Effects of Chromium and Vanadium on the Sulfate Solubility of Sodium Aluminoborosilicate Glass Natalie J. Smith-Gray[1], Jason Lonergan[2] and John S. McCloy[1,2]; [1]Washington State University, United States; [2]Pacific Northwest National Laboratory, United States

In the composition space of interest for Hanford low-activity nuclear waste glass, the waste loading of some formulations is limited by the incorporation of sulfate into the glass (i.e., its solubility). Numerous studies have been undertaken to understand the mechanism of sulfate incorporation and its affect by various other additives. In particular, the model by Vienna et al (2014, J. Amer. Ceram. Soc. 97, 3135) identified elements which tend to raise or lower sulfate solubility in borosilicate glass. In the current experimental study, we focus on representative additives that purportedly decrease (chromium) or increase (vanadium) the sulfate solubility. A baseline aluminoborosilicate composition containing Ca and Na was melted with target composition of either i) 1 wt% SO_3 and up to 2 wt% Cr_2O_3 or ii) 2 wt% SO_3 and up to 5 wt% percent V_2O_5. Thermal and physical properties were measured and structural analysis by Raman spectroscopy was performed to investigate changes in the glass structure with transition metal addition. Electron probe microanalysis was used to measure elemental compositions in melted glass for comparison with batched compositions. Increasing Cr_2O_3 concentration caused saturation of Cr concentration within the glass and formation of crystalline eskolaite (Cr_2O_3); glass transition temperature change was only dependent on the Cr which remained in glass, while measured density changes depended on both Cr in glass and eskolaite. No apparent change in sulfate solubility was observed, though not all the targeted sulfate was incorporated in the glasses containing Cr. On the other hand, all the targeted V was incorporated into the glass, and as the concentration of V_2O_5 increased, the glass transition temperature decreased. Again, not all of the batched sulfur was incorporated into the glass, but V_2O_5 showed a weak tendency to increase the observed sulfur content in the glass. Some incorporation mechanisms to explain these trends are proposed.

Defect Evolution Measured by Raman Spectroscopy and EBSD in Rare-Earth Doped UO_2 Used Nuclear Fuel Analogues Sam Karcher[1], John S. McCloy[1], Ritesh Mohun[2] and Claire L. Corkhill[2]; [1]Washington State University, United States; [2]The University of Sheffield, United Kingdom

Uranium dioxide prepared from depleted uranium is commonly used as an analogue to study used nuclear fuels. While actual used nuclear fuel is highly complex and contains a large number of fission products, synthetic analogues are often simplified by single species doping. Previous studies involving trivalent RE doped UO_2 show reduced dissolution rates compared to undoped UO_2. When U^{IV} is replaced with a RE^{III} cation, defect clusters containing U^{V} resulting from local charge compensation form which can serve to limit ability to form U_3O_8. Uranyl ions $(UO_2)^{2+}$, which are allowed to form as a result of U^{VI} in U_3O_8, have a solubility much higher than stoichiometric UO_2. To predict the long-term stability of used nuclear fuel in oxidizing conditions it is necessary to understand the relationships between fuel chemistry, microstructure and environment.

Here, a series of UO_2 pellets doped with Ce, Nd, Yb, Zr and Th at 1 at. % and 5 at. % were prepared via uranyl nitrate + RE-nitrate co-precipitation to ensure homogenous distribution of dopant ions before pelletizing and sintering at 1700° C in H-Ar reducing atmosphere. Defect signatures in the resulting near-stoichiometric $(U,RE)O_{2+x}$ ceramic pellets were analyzed using Raman spectroscopy at multiple excitation wavelengths pre and post oxidation treatment. Through collaboration with the University of Sheffield, we have also obtained Raman data on our samples after irradiation with 1 MeV Kr ions at room temperature, fluence 5×10^{15} ions/cm^2 at the Dalton Cumbrian Facility. Deconvolution of Raman spectra reveals distinct

signatures corresponding to defects such as interstitial or vacant oxygen sites or reduced lattice symmetry. The primary Raman peak observed in UO_2 at 445 cm^{-1} corresponds to the symmetric U-O stretching bond, and indicates the presence defects in the UO_2 structure by losing intensity and broadening while shifting towards higher wavenumber. Thermogravimetric analysis up to 900° C in air show a delayed transition from UO_2 to U_3O_8 in the doped samples, the effect being greatest in Yb-doped UO_2. Using Raman mapping with in-situ heating we can track the evolution of defect bands during oxidation and correlate spectral features to the orientation, size and distribution of grains and grain boundaries measured by electron backscatter diffraction (EBSD).

SESSION Tutorial F.EN09: Learning about In Situ and Operando Methods
Session Chairs: Chi Chen, Peter Crozier, Matt Newville, Katharine Page and Markus Winterer
Sunday Morning, November 29, 2020
F.EN09

8:00 AM *
***In Situ* and *Operando* TEM** Peter A. Crozier; Arizona State University, United States

Instrumentation and applications of in situ microscopy will be reviewed with special emphasis on environmental transmission electron microscopy (ETEM). The importance of experimental design and control of artifacts is critical to obtain scientifically significant results. Applications of ETEM to metal supported catalysts, reducible oxide nanoparticles, nanotube/nanowire growth, and electron beam induced deposition will be illustrated.

9:30 AM BREAK

9:45 AM *
X-Ray Absorption Spectroscopy Matt Newville; The University of Chicago, United States

X-ray absorption spectroscopy (XAS) will be introduced, reviewing the fundamental physics that give unique information for chemical speciation from XANES and local atomic coordination from XAFS. Practical considerations for using XAS will be discussed, including recent instrumentation developments in analyzers and detectors to improve detection limits. Applications to fields including materials, energy, and geological sciences will be highlighted.

11:15 AM BREAK

11:30 AM
High Throughput Quantitative *In Situ* Neutron Diffraction Study of Rechargeable Battery Materials Jue Liu[1], Zhijia Du[1], Alex Chien[1] and Xianyang Wu[1,2]; [1]Oak Ridge National Laboratory, United States; [2]Purdue University, United States

The advantages of using neutron diffraction to characterize battery materials are well known. It is highly penetrating and non-destructive, making it an ideal tool to probe structure changes in large devices like Li/Na-ion batteries without disturbing the electrochemical reactions. In addition, the nuclear scattering lengths do not increase with atomic number but instead are isotope dependent and it is very sensitive to light elements (Li, C and O) which are key ingredients of Li/Na-ion battery materials. It is also capable of distinguishing adjacent 3d TM cations. Moreover, the nuclear scattering lengths do not decrease with momentum transfer (Q), making it more accurate to quantitatively determine the atomic environments of light elements such as oxygen. Despite these great advantages, neutron diffraction characterization of charged and discharged electrode materials, has remained somewhat limited. In this talk, I will discuss our recent progress on developing quantitative *in situ* neutron Bragg diffraction and total scattering characterization of battery materials. Two examples will be given: one on the *in situ* neutron total scattering investigation of the structural origin of thermal runaway of high energy battery cathode materials; the other on quantitative and high throughput *in situ* neutron diffraction study of battery materials during electrochemical cycling.

1:00 PM BREAK

1:15 PM *
The X-Ray Absorption Spectroscopy Database and Machine Learning Chi Chen; University of California, San Diego, United States

Efforts at constructing the first-of-its-kind computed X-ray absorption spectroscopy database (XASdb), which contains over 500,000 spectra of over 100,000 materials. Machine learning (ML) models trained on this large dataset can be applied to the rapid identification of coordination environments from experimental XAS spectra.

SESSION F.EN09.12: Live Keynote I: Developing In Situ and Operando Methodology for Observation of Energy Conversion, Storage and Transport Processes in Materials and Devices

***In Situ* Microscopy of Energy Materials with Electron and Photon Techniques** Gianluigi A. Botton[1,2]; [1]Canadian Light Source, Canada; [2]McMaster University, Canada

Electron microscopes have become very power tools to study the structure of materials at unprecedented resolution. From their invention, these tools have provided essential information on the structure and properties of the broadest range of materials used today in structural and functional applications. In-situ electron microscopy has evolved over the last few decades from dynamic experiments (heating, straining) to reaction in gases, and, more recently, even electrochemical experiments either in vacuum or in liquids. While the spatial resolution remains the first motivation for such in situ experiments in electron microscopy (so that even nucleation and early stages of growth of nanostructures formed during electrodeposition can be investigated), the flexibility and the more realistic environments remain the realm of synchrotron beam lines. Higher pressures, higher (or lower) temperatures, experiments in liquids and gases, can be carried out with exquisite spectroscopic resolution, penetrating power with diffraction techniques, in realistic and macroscopic samples and experimental conditions more suitable to represent operating conditions.
In this presentation, a comparison of the types of experiments that can be carried out with electron and photon techniques are discussed, in particular in the context of the nature of the samples, the time resolved sensitivity and the potential artefacts.

2:05 PM *F.EN09.01.04
***In Situ* Scanning Transmission Electron Diffraction of Individual Electrically-Biased Phase Change Memory Ag-In-**

Sb-Te Line Cells Vadim Migunov[1,2,3], Xuan Thang Vu[2], Sebastian Walfort[4], Karina Ruzaeva[1], Benedikt Kersting[5], Martin Salinga[4] and Rafal E. Dunin-Borkowski[1]; [1]Forschungszentrum Juelich, Germany; [2]RWTH Aachen University, Germany; [3]ABB AG, Germany; [4]University of Münster, Germany; [5]IBM Research-Zurich, Switzerland

As current memory technologies approach their fundamental limits, increasing demand for novel non-volatile memories is driving the development of new architectures, which are already showing their potential in high performance computing [1, 2]. As a result of their non-volatile nature, byte-addressability and fast response times, which are comparable to those of dynamic random-access memory, resistive-switching-based phase change materials (PCMs) are strong candidates for memory applications with reduced hardware cost and power consumption [3, 4].

The use of advanced transmission electron microscopy combined with *in situ* electrical biasing provides a powerful method for studying the local relationship between atomic structure and electrical properties in individual nanoscale memory elements, in order to identify the factors that affect their switching reproducibility and dynamics.

We have developed a multi-step lithographic procedure, which allows dedicated nanostructured line cells that containPCM switching layers, electrical contacts and protective layers to be fabricated directly on electron-transparent silicon nitride membranes and used for switching experiments both outside and inside the transmission electron microscope. We used a special electrical setup to provide short (50 ns) electrical current pulses to individual line cells with sharp (approximately 3 ns) rising and falling edges. By using these pulses, PCM devices could be switched between crystalline low resistance and amorphous high resistance states inside a transmission electron microscope.

Even though each device consisted of several layers of different materials, resulting in a total thickness of between 200 and 300 nm, a fast pixelated direct electron detector could be used to record scanning electron diffraction patterns from amorphous/crystalline regions before and after successive switching cycles, while measuring the electric properties of the same devices. Newly-developed algorithms based on LiberTEM software [5] were used to follow the evolution of individual crystallites and to show that the switching mechanisms involved slow crystal growth or rapid recrystallization, depending on the details of the current pulses.

2:25 PM *F.EN09.02.01
Synchrotron X-Ray Spectroscopy Analysis of Some Nanoalloys and Nanoclusters Peng Zhang; Dalhousie University, Canada

Synchrotron X-ray absorption spectroscopy and associated techniques are useful tools for the element-specific analysis of the structure and properties of materials. In this talk, the application of such techniques in the study of some noble metal nanostructures toward catalytic applications will be presented. Materials of interest include nanoclusters, nanoalloys, and single-atomic-site catalysts. It will be demonstrated that the X-ray spectroscopy techniques, in association with other experimental and computational methods, can sensitively probe the structural and property changes of the catalysts induced by effects such as sample size, protecting ligands, and alloy bonding. The structural information revealed by the X-ray techniques is found useful to more thoroughly understand the structure-property relationships of the nanocatalysts.

2:45 PM *F.EN09.03.01
Constant Wavelength *In Situ* Neutron Powder Diffraction for Rechargeable Batteries, Fuel Cells, Hydrogen Storage and Photovoltaics Thomas C. Hansen; Institut Laue-Langevin, France

For the inspection of processes involving condensed matter, *in situ* neutron powder diffraction proves to be a versatile tool, giving insight into processes of technological pertinence. Only a few high-intensity powder diffractometers at intense neutron sources allow for this. D20 at Institut Laue-Langevin provides the highest available intensity in constant wavelength neutron powder diffraction. A stationary, curved linear position sensitive detector allows for *in-situ* diffraction studies down to a second and encourages the use of complex sample environments with inherently small sample sizes. D20 adapts to various levels of crystallographic complexity and rapidity of an observed phenomenon.
Rapid growth of the portable electronics market, as well as non-polluting ground transportation, needs portable energy

storage solutions with improved characteristics. One way to improve Li-ion batteries are solid electrolytes to overcome issues of liquid electrolytes in battery safety and high-voltage operation. Neutron diffraction determines the Li diffusion pathway in solid-state Li-ion conductors. Development of better electrode materials in terms of gravimetric and volumetric energy density, temperature operation range and cycling stability needs understanding of lithium (de)intercalation phenomena. *Operando* diffraction techniques are well suited here. Electrochemical cells based on a neutron-transparent (Ti,Zr) alloy combine good electrochemical properties and the ability to collect neutron diffraction patterns with reasonable statistics and no other Bragg peaks than those of the electrode material. This allows detailed structural determination of electrode materials by Rietveld refinement during operation.
Solid-oxide fuel cells convert chemical energy into electricity at higher efficiency than conventional methods, with less pollution. The anode (fuel electrode) must not alter at high temperature (thermal stability), not form nonconductive phases at interfaces (chemical stability) and not degrade upon reduction and oxidation cycles (redox stability). The state-of-the-art "cermet" of Ni and yttria-stabilized zirconia ceramic loses performance upon usage as its porosity is reduced by Ni agglomeration and as oxidation of Ni causes redox instability. Cermet deactivates through carbon coking and sulfur poisoning, making it unsuited for hydrocarbon fuels. Single-phase mixed ionic and electronic conductors provide microstructural stability and increase the electrode fraction accessible to oxide ions. Many of those oxides have been investigated successfully *in operando* at high temperature under oxidizing and reducing gas flow by neutron diffraction, following the crystal chemistry of oxide ions during the process.
Classical *in situ* work (thermo-diffractometry) has been done on the new photovoltaic materials, $MaPbI_3$ and derivates, and neutron diffraction turned out to be a perfect tool to screen the crystal chemistry of light organic atoms beside the heavy metal atoms over a wide range of temperatures.
Hydrogen is an attractive energy carrier for renewable energy sources due to its high energy density. Solid-state hydrogen storage provides higher storage capacities than compressed or liquefied hydrogen. Complex metal hydrides have high hydrogen storage capacities but suffer from poor kinetic and thermodynamic properties. Tuning the thermodynamics for dehydrogenation, in order to reduce the temperature at which hydrogen is evolved is achieved through the addition of a second phase, which will lead to the formation of a more stable product upon decomposition and thereby reducing the enthalpy for dehydrogenation. Neutron powder diffraction comes screens the crystal chemistry of the different phases *in situ* and localizes hydrogen in the structures.

3:05 PM *F.EN09.06.01
Advance Characterization Tools to Study and Develop Stable Anionic Redox for High-Energy Rechargeable Batteries Minghao Zhang and Y. Shirley Meng; University of California, San Diego, United States

There is a growing consensus that the theoretical limit of one electron intercalation reactions will soon be reached. Recent discoveries on anion redox electrochemistry offer new opportunities and a possible paradigm shift in energy storage. By activating anion (e.g. oxygen, sulfur) for reversible electrochemical reactions, increased energy density has been demonstrated. In the past decade, the research community has made great progress on understanding key features of the anionic electrochemical activities and dynamic phenomena that govern the performance limitations including cycling voltage hysteresis and decay. However, the exact mechanism at molecular/atomic scales is still largely under-debate. The lack of conscience on the anionic redox mechanism which can be fueled by possible misinterpretation of experimental results. Of particular importance is determining what techniques provide accurate and reliable evidence for reversible bulk oxygen redox.
Compared with transition metal cations, oxygen anions are more challenging to be probed and quantified, which requires a multi-modal experimental approach with exceptional energy and spatial resolution combining computational modelling. Here, we advance: 1) from X-ray absorption spectroscopy to resonant inelastic X-ray scattering which shows a sharp feature with the corresponding excitation energy at 531 eV corresponding to the extra unoccupied electron orbitals of oxidized oxygen; 2) from neutron diffraction to neutron pair distribution function which is enormously valuable as a local probe that can reveal local distortions, when present along the oxygen redox reactions; 3) from X-ray diffraction to Bragg coherent diffraction imaging which will enable the direct observation of the strain dynamics with the exceptional sensitivity as small as 0.05% and phase evolution induced by the oxygen redox activity at nanoscale. It is through the in-depth understanding of electrochemical reactions mechanism at microscopic and macroscopic level during the operation of batteries; we can successfully formulate strategies to achieve reversible and stable anionic redox for next generation lithium-ion batteries.

3:25 PM *F.EN09.03.04
Advanced Neutron Characterisation of Rechargeable Battery Systems Vanessa K. Peterson[1,2]; [1]Australian Nuclear Science and Technology Organisation, Australia; [2]University of Wollongong, Australia

The performance of functional materials central to energy devices, including rechargeable batteries, fuel cells, as well as gas

separation and storage technologies, is determined largely by atomic-scale materials structure and dynamic-function relations. Many energy materials function by undergoing change, such as compositional change in rechargeable battery electrodes that reversibly host charge-carrying ions and in gas storage and separation materials. Robust characterization methods that quantitatively and accurately capture these changes are essential to the strategic design of superior materials function, and consequently to improving energy device performance. Historically, a conflict existed between fast and detailed measurements of materials structure, particularly for measurements of materials within devices. This conflict was sometimes alleviated by using small model systems in which the material function was not representative of that in the corresponding commercially used device. Today, advanced characterization methods that capture material changes in detail while they are occurring is possible in whole devices under real-life operating conditions, as facilitated by advances in instrumentation.

This talk will give examples of in operando and in situ neutron measurements of energy materials used for rechargeable batteries capturing compositional change and/or non-equilibrium processes, with a focus on neutron powder diffraction using the high intensity neutron powder diffractometer Wombat at the Australian Centre for Neutron Scattering

8:00 AM *F.EN09.05.01
Novel Approaches for Electron Tomography to Investigate the Structure and Stability of Nanomaterials Under Relevant Conditions Sara Bals[1,2], Wiebke Albrecht[1,2], Hans Vanrompay[1,2], Eva Bladt[1,2], Alexander Skorikov[1,2], Thomas Altantzis[1,3], Jan Willem Buurlaege[4], Daan Pelt[4], Joost Batenburg[5,4] and Sandra Van Aert[1,2]; [1]EMAT-University of Antwerp, Belgium; [2]NANOlab Center of Excellence, University of Antwerp, Belgium; [3]ELCAT-University of Antwerp, Belgium; [4]CWI, Netherlands; [5]University of Leiden, Netherlands

Nanomaterials are important for a wide range of applications because of their unique properties, which are strongly connected to their three-dimensional (3D) structure. Electron tomography has therefore been used in an increasing number of studies. Most of these investigations resulted in 3D reconstructions with a resolution at the nanometer scale, but also atomic resolution was achieved in 3D.

In order to preserve the carefully designed morphologies and functionalities, understanding the stability of nanomaterials during application is crucial. It is hereby important to note that most electron tomography investigations have been performed at the conventional conditions of an electron microscope. An emerging challenge is therefore to fully understand the connection between the 3D structure and properties under more relevant conditions, including high temperatures as well as in the presence of liquids and gases. Therefore, innovative methodologies are required to track the fast 3D changes of nanomaterials that occur under such conditions.

Recently, we proposed an acquisition approach where a tilt series of 2D HAADF-STEM projection images is acquired within a few minutes. By continuously tilting the holder and simultaneously acquiring projection images while focusing and tracking the particle, we were able to reduce the total acquisition time for a tilt series by a factor of ten [1]. Moreover, a new approach was developed to compute high quality 2D virtual slices through nanoparticles in approximately 60 ms time. This technique drastically improves the efficiency of 3D characterization of nanomaterials by TEM. It enables explorative imaging and provides valuable information to dynamically adjust the acquisition parameters during an electron tomography experiment [2].

In this manner, we were able to study the 3D morphological evolution of anisotropic Au and AuPd nanoparticles as a function of both heating time and temperature [1,3]. Moreover, we measured the elemental diffusion dynamics of individual anisotropic Au-Ag nanoparticles in 3D [4]. We conclude that for a given composition, the shape of the nanoparticle does not influence the alloying process significantly. Based on our analysis, it is clear that interdiffusion of metals at the nanoscale is more complex than predicted by simple Fickian diffusion and that other factors such as surface diffusion need to be taken into account.

To quantify nanoparticle shape dynamics in a gaseous environment in 3D, HAADF-STEM images served as an input for atom counting procedures followed by 3D relaxation of the structure. In this manner, we characterized shape changes of a Pt nanoparticle in a gaseous environment. The conditions have been varied from vacuum to a 1 bar H2 flow, followed by a 1 bar O2 environment. To investigate the behaviour during cycling, we repeated the experiment several times using the same particle. We clearly observe morphology changes and we were even able to quantify the occurrence of the different surface facets [5].

***Operando* Characterization of Electrochemical Insertion into Hydrated and Solvated Metal Oxides** Veronica Augustyn; North Carolina State University, United States

Layered transition metal oxides that incorporate water or other solvents provide fundamental understanding of the effects of confinement on electrochemical ion transport and reactivity. They also tend to exhibit fast electrochemical ion insertion kinetics making them of interest for high power electrochemical energy storage. These materials are hybrids that consist of transition metal oxide layers separated by fluids that can be either ordered or disordered, and strongly or weakly bound to the oxide. Our group has investigated ion insertion into a range of hydrated and solvated metal oxides with *operando* characterization to connect structural changes to the electrochemical response. Since many of these materials exhibit fast kinetics (full charge/discharge in minutes), *operando* characterization techniques must have suitable temporal resolution to capture structural or chemical changes at these rates. This presentation will describe our use of three types of *operando* techniques to probe insertion kinetics at minute-to-second timescales: X-ray diffraction, atomic force microscopy, and electrochemical quartz crystal microbalance. It will also discuss how knowledge of the dynamics of ion insertion in these materials help us understand ion transport under confinement.

8:40 AM *F.EN09.07.01
Understanding Kinetic Limitations and Oxygen-Redox in Lithium Layered Transition-Metal Oxide Electrodes Through *Operando* X-Ray Scattering Karena Chapman; Stony Brook University, United States

Chemical substitution of transition metal species is often used to tune the performance and cost of electrode materials. However, substitutions that improve one performance metric can be coupled to unintended consequences. This presentation will show how we have used operando X-ray scattering to understand kinetic limitations and O-redox in Li-layered transition metal oxide electrodes.
Substituted Li layered transition metal oxide (LTMO) electrodes such as $Li_xNi_yMn_zCo_{1-y-z}O_2$ (NMC) and $Li_xNi_yCo_{1-y-z}Al_zO_2$ (NCA) show reduced first cycle Coulombic efficiency (90-87 % in standard cycling conditions) compared with archetypal Li_xCoO_2 (LCO – ~98 % efficiency). We use operando x-ray diffraction (XRD) to demonstrate that the apparent first cycle capacity loss is a kinetic effect linked to limited Li mobility at $x > 0.85$, with near full capacity recovered and slow Li reinsertion during a potentiostatic hold following the galvanostatic charge–discharge cycle. The kinetic limitation manifests not only as the kinetic capacity loss during discharge, but as a subtle bimodal compositional distribution early in charge and, also, a dramatic increase of the charge–discharge voltage hysteresis at $x > 0.85$.

9:00 AM *F.EN09.09.01
Atomic Scale Dynamics of Oxide Island Growth During *In Situ* Oxidation of Copper Judith C. Yang; University of Pittsburgh, United States

Understanding the structural changes at the atomic scale of nano-oxide formation via metal oxidation is critical for the rational design and control of oxides for a variety of technology-critical applications including heterogeneous catalysts,

sensors, and corrosion protection in extreme environments. Though classical oxidation theories, such as Cabrera-Mott, exist, little is known concerning the initial oxidation stages at the atomic scale. With the developments of in situ characterization tools, such as Environmental Transmission Electron Microscope (ETEM), we are now able to directly observe the structural changes during oxidation. In this work, we combine in situ ETEM with density functional theory (DFT) to fundamentally understand oxide island formation and growth at the atomic scale; Cu(001) was selected as the model metal system. As an example of this correlative approach, we recently observed a layer-by-layer growth of Cu_2O island along $Cu_2O(110)$ plane, where our analysis of these growth dynamics suggests a diffusion limited monolayer growth process. DFT results supported these experimental observations of preferential growth along $Cu_2O(110)$ based on surface energies, diffusion barriers and adsorption energies simulations. We are currently investigating these critical surface reactions for binary alloys. Support for this research program is from NSF-DMR 1410055, 1508417, and 1410335.

9:20 AM *F.EN09.10.01
Sustainable Energy Materials—New Routes for *In Situ* Nanoscale Characterization and Their Correlation to Functionality Stephan V. Roth; KTH Royal Institute of Technology, Sweden

The development of materials for sustainable energy conversion and storage requires new approaches on both the materials and process side. These approaches rely on the use of scattering techniques offering access to the molecular and nanoscale and exploiting both the virtues of X-rays and neutrons [1]. One crucial point is to observe the materials structural transformations in situ from the nano- to the microscale during materials' synthesis and subsequent device fabrication. These changes must be related to their (macroscopic) functionality. Preferentially the materials itself are sustainable, water-based, or biomaterials. To start with, we focus on wood-based biomaterials, such as cellulose and lignin. Introducing spray deposition as versatile process, ultrasmooth cellulose nanofibril films with controlled thickness are investigated [1,2]. Depending on their charge and roughness, the wettability can be controlled. This is crucial for optimizing the fabrication of hybrid materials, typical for energy conversion and storage. The tailoring of wettability is further pursued by surface functionalization of water-based latex colloids. These materials offer the possibility to tailor and fine-tune the wettability by tuning the core-shell colloid morphology in thin films, thus providing a facile template methodology for repellent surfaces of devices [3]. In materials synthesis, chemical modification of lignin affects the molecular network, aggregate stacking, and size of lignin thermosets. This in turn changes the macroscopic properties of the resulting thermoset [4]. Electronic properties manifest themselves for example in electrical conductivity changes and optical response. The electronic properties are governed by the nanoscale morphology. Imaging via scattering methods allows to extract the granular morphology up to and beyond the percolation threshold in situ during fabrication. At the same time, this analysis allows to predict the electrical behavior of hybrid composites and thus to optimized for example electrodes in such devices [5]. Silver nanowires offers electrical conductivity, mechanical flexibility as well as well high optical transparency when applied as meshes in top electrodes. Here, printing applications offer great potential for photovoltaics and flexible electronics. Two examples are presented: First, a tough composite for a 2D-printed film as top contact on a solar cell, and secondly a flexible composite applied for a 3D-printed flexible capacitor [6]. These examples highlight the advanced capabilities of scattering methods for in situ imaging of the nanoscale structure and for establishing the nanostructure-function relationship.

In this presentation, a comparison of the types of experiments that can be carried out with electron and photon techniques are discussed, in particular in the context of the nature of the samples, the time resolved sensitivity and the potential artefacts.

