a copper coupon, which was in contact with compacted bentonite, served as the working electrode and was held at a constant potential of +300 mV vs. Ag/AgCl electrode for up to 48 h. The chemical form of copper that migrated into the bentonite specimens were estimated by using Cu K-edge X-ray absorption near-edge structure (XANES) at Saga-Light Source, Japan. The results revealed that the oxidation state of Cu in the bentonite would be Cu(II) as shown the correlation between the amount of Cu migrated into bentonite and the corrosion current. On the other hand Cu(I) also observed on the copper coupon not in bentonite. Copper could corrode as Cu(II) then react with Cu metal and precipitate as Cu_2O on the copper metal.