Operando* Scanning Transmission Electron Microscopy of Li-O_2 Battery—*See and Believe Jiuhui Han[1], Chen Hou[2,1], Chuchu Yang[1], Pan Liu[2,1], Akihiko Hirata[3,1] and Mingwei Chen[4,1]; [1]Tohoku University, Japan; [2]Shanghai Jiao Tong University, China; [3]Waseda University, Japan; [4]Johns Hopkins University, United States

Rechargeable non-aqueous lithium-oxygen batteries with a large theoretical capacity are emerging as a high-energy electrochemical device for sustainable energy strategy. Although the fundamental electrochemical principle of lithium-oxygen batteries has been established for decades, the cathodic reaction kinetics, associated with the formation and decomposition of a solid Li_2O_2 phase during charging and discharging, remains debating. Here we report direct visualization of the charge/discharge reactions on Au and RuO_2 cathodes in non-aqueous electrolytes with and without redox mediators using liquid-cell aberration-corrected scanning transmission electron microscopy (STEM) combining with synchronized electrochemical measurements. The real-time and real-space characterization by time-resolved quantitative STEM with ~1 nm spatial resolution reveals the electrochemical correspondence of discharge/charge overpotentials with the nucleation, growth and decomposition of Li_2O_2 which are mediated by solid and liquid catalysts at constant current densities. The nano-scale operando observations unveil the underlying reaction pathways of lithium-oxygen batteries under different electrochemical conditions during round-trip discharging and charging and shed lights on the strategies in improving the performances of lithium-oxygen batteries by tailoring the cathodic reactions through cahode and electrolyte design.

Unveiling the Stable Nature of the Solid Electrolyte Interphase Between Lithium Metal and LiPON via Cryogenic Electron Microscopy Diyi Cheng and Y. Shirley Meng; University of California, San Diego, United States

The solid electrolyte interphase (SEI) is regarded as the most complex but the least understood constituent in secondary batteries using liquid and solid electrolytes. The nanostructures of SEIs were recently reported to be equally important to the chemistry of SEIs for stabilizing Li metal in liquid electrolyte. However, the dearth of such knowledge in all-solid-state battery (ASSB) has hindered a complete understanding of how certain solid-state electrolytes, such as LiPON, manifest exemplary stability against Li metal. Characterizing such solid-solid interfaces is difficult due to the buried, highly reactive, and beam-sensitive nature of the constituents within. By employing cryogenic electron microscopy (cryo-EM), the interphase between Li metal and LiPON is successfully preserved and probed, revealing a multilayer mosaic SEI structure with concentration gradients of nitrogen and phosphorous, materializing as crystallites within an amorphous matrix. This unique SEI nanostructure is less than 80 nm and is shown stable and free of any organic lithium containing species or lithium fluoride components, in contrast to SEIs often found in state-of-the-art organic liquid electrolytes. Our findings reveal insights on the nanostructures and chemistry of such SEIs as a key component in lithium metal batteries to stabilize Li metal anode.

***In Situ* Scanning Transmission Electron Diffraction of Individual Electrically-Biased Phase Change Memory Ag-In-Sb-Te Line Cells** Vadim Migunov[1,2,3], Xuan Thang Vu[2], Sebastian Walfort[4], Karina Ruzaeva[1], Benedikt Kersting[5], Martin Salinga[4] and Rafal E. Dunin-Borkowski[1]; [1]Forschungszentrum Juelich, Germany; [2]RWTH Aachen University, Germany; [3]ABB AG, Germany; [4]University of Münster, Germany; [5]IBM Research-Zurich, Switzerland

As current memory technologies approach their fundamental limits, increasing demand for novel non-volatile memories is driving the development of new architectures, which are already showing their potential in high performance computing [1, 2]. As a result of their non-volatile nature, byte-addressability and fast response times, which are comparable to those of dynamic random-access memory, resistive-switching-based phase change materials (PCMs) are strong candidates for memory applications with reduced hardware cost and power consumption [3, 4].

The use of advanced transmission electron microscopy combined with *in situ* electrical biasing provides a powerful method for studying the local relationship between atomic structure and electrical properties in individual nanoscale memory elements, in order to identify the factors that affect their switching reproducibility and dynamics.

We have developed a multi-step lithographic procedure, which allows dedicated nanostructured line cells that containPCM switching layers, electrical contacts and protective layers to be fabricated directly on electron-transparent silicon nitride membranes and used for switching experiments both outside and inside the transmission electron microscope. We used a special electrical setup to provide short (50 ns) electrical current pulses to individual line cells with sharp (approximately 3 ns) rising and falling edges. By using these pulses, PCM devices could be switched between crystalline low resistance and amorphous high resistance states inside a transmission electron microscope.

Even though each device consisted of several layers of different materials, resulting in a total thickness of between 200 and 300 nm, a fast pixelated direct electron detector could be used to record scanning electron diffraction patterns from amorphous/crystalline regions before and after successive switching cycles, while measuring the electric properties of the same devices. Newly-developed algorithms based on LiberTEM software [5] were used to follow the evolution of individual crystallites and to show that the switching mechanisms involved slow crystal growth or rapid recrystallization, depending on the details of the current pulses.

Late News: Imaging Ionic Arrangements at Liquid-Solid Interfaces by Cryo-Electron Microscopy Haokun Li[1], J. Pedro de Souza[2], Ze Zhang[1], Joel Martis[1], Kyle Sendgikoski[3], John Cumings[3], Martin Bazant[2] and Arun Majumdar[1]; [1]Stanford University, United States; [2]Massachusetts Institute of Technology, United States; [3]University of Maryland, United States

Electrically charged liquid-solid interfaces play a vital role in many electrochemical phenomena encountered in biology, energy, and the environment. At electrically charged interfaces, ions and solvent molecules rearrange to screen the surface charge, forming the electrical double layers. The ability to probe such systems with single-ion resolution is important to a basic understanding of their behaviors and the development of new ionic technologies. Although many techniques have been used to probe liquid-solid interfaces, it remains a challenge to acquire spatial information down to the single ion level. Here, using cryo-electron microscopy, we directly visualize individual ions and their distributions at electrically charged liquid-solid interfaces. We observe discrete layering of multivalent counterions, which arises from the finite ion size and the strong electrostatic interactions. In addition, correlated ion structures under extreme confinement are revealed, with the channel widths approaching the ion diameter (~1 nm). Our experiment opens up a new arena to study liquid-solid interfaces at the single ion level.

SESSION F.EN09.02: X-Ray Spectroscopy

Synchrotron X-Ray Spectroscopy Analysis of Some Nanoalloys and Nanoclusters Peng Zhang; Dalhousie University, Canada

Synchrotron X-ray absorption spectroscopy and associated techniques are useful tools for the element-specific analysis of the structure and properties of materials. In this talk, the application of such techniques in the study of some noble metal nanostructures toward catalytic applications will be presented. Materials of interest include nanoclusters, nanoalloys, and single-atomic-site catalysts. It will be demonstrated that the X-ray spectroscopy techniques, in association with other experimental and computational methods, can sensitively probe the structural and property changes of the catalysts induced

by effects such as sample size, protecting ligands, and alloy bonding. The structural information revealed by the X-ray techniques is found useful to more thoroughly understand the structure-property relationships of the nanocatalysts.

5:15 AM F.EN09.02.02
In-Operando Study of Electrochemical Strain and Charge Storage Mechanisms in Defect-Engineered MnO_2 Nanosheet Electrodes Madeleine N. Flint, Alec Ladonis, Peter Metz, Peng Gao, Robert Koch and Scott Misture; Alfred University, United States

MnO_2 nanosheets demonstrate an interesting response to reduction of Mn^{4+} to Mn^{3+}, where the Jahn-Teller distorted Mn^{3+} is displaced out of the plane of the nanosheet forming a "surface Frenkel" defect. Atomic scale point defects enhance capacitance beyond 300F/g while lowering charge transfer resistance of δ-MnO_2 nanosheets by a factor of 10 and increasing cycle stability.

In-situ and in-operando X-ray total scattering and XRD was teamed with X-ray absorption spectroscopy, Raman spectroscopy, and related tools to probe the local atomic structure and defect chemistry during electrochemical cycling. The result is a description of the charging mechanism in high surface area MnO_2 nanosheet electrodes: reversible in-plane strains of up to 0.7% occured during charging of nanosheets with little restacking, accompanied by Mn reduction. Bond distances obtained from Pair Distribution Functions correlated with the XRD where Mn-O and Mn-Mn bond lengths reversibly increased during charging. Raman spectra also demonstrate an increased number of Jahn-Teller distorted MnO_6 octahedra in the charged state.

Changes to the interlayer during electrochemical cycling were morphology dependent. Random assemblies of nanosheets with little sheet-to-sheet restacking showed only in-plane response, without changes in sheet-to-sheet distances. However, highly restacked nanosheets contract in the c direction on charging due to electrostatic changes to the interlayer. The results suggest that improved cycling stability is feasible using high-porosity, random assemblies of nanosheets and that the interlayer hydration is a key parameter in diffusion of the charging ions.

5:25 AM F.EN09.02.03
New Synchrotron Methods to Investigate the Breakdown of the Small-Polaron Hopping Model in Ternary Spinels Anuj Bhargava[1], Roni Eppstein[2], Jiaxin Sun[1], Michelle A. Smeaton[1], Hanjong Paik[1], Lena Kourkoutis[1], Darrell Schlom[1], Maytal Caspary Toroker[2] and Richard Robinson[1]; [1]Cornell University, United States; [2]Technion–Israel Institute of Technology, Israel

For the more than half a century the small polaron hopping model has been used to describe the electronic charge transport in semiconducting oxides. This model was originally developed for binary oxides, and despite its vast usage, the model's accuracy has not been rigorously tested for complex oxides (ternarys and higher order oxides). Ternary spinel oxides are an important class of materials actively researched for applications in energy storage, catalysis, and data storage due to their exciting electrochemical, catalytic, and magnetic properties; and better understanding of charge transport in such systems can lead to higher performance devices. Previous experimental investigations of charge transport in ternary spinels are sparse and limited owing to the lack of accessible characterization techniques to correlate site occupation to properties, and also due to difficulties in achieving phase-pure ternarys over a wide stoichiometric range. To overcome these challenges, we choose the $Mn_xFe_{3-x}O_4$ system, which has exciting electrochemical and catalytic properties, and mixed oxidation states that enables us to examine the mechanisms of small polaron transport. We fabricate epitaxial and phase pure $Mn_xFe_{3-x}O_4$ thin films over the complete 'x' range using molecular beam epitaxy (MBE); and use our recently developed method using x-ray emission spectroscopy (XES) to determine the site occupation of cations. Previously we have shown that XES is an accessible and a more accurate method than traditional methods such as x-ray absorption spectroscopy (XAS) in extracting cation site occupation. We find that in $Mn_xFe_{3-x}O_4$, polarons preferably localize at Mn octahedral sites and polaron hopping occurs only between like-elements (Fe to Fe and Mn to Mn), and as a result the conduction occurs along decoupled pathways formed by Mn and Fe cations. Since the role of cross-hopping and decoupled pathways have not been considered in the conventional polaron hopping model, we introduce new parameters in the conventional transport model. We test the validity of the new model on the $Mn_xFe_{3-x}O_4$ system by comparing the concentration of charge carriers calculated using the conventional and the new model to the experimental conductivity trends. An excellent overlap of the new model with experimental trends confirms the precision of our augmented model and the limitation of the conventional model for ternary spinels. With this work, we use new synchrotron methods to provide a pragmatic tool for designing non-equilibrium oxides with enhanced performance with the aim to incorporate spinels in devices such as batteries, supercapacitors, and fuel cells.

5:35 AM F.EN09.02.04

Structural Characterization of Complex Catalysts for Heterogenous Oxidation Jeremias Geiss and Markus Winterer; Universität Duisburg-Essen, Germany

Perovskite nanoparticles, composed of $LaCo_xFe_{1-x}O_3$, are a promising heterogenous catalyst for oxidation reactions. As-synthesized nanocatalysts often exhibit a complex structure with a variety of defects. During operando experiments, the complexity of the structure increases by the addition of a boundary layer. Furthermore, the catalytic activity itself can result in structural changes. However, the understanding of the structure-activity relationship is critical to ultimately improve catalytic performance.

Due to their large surface to volume ration, the bulk as well as the surface of small nanoparticles can be probed by Extended X-Ray Absorption Fine Structure (EXAFS). Measurement at the different elemental absorption edges resolves the local structure around each atom type of the complex oxide.

The presentation is focused on the EXAFS measurements of $LaCo_xFe_{1-x}O_3$ nanoparticles at the Co-K, Fe-K and La-K edge to refine a mutual particle model by Reverse Monte Carlo (RMC) analysis.

Revealing the Role of Point Defects in Nanostructured Catalyst Design with Ambient Pressure X-Ray Photoelectron Spectroscopy Jiayue Wang[1], Alexander K. Opitz[2] and Bilge Yildiz[1]; [1]Massachusetts Institute of Technology, United States; [2]Technische Universität Wien, Austria

A central theme in renewable energy technologies today is to design nanostructured catalysts towards desired reactions. Engineering the functional defects in materials is a key step in this direction. For this, we have to advance the understanding of the role of defect structures in the relevant properties of materials. Here we develop a generalizable experimental and analysis framework using ambient pressure X-ray spectroscopy (APXPS), density functional theory (DFT), and Monte Carlo (MC) calculations, to understand the role of point defects in catalyst generation under real working conditions.
A recent advance in materials for electrochemical energy and fuels conversion is to synthesize metal nanoparticles in a process termed “exsolution”. Unlike traditional nanoparticle infiltration techniques, the nanoparticle catalysts from exsolution are anchored in the parent oxide. This strong metal-oxide interaction makes the exsolved nanoparticles more resistant against particle agglomeration as compared to the infiltrated ones. In addition, the exsolved particles also open up the possibility of regeneration of catalysts. While being an exciting and promising pathway for generating stable oxide supported nanoparticles, rational control over the exsolved particles has yet to be achieved. In particular, it remains a big challenge to control the size and density of the exsolved nanoparticles.
In this work, we propose that point defect formation in the oxide lattice to be the fundamental knob to control exsolution, and demonstrate this approach in epitaxial $La_{0.6}Sr_{0.4}FeO_3$ (LSF) thin films. By quantifying surface defect states with APXPS, we identify the initial oxygen vacancy (V_O) formation and the following Schottky defect formation as the primary defect reactions in exsolution. Then, by tuning the formation energy of these two defects in LSF with biaxial lattice strain, we examined their impacts on metallic iron (Fe^0) exsolution. As a result, the LSF surface with that has more of these point defects, also has the highest Fe^0 concentration, the largest particle density, as well as the finest particle size. Finally, with the aid of DFT calculations and MC simulations, we suggest surface oxygen vacancy clusters to be the nucleation sites for the exsolved particles. These observations highlight the critical role of surface point defects in controlling the size and density of the nanoparticles.

SESSION F.EN09.03: Neutron Diffraction

F-EN09

5:00 AM *F.EN09.03.01
Constant Wavelength *In Situ* Neutron Powder Diffraction for Rechargeable Batteries, Fuel Cells, Hydrogen Storage and Photovoltaics Thomas C. Hansen; Institut Laue-Langevin, France

For the inspection of processes involving condensed matter, *in situ* neutron powder diffraction proves to be a versatile tool, giving insight into processes of technological pertinence. Only a few high-intensity powder diffractometers at intense neutron sources allow for this. D20 at Institut Laue-Langevin provides the highest available intensity in constant wavelength neutron powder diffraction. A stationary, curved linear position sensitive detector allows for *in-situ* diffraction studies down to a second and encourages the use of complex sample environments with inherently small sample sizes. D20 adapts to various levels of crystallographic complexity and rapidity of an observed phenomenon.
Rapid growth of the portable electronics market, as well as non-polluting ground transportation, needs portable energy storage solutions with improved characteristics. One way to improve Li-ion batteries are solid electrolytes to overcome issues of liquid electrolytes in battery safety and high-voltage operation. Neutron diffraction determines the Li diffusion pathway in solid-state Li-ion conductors. Development of better electrode materials in terms of gravimetric and volumetric energy density, temperature operation range and cycling stability needs understanding of lithium (de)intercalation phenomena. *Operando* diffraction techniques are well suited here. Electrochemical cells based on a neutron-transparent (Ti,Zr) alloy combine good electrochemical properties and the ability to collect neutron diffraction patterns with reasonable statistics and no other Bragg peaks than those of the electrode material. This allows detailed structural determination of electrode materials by Rietveld refinement during operation.
Solid-oxide fuel cells convert chemical energy into electricity at higher efficiency than conventional methods, with less pollution. The anode (fuel electrode) must not alter at high temperature (thermal stability), not form nonconductive phases at interfaces (chemical stability) and not degrade upon reduction and oxidation cycles (redox stability). The state-of-the-art "cermet" of Ni and yttria-stabilized zirconia ceramic loses performance upon usage as its porosity is reduced by Ni agglomeration and as oxidation of Ni causes redox instability. Cermet deactivates through carbon coking and sulfur poisoning, making it unsuited for hydrocarbon fuels. Single-phase mixed ionic and electronic conductors provide microstructural stability and increase the electrode fraction accessible to oxide ions. Many of those oxides have been investigated successfully *in operando* at high temperature under oxidizing and reducing gas flow by neutron diffraction, following the crystal chemistry of oxide ions during the process.
Classical *in situ* work (thermo-diffractometry) has been done on the new photovoltaic materials, $MaPbI_3$ and derivates, and neutron diffraction turned out to be a perfect tool to screen the crystal chemistry of light organic atoms beside the heavy metal atoms over a wide range of temperatures.
Hydrogen is an attractive energy carrier for renewable energy sources due to its high energy density. Solid-state hydrogen storage provides higher storage capacities than compressed or liquefied hydrogen. Complex metal hydrides have high hydrogen storage capacities but suffer from poor kinetic and thermodynamic properties. Tuning the thermodynamics for dehydrogenation, in order to reduce the temperature at which hydrogen is evolved is achieved through the addition of a second phase, which will lead to the formation of a more stable product upon decomposition and thereby reducing the enthalpy for dehydrogenation. Neutron powder diffraction comes screens the crystal chemistry of the different phases *in situ* and localizes hydrogen in the structures.

5:15 AM *F.EN09.03.04
Advanced Neutron Characterisation of Rechargeable Battery Systems Vanessa K. Peterson[1,2]; [1]Australian Nuclear Science and Technology Organisation, Australia; [2]University of Wollongong, Australia

The performance of functional materials central to energy devices, including rechargeable batteries, fuel cells, as well as gas separation and storage technologies, is determined largely by atomic-scale materials structure and dynamic-function relations. Many energy materials function by undergoing change, such as compositional change in rechargeable battery electrodes that reversibly host charge-carrying ions and in gas storage and separation materials. Robust characterization methods that quantitatively and accurately capture these changes are essential to the strategic design of superior materials function, and consequently to improving energy device performance. Historically, a conflict existed between fast and detailed measurements of materials structure, particularly for measurements of materials within devices. This conflict was sometimes alleviated by using small model systems in which the material function was not representative of that in the corresponding commercially used device. Today, advanced characterization methods that capture material changes in detail while they are occurring is possible in whole devices under real-life operating conditions, as facilitated by advances in instrumentation.

This talk will give examples of in operando and in situ neutron measurements of energy materials used for rechargeable batteries capturing compositional change and/or non-equilibrium processes, with a focus on neutron powder diffraction using the high intensity neutron powder diffractometer Wombat at the Australian Centre for Neutron Scattering

5:30 AM F.EN09.03.05
Late News: *Operando* Neutron Diffraction on All-Solid-State-Batteries Using a New Electrochemical Cell Cédric J. Barcha[1,2,3], Xavier Randrema[1,2,3], Théodosios Famprikis[1,3], Tatiana Renzi[4,5,3], Emmanuelle Suard[5], Mohamed Chakir[2,3],

Nathalie Delpuech[2,3], Jean-Noël Chotard[1,3], Virginie Viallet[1,3], Mathieu Morcrette[1,3], Laurence Croguennec[4,3], Vincent Seznec[1,3] and Christian Masquelier[1,3]; [1]Laboratoire de Réactivité et Chimie des Solides (LRCS), France; [2]Technocentre Renault (Groupe Renault), France; [3]Réseau sur le stockage électrochimique de l'énergie (RS2E), France; [4]Institut de Chimie de la Matière Condensée de Bordeaux (ICMCB), France; [5]Institut Laue-Langevin (ILL), France

The field of all-solid-state-batteries (ASSBs) is expected to potentially overcome associated issues of conventional LIBs and has recently attracted both industrial and academic attention (1) (2). Indeed, by removing flammable liquid solvents, this technology may enable improved intrinsic safety at cell level and increased temperature stability, resulting in system level benefits compared with conventional LIBs based on liquid electrolytes. SEs should also allow the possibility to use lithium metal anode leading to an enhancement of the energy density. To develop the ASSB technology, it is mandatory to first understand the (de)lithiation mechanisms into/from active materials and investigate the stability of the solid electrolyte itself. Among in-situ techniques used to understand electrode materials, neutron diffraction (ND) is one of the most powerful due to its high penetration depth allowing simultaneous data collection from both electrodes.

Operando ND in Li-ion batteries has been widely used to determine lattice parameters, phase transitions, and detailed structural information such as Li position and content in anode and cathode materials (3) (4) (5) (6), but also useful for commercial cell analysis (7) (8) (9). In the long term, this tool could help the ASSB community with trending problems such as SE decomposition (10) or stability of crystalline coating on active materials (11). A new operando electrochemical cell made of a Ti-Zr alloy completely transparent to neutrons was designed by the Institut Laue-Langevin, allowing operando neutron diffraction on the whole solid state battery, in a wide temperature range from -100°C to + 400 °C. The cell is completely airtight and offers the possibility of applying pressure. A first demonstration of the capabilities of the cell and of its limitations will be presented, using a solid-state battery based on a $LiCoO_2$ cathode, a $Li_4Ti_5O_{12}$ anode and Argyrodite Li_6PS_5Cl as the solid electrolyte. Temperature-controlled Li^+ extraction from $LiCoO_2$, up to 150°C, made possible by the use of an ASSB, reveal new interesting phenomena. Over one electrochemical cycle, the structural integrity of the Argyrodite solid electrolyte appears to be maintained.

SESSION F.EN09.04: Novel Microscopy Methods
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-EN09

5:00 AM F.EN09.04.01
Visualize and Quantify the Effect of Polymer Coatings on the Mechanical Behavior of $LiCoO_2$ Cathodes in Lithium-Ion Batteries Laisuo Su[1], Paul Choi[1], Nathan Nakamura[1], Harry Charalambous[2], Shawn Litster[1], Jan Ilavsky[2] and B. Reeja Jayan[1]; [1]Carnegie Mellon University, United States; [2]Argonne National Laboratory, United States

Surface engineering is the most effective method in regulating the chemo-mechanical interaction behavior of electrodes and further enhancing their electrochemical performance in lithium ion batteries (LIBs). Although extensive studies have been carried out to investigate the effect of coatings on the electrodes surface degradation, limited understanding have been obtained regarding how these coatings regulate the electrodes mechanical behavior. Here, for the first time, we combine in-operando synchrotron X-ray scattering technique and high-resolution transmission X-ray microscopy (TXM) technique to investigate the effect of a poly(3,4-ethylenedioxythiophene) (PEDOT) artificial coating on the electro-chemo-mechanical behavior of $LiCoO_2$. TXM provides straightforward time-dependent images of $LiCoO_2$ particles, while X-ray scattering offers volume-averaged quantitative information of the $LiCoO_2$ electrodes during cycling. The complimentary of the two techniques is examined by an over-lithiation experiment of $LiCoO_2$ between 3.0 V – 0.5 V, during which $LiCoO_2$ particles/agglomerates crack and eventually pulverize. The two in-operando techniques are then applied to uncover the largely improved 4.5 V high-voltage cycling stability of $LiCoO_2$ from the PEDOT coating. The results suggest that the PEDOT coating not only alleviates $LiCoO_2$ surface deterioration and electrolyte decomposition, but also inhibits $LiCoO_2$ particles/agglomerates expansion during the cycling test. The understanding of the electro-chemo-mechanical behavior of battery electrodes will stimulate the development of advanced LIBs with fast charging ability and long cycle life.

5:10 AM F.EN09.04.02
Impact of Surface Adsorbates on Charge Carrier Transport in Metal-Oxides for Solar Water Splitting Johanna Eichhorn[1], Ian D. Sharp[1] and Francesca Maria Toma[2]; [1]Technische Universität München, Germany; [2]Lawrence Berkeley National Laboratory, United States

Photoelectrochemical water splitting is a promising route for efficient conversion of solar energy into chemical fuels. The chemical transformation of water into oxygen and hydrogen takes place at the photoelectrode surface. Consequently, the activity, efficiency, and reaction pathway are critically controlled by the material surface properties. Under operating conditions, surface properties depend on the surrounding environment, and may be altered in the course of the reaction. Thereby, absorption of molecules can modify the chemistry at the surface, for example by influencing the kinetics of reactants, products, or reaction intermediates, but they can also directly impact the electronic transport properties by acting as surface trap states. In this context, improved understanding of these complex surface interactions will aid the development of highly efficient light absorbers as well as the integration of effective passivation and catalyst layers for these materials.

Among different photoelectrode materials, bismuth vanadate ($BiVO_4$) is one of the most actively investigated oxide semiconductors. Here, we employ photoconductive AFM under controlled *in-situ* conditions to gain insight into the relationship between surface interactions and interfacial charge transport characteristics in polycrystalline $BiVO_4$ thin films. We demonstrate that the low intrinsic bulk conductivity of $BiVO_4$ limits charge transport through the film, and that the transport mechanism can be attributed to space charge limited current in the presence of trap states. [1] By analyzing the space charge limited current in selective gas environments, we are able to quantify the impact of surface adsorbates on bulk transport properties. We find that surface adsorbed oxygen acts as a shallow trap state and accounts for 40% of the effective trap density in $BiVO_4$ thin films. [2] For humid environments, our results are consistent with the adsorption of water as an oriented dipole layer, which does not induce a surface charge transfer but partially inhibits the adsorption of oxygen at the surface. Disentangling the individual effects of oxygen and water on charge carrier trapping underpins the importance of trap state passivation for efficient transport of photogenerated charge carriers in $BiVO_4$.

5:20 AM F.EN09.04.03
Nanoscopic Operando Imaging-Guided Design of Photoelectrocatalysts for Energetically Efficient Water Decontamination Xianwen Mao and Peng Chen; Cornell University, United States

Super-resolved fluorescence microscopy techniques have enabled significant advances in chemical and biological sciences. However, they can only interrogate entities that fluoresce — and most chemical or biological processes do not involve fluorescent species. Here we report ‘COMPEITS’ — a ‘COMPetition-Enabled Imaging Technique with Super-resolution’, that enables quantitative super-resolution imaging of nonfluorescent processes. It is based on the incorporation of competition into a single-molecule fluorescence detection scheme. We demonstrate COMPEITS by investigating a photoelectrocatalytic reaction; we map with nanometer precision a nonfluorescent surface reaction on single photocatalyst particles that is important for water decontamination. The sub-particle-level quantitative information of reactant adsorption affinities unambiguously decouples size and shape scaling laws on specific particle facets and uncovers surprising biphasic shape dependence, leading to catalyst design principles for optimal reactant adsorption efficacy. With its ability to provide

spatially-resolved information on the behaviors of unlabeled, nonfluorescent entities under operando conditions, COMPEITS can interrogate a variety of surface processes in fields ranging from heterogeneous catalysis and materials engineering to nanotechnology and energy sciences. Operando Characterization of Charge Extraction and Recombination Profiles in Solar Cells with Nanoscale Resolution Tamir Yeshurun, Mor Fiegenbaum and Gideon Segev; Tel Aviv University, Israel

The next generation of solar energy conversion systems requires design and integration of new semiconductor materials. Detailed understanding of the opto-electronic properties of these materials, their driving forces and the loss mechanisms that limit device performance is essential to the development of high efficiency systems. However, these materials and systems are difficult to model and only few experimental methods are available for direct characterization of dominant loss processes under relevant operating conditions. To this end, empirical extraction of the spatial collection efficiency (SCE) and the spatial photon recycling efficiency (SPRE) are *operando*, analytical tools that provide functional depth profiles of the active regions in the device.
By coupling external quantum efficiency (EQE) measurements and optical modeling, SCE extraction allows quantifying charge transport properties and loss mechanisms across the device depth profile under real operating conditions with very few assumptions. Similar to SCE, combining optical modeling with wavelength dependent photoluminescence quantum yield (PLQY) measurements enables extracting the SPRE- the probability that an electron hole pair photogenerated at a specific point will contribute to photoluminescence from the device. In this contribution we will introduce the SPRE concept and will show a first demonstration of the SPRE extraction method applied to InP samples. Extracting the SPRE enables simple distinction between different losses such as surface recombination and self-absorption. The quantification of surface recombination losses makes this an excellent tool for characterizing the effect of surface passivation layers. Furthermore, since the PLQY is directly related to the obtainable photovoltage from the device, the SPRE also maps the contribution of different regions in the device to the photovoltage. As a result, combining the SPRE and SCE profiles at specific operating points provides detailed spatial information on charge extraction, contribution to the photovoltage, and discrimination between radiative and non-radiative recombination processes at the surface and in the bulk of the device.

Novel Approaches for Electron Tomography to Investigate the Structure and Stability of Nanomaterials Under Relevant Conditions Sara Bals[1,2], Wiebke Albrecht[1,2], Hans Vanrompay[1,2], Eva Bladt[1,2], Alexander Skorikov[1,2], Thomas Altantzis[1,3], Jan Willem Buurlaege[4], Daan Pelt[4], Joost Batenburg[5,4] and Sandra Van Aert[1,2]; [1]EMAT-University of Antwerp, Belgium; [2]NANOlab Center of Excellence, University of Antwerp, Belgium; [3]ELCAT-University of Antwerp, Belgium; [4]CWI, Netherlands; [5]University of Leiden, Netherlands

Nanomaterials are important for a wide range of applications because of their unique properties, which are strongly connected to their three-dimensional (3D) structure. Electron tomography has therefore been used in an increasing number of studies. Most of these investigations resulted in 3D reconstructions with a resolution at the nanometer scale, but also atomic resolution was achieved in 3D.

In order to preserve the carefully designed morphologies and functionalities, understanding the stability of nanomaterials during application is crucial. It is hereby important to note that most electron tomography investigations have been performed at the conventional conditions of an electron microscope. An emerging challenge is therefore to fully understand the connection between the 3D structure and properties under more relevant conditions, including high temperatures as well as in the presence of liquids and gases. Therefore, innovative methodologies are required to track the fast 3D changes of nanomaterials that occur under such conditions.

Recently, we proposed an acquisition approach where a tilt series of 2D HAADF-STEM projection images is acquired within a few minutes. By continuously tilting the holder and simultaneously acquiring projection images while focusing and tracking the particle, we were able to reduce the total acquisition time for a tilt series by a factor of ten [1]. Moreover, a new

approach was developed to compute high quality 2D virtual slices through nanoparticles in approximately 60 ms time. This technique drastically improves the efficiency of 3D characterization of nanomaterials by TEM. It enables explorative imaging and provides valuable information to dynamically adjust the acquisition parameters during an electron tomography experiment [2].

In this manner, we were able to study the 3D morphological evolution of anisotropic Au and AuPd nanoparticles as a function of both heating time and temperature [1,3]. Moreover, we measured the elemental diffusion dynamics of individual anisotropic Au-Ag nanoparticles in 3D [4]. We conclude that for a given composition, the shape of the nanoparticle does not influence the alloying process significantly. Based on our analysis, it is clear that interdiffusion of metals at the nanoscale is more complex than predicted by simple Fickian diffusion and that other factors such as surface diffusion need to be taken into account.

To quantify nanoparticle shape dynamics in a gaseous environment in 3D, HAADF-STEM images served as an input for atom counting procedures followed by 3D relaxation of the structure. In this manner, we characterized shape changes of a Pt nanoparticle in a gaseous environment. The conditions have been varied from vacuum to a 1 bar H2 flow, followed by a 1 bar O2 environment. To investigate the behaviour during cycling, we repeated the experiment several times using the same particle. We clearly observe morphology changes and we were even able to quantify the occurrence of the different surface facets [5].

Lithium Plating Detection in Extremely Fast-Charged Lithium-Ion Batteries Using Simultaneous Neutron and X-Ray Imaging

Maha Yusuf[1], Jacob M. LaManna[2], Partha P. Paul[3], Lambertus Hesselink[1,1], Michael F. Toney[3,4] and Johanna Weker[3]; [1]Stanford University, United States; [2]National Institute of Standards and Technology, United States; [3]Stanford Synchrotron Radiation Light source, United States; [4]University of Colorado Boulder, United States

Lithium-ion batteries (LIBs) have profoundly advanced the development of electric vehicles (EVs). However, one of their remaining bottlenecks in the widespread deployment is the long charging time required for commercial LIBs. There is a global push towards extreme fast charging (XFC) to reduce charging times to 10-15 minutes.[1] But existing LIBs cannot achieve this goal without significantly reducing battery performance, mainly due to the loss of active lithium (Li). The lost Li either becomes “dead” from being electronically disconnected after plating on the anode or “inactive” because of the irreversible reaction of Li with the electrolyte to form a solid electrolyte interphase. Since Li plating is identified as one of the major degradation mechanisms from XFC in LIBs,[2] understanding its origin and characteristics is essential to developing designs to enable fast-charged batteries. Several studies have characterized Li plating using techniques such as cryo-electron microscopy, transmission electron microscopy, X-ray diffraction, and X-ray micro-computed tomography (CT) among others.[3] While valuable, these characterization techniques have limitations in terms of their sample preparation, spatial resolution, and imaging contrast required to distinguish between materials of similar atomic number (Z). In addition, due to the complex electrochemical reactions of Li plating, multiple methods for detecting Li metal and understanding the mechanistic details of Li plating are needed.

Here, we are using simultaneous neutron and X-ray-based dual-mode micro-computed tomography, a non-destructive imaging modality, to investigate the characteristics of Li plating during XFC in LIBs. Since X-rays and neutrons are sensitive to the electron and nuclear density of the material, respectively, dual-mode X-ray and neutron CT allows an easy segmentation of the different anode components such as Li, graphite, and pores. Higher energy X-rays are needed to get through the metallic components in batteries such as copper and aluminum. However, they do not have sufficient contrast to separate Li from graphite. Thus, neutrons are used due to their high sensitivity to lighter elements such as Li, especially ^{6}Li, and carbon.

We performed multi-modal imaging experiments at the Neutron and X-ray Tomography (NeXT)[4] system located on the BT-2 beamline at the National Institute of Standards and Technology Center for Neutron Research. We characterized pristine and cycled graphite anode strips containing plated lithium at different regions. For cycled anode strips, we disassembled the battery pouch cells and imaged the graphite anodes cycled under XFC conditions for 450 cycles at fully discharged condition. The spatial resolution achieved was ~10-15 μm, thus providing sufficient resolution to pinpoint the location of Li plating within the anode thickness. With the dual-imaging datasets, we are now investigating a link between the spatial heterogeneity of Li plating and the local microstructure of the battery anode including porosity, tortuosity, and thickness. We want to investigate why and where Li plating occurs on the battery anode. Addressing these fundamental questions will inform improved battery designs, graphite anode architectures, and charging protocols that will reduce Li plating during XFC in LIBs.

5:25 AM F.EN09.05.03
Time Will Tell—Time-Dependent Material Characterization of Energy Devices Robin White, Steve Kelly and William Harris; Carl Zeiss Microscopy, United States

Recent advances in laboratory-based X-ray microscopy (XRM) have led to the development of new opportunities for the visualization and characterization of a variety of energy materials. Through X-ray tomography, the process of reconstructing a volumetric data set from a series of 2D projection images, we can gain vital insight to the internal 3D structure of these types of materials over a range of relevant length scales spanning the millimeter to nanometer range. By combining 3D visualization through repeated identical location tomography scans at various temporal stages, powerful *in-situ* investigations of dynamic material properties can be obtained. This methodology is often termed as 4DCT (4-dimensional computed tomography) and is particularly well suited to study various dynamic and evolutionary processes in energy materials. The capability to incorporate a variety of *in situ* rigs within the flexible XRM architecture provides a multitude of possibilities for the direct observation of change in a sample's microstructure in response to a stimulus. This data can lead to improved understanding of material performance, degradation, or failure processes in a quantitative fashion. Recent advances and applications of XRM for energy materials will be presented, including *in situ* visualization of polymer electrolyte fuel cells and quantification of water distribution changes while monitoring cathode catalyst layer morphological changes, solid oxide fuel cells and temperature induced structural changes. Additional examples of imaging lithium ion batteries undergoing structural changes following charge cycles, combined with correlative post-mortem analysis are also discussed.

5:35 AM F.EN09.05.04
Cobalt Oxidation—An *In Situ* and *In Operando* Study by Atom Probe Tomography Sten V. Lambeets[1], Norbert Kruse[2,1] and Daniel Perea[1]; [1]Pacific Northwest National Laboratory, United States; [2]Washington State University, United States

Heterogeneous catalysis is a stone edge of chemical industry and "green chemistry". The sparse understanding of surface mechanisms at molecular scale impedes the development of new high-performance catalysts and requires the development of new tools and methodological approaches. Cobalt is capable to dissociate CO_2, allowing further conversion to higher value compounds. Such mechanism will conduct to Co surface oxidation, which formation mechanism remains uncertain. In this work, we propose to investigate this process with Atom Probe Tomography and expose the Co to O_2(g) by two different methods: one *in-situ* using an annex reactor chamber connected on APT; and one *in operando* by introducing O_2(g) directly in APT analytic chamber during the ongoing analysis. After a cleaning process of the surface by field evaporation and surface imaging by FIM, the Co, shaped as a sharp needle, is transferred under UHV into a reactor chamber in which it is exposed to pure O_2(g) at different temperatures and times. Oxidation is quenched on the APT cryogenic stage. Oxidation is revealed to be inhomogeneous and strongly influenced by surface structures. We detect local distribution of Co_2O^{n+} and CoO^{n+} where

Co_2O^{n+} is preferentially found deep in the Co volume, drawing the progression of the oxygen in the metal. *In operando* mode allows a real time direct observation of the surface oxidation. Surface composition is probed by applying periodic electric pulses, resulting into a virtual "reconstruction" representing a stack of the different surface composition states over time. As oxidation rate progressively increases while $P(O_2)$ increases, starting from pure Co surface to successively an early and an advanced oxidation stage with Co_2O and CoO species. Inspired by the principles of the 1-D Atom Probe developed by Kruse *et al.*[1], the influence of the electric potential, the pulses frequencies and how to study surface kinetics with an *in-operando* Atom Probe will be discussed.

Late News: Operando Visualization of Thermal and Ion Transport Behaviors in Electrolytes During Electrochemical Device Operation Using Phase-Contrast X-Ray Imaging Daiko Takamatsu, Akio Yoneyama, Shin Yabuuchi and Jyun Hayakawa; Hitachi, Ltd., Japan

A fundamental understanding of transport properties (e.g., ion transport, thermal transport, etc.) in electrolytes during battery operation is important for optimal operation and design of batteries especially for high-power applications such as vehicles. It is known that internal resistance of the lithium-ion batteries (LIBs) temporarily rises by repeating high-rate charge/discharge cycles and that it decreases by stopping the battery operation and rest. Because such a reversible resistance rise occurs only during the battery operation, this phenomenon is speculated to be related to the ion concentration distributions in the electrolyte. Such ion concentration distributions in the electrolyte have more serious effect on the performance of lead-acid batteries (LABs). The development of a vertical ion concentration gradient of sulfuric acid is called electrolyte stratification, which causes inhomogeneous current distribution in the vertical distribution of the electrodes by frequent charging-discharging, reducing the life of LABs. However, there are few techniques that can be used to quantitatively characterize ion concentration distribution that arise in electrolytes during the battery operation.

Phase-contrast X-ray imaging is a technique that can be used to visualize density differences by detecting the X-ray phase shift caused by an X-ray passing through a sample. The sensitivity of the phase-contrast X-ray imaging is about 1000 times higher than that of conventional X-ray absorption imaging in a hard X-ray region for light elements. Since the electrolytes of batteries are also composed of light elements, the phase-contrast X-ray imaging is expected to be effective in visualizing small density differences in an electrolyte during battery operation. We demonstrated that in situ phase-contrast X-ray imaging technique can quantitatively visualize ion concentration distributions that arise in electrolytes during battery operation (cf. LIBs [1], LABs [2]).

Another crucial concern about batteries used in high-power applications is the thermal management. It is known that temperature of the batteries temporarily rises by repeating high-rate charge/discharge cycles and such a temperature distribution causes inhomogeneous reaction distribution of batteries. Although there are several conventional temperature measurement methods, such as thermistors, resistive temperature detectors, thermocouples, infrared thermography, etc., these methods detect the temperature directory through physical contact or using infrared and visible light from the object, and therefore, the detectable depth is limited to a few mm from its surface. So, its inner temperature distribution cannot be measured in principle. We have successfully demonstrated that nondestructive observations of inner temperature and thermal flow in heated water by using phase-contrast X-ray imaging [3]. Recently, thermo-electrochemical cells (TECs), which generate electricity directly from low-grade heat, have attracted attention for the need to power sources of Internet-of-things (IoT) sensors. We have also performed operando visualization of ion and thermal transport behavior in electrolytes of TECs by phase-contrast X-ray imaging and succeeded in visualizing the convection generation behavior caused by the temperature gradient and ion gradient occurring in the electrolyte in real time.

In this presentation, we will show the quantitative evaluation of ion concentration distribution and thermal distribution (inner temperature gradient) in the electrolyte simultaneously during electrochemical device operation with high temporal (a few seconds) and spatial (a few microns) resolutions.

Advance Characterization Tools to Study and Develop Stable Anionic Redox for High-Energy Rechargeable Batteries Minghao Zhang and Y. Shirley Meng; University of California, San Diego, United States

There is a growing consensus that the theoretical limit of one electron intercalation reactions will soon be reached. Recent discoveries on anion redox electrochemistry offer new opportunities and a possible paradigm shift in energy storage. By activating anion (e.g. oxygen, sulfur) for reversible electrochemical reactions, increased energy density has been demonstrated. In the past decade, the research community has made great progress on understanding key features of the anionic electrochemical activities and dynamic phenomena that govern the performance limitations including cycling voltage hysteresis and decay. However, the exact mechanism at molecular/atomic scales is still largely under-debate. The lack of conscience on the anionic redox mechanism which can be fueled by possible misinterpretation of experimental results. Of particular importance is determining what techniques provide accurate and reliable evidence for reversible bulk oxygen redox.
Compared with transition metal cations, oxygen anions are more challenging to be probed and quantified, which requires a multi-modal experimental approach with exceptional energy and spatial resolution combining computational modelling. Here, we advance: 1) from X-ray absorption spectroscopy to resonant inelastic X-ray scattering which shows a sharp feature with the corresponding excitation energy at 531 eV corresponding to the extra unoccupied electron orbitals of oxidized oxygen; 2) from neutron diffraction to neutron pair distribution function which is enormously valuable as a local probe that can reveal local distortions, when present along the oxygen redox reactions; 3) from X-ray diffraction to Bragg coherent diffraction imaging which will enable the direct observation of the strain dynamics with the exceptional sensitivity as small as 0.05% and phase evolution induced by the oxygen redox activity at nanoscale. It is through the in-depth understanding of electrochemical reactions mechanism at microscopic and macroscopic level during the operation of batteries; we can successfully formulate strategies to achieve reversible and stable anionic redox for next generation lithium-ion batteries.

5:15 AM F.EN09.06.02
Investigating Solid-State Synthesis Reactions by *In Situ* Synchrotron X-Ray Diffraction and *Ab Initio* Thermodynamics Matteo Bianchini[1,2], Jingyang Wang[3], Raphaele J. Clement[4,3], Bin Ouyang[5], Pascal Hartmann[1], Torsten Brezesinski[2], Jürgen Janek[2,6], Wenhao Sun[5,7] and Gerbrand Ceder[5,3]; [1]BASF SE, Germany; [2]Karlsruhe Institute of Technology, Germany; [3]University of California, Berkeley, United States; [4]University of California, Santa Barbara, United States; [5]Lawrence Berkeley National Laboratory, United States; [6]Justus-Liebig-Universität Giessen, Germany; [7]University of Michigan, United States

In the synthesis of inorganic materials, reactions often yield non-equilibrium kinetic byproducts instead of the thermodynamic equilibrium phase [1]. Why is that? And why, on the other hand, compounds predicted as thermodynamically stable often cannot be synthesized experimentally? Understanding the competition between thermodynamics and kinetics is fundamental for answering these question and towards the rational synthesis of target materials [2]. In this presentation, we will highlight the use of in situ synchrotron x-ray diffraction to yield insights on the real time behavior of powder precursors during synthesis. We investigate the multistage crystallization pathways of the important two-layer (P2) sodium oxides $Na_{0.67}MO_2$ (M = Co, Mn) [3]. We find a series of fast non-equilibrium phase transformations through metastable three-layer O3, O3' or P3 phases, before formation of the equilibrium two-layer P2 polymorph. A theoretical framework to rationalize the observed phase progression will be presented, demonstrating that even though P2 is the equilibrium phase that we target, the first phase to form will be the one with the most negative compositionally-unconstrained reaction energy from the powder precursors. In other words, the first phase to form is guided by thermodynamics and it does not necessarily have the composition corresponding to the overall precursor composition in the reaction vessel. Afterwards, the first phase may develop according to kinetic or thermodynamic arguments, depending on the system of choice. Further examples will be presented for industrially-relevant $LiNiO_2$ and related compounds [4], where lithiation pathways can be instead more straightforward than sodiation ones; nonetheless, the high resolution of synchrotron XRD allows to observe detailed structural information revealing a complex behavior where metal vacancies play an important role. The insights we present constitutes a step forward towards unraveling the complex interplay between thermodynamics and kinetics during synthesis. Moreover, they can guide the choice of precursors and parameters towards the optimization of the solid-state synthesis of ceramic materials.

5:25 AM F.EN09.06.03
Correlative *Operando* Structural, Chemical and Electrochemical Microscopy of Oxygen Evolving Electrocatalysts J T. Mefford; Stanford University, United States

The properties of emerging non-precious metal oxide electrocatalysts for the alkaline oxygen evolution reaction (OER, $4OH^- \rightarrow O_2 + 2H_2O + 4e^-$) evolve dynamically with voltage during operation. While it is appreciated that the voltage-dependent behavior of the electrode may convert an inactive material into an active electrocatalyst or *vice versa* through bulk and surface ion-coupled electron transfer, the chemical and structural identity of the electrode in its active state cannot be directly extracted from the electrochemical data alone. Importantly, the active state of the electrocatalyst is generally a non-equilibrium state that can only be obtained at the voltages necessary to drive the OER. Thus, the accurate understanding of how material properties govern the kinetics of electron and ion transfer during the OER requires integrating electrochemical cells into advanced characterization methods to study reactivity during operation. Further, the sub-particle spatial heterogeneity of electrocatalysts during operation requires that these *operando* methods resolve the local chemical, physical, and electronic structure at the nanoscale and link these properties to the local electrochemical activity.

This talk will describe a suite of correlative *operando* microscopy techniques developed to study the OER on faceted Co (oxy)hydroxide nanoplatelets. Using operando Scanning X-Ray Transmission Microscopy (STXM) and Electrochemical Atomic Force Microscopy (EC-AFM), the local Co oxidation state and particle morphology are mapped across voltages spanning the bulk ion insertion reactions and OER regimes. These results are correlated to local electrochemical activity maps obtained through Scanning Electrochemical Cell Microscopy (SECCM) providing insight into where and why oxygen is evolved on the Co (oxy)hydroxide platelets. Combined with ensemble averaged bulk techniques including *operando* X-ray diffraction (XRD), UV-Vis spectroelectrochemistry, and Electrochemical Quartz Crystal Microbalance (EQCM), we provide a comprehensive description of the chemistry of an operating OER electrocatalyst. These experimental material properties and local reactivity measurements are integrated into a computational model that combines first principles thermodynamic adsorption energetics of OER surface intermediates and microkinetic modeling to derive the experimental electrochemical Tafel behavior. The results from our multi-modal correlative approach alter long standing assumptions about the OER-active properties of the Co (oxy)hydroxide system and provide an improved methodology towards developing predictive electrocatalytic theories based on material properties that govern reactivity away from open circuit conditions.

5:35 AM *F.EN09.06.04
***Operando* Characterization of Electrochemical Insertion into Hydrated and Solvated Metal Oxides** Veronica Augustyn; North Carolina State University, United States

Layered transition metal oxides that incorporate water or other solvents provide fundamental understanding of the effects of confinement on electrochemical ion transport and reactivity. They also tend to exhibit fast electrochemical ion insertion kinetics making them of interest for high power electrochemical energy storage. These materials are hybrids that consist of transition metal oxide layers separated by fluids that can be either ordered or disordered, and strongly or weakly bound to the oxide. Our group has investigated ion insertion into a range of hydrated and solvated metal oxides with *operando* characterization to connect structural changes to the electrochemical response. Since many of these materials exhibit fast kinetics (full charge/discharge in minutes), *operando* characterization techniques must have suitable temporal resolution to capture structural or chemical changes at these rates. This presentation will describe our use of three types of *operando* techniques to probe insertion kinetics at minute-to-second timescales: X-ray diffraction, atomic force microscopy, and electrochemical quartz crystal microbalance. It will also discuss how knowledge of the dynamics of ion insertion in these materials help us understand ion transport under confinement.

5:50 AM F.EN09.06.05
Late News: *Operando* Characterization of Low Temperature Surface Oxygenated Multicomponent Oxidation Catalysts Shiyao Shan[1], Shan Wang[1], Jing Li[1], Dominic Caracciolo[1], Casey O'Brien[2], Dat Tran[2], Valeri Petkov[3], Jin Luo[1] and Chuan-Jian Zhong[1]; [1]State University of New York at Binghamton, United States; [2]U.S. Army Research Laboratory, United States; [3]Central Michigan University, United States

Catalytic oxidation of air pollutants plays a major role in in sustainable energy and environment fronts, e.g., fuel reforming and elimination of atmosphere emission exhaust. Recent interests in low temperature catalytic conversion of air pollutants are largely driven by increasingly-stringent environmental regulations. Understanding how surface atomic-scale active sites are created and stabilized on supported nanoalloy catalysts under reaction conditions is crucial for the understanding of catalytic

activity and stability which requires probing the dynamic structures in real time. However, little has been understood about the role of metal components in surface oxygenated highly active sites creation and stabilization in hydrocarbon and carbon monoxide oxidation. In this work, we will focus on recent findings in the investigation of oxygenated Pt (and/or Pd, Au) alloyed bi-/trimetallic catalysts for low temperature carbon monoxide and propane oxidation. The analysis of operando results on catalytic synergy from *in-situ/operando* characterization technique combining Diffuse Reflectance Infrared Fourier Transform Spectroscopy (DRIFTs), Synchrotron High-Energy X-ray Diffraction coupled with Pair Distribution Function analysis (HE-XRD/PDFs) and online mass spectrometer will be discussed. The results reveal largely-irregular oscillatory kinetics associated with the dynamic lattice expansion/shrinking, ordering/disordering, and formation of surface-oxygenated sites and intermediates. This work reveals new insights on catalyst design strategies into the catalytic reaction pathways and the structure-composition-activity correlation.

6:00 AM F.EN09.06.06
Late News: An *In Situ* Testing Platform for the Multi-Dimensional Diagnostic of Solid-State Li Batteries Zheng Fan; University of Houston, United States

Global demand for high-performance energy storage systems has grown tremendously in recent years. The all-solid-state lithium-ion batteries (ASSLIBs) are promising for such storage solutions on account of the lithium metal anodes with high areal capacity and the solid-state electrolytes (SSEs) with critical safety.[1] However, the interfacial failure of the ASSLIBs poses a major hurdle towards the implementation of practical high-performance energy storage devices.[2,3,4] Time-resolved in operando techniques (*e.g., in situ* microscopy, synchrotron X-ray tomography) are ideal for the direct and quantitative characterization of the interfacial deteriorations. However, the *in situ* analysis of solid-state batteries is still in its primary stage due to the difficulties in probing the buried interfacial layer. The specific causes of the high interfacial impedance and the lithium dendrite growth that deteriorates the battery in a few cycles remain nebulous.

To this end, we developed a multi-dimensional diagnostic platform that allows the direct probe of the chemical and spatial distribution on the interface while the cell operates. Parameters such as pressure and temperature, which have a strong influence on cell behavior, are also enabled by the platform. Moreover, the platform can be air-free transferred between analytical instruments like SEM, ToF-SIMS, and Raman, for a synergistic diagnose of the structural and chemical evolutions in the interfaces. A deeper understanding of interfaces and dendrites evolutions can be acquired by the testing platform, including (1) correlation between void formation and electrolyte decomposition, and (2) creeping mechanical properties of the lithium metal during the cell operations. These in-depth understandings will allow us to effectively optimize and enable further enhancements of solid-state Li batteries.

Understanding Kinetic Limitations and Oxygen-Redox in Lithium Layered Transition-Metal Oxide Electrodes Through *Operando* X-Ray Scattering Karena Chapman; Stony Brook University, United States

Chemical substitution of transition metal species is often used to tune the performance and cost of electrode materials. However, substitutions that improve one performance metric can be coupled to unintended consequences. This presentation will show how we have used operando X-ray scattering to understand kinetic limitations and O-redox in Li-layered transition metal oxide electrodes.
Substituted Li layered transition metal oxide (LTMO) electrodes such as $Li_xNi_yMn_zCo_{1-y-z}O_2$ (NMC) and $Li_xNi_yCo_{1-y-z}Al_zO_2$ (NCA) show reduced first cycle Coulombic efficiency (90-87 % in standard cycling conditions) compared with archetypal Li_xCoO_2 (LCO – ~98 % efficiency). We use operando x-ray diffraction (XRD) to demonstrate that the apparent

first cycle capacity loss is a kinetic effect linked to limited Li mobility at $x > 0.85$, with near full capacity recovered and slow Li reinsertion during a potentiostatic hold following the galvanostatic charge–discharge cycle. The kinetic limitation manifests not only as the kinetic capacity loss during discharge, but as a subtle bimodal compositional distribution early in charge and, also, a dramatic increase of the charge–discharge voltage hysteresis at $x > 0.85$.

Electrochromism as an *In Operando* Tool to Deconvolute Dynamic Charging Processes in Nanocrystal Li-Ion Electrodes Clayton J. Dahlman[1,2], Sungyeon Heo[3,2], Youtian Zhang[4], Lauren Reimnitz[2], Daniel He[2], Ming Tang[4] and Delia Milliron[2]; [1]University of California, Santa Barbara, United States; [2]The University of Texas at Austin, United States; [3]Princeton University, United States; [4]Rice University, United States

Li-ion insertion electrodes store and release charge through an assortment of reversible interactions, including surface capacitance, single-phase Li insertion and two-phase transformations. Several *in situ* and *in operando* characterization tools have been developed to deconvolute and quantify these processes to engineer better batteries. However, it is very difficult to resolve how batteries charge *in operando* at the time and length scales relevant to these processes simultaneously. Color is a simple, yet often overlooked, indicator of the convoluted processes that occur in electrodes. Indeed, electrochromism is commonly observed in many ion-insertion electrodes (e.g. graphite, $Li_xTi_5O_{12}$, Li_xFePO_4 and Li_xCoO_2). Transitions due to the band-gap (UV-visible), local defects (visible), electronic oscillations (near-IR) cause distinct features, which can be used to deconvolute charging processes. Coupled with electrochemistry, these measurements reveal rate-limiting processes and track the state-of-charge of independent charging transformations.

In this talk, we demonstrate how optical characterization of nanostructured TiO_2 thin-film electrodes deconvolutes dynamic charging processes and reveals rate-limiting steps during (de)lithiation. Anatase TiO_2 nanocrystal films, synthesized with nm-scale control of size and shape, are studied as a reliable model Li-ion anode that undergoes a distinct phase transformation between low- and high-Li content states. Using optical measurements during charge titration experiments, coupled with phase-field models of individual particles, we find that particle size systematically tunes the two-phase transformation potentials of nanocrystalline TiO_2. We demonstrate how the distribution of critical transformation potentials in an ensemble of particles changes non-equilibrium charging rates. These measurements yield an unexpected relationship between the initial state-of-charge and charging rates across a range of different nanocrystal particle morphologies. We conclude that neither Li diffusion nor phase propagation kinetics limit charging rates in this system. Rather, kinetics are limited by slow accumulation of Li in the particle ensemble *prior* to distinct crystalline transformations. More broadly, these results indicate a path forward to deconvolute non-equilibrium charging behavior in nanostructured systems through a combination of precise colloidal synthesis, first-principles modeling, and *in operando* resolution of dynamic processes with optical spectroscopy.

The Effect of Mechanical Strain on Lithium Staging in Graphene Joshua Pondick[1,2], Sajad Yazdani[1,2], Milad Yarali[1,2], Serrae N. Reed[1,2], David Hynek[1,2] and Judy Cha[1,2]; [1]Yale University, United States; [2]Yale West Campus, United States

The development of next-generation electrodes for metal-ion batteries requires an understanding of intercalation dynamics in nanomaterials. Lithium intercalation into graphite is the foundation for the lithium-ion battery, and the thermodynamics of the lithiation of graphitic electrodes have been heavily investigated. Intercalated lithium undergoes structural ordering known as staging. Initially, lithium atoms are randomly distributed throughout the gaps between carbon sheets (Dilute Stage I), but increasing lithium concentration triggers a phase transition to ordered structures comprised of intercalated regions vertically separated by unintercalated regions. Lithium typically initiates staging by forming a Stage IV structure in graphite at a concentration around LiC_{24}, where the staging index indicates the number of graphene layers between the intercalant layers. This process is well-understood for bulk graphite; however, confinement effects become important at the nanoscale, which can significantly impact the electrochemistry of nanostructured electrodes.
Here, we show that small mechanical strain in graphene microflakes can significantly modulate the thermodynamics of lithium staging. We performed electrochemical lithium intercalation on nanodevices with mechanically exfoliated graphene microflakes and monitored the staging of intercalated lithium *in situ*. *In situ* Raman spectroscopy of graphene microflakes mechanically constrained at the edge during lithium intercalation reveals a thickness-dependent increase of up to 1.26 V in the electrochemical potential that induces lithium staging, marking a clear departure from the bulk behavior. Thus, we show that microscale mechanical strain significantly affects the formation of ordered lithium phases in graphene. While the induced mechanical strain energy increases with graphene thickness to the fourth power, its magnitude is small compared to the observed increase in electrochemical energy. We hypothesize that the mechanical strain increases a nucleation barrier for lithium staging, greatly delaying the formation of ordered lithium phases.
Our results suggest that electrode assembly can critically impact lithium staging dynamics important for cycling rates and

power generation for batteries. The observed effects of strain reach beyond energy storage. Strain engineering has been used to modify the local electronic band structure of two-dimensional (2D) nanomaterials for optoelectronics and catalysis, and our results indicate that strain can also be used to modulate the intercalation-induced phase transitions of 2D materials.

***In Situ* Characterization of Single-Crystalline Oxide Materials During Electrocatalysis** Andrew Akbashev; Paul Scherrer Institut, Switzerland

In situ studies of model systems have always been central to fundamental electrochemistry as they provide precise potential-dependent quantities that can be used to assess theoretical models. In both fields of energy sciences and electrochemistry, structural evolution of electrocatalysts exposed to harsh oxidizing environment and the associated (electro)chemical pathways have remained rather mysterious. To gain the necessary insight, one has to employ not only a combination of advanced *in situ* characterization techniques, but also well-defined materials that can be directly modelled.
For example, some complex oxides demonstrated a high activity toward electrochemical water oxidation, and yet they are rarely used in precise *in situ* surface studies due to the difficulty in their controlled synthesis. The progress in the growth of epitaxial oxide films and superlattices (the area primarily being the realms of condensed matter physicists) has enabled us with a perfect tool to address some of the most pressing questions in the field of oxide electrocatalysis. A perfect control over the quality and composition of epitaxial films provides specimens that are ideally suited for precise *in situ* experiments. In this talk, I will discuss how model systems such as epitaxial films can be used for real-time observations of materials' evolution during electrocatalytic water splitting.

Quantification of Local and Global Degradation Mechanisms During Extreme Fast Charging in Lithium-Ion Batteries Partha P. Paul[1], Vivek Thampy[1], Chuntian Cao[1], Hans-Georg Steinrueck[1,2], Andrew Jansen[3], Alison Dunlop[3], Tanvir Tanim[4], Johanna Weker[1] and Michael F. Toney[1]; [1]Stanford Synchrotron Radiation Lightsource, United States; [2]Universität Paderborn, Germany; [3]Argonne National Laboratory, United States; [4]Idaho National Laboratory, United States

With the increasing demand for electric vehicles, there is an urgent need for Li-ion batteries (LIBs) with extreme fast charging (XFC) capabilities [1]. The need arises from making recharging times for commercial electric vehicles comparable to traditional refueling times. However, such XFC rates are associated with a drastic decrease in performance, as well as safety hazards. Current literature suggests that parasitic Li plating on the anode is the major factor contributing to decreasing battery capacity and therefore shortened battery life in LIBs [2]. Techniques used for understanding Li plating under in situ conditions have primarily involved two approaches. The first involves taking global measurements, averaged over the entire cell, to quantify the losses associated with lithium plating [3]. While such studies provide a good staring point, the lithium plating process is also known to be spatially heterogeneous across the cell. Therefore, other approaches probe the spatially heterogeneous nature of lithium plating across the cell, often using imaging based methods [1, 4]. There is a need to tie the two length scales together, in order to obtain a comprehensive picture of the origins and properties of lithium plating across the cell. In this work, high-energy X-ray diffraction (XRD) is presented as such a method, to bridge the two length scales. Firstly, XRD provides a way to quantify the amount of Li plating, as well as other loss mechanisms, and tie them to the global cell performance after XFC cycling. Second, XRD is an in-situ technique, allowing to characterize the entire battery in the fully assembled condition. Thus, local heterogeneities in the cathode and anode can be studied and correlated to heterogeneities in Li plating.

In this woork, single layer pouch cells (3.5cm x 4cm, 3 mAh/cm^2) with a porous graphite anode, NMC ($LiNi_xMn_yCo_zO_2$) cathode and EC:MC (with $LiPF_6$ additive) electrolyte were charged at different rates within the XFC regime (4C-9C, 10-15 minutes charge) and characterized using in-situ XRD. The cells are all characterized after hundreds of cycles, in the fully discharged condition. At the local level, the characteristics of plated lithium crystallites such as the preferred crystallographic orientations and size of plated Li on graphite are revealed. Additionally, the regions with local lithium plating are correlated

with the local SOC (lithium occupancy) and loss of active surface area in the cathode and anode, in the discharged state. Finally, the capacity fade of the cycled cells is correlated to the amount of dead Li, with separated contributions from irreversibly plated Li, Li trapped in graphite as Li\textsubscript{x}C (which cannot be reversibly extracted from the anode) and reaction of plated Li with the electrolyte. Based on this knowledge of the properties of lithium plating and the conditions that favor it, as well as it's effect on overall battery performance, new approaches towards designing batteries can be realized, such that irreversible Li plating is minimized. This step will in turn help to guide the rational design of the next generation of XFC capable LIBs with a consistent and safe performance.

Understanding the Electrode-Electrolyte Interface of Polyethylene Oxide-Based Electrolyte for Lithium Secondary Batteries Using *Operando* Infrared Spectroscopy Koki Yamada, Riho Matsuoka, Ryansu Sai, Yu Katayama and Hiromori Tsutsumi; Yamaguchi University, Japan

(Electro)chemical reaction at the electrode-electrolyte interface dramatically affects the performance of lithium secondary batteries, including cycle life and capacity[1]. Much effort has been made to reveal the (electro)chemical reaction at the electrode-electrolyte interface by using *operando* measurements, e.g., *operando* attenuated total reflection infrared (ATR-IR) spectroscopy, which successfully probes the surface reaction in liquid electrolyte[2]. Although solid polymer electrolyte (SPE) is considered as a next-generation electrolyte with flame retardancy and high mechanical stability[3], its (electro)chemical reaction at the electrode-electrolyte interface is not well understood.
Here, we employed *operando* ATR-IR and various electrochemical measurements, including electrochemical impedance spectroscopy (EIS) and linear sweep voltammetry (LSV), to understand the surface reaction on model electrode surface in the SPE system. We selected the most widely used polymer electrolyte, polyethylene oxide (PEO)-based electrolyte with LiTFSA[4], as a target material. Cu nanofilm was used as a model electrode to achieve good S/N and avoid the undesirable reaction.
Linear sweep voltammetry (LSV) showed a small reduction current at *ca.* 2.0 V_{Li} and *ca.* 1.0 V_{Li}, which suggested the growth of the solid-electrolyte interphase (SEI) layer on the Cu electrode. The assignment was further supported by the EIS spectra, where we observed the increase in low-frequency semicircle during LSV, indicating the change in the charge transfer and SEI resistance. *Operando* ATR-IR spectra, obtained simultaneously with LSV, showed the voltage-dependent peaks at *ca.* 1000 cm^{-1} and *ca.* 1200 cm^{-1} along with the small reduction current, which corresponds to the vibration signals from SEI components. In this talk, we will discuss the formation mechanisms of the SEI and surface (electro)chemical reaction in the SPE system, based on the detailed analysis of *operando* ATR-IR spectra. Our findings will highlight the importance of the electrode-electrolyte interface in the SPE system, which enables the design of polymer electrolytes with superior cyclability and ion conductivity.

5:20 AM F.EN09.08.04
Using *In Situ* Neutron Reflectometry to Study Solid-Electrolyte Interphase Formation in aSi Anode Materials Jim Browning[1], Mathieu Doucet[1], Gabriel Veith[1] and Katie Browning[2]; [1]Oak Ridge National Laboratory, United States; [2]Vanderbilt University, United States

A battery is comprised of a large number of interfaces, each of which are subject to reactions. The most important of these reactions being that occurring between the electrode and electrolyte – the so called solid-electrolyte interphase (SEI). Understanding the underlying mechanism that promotes the formation and dynamics of the SEI on battery electrode surfaces

is central to the development of better performing lithium-ion batteries. Neutron reflectometry (NR) is ideal for studying interfacial processes in battery materials, *in situ.* We have used NR to study SEI formation and growth on amorphous silicon (aSi) anodes. Silicon electrodes are of interest to battery researchers due to their large theoretical capacity ($Li_{15}Si_4$ – 3579 mAh g^{-1}) and low potential versus Li (< 0. 4 V). In our work we have focused on investigating the amorphous silicon electrode surface with a standard battery electrolyte (1.2M $LiPF_6$-3:7 wt% ethylene carbonate (EC):dimethyl carbonate (DMC)). Combining NR with various ex situ complementary techniques we have determined the chemical reactivity of an aSi anode with electrolyte, the formation and growth of the SEI as a function of charge state, the formation and growth of the SEI with electrolyte additive as a function charge state and the role of binder material on SEI formation.

Insights into Ionic Fluxes at Electrode/Electrolyte Interface in Carbon-Based Electrochemical Capacitors with SPECS Technique and Electrochemical Dilatometry Przemyslaw Galek[1], Jakub Menzel[1], Paulina Bujewska[1], Scott Wilfred Donne[2] and Krzysztof Fic[1]; [1]Institute of Chemistry and Technical Electrochemistry, Poznan University of Technology, Poland; [2]University of Newcastle, Australia

It is often said that the highly developed surface area of electrode materials based on activated carbons (AC) ensures high capacitance, power and energy especially in electrochemical capacitors (EC). However, the real 'efficiency' of the surface exploited in charge storage remains often unknown. The unexploited potential of a highly developed AC surface comes often from a limited packing of electrolyte ions in carbon micropores, namely - relatively poor matching between pore and ion size. Only several techniques for effective specific surface area involvement in charge accumulation have been proposed recently. It turned out that the Step Potential Electrochemical Spectroscopy (SPECS) technique can be a useful tool for determining the real electrode/electrolyte interface surface during the operation of the device.

The SPECS technique allows for the comprehensive analysis of the total current output and evaluation of the capacitive, redox and other components. Together with the physicochemical data from nitrogen and CO_2 adsorption techniques, we aim at the determination of the real surface area of AC used for charge accumulation in EC. SPECS measurements have been done in Swagelok® system equipped with reference electrode. Organic electrolyte 1-Ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide ($EMIM^+TFSI^-$) was used as an electrolytic medium. The basis for choosing such an electrolyte was very small difference between cation and anion dimensions. The results will be supported by the recent findings from electrochemical dilatometry experiments. The tested materials include popular Kuraray YP-50F and Cabot BP-2000 with significant differences in pore distribution and structure.

Based on the knowledge gained to date, we assume that the efficiency of the interface 'exploitation' depends on many factors: pore size distribution, wettability of the electrode material by electrolyte, as well as the size of the ions. Thus, inappropriate selection of one of these parameters can aggravate the device performance, even if the excellent carbon material is applied as electrode component. The paper will provide the results from SPECS correlated with the physicochemical properties of carbon materials. It appears that the electrochemically accessible surface does not exceed 30% of the values estimated by N_2 or CO_2 adsorption.

5:40 AM F.EN09.08.06
Late News: Fundamental Study of Interfaces in All-Solid-State Batteries (ASSB) by Environmental Scanning Electron Microcopy (ESEM) Neelam G. Yadav[1], Xavier Randrema[1,2], Alexis Maurel[1], Jean Baptiste Chabert[1], Arash Jamali[3], Carine Davoisne[1] and Mathieu Morcrette[1]; [1]Reactivity and Chemistry of Solids Laboratory (LRCS) University of Picardy Jules, France; [2]Renault, France; [3]Plateforme de Microscopie Electronique (PME) University of Picardy Jules, Amiens (France), France

The interest in all solid-state batteries (ASSB) is widely known for two main things, one cited for its safety and the other its' ability to use the metallic anodes for enhancing the gravimetric energy density. In order to make solid state batteries a reality it's important [1] to understand the process responsible for failure in ASSB. **1**. During the cell assembly of all solid-state batteries, parameters such as pressure, temperature, preparation of the cathode composite[2], etc. will influence the interface quality and in turn affect the battery cycling. **2**. Also, during battery operation, parameters such as the operating current density[3] and stack pressure influence battery cycling. They both (1&2) impact cycling performance leading to formation of new phases or interphases, the grains volumetric expansion inducing contact loss and crack formation, **t**he possible dendrites formation leading to the battery short circuit. Among different techniques being used to understand the fundamentals of battery degradation, the scanning electron microscopy (SEM) offers a good compromise in terms of size and resolution of observation with the possibility to perform studies on the different types of interface with a good spatial resolution. By

combining the imaging with chemical analyses by X-ray energy dispersive spectroscopy (EDX), a complete survey of morphological and chemical modification induced at the interfaces is possible.
A home-made ASSB cell has been designed to perform in-situ and operando studies under real time in ESEM.To begin with, we studied the impact of current density(J) for NMC-LPS-Li ASSB system, keeping other parameters of ASSB constant and relating cycling at different J to the battery degradation. This study has been carried out in two parts coupled with other techniques, ex-situ (SEM, XRD, Raman) and in-situ (SEM). The investigated ASSB system shows degradation of LPS at both interfaces, formation of voids, changes in LPS morphology depending on the cycling conditions. The plating and stripping of Li-metal was also investigated. These observations, along with other researches[3] aimed at improving the primary metal anode[4] or interface between metal anode and electrolyte[5] and understanding solid electrolyte[6] will help us to deal and design our future ASSB with improved performances. This kind of study will be further extended to understand other interesting ASSB system.

Atomic Scale Dynamics of Oxide Island Growth During *In Situ* Oxidation of Copper Judith C. Yang; University of Pittsburgh, United States

Understanding the structural changes at the atomic scale of nano-oxide formation via metal oxidation is critical for the rational design and control of oxides for a variety of technology-critical applications including heterogeneous catalysts, sensors, and corrosion protection in extreme environments. Though classical oxidation theories, such as Cabrera-Mott, exist, little is known concerning the initial oxidation stages at the atomic scale. With the developments of in situ characterization tools, such as Environmental Transmission Electron Microscope (ETEM), we are now able to directly observe the structural changes during oxidation. In this work, we combine in situ ETEM with density functional theory (DFT) to fundamentally understand oxide island formation and growth at the atomic scale; Cu(001) was selected as the model metal system. As an example of this correlative approach, we recently observed a layer-by-layer growth of Cu_2O island along $Cu_2O(110)$ plane, where our analysis of these growth dynamics suggests a diffusion limited monolayer growth process. DFT results supported these experimental observations of preferential growth along $Cu_2O(110)$ based on surface energies, diffusion barriers and adsorption energies simulations. We are currently investigating these critical surface reactions for binary alloys. Support for this research program is from NSF-DMR 1410055, 1508417, and 1410335.

5:15 AM F.EN09.09.02
Probing Electrified Liquid-Solid Interfaces with Scanning Electron Microscopy Hongxuan Guo[1], Alexander Yulaev[2], Evgheni Strelcov[2], Alexander Tselev[3], Christopher Arble[2], Andras Vladar[2], John Villarrubia[2] and Andrei A. Kolmakov[2]; [1]Southeast University Nanjing, China; [2]National Institute of Standards and Technology, United States; [3]University of Aveiro, Portugal

The processes related to the formation and dynamics of the electrical double layers (EDLs) at the solid-liquid electrolyte interfaces are crucial to numerous applications. However, EDLs formed in realistic interfaces are nanometer(s) thin. The shortage, therefore, exists in the experimental analytical tools capable of probing the concentration, composition, and potential profiles within nanometers thin EDLs with sufficient depth and spatial resolution. The escape depth of low energy electrons in liquids, on the other hand, is in the order of nanometer making electrons, and SEM in particular, to be a suitable probe for EDL. There is, however, an apparent experimental challenge to probe EDL with SEM due to ca. nine orders of magnitude pressure gap between the liquid sample and microscope chamber environments.
In our current communication, we report on a novel experimental approach to probe and image the electrical double layers (EDLs) at the electrified solid-liquid electrolyte interfaces using SEM. Our work resolves the “pressure gap” challenge using graphene as an electron-transparent vacuum separating membrane and demonstrates the sensitivity of the secondary electron yield from the electrified graphene-electrolyte interface to the interfacial processes such as electrolyte polarization and Faradaic processes. We developed finite element analysis models of the potential distribution near the interface and relay them with Monte Carlo simulations to explain the experimentally observed trends of bias-dependent SEM contrast [1]. The proposed method is most useful for studying electrochemical systems where laterally heterogeneous interfaces are present and high-resolution polarization mapping is required

***In Situ* SEM and XRD Study of Redox Cycling in Transition Metal Oxide Regenerable Catalysts** Alec Ladonis, Scott Misture, Brendan Hill, M. Miller and K.D. McDevitt; Alfred University, United States

Selectively reducible oxides form the foundation of "regenerable" oxide-supported metal catalysts, where transition metals may be reduced from the oxide, then resorbed via oxidation to regenerate spent catalysts. We present in-situ studies of a model defective spinel catalyst under redox cycling conditions that mirror operation conditions for methane reforming and related reactions. Experiments show that these catalysts have excellent sulfur tolerance and high turnover frequencies for methane dry reforming. In-situ studies show that reduction causes crystallographically oriented surface cracking and complex surface structures decorated by metal nanoparticles assembled on crystal facets. In-situ XRD shows the spinel is completely regenerable during redox cycling, allowing for oxidative sulfur removal and metal oxide reincorporation. Microstructural development upon redox cycling is observed by in-situ HT-FESEM and is linked to improved catalytic performance upon redox cycling. Subsequent redox cycles create more surface roughness, as demonstrated by surface investigation after each redox cycle. The in-situ FESEM study even at high vacuum provides sufficient oxygen for reoxidiation of the active metal particles, and agrees with calculated thermodynamic stability. Metal particle coarsening and migration is shown to be a function of temperature and the extent of faceting of the oxide, and re-oxidation is found to be a function of the ambient pO2. Under high oxygen activity, the transition metal first oxidizes and then reacts with the defect spinel to regenerate the spinel, while at pO2<200 ppm full oxidation does not occur but instead the oxidation and resorption occur at the triple phase boundaries. Enhanced mass transport on the surfaces of the partially-reduced and defective spinel is likely a major contributor to the high catalytic activity and unusually high oxidative sulfur removal reaction.

5:35 AM F.EN09.09.04
Investigation of the Photocorrosion of GaP, III-V Photoanode in Acid with *In Situ* UV/vis Spectroscopy Sahar Pishgar and Joshua M. Spurgeon; University of Louisville, United States

Development of high efficiency and stable solar fuels production systems is one of the most promising routes to address the increasing energy demands and finite source of fossil fuels available around the world. Long-term stability of such systems has always been an obstacle for widespread implementation of solar fuels; hence, investigation of the mechanism of self-decomposition and corrosion of photoelectrodes under photoelectrochemical operation is of significant importance. In Striving to develop an in-situ photo-corrosion detection technique which is widely available in most labs we studied the photo-corrosion of GaP photoanodes, a promising III-V material for tandem top subcells ,in strongly acidic condition via in-situ UV-Vis spectroscopy technique along with ex-situ SEM and XPS characterization to monitor the dissolved Ga and P species during photoelectrochemical reaction. The corrosion faradaic efficiency of n-GaP and p^+-GaP was calculated as a function of applied bias and time and found to be very different in corrosion process. p^+-GaP was uniformly dissolved across the active area, while n-GaP was etched in an anisotropic way with micropores formed on the surface of photoanode. Ultimately, a thin layer of TiO_2 protective layer was coated on n-GaP photoanodes to explore its consequences on corrosion mechanism which slowed the rate of GaP dissolution but also introduced a large charge-transfer resistance to the system.

Sustainable Energy Materials—New Routes for *In Situ* Nanoscale Characterization and Their Correlation to Functionality Stephan V. Roth; KTH Royal Institute of Technology, Sweden

The development of materials for sustainable energy conversion and storage requires new approaches on both the materials and process side. These approaches rely on the use of scattering techniques offering access to the molecular and nanoscale and exploiting both the virtues of X-rays and neutrons [1]. One crucial point is to observe the materials structural

transformations in situ from the nano- to the microscale during materials' synthesis and subsequent device fabrication. These changes must be related to their (macroscopic) functionality. Preferentially the materials itself are sustainable, water-based, or biomaterials. To start with, we focus on wood-based biomaterials, such as cellulose and lignin. Introducing spray deposition as versatile process, ultrasmooth cellulose nanofibril films with controlled thickness are investigated [1,2]. Depending on their charge and roughness, the wettability can be controlled. This is crucial for optimizing the fabrication of hybrid materials, typical for energy conversion and storage. The tailoring of wettability is further pursued by surface functionalization of water-based latex colloids. These materials offer the possibility to tailor and fine-tune the wettability by tuning the core-shell colloid morphology in thin films, thus providing a facile template methodology for repellent surfaces of devices [3]. In materials synthesis, chemical modification of lignin affects the molecular network, aggregate stacking, and size of lignin thermosets. This in turn changes the macroscopic properties of the resulting thermoset [4]. Electronic properties manifest themselves for example in electrical conductivity changes and optical response. The electronic properties are governed by the nanoscale morphology. Imaging via scattering methods allows to extract the granular morphology up to and beyond the percolation threshold in situ during fabrication. At the same time, this analysis allows to predict the electrical behavior of hybrid composites and thus to optimized for example electrodes in such devices [5]. Silver nanowires offers electrical conductivity, mechanical flexibility as well as well high optical transparency when applied as meshes in top electrodes. Here, printing applications offer great potential for photovoltaics and flexible electronics. Two examples are presented: First, a tough composite for a 2D-printed film as top contact on a solar cell, and secondly a flexible composite applied for a 3D-printed flexible capacitor [6]. These examples highlight the advanced capabilities of scattering methods for in situ imaging of the nanoscale structure and for establishing the nanostructure-function relationship.

***In Situ* R2R Spray Deposition of Flexible Nanocellulose/PEDOT:PSS-Based Supercapacitors Studied Using Surface Sensitive X-Ray Scattering** Calvin Brett[1,2,1], Mehmet G. Say[3], Isak Engquist[3], Magnus Berggren[3], Daniel Söderberg[1,1] and Stephan V. Roth[2,1]; [1]KTH Royal Institute of Technology, Sweden; [2]Deutsches Elektronen-Synchrotron, Germany; [3]Linköping University, Sweden

Large scale production of sustainable devices experiences a massive increase of attention over the last years. The global economy is initiating projects to minimize the use of fossil resources. However, it is yet unclear how sustainable bio-based devices perform and degrade under environmental influences and how we could improve possible drawbacks. We believe that wood-based cellulose is a key enabler for hierarchical bio-nanocomposites with unprecedented properties as lightweight, flexibility and durability [1]. Poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) is nowadays widely used as high performance conductive polymer in the field of bioelectronics, solar cells, supercapacitors. Due to its water-solubility, it fulfils the sustainable approach of using less solvents to achieve environmentally friendly devices. The aim of this in situ spray deposition study was to correlate directly the inner morphology of the deposited thin films with its macro-scale physical properties. Herein we used spray deposition as industrial deposition technique on a roll-to-roll coater to fabricate large-scale films with unprecedented low surface roughness down to 2 nm [2-3]. The sprayed flexible and conductive bionanocomposite with thicknesses up to 30 µm are fabricated to provide high energy densities for battery and supercapacitor technologies. We investigated the effect of different layer formation parameters such as drying times, temperature and additives, in particular organization of PEDOT:PSS on CNF and film formation mechanism with spray coating method by means of surface sensitive X-ray scattering [2-4].We thus achieved a better understanding of the morphology of such films and their electrochemical performance in order to create better energy storage and healthcare devices in the future.

***In Situ* Probing of Structure and Deagglomeration of SnO_2 Colloids via Small-Angle X-Ray Scattering** Viktor

Mackert and Markus Winterer; University of Duisburg-Essen, Germany

Nanoparticles are promising building blocks for materials in various energy applications i. e. fuel cells, batteries, photocatalysts. These materials are often produced by solution-based processing of colloidal nanoparticles. Detrimental in this process is the tendency of nanoparticles to agglomerate due to their high surface energy. Thus, agglomeration also influences for example catalytic properties and adsorption behavior of nanoparticles, as the effective specific surface area available is reduced. Nevertheless, it can be prevented by colloidal stabilization. However, before stabilization the agglomerates must be broken apart at best into individual (primary) nanoparticles. This can be achieved by energy input into the colloidal system. Ultrasonic deagglomeration is promising because, through ultrasonic cavitation, it generates high mechanical shear forces, shock waves and microjets that break down nanoparticle agglomerates.

In this context, it will be shown how synchrotron-based *in situ* small-angle X-ray scattering (SAXS) can be used to study the deagglomeration process in order to possibly produce tailor-made agglomerates on the nanoscale with respect to morphology and size. Therefore, the fractal structure and radii of gyration of differently sized SnO_2 nanocrystals synthesized in the gas phase are continuously monitored during sonication in a specifically designed X-ray transparent *in situ* cell as a function of time and energy input.

Pathways for *In Situ* X-Ray Absorption Investigation of the Chemical Vapor Synthesis Process Oleksandr Levish and Markus Winterer; University of Duisburg Essen, Germany

Chemical vapor synthesis (CVS) is a technique enabling reproducible synthesis of narrow sized nanocrystals of high purity from the gas phase. By variation of essential synthesis parameters, such as the time-temperature (t-T) -profile, synthesis pressure and partial pressure of the reactants, different materials and morphologies can be created in the form of nanoparticles with the same synthesis assembly [1, 2]. One of the commonly used materials is iron. In combination with oxygen it can form a variety of compounds (e.g. FeO, Fe_2O_3) and phases (e.g. α-Fe_2O_3, γ-Fe_2O_3) containing iron in different oxidation states and crystalline systems.

In order to design efficient and sustainable processes for the synthesis of tailored materials with desired properties and access to novel materials or morphologies, the synthesis process must be studied and understood in detail. This is enabled by providing an in-situ view of the synthesis process.

X-ray absorption spectroscopy (XAS) reveals the electronic properties of the material, its local structure and composition. We will present our ongoing study on the in-situ investigation of the CVS process using compounds containing iron and oxygen as model system. So far we studied the precursor and its vapor [3]. Furthermore, we describe the design of the mobile CVS reactor for in-situ investigation of the process with control over the t-T-profile. The parameter window for the reactor is defined based on investigations of iron oxide nanoparticles and evaluation of the reaction chamber with computational fluid dynamic simulations.

High Efficiency Water Oxidation Through Oxide Bilayers with Electronically Coupled Phase Boundaries Aida Raauf, Dennis Grödler, Lasse Jurgensen and Sanjay Mathur; University of Cologne, Germany

New semiconductor metal oxides capable of driving water-splitting reactions by solar irradiation alone are required for sustainable hydrogen production. Whereas most metal oxides only marginally deliver the photochemical energy to split water molecules, uranium oxides are efficient photoelectrocatalysts due to their absorption properties (E_g ~ 2.0 - 2.6 eV) and easy valence switching among uranium centers that additionally augment the photocatalytic efficiency. Although considered a scarce resource, the abundance of uranium compounds in the environment is manifested in the huge quantities of stored UF_6 gas, produced as waste streams in the nuclear fuel enrichment process. Here we demonstrate that thin films of depleted uranium oxide (U_3O_8) and their bilayers with hematite (a-Fe_2O_3) are high activity water oxidation catalysts due to electronically coupled phase boundaries. The electronic structure of uranium oxides showed an optimal band edge alignment in U_3O_8//Fe_2O_3 bilayers (DFT calculations) resulting in improved charge-transfer at the heterojunction as supported by TAS and XAS measurements. The enhanced photocurrent density of the heterostructures with respect to well-known hematite offers unexplored potential of uranium oxide in artificial photosynthesis.

F.EN09.11.03

Enhanced Photocatalytic Oxygen Evolution Reaction—Surface Modification of the Multiferriocs $BiFeO_3$ Nanostructure Using IrO_2 Nanoparticles Wegdan Ramadan[1] and Detlef Bahnemann[2,3,4]; [1]Alexandria University, Egypt; [2]Institut für Technische Chemie, Leibniz Universität Hannover, Germany; [3]Saint-Petersburg State University, Laboratory ‘‘Photoactive Nanocomposite Materials’’, Russian Federation; [4]Laboratorium fur Nano- und Quantenengineering, Gottfried Wilhelm Leibniz Universitat Hannover, Germany

$BiFeO_3$ (BFO) is a multiferriocs that combines antiferromagnetic and ferroelectric order well above room temperature. It is narrow band gap semiconductor (~ 2.2-2.7 eV) hence, it can harvest significant amount of visible light. Combining such desired properties on simple ternary compound makes it easier to utilize in many different folds. However, the performance of BFO in the field of photocatalysis is still poor due to the fast recombination of the photogenerated charges which will negatively affect their performance. Here we report on the photocatalytic oxygen evolution reaction, OER, of $BiFeO_3$ nanoparticles synthesized by sol gel. Oxygen evolution reaction is challenging because production of one molecule of gaseous oxygen, O_2, requires four holes (oxidize two molecules of water), and occurs on a time scale approximately 5 orders of magnitude slower than that required for H_2 evolution. There are two important issues to address when photocatalysis intended for water redox reaction to takes place; sacrificial agents to be used and the co-catalyst to be loaded on surface. For the former and in case of OER a sacrificial agent acts as an electron acceptor. Although many choices of sacrificial electron donner are available for water reduction to produce H_2, the choices are narrowing down to only few for sacrificial electron acceptors used for water oxidation to produce O_2. Ag^+ and Fe^{+3} ions are commonly used for this purpose and to a lower extend sodium persulfate, $Na_2S_2O_8$. The redox potential of Ag^+, $Fe^{3+}$and S_2O_8 at pH zero are 0.8 V, 0.77 V and 2.05 V, respectively. It is reported that both the quantum efficiency and the stability of the colloidal nanocrystals in solution improve with increasing redox potential of the scavenger.The higher redox potential leads to faster scavenging, which in turn increases quantum efficiency and stability of the catalyst since electron hole recombination and oxidation or reduction of the catalyst become less important.This finding is important for choosing hole/electron scavengers and for comparing efficiencies and stabilities for different photocatalytic nano systems. Hence the resolve to $Na_2S_2O_8$ as electron scavenger. Mott Schottky measurements and the Uv-Vis spectroscopy showed that the band positions of BFO, the conduction band and valence band lie at 0.46V and 2.69 V with respect to NHE, respectively.To enhance BFO photocatalytic OER, IrO_2 nanoparticles as a co-catalyst were loaded on the surface using impregnation method. OER showed two folds enhancement upon loading with 2wt% IrO_2. IrO_2 is one of the best catalysts for OER, unfortunately it is also one of the most expensive rare elements, so their applicability is limited by the high cost. Reducing IrO_2 content onto the system should be an option to make its application feasible and cost effective and loading on IrO_2 nanoparticles on the surface could be feasible solution. Scanning the loaded IrO_2 content on BFO from 0.5 wt% up to 4 wt% showed a maximum of the evolved oxygen at 2wt % followed by a decrease in activity. XPS showed the 4f peaks of Ir, it shows symmetric two peaks at binding energies 64.9 and 61.87 eV corresponding to the 4f 5/2 and 4f 7/2 of Ir (IV) respectively. TEM indicated non uniform distribution of it on the surface.

Charge carrier lifetime and dynamics for pure BFO and IrO_2 loaded BFO have been studied by means of laser transient absorption spectroscopy, TAS, laser pulses of 20 ns and of $\lambda = 540$ nm were used. 2wt.% IrO_2 loading showed the fastest decay of holes compared to other loading percentage indicating a significant role of the IrO2 nanoparticles mediating the hole transfer process of the solar irradiated BFO system. This loading percentage corresponds to the observed highest OER. Band positions between BFO and IrO_2 favors the formation of heterojunction at the interface between IrO_2 and $BiFeO_3$ that enhances the separation of the photogenerated charges and the photocatalytic OER performance.

F.EN09.11.05
Probing the Effects of Electrolyte Anions on the Adsorption of CO on Polycrystalline Cu Electrodes with Surface-Enhanced Infrared Absorption Spectroscopy Vincent J. Ovalle and Matthias Waegele; Boston College, United States

On Cu electrodes, the electrochemical conversion of CO_2 to hydrocarbons occurs via surface-adsorbed CO. Understanding the molecular factors that determine the adsorption of CO on Cu under electrochemical conditions is therefore essential to improving the product selectivity of this electrocatalytic process. Previous studies probing the adsorption of CO on Cu electrodes have suggested that, at low overpotentials, CO likely competes with anions from the electrolyte for surface sites. However, prior work has not systematically explored the effects of anion concentration and identity on the coverage of CO on the electrode. In this work, we examine the impact of adsorbing and non-adsorbing anions (Cl^-, SO_4^{2-}, ClO_4^-) at varying concentrations (10 mM and 1 M) on the adsorption and desorption of CO from polycrystalline Cu electrodes. Using surface-enhanced infrared absorption spectroscopy (SEIRAS), we observed the interplay between adsorbed CO and interfacial anions through the lens of the anion hydration shells, CO coverage, and CO stretch frequency under electrochemical conditions. In the presence of 10 mM anion, the potential dependent CO coverage and stretch frequency during a cyclic voltammogram (CV) is virtually independent of the anion identity. By contrast, at 1 M anion, the CO coverage and stretch frequency are distinctly dependent on the anion identity of the electrolyte. With weakly adsorbing and non-adsorbing anions (SO_4^{2-} and ClO_4^-), the CO saturation coverage is lowered by ≈35% compared to the corresponding 10 mM experiments. We attribute the lower coverage to quasi-specifically adsorbed anions that block adsorption sites. With 1 M Cl^-, the CO saturation coverage is only lowered by ≈12% relative to the coverage in the presence of 10 mM Cl^-. This moderate decrease is attributed to a decrease in the binding strength of CO to Cu in the presence of co-adsorbed Cl^-, which is evidenced by the ~19 cm^{-1} blue shift in the CO stretch frequency. In contrast to all other electrolytes, there is no hysteresis in the adsorption/desorption profiles of CO in the presence of 1 M Cl^-. This hysteresis between the forward and reverse scans in the CV is due to a CO-induced reversible reconstruction of the Cu electrode surface. In the presence of Cl^-, this reconstruction is suppressed. We discuss our findings in the context of the effects of halides on the product selectivity of the CO_2 reduction reaction on Cu electrodes. Our study provides critical insight into the structure of the electric double layer and its evolution during the CO adsorption process.

F.EN09.11.06
Identifying the Prevalent Surface Facets of Rough Cu Electrodes During CO Reduction Electrocatalysis Charuni Gunathunge, Jingyi Li, Xiang Li, Julie Hong and Matthias M. Waegele; Boston College, United States

The surface morphology of rough Cu electrodes can profoundly affect the product selectivity and activity for the reduction of CO and CO_2 to hydrocarbons. Because of the scarcity of in situ methods for probing the atomic-level surface structure under electrochemical conditions, it is still debated how the atomic-level surface morphology gives rise to desirable catalytic activity and selectivity. In this work, we introduce a novel method for the determination of the prevalent surface facets on rough metal electrodes under electrochemical conditions. As model systems, we employed two types of rough Cu thin-film electrodes that are widely applied in surface-enhanced infrared absorption spectroscopy (SEIRAS). With differential electrochemical mass spectrometry (DEMS), we show that Cu films that are electrochemically deposited on Si-supported Au films (CuAu–Si) exhibit an onset potential for ethylene that is ∼200 ± 65 mV more cathodic than the one of copper films (Cu–Si) that are electrolessly deposited onto Si crystals. With SEIRAS, we find that lineshapes of the CO stretch mode of surface-adsorbed CO exhibit greatly different potential-dependences for the two types of electrodes. Lineshape analysis reveals the presence of different prevalent terraces on these two types of electrodes. On the basis of this finding, we rationalize the higher overpotential for the formation of ethylene on the CuAu-Si film. We expect this novel methodology to be broadly applicable for the in situ surface characterization of rough metal electrodes. This structural information is critical for the development of rough metal electrodes with desirable catalytic characteristics.

F.EN09.11.07
***In Operando* Study of the Role of Ni Nanoparticles and Their Coarsening on the Catalytic Activity of Solid Oxide Fuel Cell Anodes Using Distribution of Relaxation Times Analysis** Boshan Mo, Jillian Rix, Uday Pal, Srikanth Gopalan and Soumendra Basu; Boston University, United States

Mitigating activation polarization and maintaining long-term stability in solid oxide fuel cell (SOFC) electrodes represent major challenges in improving their intermediate-temperature operation and applications. It has been shown that the infiltration of nanoparticle electrocatalysts increases the number of electrochemically active sites to decrease charge transfer polarization losses and improve performance. In this study, nickel and mixed ionic and electronic conducting (MIEC) phases were infiltrated into Ni-YSZ and Ni-doped YSZ anodes of symmetric cells, and their performances characterized in-operando using electrochemical impedance spectroscopy (EIS). The kinetics of various charge transfer processes are modeled by distribution of relaxation times (DRT) analysis of the EIS spectra, allowing for an understanding of the role of the nickel nanoparticles and the consequences of nickel coarsening on the catalytic activity of the anode.

F.EN09.11.09

Electrochemomechanical Effects of Aqueous Cation Intercalation into Prussian Blue Saeed M. Saeed[1], Shelby Boyd[1], Wan-Yu Tsai[2], Ruocun Wang[1], Nina Balke[2] and Veronica Augustyn[1]; [1]North Carolina State University, United States; [2]Oak Ridge National Laboratory, United States

Prussian blue ($Fe_4[Fe(CN_6)]_3$) and its analogues are of interest as electrode materials for electrochemical energy storage. The open cubic framework of Prussian blue allows for long cycle life and reversible intercalation kinetics during cation insertion/extraction with capacities of up to 125 mAh/g in aqueous electrolytes. However, this performance is highly dependent on the electrolyte cation, and prior results indicate that a smaller hydrated cation radius leads to the best cyclability. The hypothesis guiding this study is that the cycling stability with smaller hydrated cations is tied to lower structural deformation of Prussian blue during electrochemical intercalation. In this study, we investigate the electrochemomechanics of Prussian blue due to the intercalation of three different aqueous cations, K^+, Na^+, and Li^+. *Operando* atomic force microscopy (AFM) is used to measure the mechanical deformation of the electrode during electrochemical cycling as a function of electrolyte and cyclic voltammetry sweep rate. This technique confirms that the electrochemical stability as well as the local deformation of the Prussian blue is dependent on the hydrated cation radius, with smaller cations giving rise to larger deformation. The superior cycling stability seen during K^+ insertion is commensurate with the high mechanical stability measured via *operando* AFM. This presentation will provide an understanding of the coupling between electrolyte cation size and electrochemomechanical response of a framework-type energy storage material.

F.EN09.11.10

Metal-Organic Frameworks as Sacrificial Template—Novel Bimetallic Co-W-S Chalcogenide Confined in N, S Codoped Porous Carbon Matrix for Highly Stable Electrochemical Supercapacitors Aya M. Mohamed[1,2], Ahmed O. Abo El Naga[3], Hanna B. Hassan[1], Tamer Zaki[3] and Nageh K. Allam[2]; [1]Cairo University, Egypt; [2]American University in Cairo, Egypt; [3]Egyptian Petroleum Research Inst, Egypt

Transition metal dichalcogenides are gaining much interest in the energy storage sector due to the 2D nature and conductivity of the materials. However, single transition metal dichalcogenides are not stable, preventing their practical use in real devices. Herein, we demonstrate the synthesis of binary metal dichalcogenides (Co-W-S) via carbonization of (ZIF-67) metal organic framework encapsulated with phosphotungstic acid (PTA@ZIF-67). The morphology and surface functional groups of the as-synthesized Co-W-S composite are characterized via (FESEM), (HRTEM), and (FTIR). Furthermore, the crystal structure and the elemental composition of the fabricated Co-W-S composite are elucidated using (XRD) and (XPS) analyses. Upon testing its electrochemical performance as a supercapacitor electrode, the fabricated Co-W-S@N,S co-doped porous carbon (N,S-PC) shows exceptional specific capacitance (1929 Fg^{-1} at 5 mVs^{-1}). Furthermore, the constructed asymmetric supercapacitor device using Co-W-S@N,S-PC and activated carbon as positive and negative poles, respectively displays superior energy density and power density of 32.9 Wh Kg^{-1} and 700.2 W kg^{-1}, respectively with a high Columbic efficiency over 10000 charge/discharge cycles at 10 A g^{-1}.

***In Situ* Raman Scattering of Photovoltaic Iron-Hydroxide Nanostructures in Dye-Sensitized Solar Cells** Mikel Tucker, Kit Sze, Saroj Pramanik and Yucheng Lan; Morgan State University, United States

Iron hydroxide is a promising photovoltaic material because of its abundance on earth, chemical stability in aqueous media, and outstanding optical absorbance. Here, iron hydroxide nanostructures are synthesized by the atmospheric micro-plasma and characterized. The nanostructures are fabricated into dye-sensitized solar cells and their photovoltaic behaviors are measured. The *in-situ* Raman scattering of the integrated nanostructures is investigated under various experimental conditions. The *in-situ* investigation would enhance our understanding of the dynamic behaviors of the photovoltaic nanomaterial in solar cells.

F.EN09.11.12

Operando Metrology with Photoelectron Spectroscopy and Organic Field-Effect Transistors for Interfacial Charge Transfers of Organic Semiconductor Kyung-Geun Lim[1], Jeong Won Kim[1] and Jaeyoon Baik[2]; [1]Korea Research Institution of Standards and Science (KRISS), Korea (the Republic of); [2]Pohang Accelerator Laboratory (PAL), Korea (the Republic of)

Many chemical transitions of organic semiconductors occur at the interface during device operations. Charges are transfered or accumulated at the interface between organic semiconductors and intimate functional materials as function of operating conditions. However, the kinetic materials properties at the interface of organic semiconductor are hardly observed with real-time operational transition. Operando metrology is used to analyze charge transfers at the interface of organic semiconductors by photoelectron spectroscopy during operating bottom gate top electrode p-type organic field-effect transistors (OFETs). The interfacial chemical potential shift of organic semiconductor is simultaneously compared according to electrical behaviors. The electronic activation in the nearest effective monolayers of organic semiconductors at the interface is explained to correlate with gating, doping, or transporting behaviors of OFETs. This operando metrology will shed a light on many veiled intermediate transitions during the operatation of organic semiconductors.

F.EN09.11.13

Fabrication of Nanoscale Multilayered Thin-Film Thermoelectric Materials and Devices Lauren Williams, Rodricka Miller, Alandria Henderson and Zhigang Xiao; Alabama A&M University, United States

We report the growth of nanoscale multilayered thermoelectric thin films and the fabrication of integrated thermoelectric devices for high-efficiency energy conversion and solid-state cooling. Nano multilayered Bi_2Te_3/Sb_2Te_3, Sb/Sb_2Te_3, and Te/Bi_2Te_3 thermoelectric thin-film materials were grown using the e-beam evaporation. The multilayered thin films were prepared with 100 to 300 layers, where each layer is about 3 to 5 nm thick. The effects of DC substrate bias on the growth of films such as the crystalline structures in the films were studied. Integrated thermoelectric devices with a high density of thermoelectric elements were fabricated with the nanoscale multilayered thin films using the clean room-based microfabrication techniques such as UV lithography. Plasma-enhanced atomic layer deposition (PE-ALD) was used to grow zirconium dioxide (ZrO_2) as the insulation layer in the device fabrication. X-ray diffraction and high-resolution tunneling electron micrograph (HR-TEM) were used to analyze the nanoscale multilayered thin films. The fabricated device was cooled in liquid nitrogen or annealed at 150 ^oC for 30 min, respectively. HR-TEM was used to analyze the cross-section of the nanoscale multilayered thin films for the three cases: as-grown, after being cooled in the liquid nitrogen, and after being annealed, showing that the cooling made the multilayer structures to be sharper while the annealing made the multilayer structures to become weaker. The thermoelectric characteristics of the devices were measured and analyzed for the three cases of as fabricated, after being cooled, and after being annealed, respectively, showing that the integrated thermoelectric device had the highest efficiency of thermal-to-electrical energy conversion after being cooled in the liquid nitrogen.

F.EN09.11.14

Late News: Correlating Cu-Based Catalyst Properties to Activity and Selectivity from *Operando* Studies of CO Electroreduction in a Gas-Fed Device Soohong Lee[1], Ian Sullivan[2], Chengxiang Xiang[2] and Walter Drisdell[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]California Institute of Technology, United States

Identifying the catalyst properties that determine catalyst activity and selectivity is of significant importance, as an understating of the catalytic mechanism can provide a rational catalyst design principle for efficient energy devices. However, understanding the relationships between catalyst properties and performance remain challenges in general because of the co-existence of multiple factors that are irrelevant to the catalytic cycle, and the dynamic nature of the catalytic chemistry which is responsive to reaction rates. To investigate the complex dynamic catalyst structure, an *operando* characterization under realistic operation, particularly at electrochemical conditions approaching those used to evaluate and benchmark electrocatalysts, is needed. Here, we report a comprehensive study of catalyst properties that can determine the electrochemical CO reduction reaction (CORR) in a gas-fed cell. We first employed *operando* X-ray absorption spectroscopy (XAS) synchronized with simultaneous measurements of catalyst performance by gas chromatography (GC) to investigate the relationship between valence states of Cu-based catalysts and activity for ethylene (C_2H_4) production. By introducing an anodic oxidation process, which enhanced CORR performance, we demonstrated that the oxidation states do not correlate with the activity or selectivity of Cu-based catalysts. We also found that an increase in the number of active sites estimated by electrochemical surface area (ECSA) was not proportional to the C_2H_4 yield, whereas hydrogen evolution reaction (HER) activity is positively correlated to the ECSA changes. Based on the post-mortem microscopic investigations of Cu-based catalysts, we suggest that the increased C_2H_4 activity and selectivity may arise from a

morphological reconstruction that originates from the electrochemical oxidation-reduction process. The rapid reduction of the initial oxide structure into metallic Cu at the early stage of the CORR could generate a more active structure. This electrochemical oxidation-reduction process was used as a regeneration method that recovered the original catalyst activity and selectivity in the gas-fed cell without requiring cell disassembly.

F.EN09.11.15
Late News: Determining the Effect of Local Heterogeneity on the Activity and Selectivity of Au1-xPdx Particles for the Hydrogenation of Alkynes with *In Situ* and *Ex Situ* Transmission Electron Microscopy Alexandre Foucher and Eric Stach; University of Pennsylvania, United States

Heterogeneous catalysis plays a crucial role in the production of chemicals and requires the design of active and selective nanostructures. In situ transmission electron microscopy (TEM) can determine morphology or chemistry changes in novel catalysts during a chemical reaction. In this work, bimetallic Au1-xPdx particles supported on a raspberry colloid templated (RCT) silica support were studied under oxidative and reactive conditions with a temperature of up to 500 °C and a pressure of 1 bar. Pd is the minority component, representing no more than 25 weight percent of the total metallic loading, and the particles have an average size of 5.5 nm. The remarkable stability of this system, with limited particle migration and coalescence phenomena, was demonstrated. Sharp facets perpendicular to [100] and [111] directions are present when Pd's concentration is below four atomic percent. When the concentration of Pd exceeds four atomic percent, the particles have a spherical shape, and high-resolution spectroscopy revealed the presence of small Pd clusters on the surface of the as-prepared particles with an average size of 1-2 nm. In situ results combined with ex situ TEM and infrared spectroscopy show the growth of small Pd clusters on the nanoparticles' surface that explain changes in activity and selectivity observed after treating the sample with oxygen or hydrogen. These observations demonstrate how a combination of operando methods, aberration-corrected microscopy, and direct electron detection can be used to guide the design of future catalytic structures.

F.EN09.11.16
Late News: Assessing the Durability and Composition of Pt-Based Ternary Nanoalloys in Proton Exchange Membrane Fuel Cells Using *In-Situ/Operando* High-Energy XRD Technique Dominic Caracciolo, Shiyao Shan and Chuan-Jian Zhong; SUNY Binghamton, United States

Due to the rising demand for sustainable energy, there has been a global drive for developing clean energy from renewable sources (solar, wind, etc.) which will reduce our dependence on fossil fuels. Fuel cells represent an important vector in the development of clean and renewable energy, but major challenges for the mass commercialization of fuel cells are the high cost and poor durability of the catalysts at the cathode, which requires the prohibitive Pt as a catalyst to overcome the sluggish oxygen reduction reaction kinetics. This presentation will discuss recent results of our investigations of low-Pt binary and ternary nanoalloy electrocatalysts using different characterization techniques, including in operando synchrotron X-ray diffraction technique in standard electrochemical cells and proton exchange membrane fuel cells (PEMFC). The focus is to develop the fundamental understanding of the nanophase structures of the catalysts, which provide insights into the correlation between the durability and the composition of the nanoalloy catalysts in the PEMFCs.

F.EN09.11.17
Late News: Self-Constructed MnCo2O4 via Atomic Layer Deposition as an Efficient Bifunctional Catalyst for Zn-Air Battery Arim Seong and Guntae Kim; Ulsan National Institute of Science and Technology, United States

The discovery of electrocatalysts for efficient oxygen reduction reaction (ORR) and oxygen evolution reaction (OER) is pivotal to the growth of a new generation of energy technologies. In this study, for the first time, we present an effective strategy for a nano-dispersed low amount of Co_3O_4 materials (*i.e.,* 2.67 wt %) on $La_{0.5}Sr_{0.5}MnO_{3-\delta}$ catalyst substrate for synthesizing an efficient bifunctional ORR/OER catalyst by utilizing an advanced ALD technique. Interestingly, the cation diffusion between LSM and Co_3O_4 introduces a self-intercalated $MnCo_2O_4$ spinel structure at the interface. The existence of $MnCo_2O_4$ was assisted by TEM-EDS, XANES. Benefiting from the $MnCo_2O_4$ interlayer, the LSM-20-Co catalyst exhibits excellent maximum power density (146.5 mW cm^{-2}), specific capacity (755.0 mA gZn^{-1}) and outstanding stability over 450mn without any increase of charge-discharge voltage gap. Consequently, the LSM-20-Co catalyst is an attractive bifunctional catalyst as an efficient air cathode catalyst for the alkaline metal-air system and provides insight into the rational design of a thin metal oxide with the ALD process.

Label-Free Optical Detection of Bioelectric Potentials Using Electrochromic Thin Films Bianxiao Cui, Felix S. Alfonso, Yuecheng P. Zhou and Erica Liu; Stanford University, United States

Understanding how a network of interconnected neurons receives, stores, and processes information in the human brain is one of the outstanding scientific challenges of our time. The ability to reliably detect neuroelectric activities is essential to addressing this challenge. Optical recording using voltage-sensitive fluorescent probes has provided unprecedented flexibility for choosing regions of interest in recording neuronal activities. However, when recording at a high frame rate such as 500 to 1,000 Hz, fluorescence-based voltage sensors often suffer from photobleaching and phototoxicity, which limit the recording duration. Here, we report an approach called electrochromic optical recording (ECORE) that achieves label-free optical recording of spontaneous neuroelectrical activities. ECORE utilizes the electrochromism of poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) thin films, whose optical absorption can be modulated by an applied voltage. Being based on optical reflection instead of fluorescence, ECORE offers the flexibility of an optical probe without suffering from photobleaching or phototoxicity. Using ECORE, we optically recorded spontaneous action potentials in cardiomyocytes, cultured hippocampal and dorsal root ganglion neurons, and brain slices. With minimal perturbation to cells, ECORE allows long-term optical recording over multiple days

Organic Materials and Devices for Neural Interfacing George G. Malliaras; University of Cambridge, United Kingdom

One of the most important scientific and technological frontiers of our time is the interfacing of electronics with the human brain. This endeavour promises to help understand how the brain works and deliver new tools for diagnosis and treatment of pathologies including epilepsy and Parkinson's disease. Current solutions, however, are limited by the materials that are brought in contact with the tissue and transduce signals across the biotic/abiotic interface. Recent advances in organic electronics have made available materials with a unique combination of attractive properties, including mechanical flexibility, mixed ionic/electronic conduction, enhanced biocompatibility, and capability for drug delivery. I will present examples of novel devices for recording and stimulation of neurons and show that organic electronic materials offer tremendous opportunities to study the brain and treat its pathologies.

Translating Conformable Neural Interface Research Towards Clinical Reality Giuseppe Schiavone, Florian Fallegger, Nicolas Vachicouras and Stephanie P. Lacour; Ecole Polytechnique Federale de Lausanne, Switzerland

The recent introduction of soft materials to design electrodes that conform and mimic neural tissue drives the development of neural interfaces with improved functionality and biointegration. While being used routinely in academic research, soft neural interfaces have not reached clinical translation, in part because scaling, reproducibility and reliability standards are yet to be established. Materials science and engineering is therefore at the core of translational research.
We propose a translational framework focused on electrode implants and based on systematic steps in design, manufacturing, in vitro biomimetic validation and in vivo functional evaluation to advance the technological readiness of soft neural interfaces. Geometrical scaling is driven by anatomy but also surgical handling and procedure. Systematic control of manufacturing processes guides reproducibility in terms of layout, electrical and electrochemical properties. Validation is first conducted in vitro using a multimodal platform that mimics the biological environment within which the interface is to be implanted, applies mechanical loading similar to those to be withstood in vivo, and enables electrochemical ageing and characterization. The shift from stiff to soft electrode materials requires adaptation of the models and characterization

methods to understand and predict electrode performance. Following iterations in characterization and manufacturing improvement, the soft neural interface is next evaluated in large animal models where therapeutic use may be implemented. Transition to medical grade materials and quality-controlled manufacturing are the next technological steps to implement and envision clinical evaluation of the soft neural interface.
This talk will illustrate this translational framework taking the example of the soft neurotechnology named e-dura – surface electrode arrays that mimic the natural dura mater and record or modulate neural activity in the central nervous system.

Pushing the Limits of Intracortical Neural Recording Chong Xie; Rice University, United States

The brain is a massively-interconnected and constantly-evolving network of specialized circuits, a systematic understanding of which requires an interface that functions at diverse spatial and temporal scales. Implanted electrodes provide a unique approach to decipher brain circuitry by allowing for time-resolved electrical detection of individual neuron activity. However, scalable and stable neural recording that can track and map a large ensemble of neurons across days, weeks and months remains challenging. We recently demonstrated that ultraflexible, cellular-dimensioned neural electrodes afford seamless integration with brain tissue and stable recording of individual neurons for over a year. Building upon this platform, I will also present our recent progress in further decreasing their form factors, and their massive scaling-up of channel count and density in behaving animals. I will finally discuss about our on-going efforts in applying these ultraflexible electrodes in fundamental and translational neurosciences.

5:30 AM *F.FL01.01.03
Translational Neuroelectronics Dion Khodagholy; Columbia University, United States

As our understanding of the brain's physiology and pathology progresses, increasingly sophisticated technologies are required to advance discoveries in neuroscience and develop more effective approaches to treating brain disease. There is a tremendous need for advanced materials solutions at the biotic/abiotic interface to improve the spatiotemporal resolution of neuronal recording and stimulation. Organic electronic devices offer a unique approach to these challenges, due to their mixed ionic/electronic conduction, mechanical flexibility, enhanced biocompatibility, and capability for drug delivery. We designed, developed, and characterized conformable organic electronic devices in the form of electrodes, ion gated transistors, conformable batteries and ionic communication units to efficiently interface with the brain and acquire neurophysiological activity not previously accessible with recordings from the brain surface. These devices have facilitated large-scale rodent neurophysiology experiments and uncovered a novel oscillatory interaction. The biocompatibility of the devices allowed intra-operative recording from patients undergoing epilepsy and deep brain stimulation surgeries, highlighting the translational capacity of this class of neural interface devices. In parallel, we are developing the high-speed electronics and embedded acquisition and storage systems required to make high channel count, chronic neurophysiological recording from animals and human subjects possible.This multidisciplinary approach will enable the development of new devices based on organic electronics, with broad applicability to the understanding of physiologic and pathologic network activity, control of brain-machine interfaces, and therapeutic closed-loop devices.

5:45 AM *F.FL01.01.04
Organic Materials and Devices for Neural Interfacing George G. Malliaras; University of Cambridge, United Kingdom

One of the most important scientific and technological frontiers of our time is the interfacing of electronics with the human brain. This endeavour promises to help understand how the brain works and deliver new tools for diagnosis and treatment of pathologies including epilepsy and Parkinson's disease. Current solutions, however, are limited by the materials that are brought in contact with the tissue and transduce signals across the biotic/abiotic interface. Recent advances in organic electronics have made available materials with a unique combination of attractive properties, including mechanical flexibility, mixed ionic/electronic conduction, enhanced biocompatibility, and capability for drug delivery. I will present examples of novel devices for recording and stimulation of neurons and show that organic electronic materials offer tremendous opportunities to study the brain and treat its pathologies.

6:00 AM F.FL01.01.05
A Flexible, Transparent Microcoil Array for Precise Neuronal Stimulation Vineeth Raghuram[1,2,3], Aditya Datye[2], Shelley Fried[2,3,1] and Brian Timko[1]; [1]Tufts University, United States; [2]Massachusetts General Hospital - Harvard Medical School, United States; [3]Boston VA Healthcare System, United States

The use of microcoils to magnetically stimulate neurons of the cortex has been shown to have several important advantages over conventional electrode-based stimulation. For example, the spatially asymmetric electric fields arising from microcoils can be used to activate specific populations of neurons [1] while avoiding others. This helps to confine activation to a focal region around the coil, and as a result, a microcoil-based approach may be an attractive platform where focal activation is critical, e.g. for next generation cortical visual prostheses that strive to restore high acuity vision. Initial studies have validated, using both computational and experimental approaches, the ability of a single microcoil to generate small, focal regions of activation [1], and the effects of varying coil shape/design on the both the spatial selectivity and strength of activation [2]. While devices that consist of a single microcoil may be useful in targeting a single, isolated region of the cortex, the ability to focally activate multiple cortical columns, or multiple layers within a single cortical column, either in synchrony or in temporally modulated intervals (interleaved), would be useful where the creation of multiple regions of neural activity is the goal, e.g. to elicit complex spatial patterns with a prosthesis. As a step towards this goal, we designed and fabricated an array of four individually accessible microcoils, each capable of activating a distinct region. Coils and interconnects were fabricated from copper and sandwiched between two layers of SU-8, which functioned as both conformable support substrate and passivation layer; the low young's modulus of SU-8 helped to minimize mechanical mismatch with brain tissue. Individual coils were V-shaped, a geometry previously shown to be effective in activating pyramidal neurons [2]. Inter-coil spacing was 250um, the approximate separation between adjacent cortical columns. Computational modeling of this design revealed that the magnitude of electric field gradients along the length of pyramidal neurons would be strongest along the edge and at the tip of the "V" , thus increasing the likelihood of focal activation of neuronal processes located close to the tip while minimizing activation further away. Basic functionality of the array was confirmed by the measurement of electrical artifacts resulting from the passing of electrical current through individual coils. Use of a patch-clamp setup helped to prevent saturation of amplifiers and revealed that artifact shape was consistent with theoretical predictions. *In-vitro* experiments using GCaMP6 mice allowed the fluorescent response from neuronal populations to be measured in response to stimulation from individual coils; the transparency of SU8 allowed clear visualization of the fluorescent signals. As expected, activation from a single coil was largely confined to a focal region around the coil tip, thereby confirming functional performance of the coils. Future efforts will investigate the spatial activation patterns which result from the stimulation of multiple coils in the array.

Implantable Cardiac Motion Sensor for *In Situ* Disease Diagnosis and Treatment Jae Chul Hwang, Moohyun Kim and Jang-Ung Park; Yonsei University, Korea (the Republic of)

As a leading cause of death worldwide in recent years, cardiac disease needs continuous monitoring of cardiac activity for its prompt diagnosis and treatment. Pacemaker, a conventional technique for diagnosing and treating cardiac diseases such as arrhythmia, has adverse side effects at implantation sites such as infection and damage to blood vessels, and also causes discomfort in daily life due to its rigid and bulky form. Currently, with the emergence of soft bioelectronics that intimates 3D curvilinear bio tissues, various studies have been conducted to monitor the function of cardiac activities by attaching a device onto cardiac surface. Most recent soft electronic devices that detect cardiac functions are based on electrophysiology sensing such as electrocardiograms (ECGs). However, these devices that measure the electrical flow of cardiac surface as their sensing mechanism have limitations in implementing simultaneous electrical stimulation while sensing the electrical signal. This is due to the electrical interdependent between sensing and stimulation electrodes, resulting in unnecessary signal interferences in ECGs. Herein, we demonstrate an implantable and flexible cardiac motion sensor that can simultaneously detect cardiac beating rate and intensity, via pressure measurement of cardiac relaxation, and apply electrical pacing to modulate cardiac contractile function. This cardiac motion sensor consists of active-matrix arrays of pressure-sensitive Si transistors with air dielectric layers, and integrated platinum black electrodes for electrical stimulation. Also, an alginate-based hydrogel patch that is functionalized by multi-crosslinking moieties to enhance tissue adhesiveness and elastic modulus is reported. This hydrogel patch amplifies the pressure sensitivity of the motion sensor while securely fixing the motion sensor onto the epicardium surface without any surgical adjustment. Our results have shown that the flexible cardiac motion sensor is able to accurately detect cardiac mechanical activity such as systole and diastole, which are comparable with ECG trace during *in-vivo* trials using New Zealand White rabbits. Stimulation of synchronized electrical pulses to the left ventricle by our flexible cardiac motion sensor has modulated the cardiac beating frequency at a low threshold voltage while

simultaneously detecting changes in the beating frequency and intensity of the pressure signals without any signal noise. Our motion-sensing diagnostic tool specifically targets those associated with abnormal cardiac activities such as arrhythmia, cardiac hypertrophy, and dilated cardiomyopathy, etc. Thus, we envision that our demonstration will provide a new intuitive platform that enables the diagnosis and treatment of various cardiac diseases.

6:20 AM F.FL01.01.07
Cardiac Organoid Pressure Mapping for Biomedical Modelling Moohyun Kim, Jae Chul Hwang and Jang-Ung Park; Yonsei University, Korea (the Republic of)

Human stem cell derived organoids provide cellular models of human diseases without the need for in vivo trials, removing non-genetic pathological factors in disease modelling. Current physical modelling of myocardial infarction and drug cardiotoxicity in cardiac organoid is limited to optical image analysis. This method of analysis ranges from spatial proteomics to fluorescent imaging. However, diagnostic modelling of cardiac organoids requires a higher degree of precision and sensitivity in order to accurately measure beating frequency and intensity. In mechanically energetic cardiac organoids, actual collection and interpretation of raw physical data of organoid beating are important to better understand the contractility implication after drug screening. Herein, we introduce an innovative technology that analyzes the activity of cardiac organoid using a highly sensitive pressure sensor, which is fabricated from Si transistor with an air dielectric component. This device is integrated with electrical stimulating capability that can detect and modulate cardiac organoid beating simultaneously. This sophisticated active-matrix pressure array has a high spatial resolution, providing 2D tactile pressure mapping of cardiac organoid beating. Our novel device is capable of detecting real-time cardiac organoid physical functions, such as beating frequency and intensity, to model various cardiac conditions based directly on the organoids' mechanical parameter. The periodic beatings of cardiac organoids are converted from physical parameters into electrical signals within the pressure sensor. Our device innovatively replaces the conventional method of image analysis, where the organoid beating measurement is derived by dissecting video frames, for myocardial infarction and drug cardiotoxicity modelling.

Designing Soft-Hard Composites for Neural Interfaces Bozhi Tian; University of Chicago, United States

Biointerface materials and devices can probe fundamental biological dynamics and improve the lives of human beings. However, the direct application of traditional rigid electronics onto soft tissues or cells can cause signal transduction and biocompatibility issues, partly due to the mechanical mismatch at the biointerfaces. One solution to this mismatch is the use of a soft-hard composite as a biomaterial; the hard components are stable, easy to control and provide the active functionalities, while the soft components promote compliant mechanical adhesion or active biointegration. Additionally, as substrates or encapsulation layers, the soft components can protect the high modulus electronic elements, and can facilitate mechanical operations (*e.g.*, stretching, bending, delivery, removal) of the entire composites. Advanced soft materials can also display dynamically responsive or even living behaviors currently lacking in rigid electronic systems.
In this talk, I will discuss our recent efforts of designing different soft-hard composites for neural interface applications, such as *in vitro* and *in vivo* non-genetic neuromodulation. For example, dopant-modulated silicon membranes, when integrated with porous PDMS, can be implanted over the motor and somatosensory cortex regions and are capable of inducing limb motion in animals upon light stimulation. Silicon carbide-based devices can be produced directly with laser ablation from a PDMS substrate and were used for neural and cardiac modulation in flexible configurations. Besides using nonliving composites, our lab has also explored several living composites for neural and cardiac interfaces. These bio-hybrids hold great promise as minimally invasive interfaces to naturally occurring cells and tissues for cell-based therapeutics and control. Finally, we have started the initial effort in creating tissue-like materials for neural interfaces. For example, we recently found that granules-based hydrogel composites can be considered better analogs of biological tissues in terms of both the structure and the static and dynamic mechanical properties. I will end this talk by proposing new soft-hard components for future neural interfaces.

5:15 AM F.FL01.02.02
Predictive Model of Piezoresistive Response of Conductive-Nanowire-Elastomer Composites Csaba Forro[1,2], Stephan

Ihle[3], Sean Weaver[3], Andreas Reichmuth[3], Anne Bonnin[3,4], Marco Stampanoni[3,4], Klas Tybrandt[5] and János Vörös[3]; [1]Istituto Italiano di Tecnologia, Italy; [2]Stanford University, United States; [3]ETH Zürich, Switzerland; [4]Paul Scherrer Institut, Switzerland; [5]Linköping University, Sweden

Composites based on conductive nanowires embedded in elastomers are popular in a wide range of stretchable electronics applications where the requirements are either a stable (electrodes) or a highly increasing (strainsensors) electrical resistance upon strain. Despite the widespread use of such composites, their production protocol is not based on solid theoretical grounds but rather in empirical observations. There is a lack of a predicitive framework for the piezoresistive quality of samples based on their production parameters. This is due to limitations in the methods for studying nanowire meshes, in particular the lack of knowledge on the spatial distribution of the nanowires and their rearrangement under strain. We overcame this hurdle by collecting 3D reconstructed X-ray tomographies of silver nanowires embedded in polydimethylsiloxane (PDMS) under variable deformations and obtained the missing structural information of the nanomaterial by unsupervised artificialintelligence image analysis[1]. This allowed us to reveal the precise assembly mechanisms of nanowire systems and derive a precise analytical formula for the piezoresistive response of the composites based on the nanowire material, the number of wires used,their aspect ratio, and the contact resistance between the wires[2]. We demonstrate a lower bound on the relative increase in resistance of the sample (gauge factor) –in particular, these systems cannot exhibit less than a 3-fold increase in their resistance when strained 100%. Finally to simulate the behavior of arbitrary samples in-silico and propose an exploratory design framework, we made an open-source simulation framework, validated by our experimental observations, which allows to simulate any arbitrary nanowire mesh and its piezoresistive behavior.

Modulating Neuronal Activity with Out-of-Plane Grown Three-Dimensional (3D) Fuzzy Graphene Tzahi Cohen-Karni; Carnegie Mellon University, United States

The ability to modulate cellular electrophysiology is fundamental to the investigation of development, function, and disease. Currently, there is a need for remote, non-genetic, light-induced control of cellular activity in two-dimensional (2D) and three-dimensional (3D) platforms. Here, we report a breakthrough hybrid-nanomaterial for remote, non-genetic photothermal stimulation of 2D and 3D neural cellular systems. We combine one-dimensional (1D) nanowires (NWs) and 2D graphene flakes grown out-of-plane for highly controlled photothermal stimulation at subcellular precision without the need for genetic modification, with laser energies lower than hundred nanojoules, 1-2 orders of magnitude lower than Au-, C- and Si-based nanomaterials. Photothermal stimulation using NW-templated 3D fuzzy graphene (NT-3DFG) is flexible due to its broadband absorption and does not generate cellular stress. Therefore, it serves as a novel powerful toolset for studies of cell signaling within and between tissues and can enable new therapeutic interventions.

Label-Free Optical Detection of Bioelectric Potentials Using Electrochromic Thin Films Bianxiao Cui, Felix S. Alfonso, Yuecheng P. Zhou and Erica Liu; Stanford University, United States

Understanding how a network of interconnected neurons receives, stores, and processes information in the human brain is one of the outstanding scientific challenges of our time. The ability to reliably detect neuroelectric activities is essential to addressing this challenge. Optical recording using voltage-sensitive fluorescent probes has provided unprecedented flexibility for choosing regions of interest in recording neuronal activities. However, when recording at a high frame rate such as 500 to 1,000 Hz, fluorescence-based voltage sensors often suffer from photobleaching and phototoxicity, which limit the recording duration. Here, we report an approach called electrochromic optical recording (ECORE) that achieves label-free optical recording of spontaneous neuroelectrical activities. ECORE utilizes the electrochromism of poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) thin films, whose optical absorption can be modulated by an

applied voltage. Being based on optical reflection instead of fluorescence, ECORE offers the flexibility of an optical probe without suffering from photobleaching or phototoxicity. Using ECORE, we optically recorded spontaneous action potentials in cardiomyocytes, cultured hippocampal and dorsal root ganglion neurons, and brain slices. With minimal perturbation to cells, ECORE allows long-term optical recording over multiple days

5:15 AM F.FL01.03.02
Highly-Integrated, Flexible Phototransistor Arrays Based on Three-Dimensional Soft Stimulation Electrodes for Vision Restoration of Live Mouse Hyobeom Kim, Jiuk Jang and Jang-Ung Park; Yonsei University, Korea (the Republic of)

With the aging of global populations, there are emerging retinal disorder cases such as retinitis pigmentosa and macular degeneration. The patients lose their vision due to the damage in their photoreceptors; however, the ganglion cells, which transfer the signals from photoreceptors to the optic nerve, are well preserved in most cases. By stimulating the ganglion cells electrically, the sense of vision can be induced intentionally. Based on these principles, retinal prosthetic devices have been developed by combining photodetectors, such as cameras, and stimulating electrodes. Although there have been many studies of the retinal prosthesis that restore vision through electrical stimulus, several challenges remain to be solved. First, the resolution of the conventional retinal prosthesis is significantly lower than that of the actual vision. Second, the planar structure of stimulation electrodes leads to high impedance and high threshold current, resulting in interference between the surrounding pixels in electrical stimulation. Third, the integration of an optoelectronic array device, which detects the external light, and stimulation electrode for the in-vivo test is rarely reported.
Herein, we introduce highly-integrated, flexible phototransistor arrays based on three-dimensional (3D) stimulation electrodes for vision restoration of live mice. The phototransistor arrays allow the device to electrically stimulate the retina with high-resolution. Since we implemented the 3D structured stimulation electrodes instead of the planar, the device shows the much lower impedance, suggesting less interference between the surrounding pixels in electrical stimulation. These improvements enable the target cells of the retina to be accurately stimulated with the light intensity changes. Furthermore, these 3D stimulation electrodes are made of soft, self-healable material to prevent secondary damage to the retina and enable long-term operation. In-vitro and in-vivo animal trials have confirmed real-time array signals generated by retinal cells in electrical stimulation with the change in light intensity. We completed the verification of the biocompatibility and long-term stability of the device. We envision that retinal implants with the soft 3D stimulating electrode will provide a promising strategy to the biomedical field regarding retinal disorders soon.

5:25 AM *F.FL01.03.03
Light Actuators for Cell Photo Stimulation Guglielmo Lanzani[1,2]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy

We develop and study non-genetic cell opto-stimulation techniques based on artificial light actuators that establish functional abiotic-biotic interfaces able to transduce a light signal into a biological stimulus. This talk reports on the state of our research regarding organic bio interfaces for inducing light sensitivity in cells, both in vitro and in vivo. Light actuators comes in different shapes: planar patches, nanoparticle, intramembrane probes. Their coupling mechanism is still far from being understood and attempts to shed light will be introduced. It seems that membrane modification is a crucial step in the photostimulation. Rescue vision in blind people is one of the most appealing practical outcome of this emerging technology, and recent achievements will be summoned.

5:40 AM F.FL01.03.04
Bacterial Proliferation Modulation by a Membrane-Targeted Amphiphilic Azobenzene Giuseppe M. Paternò[1], Gaia Bondelli[1,2], Stefano Donini[1], Vito Vurro[1,2], Valentina Sesti[2,1], Chiara Bertarelli[2,1] and Guglielmo Lanzani[1,2]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy

Optogenetics and covalent approaches to bio conjugation allow achieving large and effective cell photo-stimulation, yet these are invasive methods that might encounter severe limitations on the way towards clinical applications in photopharmacology.[1] The non-covalent affinity of photoresponsive molecules to biotargets represents an attractive alternative. In this context, we have recently proposed an amphiphilic azobenzene photochromic molecule (ZIAPIN2) whose selective dwelling in the plasma membrane enables modulation of the cell potential, remarkably permitting to evoke light-induced neuronal firing *in vitro* as well *in vivo*.[2,3]
Here, we show that the affinity of ZIAPIN2 to bacterial cell wall can be exploited to modulate bacterial proliferation. In

particular, we demonstrated that while in the dark proliferation is hindered, light illumination in the visible range leads to a total restoration of bacterial growth for both *Escherichia coli* (Gram (-)) and *Micrococcus Luteus* (Gram (+)). We preliminary attribute this effect to a light-triggered modification of the bacterial membrane potential brought about by ZIAPIN2 isomerization.

Organic Printed Electronics Towards Opto-Stimulated Bio-Interfaces Maxim Shkunov[1], A.N. Solodukhin[2], Pavlos Giannakou[1], Leslie Askew[1], D.O. Balakirev[2], Y.N. Luponosov[2] and S.A. Ponomarenko[2,3]; [1]University of Surrey, United Kingdom; [2]Enikolopov Institute of Synthetic Polymeric Materials of the Russian Academy of Sciences, Russian Federation; [3]Lomonosov Moscow State University, Russian Federation

Opto-stimulation of semiconductor-biointerfaces provides efficient pathways towards eliciting neural activity through selective spectral excitation. In visual prosthesis, tri-colour excitation capability, is the key to restoring full-colour vision. Among organic semiconductor materials, donor–acceptor molecules have the most promising properties due to excellent light absorption, high stability and good solubility in organic solvents. Varying the donor and acceptor functionalities, allows fine tuning of the optical properties. These carbon based molecules bear intrinsic affinity to biological systems, and also demonstrate excellent photoresponses, electronic and ionic conductivity, and allow intimate interface with liquid bioenvironment.
We demonstrate tri-colour optoelectronic devices based on solution-processable conjugated donor-acceptor molecules with absorption in red, green and blue spectral regions, mimicking the absorption of human retinal cones. Photo-response is studied via interfacing with biological electrolyte solution and using long-pulse, narrow-band excitations, where both photo-voltage and photo-current responses show clear signatures of capacitive charging at the electrolyte/device interface.
We further explore ink-jet printing to reproduce individual photo-pixels with red, green and blue absorption characteristics, with small diameters of 35 to 45 microns.
We discuss the suitability of organic semiconductors for potential medical applications as retinal bio-engineered prosthesis for the restoration of human vision, and evaluate prospects of wider, colour-selective excitations of bio-interfaces.

6:00 AM F.FL01.03.06
Nanoengineered Bioelectronic Systems Using Semiconducting Polymers for All-Optical Control of Neuron Growth and Stimulation Matthew Griffith[1], Connor Sherwood[2], Rafael Crovador[2], Krishna Feron[2], Julie Cairney[1], Paul Dastoor[2], Alan Brichta[2] and Rebecca Lim[2]; [1]The University of Sydney, Australia; [2]The University of Newcastle, Australia

Implantable neurostimulation devices play a key role in treating many serious injuries and diseases by providing a direct therapeutic link to the nervous system. This enables brain stimulation for treatment of Parkinson's disease and epilepsy, nerve guidance and regeneration to remedy spinal cord injury, and retinal prosthetic devices that could cure blindness.[1] To address such issues, new bioelectronic systems that can deliver electrical stimulation to nerve cells are required. Although silicon microelectronics and metal electrodes have been the historic gold standard for bioelectronic interfaces, their use in clinical practice is limited. The main obstacles to further translation of these devices include a low biocompatibility that reduces *in vivo* lifetimes,[2] a mechanical rigidity that is poorly matched with soft tissue, causing inflammation and ineffective electrical contact, and a requirement for costly external power supplies to deliver current.[3] These issues result in indiscriminate tissue activation, with a consequent lack of spatial selectivity.[4]

In this work, we report a strategy to simultaneously address these issues by combining soft carbon-based organic conductors and nanoscale science to build new bioelectrodes that allow optical neurostimulation without external power. Our approach creates bioelectronic interfaces from organic conductors that can be formed into customized nanoparticles with established solution-based chemistry methodologies. This approach enables the stimulating electrodes to be combined with targeted pharmaceutical factors in the fabrication procedure, which subsequently optimise connections to the neural network. We tune the optoelectronic properties of the organic conductors to cover standard red, green, and blue spectral regions, allowing spectrally selective platforms for neurostimulation. These conductors are turned into electroactive inks, and subsequently fabricated into pixelated arrays using inkjet printing. This approach establishes a new low-cost manufacturing methodology that is generally applicable to other organic materials and can be used for a variety of bioelectronic devices, creating a new manufacturing paradigm for biomedical technology.

We demonstrate both the anatomical and functional biocompatibility of neural tissue with our organic bioelectronic systems using immunolabelling with neuronal marker MAP2 and visualisation with epifluorescence microscopy to detect neurons cultured on the organic conductors. We demonstrate the controlled release of drugs from the organic conductive nanoparticles, aiding in precise spatial delivery of pharmaceutical factors. Finally, we employ whole-cell patch clamp electrophysiology recordings to demonstrate an exciting result; purely optical neurostimultation of dorsal root ganglion nerve cells. We demonstrate that the organic conductors can trigger changes in the nerve cell membrane potentials via a *capacitive coupling* mechanism, the efficacy of which can be improved by judicious selection of the device architecture. Importantly, capacitive neurostimulation does not require injection of current into biotic tissue to trigger changes in the membrane potentials. This means very confined stimulation is possible and therefore spatial selectivity is no longer limited by current spread and undesirable electrochemical reactivity is minimised.

***In Situ* Optical Quantification of Biological Electron Transfer Using Plasmonic Semiconductor Nanocrystals** Stephen Gibbs, Austin J. Graham, Camila Saez Cabezas, Yongdan Wang, Delia Milliron and Benjamin K. Keitz; The University of Texas at Austin, United States

Plasmonic semiconductor nanocrystals are more sensitive to electron transfer events than traditional plasmonic materials such as Au and Ag due to their lower free electron concentrations. Because the plasmon peak position and intensity depend on the free electron concentration, we can quantify electrons transferred to and from the semiconductor nanocrystals in real-time through simple spectroscopic measurements. Further, the surface of doped semiconductor nanocrystals can be functionalized with various ligands post-synthetically to customize solvent compatibility, ensure colloidal stability, and tune the interactions with other species in solution. Leveraging our ability to quantify the change in optical response with the aqueous biocompatibility of colloidal nanocrystal dispersions, we aimed to quantify redox activity from cell metabolism. Specifically, we quantified extracellular electron transfer (EET) rates from *Shewanella oneidensis.* EET is process by which electron flux from carbon metabolism is directed to metallic substrates in anaerobic environments. The utility of EET as a power source for microbial fuel cells, bioelectronics, and material synthesis has led to significant interest in quantification methods for microbial electron flux.

When dispersed together, plasmonic semiconductor nanocrystals serve as electron accepting substrates for *S. oneidensis*. We dispersed tin-doped indium oxide (ITO) nanocrystals with *S. oneidensis* in an aqueous buffer by stripping the nanocrystals of their native, hydrophobic ligands and wrapping them in a hydrophilic, random co-polymer. We used *in-situ* spectroscopy to track the plasmonic response of ITO in real-time and quantified kinetic EET rate constants from *S. oneidensis* on a per cell basis. Using this method, we distinguished EET rates of healthy cells from those starved of a carbon source. The consistent measurement of a steady-state electron transfer regime indicated that cellular respiration was primarily directed toward energy production via EET as opposed to growth. Lastly, we quantitatively differentiated electron flux from *S. oneidensis* strains that were genetically engineered to tune EET activity. The generated current ranged from 0.1 to 6.9 fA per cell, depending on expression levels of a key EET gene, *mtrC*. Overall, our results indicate that colloidal plasmonic semiconductor nanocrystals are a reliable sensing platform for probing metabolic activity in native biological environments. Looking forward, we aim to assess EET gene turn-on in real-time in response to environmental stimuli, enabling understanding of fundamental gene expression dynamics.

5:00 AM *F.FL01.04.01
Ion-Electron Coupling Defines the Principle of Operation in Organic Bioelectronic Devices Magnus Berggren; Linköping University, Sweden

The coupling of electronic charges and ions, in bioelectronic devices based on conjugated polymers, is unique and offers us a great opportunity to explore novel device concepts and also new science. The fundamental principles of charge accumulation and ion exchange in conjugated polymers, often referred to as doping, will be discussed. The dynamic control over doping can be achieved via electrochemical addressing and serves as the principle of operation in an array of organic electrochemical devices. Examples of such devices are the organic electronic sensors and actuators, devices that rely on *iontronic* electrode, transistor, conductor or diode configurations. Such devices and systems have then been applied to several biological and medical settings, targeting new biotech/med-tech tools, therapy and monitoring of physiology and neuronal functions.

5:15 AM *F.FL01.04.02
Electron Transporting Polymers for Metabolite Detection and Energy Conversion from Bodily Fluids Sahika Inal; King Abdullah University of Science and Technology (KAUST), Saudi Arabia

Being the primary energy source of mammalian cells, glucose is involved in numerous biological events. In this work, I will present an electronic platform based on an n-type conjugated polymer for detecting glucose as well as extraction of power from bodily fluids. We employ the n-type mixed (ionic and electronic) conductor in an accumulation mode organic electrochemical transistor (OECT). The polymer is engineered to have specific interactions with catalytic enzymes and requires no electron mediators to transduce enzymatic reactions. This micron-scale device detects glucose alongside lactate and shows excellent sensitivity and selectivity over five orders of magnitude wide detection range (1,2). When assembled as an enzymatic biofuel cell, the same polymer serves as the anode, converting the glucose metabolism in an aqueous medium into power (2). These devices can be fabricated on flexible substrates, paving the way for implantable self-powered metabolite sensing. While introducing these bioelectronic device concepts, I will touch upon approaches to further improve the performance of n-type mixed conductors.

Low-Impedance Electropolymerized Coatings on Microelectrodes for Higher Neuro-Transduction Anna Susloparova[1], Mahdi Ghazal[1], David Guérin[1], Sophie Halliez[2], Yannick Coffinier[1], Thomas Dargent[1], Fabien Alibart[1,3] and Sébastien Pecqueur[1]; [1]Univ. Lille, CNRS, Centrale Lille, Univ. Polytechnique Hauts-de-France, UMR 8520 - IEMN, France; [2]Université de Lille, Univ. Lille, Inserm, CHU-Lille, Jean-Pierre Aubert Research Centre (JPArc, UMR - S 1172), France; [3]Université de Sherbrooke, Unité mixte internationale - Laboratoire Nanotechnologies & Nanosystèmes (UMI-LN2), Canada

Microelectrode arrays (MEAs) are widely used tools for investigating neural activity. To ensure the best sensitivity of the electronic devices to ionic signals and the lowest information loss, their electrochemical interface must be optimized by lowering their surface impedance, with materials that ensure the highest compatibility with the cells at the same time.
Here, we show that by the electropolymerization of thiophene-derivatives, functionalized for higher cell biocompatibility and higher electrochemical performances, one can lower the microelectrodes' surface impedance by the control of the polymer morphology. The microelectrode structuring with bottom-up grown conducting polymers was monitored in-situ by voltage-ramped impedance spectroscopy upon electropolymerization to track its circuit-elements modification.
Iterative impedance modeling over the growth confirmed the material's electrochemical dynamic to be controlled by the gradual modifications of specific discrete circuit elements at different frequency ranges, thanks to the surface electrodes microstructuring. More particularly, we systematically evidenced a monotonic change of the electrode charging from ideal capacitor to constant phase element dominated modes, due to the bulk charging of the conducting polymer. The evolution of the materials morphology screened by atomic force microscopy and electron microscopy has been confronted to the modification of the materials circuit element, and confirmed distinctive charging modes for the electrodes that are governed by their different texturing. In addition to the surface morphology, chemical tuning of the electrodeposited polymer has been performed and showed that a fine tuning of the polymer's glycolation promotes the decrease of the electrodes' electrochemical impedance down to -15% compared to the unglycolated polymers thanks to a right balance between ionic permeability and electronic performances.

Overall, lower impedance values than commercial MEAs have been systematically reached with performances comparable to spin-coated polymer electrodes', and with low performance dispersion over the whole population of electrodes in the MEAs. With the presented preliminary biocompatibility and stability tests, this study aims is to demonstrate that unusual microfabrication techniques derived from electrochemistry can provide unique features at the material level to match properties of future emerging bioelectronics technologies to the strong requirements of sensing involving biological materials with rich material chemistry and morphology.

5:40 AM F.FL01.04.04
Conducting Polymer Composites with DNA as Counterion for Bioelectronics Serpil Tekoglu, Dominik Wielend, Clark Markus Scharber, Cigdem Yumusak and Niyazi Serdar Sariciftci; Johannes Kepler Universität Linz, Austria

Conductive polymers (CPs) are in the particular interest of bioelectronics as they combine the mechanical flexibility with the electrical and ionic conductivity. Poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) has been widely studied as the most promising CP due to its conductivity, processability, and commercial availability.[1] However, the biocompatibility of this benchmark material for long-term applications is still under debate,[2] even though a recent study has demonstrated its stability in cell culture for up to four months.[3] Therefore, for interfacing electronics with biology, there is still a high demand for biocompatible devices and materials showing mixed electronic/ionic conductivity. Recently, PEDOT has been incorporated with biomolecule dopants, e.g., deoxyribonucleic acid (DNA), hyaluronic acid, dextran sulfonate, heparin, pectin, guar gum to modify the properties.[4] Among those, PEDOT:DNA has the main advantage of higher ionic conductivity with respect to PEDOT:PSS.[5]

In our work, we prepared PEDOT:DNA and polypyyrole:DNA aqueous dispersions by oxidative chemical polymerization. DNA was engaged as a stabilizer and dopant during the polymerization process of EDOT and pyrrole monomers. Different surfactants and secondary dopants were added into the dispersed solutions to support the thin-film processing using the spin-coating technique as well as to avoid the delamination of the films. Subsequently, we investigated the electrical, optical, and morphological properties of the biocomposite films. We fabricated organic electrochemical transistors (OECTs) involving conducting polymer biocomposites as the organic active layer and compared the transistor characteristics to PEDOT:PSS based OECTs.[6] Additionally, biocompatibility tests on the conductive films were carried out. The results showed that DNA-based conductive polymers can be considered as novel biocomposites for iontronics such as OECTs and biosensors.

Peptide Based Biomaterials with Tunable Electron/Proton Conductivity Nurit Ashkenasy; Ben Gurion University of the Negev, Israel

The emerging need for bioelectronic devices that interface with biological substances is accompanied by a growing need for biocompatible, biodegradable, conducting materials. Biomaterials, which are inherently biocompatible, biodegradable, are commonly considered to be "bad conductors". In order to overcome this challenge, our group is developing bio-inspired materials based on *de-novo* design of peptides that capture many of the features of proteins on one hand, and are optimized for electronic and/ or protonic conduction applications on the other hand. In this talk, I will demonstrate the use of *b*-sheet forming peptides for the development of conductive materials. Specifically, I will show that the sequence of the peptide can greatly influence the conductivity with sensitivity to even single sequence mutation. These effects are shown to originate both from the differences in the intrinsic ability of a specific amino acid to participate in the charge transport process, and also from their effects on the assembly of the structure, which in return affect the conductivity. Design concepts for improving

either electron[1,2] or proton[3] conductivity, or both,[4] will be presented. The structure function relationships we reveal can be used for the design of novel biocompatible organic bio-electronic devices.

Ions-Based High Bandwidth Communication for Implantable Bioelectronics Zifang Zhao, Georgios Spyropoulos, Claudia Cea, Jennifer Gelinas and Dion Khodagholy; Columbia University, United States

Implanted devices such as pacemakers and brain stimulators are critical treatment modalities for certain patients. Establishing communication with implanted devices wirelessly remains a difficult task because biologic tissue absorbs most of the electromagnetic waves. Instead, we hypothesized that ions in biological tissue could serve as communicating carriers. The key parameters to achieve megahertz-bandwidth ionic communication with controllable propagation radius is unknown. Here, we describe the working principles of ionic communication (IC) and the effect of material and geometrical properties such as electrode area, material composition, ion type/concentration, and operating frequency on this process. For each of these properties, we performed electrochemical impedance spectroscopy (EIS) and a gain-bandwidth test. Using this approach, we were able to optimize the electrode design for different applications towards such as higher bandwidth or longer-range transmission. We then designed implantable transdermal IC electrodes with several MHz bandwidth. We used these devices to acquire high quality *in vivo* electrophysiological data from freely moving rats. The proposed working theory of IC and the resulting devices set the foundation for advanced biomedical implantable systems, such as brain-computer interfaces, that require a low consumption, high bandwidth wireless communication system.

6:10 AM F.FL01.04.07

Late News: Probing the Impedance of a Biological Tissue with PEDOT:PSS Coated Metal Electrodes—Effect of Electrode Size on Sensing Efficiency Dimitrios Koutsouras, Leona V. Lingstedt, Katharina Lieberth, Jonas Reinholz, Volker Mailänder, Paul W. Blom and Paschalis Gkoupidenis; Max Planck Institute for Polymer Research, Germany

PEDOT:PSS (Poly(3,4 ethylenedioxythiophene):polystyrene sulfonate) coated electrodes have been widely used to evaluate the integrity of cellular barriers. Nevertheless, an experimental and systematic study of the correlation between tissue integrity and impedance of the sensing device has not yet been conducted. In this work, with the use of impedance spectroscopy, we investigate the way that impedance ratio of the biological tissue to the recording device affects the recording ability of the latter. Various sized PEDOT:PSS coated electrodes are employed and the effect of their dimensions to their sensing ability is determined. A simple equivalent circuit is proposed to model the biotic/abiotic ensemble and an analytical expression of the total impedance as a function of frequency is extracted. The study results in a critical impedance ratio of the biological tissue to the sensor, which allows for efficient sensing of the tissue integrity. This work opens new pathways for the realization of improved impedance based biosensors with optimized sensitivity.

Lluís Companys 23, 08010 Barcelona, Spain, Spain

Organic electrochemical transistors (OECTs) have been widely used as transducers in electrophysiology and other biosensing applications. Their identifying characteristic is a transconductance that increases with channel thickness, and this provides a facile mechanism to achieve high signal amplification. However, little is known about their noise behaviour. Here, we investigate noise and extract metrics for signal-to-noise ratio and limit of detection in OECTs with different channel thickness. These metrics are shown to improve as channel thickness increases, but the improvement is not proportional and tends to saturate for thicker channels. The results show that OECTs can be easily optimised to show not only high amplification, but also low noise.

5:10 AM F.FL01.05.02
Self-Aligned Laser-Cut OECTs for Biological Sensing Reem B. Rashid and Jonathan Rivnay; Northwestern University, United States

Organic electrochemical transistors (OECTs) have gained popularity for biological sensing, for a variety of applications, ranging from neural signal recording to ion detection, due to their amplification capabilities. OECTs are three terminal devices where the organic semiconducting channel's bulk conductance is modulated via ionic/electronic interactions when operated in electrolyte. The main differences between OECTs and OFETs is the prevalence of bulk (as opposed to interfacial) charging and transport. As such, OECTs can take on smaller form factors, have high transconductance, and do not require the pristine interfaces that OFETs require which allows for more relaxed fabrication constraints. The same advantageous bulk charging, however, can result in parasitic capacitance when the mixed conductor/contact overlap in devices are large. In micro-OECT devices patterned photolithographically, these overlaps (which aid in layer-to-layer alignment) can account for >50% of the total measured device capacitance, slowing device response time.

In this work we simplify pattering and eliminate parasitic capacitance by fabricating OECTs with laser-cut channels and a self-aligning insulation. The self-aligning insulation is made of a hydrophobic coating that allows the semiconducting material to be "dragged and dropped" into the laser cut channel between the source and drain contacts, eliminating the need for photolithography, dry etching and a sacrificial insulation layer to pattern the organic material in the channel. The self-aligned OECTs showed one hundred percent yield and electronic properties (mobility and threshold voltage) similar to those fabricated with traditional methods. These self-aligned OECTs were also fabricated onto flexible substrates to show the applicability for biological applications.

This method of manufacturing was extended for use with vertical OECTs (vOECTs), by stacking another layer of gold contact to create a vertical channel between the source and drain contacts, which eliminates parasitic capacitance once again. Finally, we used these vOECTs to create simple circuits that allow for the possibility of simultaneous on-site amplification and signal processing, for applications such as differential and biochemical sensing, without increasing overall device footprint.

5:20 AM F.FL01.05.03
Post-Fabrication Optimization Technique of Organic Electrochemical Transistor (OECT) for Electrophysiology by Electropolymerization Mahdi Ghazal[1], Anna Susloparova[1], Sophie Halliez[2], Morvane Colin[2], Luc Buée[2], Yannick Coffinier[1], Sébastien Pecqueur[1], Thomas Dargent[1] and Fabien Alibart[1,3]; [1]Institut d'électronique de microélectronique et de nanotechnologie, France; [2]Jean-Pierre Aubert Research Centre, France; [3]Laboratoire Nanotechnologies and Nanosystemes, Canada

The recent progress in the extracellular microelectrode arrays (MEAs) have greatly improved our ability to probe cellular electrophysiological activities. Nevertheless, passive MEAs are subject to small signal-to-noise ratio and small potential detection.
Recently, organic electrochemical transistors (OECTs) have been identified as a promising device architecture to improve extracellular potentials recording in electroactive cells culture both in-vitro and in-vivo. In addition to unique properties of interest for electrophysiology such as biocompatibility, transparency and flexibility, OECTs operating principle is based on the transduction of ionic currents in the biological medium into electronic currents in the organic semiconductor (e.g. PEDOT:PSS) via electrochemical coupling. The transconductance represents an important figure of merit of OECTs and depends on geometrical and material parameters that rules largely OECTs performances for sensing electrophysiological

signals. However, as an organic electronic technology, larger device-property distributions are often encountered with respect to the one of metal- or inorganic-based technologies, inherent to the very nature of the soft organic materials involved in the OECTs transduction process.

Here, we explore the possibility to tune post-fabrication material and geometrical parameters of OECTs with electropolymerization of EDOT. We show that this strategy can be used to simultaneously improve OECT transconductance and its geometrical capacitance. The addressed OECT chips were micro-fabricated on a glass substrates with spin coated PEDOT:PSS. Electropolymerization of EDOT on top of spin-coated PEDOT:PSS was carried on with both fix voltage and ramp voltage techniques. A detail impedance analysis was performed during OECTs functionalization. DC electrical characterizations was used to correlate the transconductance and capacitance tuning due to electropolymerization and to assess device performances improvements. Scanning Electron Microscopy (SEM) was used to correlate morphological changes due to electropolymerization with the enhancement in the transconductance and capacitance of the OECTs. Finally, we performed bio-compatibility assessment between primary neural cells culture and the different possible monomers used for electropolymerization to evaluate the possibility to improve affinity between cultured neurons and electropolymerized materials.
The key novelty of this material engineering technique is to propose a promising method for tunable OECTs sensors development. For instance, this back-end-of-line tuning technique can reduce chip variability in terms of performance yield and bring OECTs technology to the next maturity level. Furthermore, such flexibility can enable matching the electrochemical impedance of the device to the one of the cells, and in the future promote exploratory sensing missions, merging brain-inspired information processing with neuro-sensing.

5:30 AM F.FL01.05.04
Ultra-Low Power Neurotransmitter Sensor Using Aptamer Functionalized Deep Subthreshold Schottky-Barrier IGZO TFT Abhijeet Barua, Ryan White and Rashmi Jha; University of Cincinnati, United States

Aptamer-based target biomolecule sensing is attracting much interest due to their excellent reception with high selectivity and specificity. The 3D structure coupled with the short strand length of aptamers enables detection within the Debye limit of ionic solutions [1]. Field effect transistors (FETs) offer an excellent platform to transduce and amplify the effective change in the charged aptamer morphology on target binding into electrical signals. However, these FETs need to be ultralow power and portable on flexible substrates for seamless integration with micro-probes or wearable devices. Amorphous oxide semiconductors such as InGaZnO (IGZO) demonstrate high mobility, low process complexity, good uniformity, stability in threshold voltage, and reduced leakage due to the wide bandgap [2]. Moreover, their low thermal budgets will allow them to be integrated heterogeneously on Si CMOS fabrication in Back End of Line (BEOL) processes. However, IGZO TFTs have been mostly studied at near threshold operations that require high bias voltages. Interestingly, recent reports have investigated Schottky barrier (SB) source and drain regions where the presence of two reverse biased Schottky diodes facilitate deep subthreshold operation due to gate-bias induced modulation of current injection or extraction at these terminals through the presence of a depletion region that impinges on the channel [3]. The diodes also enable early saturation of the transistor output curves and shield it from deleterious contact effects. Prior work has demonstrated SB formation in IGZO TFT with Ohmic metals such as Ti/Pt/Mo by modulating the vacancy concentration in IGZO via deposition under higher oxygen partial pressure [3], [4]. We report deep subthreshold SB IGZO TFTs by metal-IGZO contact engineering. Experimental verification of the deep subthreshold enabled ultra-low power operation with below unity switching voltages has been completed and almost infinite output resistance (~10^{12} Ohms) and subsequent high intrinsic gain (>100) have been derived. Stability tests in this regime have demonstrated extremely low drifts in device behavior. A model is under development for the behavior of the device in this subthreshold region, influenced by a reverse biased Schottky and a diffusion/drift behavior. The low-voltage operation is important for biosensors, where this would allow sensing within the electrochemical window (< 1V) of the analyte solution, prevent local work function change of the electrodes, and enable stable bias stress operation to sample the analyte at regular intervals. We propose a platform of aptamer functionalized low power operation TFTs that can selectively and specifically detect physiological neurotransmitter (NT) concentrations in solutions to be used for diagnosis of mental disorders. Dopamine [2-(3,4-dihydroxyphenyl) ethylamine] is an important catecholamine NT that plays a crucial role in the central nervous, hormonal, renal and cardiovascular system and helps in the control of cognitive/motor and neuroendocrine functions. Imbalances in dopamine secretions can lead to neurological disorders such as post-traumatic stress disorder (PTSD), Parkinson's, Schizophrenia and Alzheimer's disease [1]. Therefore, preliminary tests have been conducted to evaluate TFTs for dopamine detection through a novel 'click chemistry' functionalization technique. This process incorporates the catalytic adhesion of an alkyne terminated molecule with an azide anchored aptamer which precludes the need for an intermediate molecular adhesion step. Hence, this would lead to a shorter overall bond length as well as lower steric hindrance. The aptamer was specifically synthesized for selectivity towards dopamine target and in vitro initial experiments with a lower limit of 10nM have been performed.

5:40 AM F.FL01.05.05
Late News: Monitoring Reversible Tight Junction Modulation with a Current-Driven Organic Electrochemical Transistor Katharina Lieberth[1], Maximilian Brückner[1,2], Fabrizio Torricelli[3], Volker Mailänder[1,2], Paschalis Gkoupidenis[1] and Paul W. Blom[1]; [1]Max-Planck Institute for Polymer Research, Germany; [2]University Medical Center of the Johannes Gutenberg-University Mainz, Germany; [3]University of Brescia, Italy

Present characterization techniques for the tight junction modulation are either invasive, such as fluorescence marking[1], or have low ion sensitivity, like trans-epithelial electrical resistance[2]. The organic electrochemical transistor (OECT) is able to operate in aqueous solutions at low voltages, so it is a biocompatible, label-free and low-cost ion-to-electron converter.[3] Therefore, OECTs are suited biosensors for drug delivery and related processes as cell barrier integrity.[4] The passage of nutrients and drugs into the blood is regulated by the barrier functionality of a cell layer. Hence, modulating the barrier functionality by external chemical agents like poly-L-lysine (PLL) is crucial for drug delivery.[5] The ability of a cell layer to impede the passage of ions through it and therefore to act as a barrier, can be assessed electrically by measuring the resistance across the cell layer. Here, we used an OECT in a current-driven configuration for the evaluation of reversible modulation of tight junctions in the epithelial colon carcinoma (Caco-2) cell line,[6] found in the small intestine, over time. Operating the OECT in current-driven configuration enhances the sensitivity,[7] required to study reversible ion permeability through tight junctions of Caco-2 cells. The reversible opening and closing of tight junctions was detected using the PLL at RT and under physiological conditions. Concentration and time dependent experiments resumed that the exposure to low and medium concentrations of PLL initiates reversible modulation, whereas a too high concentration induces an irreversible barrier disruption due to non-functional tight junction proteins. To support electrical measurements occluding-staining has been performed using immunofluorescence imaging. The results demonstrate the suitability of OECTs to *in-situ* monitor temporal barrier modulation and recovery, which can offer valuable information for drug delivery applications.

5:50 AM F.FL01.05.06
Late News: Operation Mechanism and Design Rules for Organic Electrochemical Transistors as Redox Chemical Transducers Siew Ting Melissa Tan and Alberto Salleo; Stanford University, United States

Organic Electrochemical Transistors (OECTs) have exhibited promising performance as transducers and amplifiers of low potentials due to their exceptional transconductance, enabled by the volumetric charging of Organic Mixed Ionic/Electronic Conductors (OMIECs) employed as the channel material. OECT performance in aqueous electrolytes as well as the OMIECs' redox activity has spurred a myriad of studies employing OECTs as chemical transducers. However, the OECT's large (potentiometrically derived) transconductance is not fully leveraged in common approaches that directly conduct chemical reactions amperometrically within the OECT electrolyte with direct charge transfer between the analyte and the OMIEC, which results in sub–unity transduction of gate to drain current. Hence, amperometric OECTs do not truly display current gains in the traditional sense, falling short of the expected transistor performance. We have demonstrated in our previous work an alternative device architecture that separates chemical transduction and amplification processes on two distinct electrochemical cells (*1*). This approach fully utilizes the OECT's large transconductance to achieve current gains of 10^3 and current modulations of four orders of magnitude. Furthermore, harvesting energy from the chemical reaction on the reaction cell renders the gate circuit self–powered. This simple yet overlooked transduction mechanism represents a general

approach enabling high–gain chemical OECT transducers.

In this current work, we investigate the device physics behind the different architectures and operation modes of the OECT as redox chemical sensors. Analyses reveal that in the amperometric operation of the OECT, approaches to optimize both chemical transduction and OECT operation are challenging at best, and even contradictory in some cases. Furthermore, conducting faradaic reactions at non-equilibrium conditions within the OECT result in complex effects arising from voltage-dependent redox reaction rates, spatially asymmetric voltage variations across the channel, and mass transport dependencies. In contrast, the operation of the RC-OECT at equilibrium conditions allows for a simple model to describe its operation, enabling straightforward optimization of its performance by materials selection and device design. Furthermore, the separation of chemical transduction and electronic amplification on two separate compartments allow for more feasible optimization of the individual components.

This study sheds light on the challenges faced by the conventional approach of conducting redox sensing reactions within the electrolyte of the OECT. Additionally, it suggests a promising alternative approach to simultaneously achieve chemical transduction and reap the full amplification capabilities of the OECT, including a simple model for understanding device operation. The RC-OECT's superior performance and predictability of device performance from fundamental materials properties will aid the future development of high-performance chemical sensors for early disease diagnosis.

Electron Transporting Polymers for Biological Interfacing Sahika Inal; King Abdullah University of Science and Technology (KAUST), Saudi Arabia

Fluidity, mobility, and resistivity are key characteristics of native membranes in our cells where cation channels regulate numerous molecular mechanisms (e.g., the excitation of neurons). Interfacing with biomimetic membranes via electronic devices promises to expand our understanding of the function of these membranes in disease states. The challenge is to form supported lipid bilayer (SLBs) on (semi)conducting films while sustaining high sensitivity and operational stability. In this talk, I will show the traits of n-type organic semiconductors for such biological interfaces. I will show the very first ion channel sensor based on an n-type, accumulation mode, microscale organic electrochemical transistor (OECT), which interfaces an SLB embedded with a pore-forming protein. The polymer is particularly sensitive to divalent cations, endowing the system with biomimetic properties. The side-chain engineering of semiconducting polymers prompts the development of next-generation bioelectronic hybrids where electron-transporting polymers establish bilateral electronic communication with living systems.

5:15 AM *F.FL01.06/SM05.05.02
Thin-Film Organic Electrochemical Devices for Applied Neural Control—Capacitive and Faradaic Effects Eric Glowacki; Linkoping University, Sweden

A great demand exists for minimally-invasive neuromodulation technologies to enable next-generation bioelectronic medicine. We report on our developments of ultrathin organic (opto)electronic devices for neurostimulation. All of these devices rely on far red/near infrared irradiation in the tissue transparency window to actuate nanoscale organic semiconductor components. Our flagship technology is the organic electrolytic photocapacitor (OEPC) – a device that mimics biphasic current-pulse neurostimulation and thus transduces an optical signal into directly-evoked action potentials in neurons. These devices are not only wireless, but also 100-1000 times thinner than most existing technologies. We will discuss chronic

implants capable of stimulating peripheral nerves (sciatic and vagus) when actuated from outside of the body using diode lasers. We have observed stable operation in rodent models for at least 100 days. As a different approach, we will report on favorable harnessing of DC electrochemistry effects, normally considered spurious and undesired. Specifically, we show how electrochemical generation of low doses of hydrogen peroxide can be used to reversibly stimulate M-type potassium channels, providing a novel method of controlling neural excitability.

Enhancement-Mode Ion-Based Transistors for *In Vivo* Electrophysiology and Real-Time Data Processing Claudia Cea, Georgios Spyropoulos, Jennifer Gelinas and Dion Khodagholy; Columbia University, United States

Bioelectronic devices must have high speed and high performance to interact with the often rapid, low amplitude signals generated by neural tissue. They should also be capable of forming complementary logic and analog circuits to allow acquisition, processing and manipulation of a biological environment. However, the lack of readily available p-type polymers for use in enhancement mode transistors and their complicated synthesis significantly limits the investigation and application of such devices in bioelectronics. Here, we develop an enhancement mode ion-gated transistor (e-IGT) that functions based on a reversible redox reaction and hydrated ion reservoirs within the conducting polymer channel to enable long-term stable operation and shortened ion transit time. We combined a highly conductive poly(3, 4-ethylenedioxythiophene) doped with polystyrene sulfonate (PEDOT:PSS) and a reducing agent polyethylenimine (PEI) to enable doping of the polymer in an aqueous environment. The transistor operates as following: (1) the protonated PEI bonds with the PSS- and de-dopes the PEDOT:PSS chain resulting in an initial off-state of the transistor, (2) a subsequent application of negative gate voltage dopes the PEDOT:PSS switching the channel on. To determine an optimal transistor configuration and material composition, we microfabricated transistor arrays of varying geometrical parameters. The high-transconductance and high-speed of the e-IGTs resulted in a gain bandwidth product that is several orders of magnitude above other ion-based transistors. We used these transistors to acquire a wide range of electrophysiological signals, including in vivo recording of neural action potentials. Furthermore, we combined E-IGTs with d-IGTs to create a real-time non-linear rectifier to accurately detect epileptic discharges in vivo. In conclusion, E-IGTs offer a safe, reliable, and high performance building block for chronically implanted bioelectronics, with spatiotemporal resolution to the scale of individual neurons.

5:40 AM F.FL01.06/SM05.05.04
Organic Electrochemical Transistors Based on Electropolymerized Dendritic Structures Kamila Janzakova[1], Mahdi Ghazal[1], Ankush Kumar[1], Yannick Coffinier[1], David Guérin[1], Sébastien Pecqueur[1] and Fabien Alibart[1,2]; [1]University of Lille, France; [2]Laboratoire Nanotechnologies & Nanosystèmes (LN2), Canada

One of the neuromorphic engineering aims is using nanoelectronics' materials and devices to reproduce key features that are used by the brain for computing. Currently, neuromorphic engineering has explored standard silicon-based technologies (i.e. such as complementary metal–oxide–semiconductor) or more emerging material and devices (iono-electronic materials and resistive memory devices, for example). Most of these technologies are still bounded to a top down approach. However, brain computing largely rely on bottom-up processes. For instance, interconnectivity between cells and formation of communication pathway in neural networks result principaly from bottom-up organization. Here, we show how dendritic growth of organic conductive polymers (PEDOT) can be used to mimic structural branching observed in neural network. Conducting-polymer based dendritic structures with different morphology are synthesized in a two-electrode setup by pulsed voltage-driven electropolymerization derived from state-of-the-art bipolar AC-electrochemical synthetic methods. We show how various AC signals can lead to a large variety of dendritic structures and PEDOT morphologies. In a second part, such dendritic structures are used to implement functionnal OECTs. More importantly, we focus on the transconductance and memory effects that can be obtained in such dendritic OECTs such as short tem plasticity. We report on the relationship between dendrites morphologies and STP time constant.
This work paves the way to new approaches for neuromorphic engineering, such as structural plasticity and neural network topology exploration.

5:50 AM *F.FL01.06/SM05.05.05
Forming Input/Output (i/o) Interfaces with Excitable Cells And Tissue Using Nanocarbons Tzahi Cohen-Karni; Carnegie Mellon University, United States

We focus on developing a new class of nanoscale materials and novel strategies for the investigation of biological entities at multiple length scales, from the molecular level to complex cellular networks. Our highly flexible bottom-up nanomaterials synthesis capabilities allow us to form unique hybrid-nanomaterials that can be used in various input/output bioelectrical interfaces. For example, we have developed several bioelectrical platforms based on graphene, a two-dimensional (2D)

atomically thin carbon allotrope. We have demonstrated recording of the electrical activity of excitable cells with graphene-based ultra-microelectrodes as small as the size as an axon ca. 2μm in size. Using graphene-based hybrid-nanomaterials, we have formed remote, non-genetic bioelectrical interfaces with excitable cells and modulated cellular and network activity with high precision and low needed power. We have also developed a breakthrough bioelectrical interface, a 3D self-rolled biosensor arrays (3D-SR-BAs) of either active field effect transistors or passive microelectrodes to measure both cardiac and neural spheroids electrophysiology in 3D. Our approach enables electrophysiological investigation and monitoring of the complex signal transduction in 3D cellular assemblies toward an organ-on-an-electronic-chip (organ-on-e-chip) platform for tissue maturation investigations and development of drugs for disease treatment. In summary, the exceptional synthetic control and flexible assembly of nanomaterials provide powerful tools for fundamental studies and applications in life science and open up the potential to seamlessly merge either nanomaterials-based platforms or unique nanosensor geometries and topologies with cells, fusing nonliving and living systems together.

6:05 AM *F.FL01.06/SM05.05.06
High-Resolution Bioelectronic Interfaces Enabled by Nanoscale Soft Conductors Flavia Vitale; University of Pennsylvania, United States

The rapid rise of bioelectronics has enabled a number of innovative approaches to treat neurological disorders, restore and repair lost functions, and modulate neural circuitry to control mood and behavior. The vast majority of bioelectronic interfaces, however, still rely on traditional noble metal and silicon materials, which are expensive to source and process and are intrinsically inadequate to address the mechanical, chemical, and electrical properties of excitable circuits in the body. To establish bioelectronic technologies as the clinical standard, significant innovations in materials and fabrication strategies are still required to achieve safety, softness, biocompatibility, and long-term stability. Nanostructured materials are uniquely positioned to address these challenges because they combine high electrical conductivity with intrinsically high mass-specific surface area and mechanical flexibility. Furthermore, they can interact with biological systems on a molecular scale and can be easily integrated within scalable solution-based processing, thus allowing easy modulation of their electronic and optical properties.
In this talk I will present the ongoing work in my lab to leverage the unique properties of nanostructured materials and engineer novel bioelectronic interfaces for sensing and stimulating neural and neuromuscular circuits. Specifically, I will describe the fundamental electronic, electrochemical, and mechanical properties of 2D transition metal carbides nanomaterials (a.k.a. MXenes) and how these translate into significant impedance and noise reduction when MXenes are integrated bioelectronic interfaces. Then, I will present *ad hoc,* scalable, rapid manufacturing processes developed in my lab to translate the exceptional material properties at the molecular scale into high-resolution, low impedance bioelectronic interfaces that are also compatible with clinical neuroimaging modalities, such a magnetic resonance imaging (MRI) and computerized tomography (CT). Finally, to illustrate the potential of MXene-based bioelectronics, I will present different example of applications in both implantable and wearable interfaces.

6:20 AM F.FL01.06/SM05.05.07
Late News: Spatiotemporal Response of Organic Electrochemical Transistors Dimitrios Koutsouras[1], Morteza Hassanpour Amiri[1], Katharina Lieberth[1], Kamal Asadi[1], Fabrizio Torricelli[2], Paul W. Blom[1] and Paschalis Gkoupidenis[1]; [1]Max Planck Institute for Polymer Research, Germany; [2]University of Brescia, Italy

Organic electrochemical transistors (OECTs) have recently attracted tremendous attention in the scientific community due to their unique set of features. Especially, the lack of an insulating layer that separates gate from channel, like in conventional field effect transistors, and their feature to support electrolyte gating open new pathways in the field of bioelectronics. In particular, they render the device ideal for measurements in the aqueous environments that dominate the biological world. Additionally, they provide extra possibilities in terms of the device architecture as the gating electrode can be patterned on the same plane as the conducting channel. In a set up like that, what is of extreme interest is the effect of the gate position with respect to the channel. In this work, the spatiotemporal response of a poly(3,4 ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) OECT is examined and its device physics is studied. This work opens new routes for exploiting the physics of multi terminal OECT devices in bioelectronics, sensing and neuromorphic electronics.

Cost-Effective Manufacturing of a Bioelectronic Smart System Array (SiMBiT EU Project) Fabrizio A. Viola and Mario Caironi; Istituto Italiano di Tecnologia - IIT, Italy

Digitizing biomarkers analysis by quantifying them at the single-molecule level is the new frontier for advancing the science of precision health. Such an occurrence will enormously enhance their ability of curing diseases by supporting better prognosis and permitting the application of precise treatment methods. The SiMBiT project will develop a bio-electronic smart system leveraging on an existing lab-based proof-of-concept that can perform single-molecule detection of both proteins and DNA bio-markers (pancreatic cancer precursors) in a minimal sample volume, with enhanced sensing capabilities. In its final shape, it comprises a 96-well plate with the electrolyte gated organic transistors (EG-TFTs) sensing array and the bio-functionalized gates module along with addressing and front-end electronics and an electronic plate reader. Here we present the activity of IIT group on SiMBiT project which is related to the fabrication, with large-area compatible processes such as printing, and optimization of the EG-TFT structure, which will be integrated in a 8x12 matrix. We will show the complete fabrication process and the electrical characterization of the EG-TFTs, together with the the firsts sensing measurements which can show the high sensitivity and specificity of the devices, together with the high reproducibility and stability, which are fundamental for the development of a platform of biosensors.

Towards Next-Generation Nerve Repair—Using Amorphous Ferromagnetic Microwires to Promote Nerve Regeneration Xiaoyu Zhang[1], Caroline Mills[1], Yinying Hua[1], Ryan Koppes[1], Rafael Pérez del Real[2], Manuel Vázquez Villalabeitia[2], Abigail Koppes[1] and Laura Lewis[1,1]; [1]Northeastern University, United States; [2]Instituto de Ciencia de Materiales de Madrid, CSIC, Spain

Peripheral nervous system (PNS) injuries affect millions of people worldwide each year, and peripheral nerve repair remains challenging due to the limited functional recovery and the associated co-morbidities seen in current methods [i]. Modern nerve repair often relies on nerve regeneration, which has been reported to be sensitive to multiple external stimuli, including electromagnetic stimulus and topographical cue. Here we present encouraging results that neurite outgrowth of dorsal root ganglia (DRG) neurons is promoted by applied static magnetic field and, separately, also by topographical guidance from glass-coated magnetic microwires in their demagnetized state. These microwires (diameter ~ 20 microns), comprised of a metallic glass Fe(Co)SiB-based core coated with pyrex glass, possess an extraordinarily responsive magnetic character, with a saturation magnetization around 1.5 T of the metallic core, coercivity in the range of several A/m, and permeability up to around 10^5 [ii]. We hypothesize that employment of magnetized glass-coated microwires will significantly enhance nerve regeneration with combined applications of magnetic and topographical cues.
Magnetic stimulation was applied to DRG neurons using an apparatus developed with Ansys electromagnetic simulation software. This apparatus employed a pair of axially magnetized neodymium-iron-boron magnets joined by an electrical steel flux path to deliver a nominally uniform in-plane magnetic field $\mu_0 H_{app}$ ~500 G (0.05 T) to the cells. Topographical guidance was provided to these cells by a parallel assembly (1:5 mesh density) of glass-coated microwires in the absence of an applied magnetic field. As these magnetic microwires were in a demagnetized state, the cells were not subjected to a magnetic field. All cells were cultured for three consecutive days under controlled conditions in an incubator. Data derived from immunocytochemistry and image analysis with MATLAB revealed that the magnetic field application increased the overall neurite outgrowth volume by up to 152% compared to unstimulated controls. No directional guiding effect was observed from the applied magnetic field. However, the topographical cues from the aligned microwire assembly enhanced the directionality of neurite extension with an increase of 39% in average longest neurite length along the wires, but not in total outgrowth. Future investigations involve growing DRG neurons on magnetized glass-coated microwires meshes, providing combined magnetic and topographical stimuli.

Late News: Multifunctional Nanomaterials for Surface Enhancement Raman Spectroscopic Detection of Cancer Biomarkers Justine S. Gordon, Chuan-Jian Zhong and Shiyao Shan; SUNY Binghamton, United States

Cancer is one of the leading causes of death with approximately 7 million deaths each year. Although knowledge surrounding the prevention and treatment of cancer is increasing, there is a clear need of highly-sensitive techniques for early detection of cancer to increase the survival rate. This presentation describes recent findings of our investigations of multi-functional nanomaterials for Surface-enhanced Raman scattering (SERS) detection of cancer biomarkers. One important focus is the preparation of magnetic and plasmonic nanoparticles as the SERS probes with high sensitivity, high selectivity, and low detection limit. We have developed a duel-functional nanoprobe system for the SERS detection of the biomarkers. Results on the preparation of gold and core-shell nanoparticles with a magnetic core and plasmonic gold shell will be discussed, focusing on the control of size, composition, and surface properties. Tunable bio-conjugation of the nanoprobes with detection/capture antibodies for the detection of the cancer biomarker, e.g., carcinoembryonic antigen, has been demonstrated. Implications of the results for optimizing the magnetic-plasmonic properties and multiplexing detection of cancer biomarkers will also be discussed.

Off-Stoichiometric-Thiol-ene Epoxy Polymers for Soft Implantable Electrode Array Eleonora Borda, Marta Airaghi Leccardi and Diego Ghezzi; École Polytechnique Fédérale de Lausanne, Switzerland

Implantable electrode arrays have been widely used to treat neurological disorders such as Parkinson's disease, epilepsy, hearing loss, and chronic pain by applying electrical stimulation and/or recording neural activity. One of the main requirements for these devices is the ability to evoke minimal inflammatory tissue response to guarantee the long-term use of integrated functions. However, this can be limited by a mechanical mismatch between the implant, very stiff, and the tissue, very soft, inducing neural damages and leading to glial scar formation. So far, the most common materials used for fabrication of such neural interfaces are PI and PDMS. On one hand, thin-film microfabrication techniques allow the fabrication of flexible miniaturized and highly integrated stimulating or recording arrays in PI. However, the Young's modulus of PI is about a few GPa. On the other hand, PDMS because of its low Young's modulus (approximately 1 MPa)

and its elastic behaviour leads to less damage to the neural tissue, but it presents challenging steps in the microfabrication process, especially for the encapsulation of the active sites. Off-Stoichiometric-Thiol-ene Epoxy polymers (OSTE+) were developed firstly for rapid prototyping of microfluidic chips because they are less permeable to gas. OSTE+ materials are a good compromise between PI and PDMS. In fact, by adjusting the stoichiometry of the constituting monomers, the Young's modulus of OSTE+ can be decreased down to a few MPa at physiological temperature. The preparation of OSTE+ consists of two curing steps in which (1) thiol-ene photopolymerization allows to pattern the polymer surface and remove the non-polymerized areas before (2) thermal curing. Thus, it is possible to encapsulate the electrode array simply using photolithographic techniques. Taking advantage of these properties, we fabricated OSTE+ implantable multielectrode arrays with Pt serpentines in monolayer and bi-layer. The functional characteristics of these arrays have been tested by electrochemical characterization and recordings.

F.FL02.09.02
Parylene-Based Double-Faced Electrode Array for Retinal Prosthesis Namju Kim, Heewon Seo and Sohee Kim; Daegu Gyeongbuk Institute of Science & Technology, Korea (the Republic of)

Retinal prostheses require high-density electrode arrays to attain high spatial resolution in vision. However, the transmission lines panning out in the same layer with electrodes may hamper achieving high-density electrodes. Double-faced electrode arrays may circumvent this problem, in which the electrodes and bonding pads are arranged face-to-face and the transmission lines are absent. The electrodes can be connected with stimulation drivers such as photovoltaic cells directly through bonding pads. Here we present the fabrication of a flexible and transparent parylene-based double-faced electrode array and the method of integrating it with the stimulation driver IC.

F.FL02.09.03
Transparent and Flexible Ultrathin Gold Microelectrode Arrays Using Layer-by-Layer Coated Polyelectrolytes for Electro-Optical Neural Interface Woongki Hong, Yujin Hwang, Junil Kim, Hyuk-Jun Kwon, Jae Eun Jang and Hongki Kang; DGIST, Korea (the Republic of)

In recent years, neural interface technologies have been focused on flexible and transparent neural electrodes for high spatiotemporal resolution mapping of neuronal activities using electro-optical measurements. There had been several new material suggestions for the transparent, flexible neural electrodes such as ITO, graphene, conductive polymer, or patterned metal (nanowires, mesh patterns).**[1, 2]** However, these materials have shown several limitations such as high processing temperature, limited mechanical/electrical reliability, fabrication complexity and incompatibility with conventional microfabrication processes etc. To resolve these problems, in this work, we developed a flexible microelectrode array (MEA) using polymer-metal hybrid structures for high optical transparency and good electrical conductivity.
We used layer-by-layer assembly of polyelectrolytes as a nucleation inducing coating layer on transparent substrates (glass, polymer) to realize highly conductive vacuum deposited gold film at sub 10 nm thickness. We optimized the electrical and optical properties of the ultrathin gold electrodes, showing sheet resistance as low as 7.24 Ω/sq at 8 nm thickness and electrical conductivity of 1.327×10^6 S/m. Despite the opaque characteristic of typical thick gold film, the ultrathin film of gold in this work still showed optical transparency of 77% at 550 nm, which is comparable to or better than most of transparent neural electrode materials. In addition, excellent mechanical stability is also demonstrated with bending radius down to 1 mm for at least 500 times of bending. We further measured the baseline noise properties of our ultrathin 40-μm diameter gold MEA for *in vitro* neural recording setup. We have confirmed that it shows low RMS noise level of 9.62 ± 2.24 μV_{rms} (n=60, bandpass filtered in 200 Hz – 3.5 kHz). These results confirm that the polymer-metal hybrid structure based MEA we developed in this work can be used for simultaneous extracellular electrical neural recording and optical neural recording such as calcium imaging.

F.FL02.09.04
Bioresorbable Endovascular Neural Interface for Minimally Invasive Neural Stimulation and Recording Adele Fanelli, Laura Ferlauto and Diego Ghezzi; EPFL, Switzerland

Neural signal recording and direct stimulation of the brain have been widely used to mitigate neurological disorders, such as

epilepsy and Parkinson's disease. Current available techniques in this field commonly require invasive surgery potentially entailing both transient and permanent complications. A promising strategy designed to overcome these risks involves the exploitation of the cerebrovascular system as access route to the neural tissue. Cardiovascular stent technology, exceptionally designed for a minimally invasive procedure and maximum adherence to the vessel wall, represents an optimal scaffold for the recording/stimulating system. Moreover, given the versatility of this type of implant, peripheral nervous system could also be targeted for neural stimulation aimed at relieving intractable pain or supporting motor rehabilitation. Therefore, our goal is the development of a stent-inspired device, with electrodes embedded on its surface facing the vessel walls, for minimally invasive active and passive interaction with the surrounding neural tissue. In order to reduce the possibility of chronic local inflammation and delayed endothelialization, commonly occurring with metallic implants, our device has been fabricated using only biodegradable and biocompatible soft polymers such as poly-ε-caprolaptone (PCL) and (3-glycidyloxypropyl)trimethoxysilane-doped poly(3,4-ethylenedioxythiophene) : poly(styrenesulfonate) (GOPS-doped PEDOT:PSS), for encapsulation and electrodes respectively. Electrochemical properties of the prototypes have been tested in both static and dynamic conditions, with the latter simulating the vascular environment and its pulsatile flow. Degradation analysis in vitro has been performed as well to define the device durability. The promising results open the doors to further investigation of the potentialities of this innovative device, able to replace invasive systems currently used for neural recording and stimulation. Its development will have a huge impact in the treatment of neuropathological conditions related to both central and peripheral nervous system.

F.FL02.09.07

Enhanced Antioxidant Activity of Cerium Oxide Nanoparticles by Surface Modification and Their Potential Application for Mitigating Foreign Body Response in Implantation of Active Chronic Medical Devices Yue Hu, Vicki L. Colvin and Vivian Ling; Brown University, United States

There are roughly 175,000 different medical devices in the US market. The global market for medical devices grows fast yearly, it reached nearly $521.2 billion in 2017 and should reach $674.5 billion by 2022, at a compound annual growth rate (CAGR) of 5.3% for the period of 2017-2022. Some relevant examples include joint replacements, cardiac pacemakers, hernia meshes, subcutaneous real-time glucose sensors, and neural recording devices. An important and growing subset of these devices termed here 'active' implants, require electrical contact to tissues. Their function demands that they have long-term electrical contact to host tissue; perhaps the most widely known example is cardiac pacemakers now found in over 235,000 people in the US alone. Important emerging disease treatments, however, also rely on active medical devices including subcutaneous glucose sensors and neural recording devices. In the case of glucose sensors, the real-time information can drive both dietary choices and mitigate Type 2 diabetes or be part of an automatic insulin delivery system that frees patients with Type 1 diabetes from self-administered insulin injections. In these cases, the implant must stay functional and non-changing in their tissue interactions for years.

Every medical device that is implanted in a person encounters the body's foreign body response (FBR) which in short results in the body physically walling off an object from its physiology. Initially discovered in the 1970s, this multi-stage process is initiated by the innate immune system upon the introduction of foreign material. After injury and implantation, FBR activated by blood/material interaction, followed by protein adsorption, immune cells adhesion, activation, and differentiation. The whole process undergoes acute inflammation, chronic inflammation, the generation of granulation tissue and end up with the fibrous encapsulation generated by FBGCs. Foreign body response (FBR) triggered by the implantation of medical devices limits the lifespan of devices.

One of the widely used solutions is to suppress the immune system response to medical devices. Reactive oxygen species (ROS) generated during the FBR process play a key role in immune responses to implantation. ROS are generally linked to aging, cancer, and nervous system diseases. Anti-inflammatories and antioxidants, such as nonsteroidal anti-inflammatory drugs (NSAIDs), dexamethasone, masitinib, and resveratrol have been combined with implantable devices in local delivery to fight against FBR. However, molecular antioxidants are facing several problems, such as short lifetime, instability in micro-environment, and ineffectiveness induced high doses, limiting the chronic efficiency of implanted devices. Nanoparticles, well known with their high surface to volume ratios, are widely used in biomedical engineering these days. Cerium oxide nanoparticles exhibit recyclable antioxidant properties due to facile electron transfer between Cerium (III) and Cerium (IV). Recent studies reveal that ceria nanoparticles with diameters of 5 nm are non-toxic and efficient for quenching ROS in vivo. We developed a PEGylated polymeric ceria nanoparticle which is stable and biocompatible. We also observed that the antioxidant activity of cerium oxide nanoparticle is enhanced by this PEGylated surface modification which can be widely used in vivo to control the ROS levels at the implant site and relief FBR.

SYMPOSIUM F.FL02

Advanced Neural Interfacing Materials, Devices and Microsystems
November 21 - December 1, 2020

Symposium Organizers
Mohammad Reza Abidian, University of Houston
Hui Fang, Northeastern University

SESSION Tutorial F.FL02: Materials Advances for Neural Interfaces—Materials Meet the Mind
Session Chair: Hui Fang
Sunday Morning, November 29, 2020
F.FL02

10:00 AM *
Materials Advances for Neural Interfaces—Materials Meet the Mind Guosong Hong; Stanford University, United States

The dichotomy between the materials world and the mental world has driven the curiosity of scientists to explore the wonders of the brain, as well as motivated the continued innovations of novel technologies based on advances in materials science and engineering to understand the brain. This tutorial introduces the basic principles of materials design and fabrication for probing the inner workings of the brain, discusses the fundamental challenges of state-of-the-art neurotechnologies, and explores the latest breakthroughs in materials-assisted neural interfaces. The tutorial will cover the following topics: understanding of the nervous system from a materials science perspective, physical, chemical and biological requirements of neural interfacing materials, materials for electrical/magnetic/optical/biochemical/thermal/acoustic neural interfaces and other materials as contrast agents for neuroimaging. After the tutorial, the attendees should be able to obtain a broad overview on how materials advances have been and will continue to be a main driving force to address pressing neuroscience challenges.

This tutorial will cover: Understanding Neuroscience Challenges with a Materials Science Perspective; Fundamental Requirements for Neural Interfacing Materials; Bidirectional Electrical Neural Interfaces; Bidirectional Optical Neural Interfaces; Bidirectional Biochemical Neural Interfaces and Materials for Neural Tissue Engineering; and Emerging Acoustic and Magnetic Neural Interfaces.

Bioresorbable Materials in Temporary Implants for Neurostimulation, Sensing and Drug Delivery John A. Rogers; Northwestern University, United States

Bioresorbable electronic materials serve as the basis for emerging classes of biomedical implants with operational lifetimes designed to match those of transient biological processes. These devices provide important functionality during a relevant timeframe and then naturally disappear within the body, thereby eliminating the need for surgical extraction. This talk presents our latest work in this area, with emphasis on materials aspects of (1) platforms for wireless neuromuscular electrical stimulation, with demonstrations of alleviated muscle atrophy resulting from denervation in rodent models via multiple

episodes of the distal nerve engagement and (2) devices for programmable release of drugs from multiple, independently addressable reservoirs, with illustrations in insulin and lidocaine delivery in animal models for control of blood glucose concentrations and pain responses, respectively.

8:00 PM *F.FL02.03.01
Magnetic Nanomaterials for Wireless Neuromodulation Polina Anikeeva; Massachusetts Institute of Technology, United States

Ion channels offer direct means to manipulating neural activity with specificity and temporal precision. The nanometer dimensions of these molecular machines inspire the design of neuromodulation tools operating at comparable spatial scales. In this talk I will discuss how magnetic nanotransducers based on synthetic magnetic materials can be applied to convert external weak magnetic fields into stimuli, such as heat, force, torque, pH change, and chemicals, commonly perceived by ion channels. I will illustrate the importance of magnetic properties in controlling magnetically-mediated neuronal modulation in the context of ion influxes and rodent behavior. This talk will also highlight opportunities offered by wireless magnetic modulation of cell function in neuroscience and beyond.

High Channel Count Electrophysiology—Materials and Technology Toward "Whole Brain" Recording Timothy Harris[1,2]; [1]HHMI Janelia Research Campus, United States; [2]Johns Hopkins University, United States

Application of more advanced microelectronics technologies over the past decade has increased routine extracellular recording capacity from dozens to thousands of neurons. The NIH BRAIN Initiative has catalyzed an explosion of innovative small area low noise analog circuit designs. A next generation of devices under development promises capacity of 10's to 100's of thousand neurons. I will review our work to develop high channel count devices, Neuropixels, and the pathway to an additional 10-50X capacity increase. Important materials innovation in recording electrodes, stress compensation layers, and circuit design are required to fuel this transformation of electrophysiology capability. This data volume has created

bottlenecks for analysis. Discuss the current state of current practice and the paths needed to convert the avalanche of data to neuroscience understanding. The scale of data is so much larger than historically typical that a complete alteration of analysis and visualization is required. Finally, I will open a discussion of limits, how do we understand when we have adequately sampled the relevant neural activity for each behavior. How can we estimate that needed sampling in advance?

8:00 PM *F.FL02.01.02
Nanoporous Materials for Neural Interfaces Bozhi Tian; University of Chicago, United States

There is a pressing need for the development of novel materials-based tools that enable seamless biointerfaces across various spatiotemporal scales and can interrogate the nervous system with unprecedented resolution. Nanostructured materials have the potential of meeting the demands for next-generation devices given their small feature size, synthesis scalability, mechanical properties, and diverse signaling capabilities. Many forms of nanostructures, such as nanoparticles, nanowires/nanotubes, and nanomembranes, have been used for neural interfaces. They can enable electrical, optical, or magnetic interrogation of tissues, single cells, or even organelles.
In this talk, I will focus on nanoporous materials-based neural interfaces. The materials include nanoporous carbon membranes synthesized from micelle-enabled self-assembly, nanoporous silicon particles developed from nano-casting method, and nanoporous silicon membranes fabricated by wet chemical etching. They can deliver stimuli to cells and tissues through electrochemical, photothermal, and photoelectrochemical mechanisms. I will discuss the fundamentals and rationales of using the nanoporous structures for these studies, as well as diverse neural interface applications. Finally, I will discuss new materials and biological targets that could catalyze future advances.

5:15 AM F.FL02.01.02
Ultra-Low Friction Neural Probe Implantation for Long-Term Recording in Large Scale Brains Luizetta V. Elliott, Jialiang Lu, Doris Tsao and Julia R. Greer; California Institute of Technology, United States

Chronic reliability, and thus a reduced foreign body response, is key to realizing the promise of neural probe technology in applications such as brain-machine interfaces, connectome mapping and brain disorder investigations. A variety of flexible, low density probes with small footprints have been designed to minimize the foreign body response in mouse models. However, few are applicable to larger systems such as primate brains. Such implantations are challenging; probes must be inserted ~30cm into the brain, which could require ~100mN of force. Further, accurate targeting requires less than 2 degrees deflection and may involve repeated insertions during the up to 6 hour surgical procedure. Recent micro-scale characterization of insertion mechanics into brain tissue has demonstrated that, following an initial loading peak during tissue penetration, continued load increase is attributable to friction between the implant and the surrounding tissue. These forces often exceed the initial loading peak past 2mm of insertion, and are particularly relevant for large brain implantation. We therefore present a new strategy for reaching large brain targets with smaller probes: minimizing the coefficient of friction.

By minimizing the friction coefficient of the probe we can substantially decrease the insertion load and thus minimize the critical buckling load (P_{crit}) required for successful implantation. Since for an Euler beam with one free end $P_{crit}= \pi^2EI/4L^2$, this enables probes with smaller cross-sectional areas (lower moment of inertia I) and lower moduli E to be inserted to the target depth L without deflection due to buckling. To demonstrate this principle, we fabricated a carbon fiber/platinum insertion device with a muscle inspired polydopamine/ poly-2-methacryloyloxyethyl phosphorylcholine ultra low friction coating (previously reported coefficient of friction μ=0.02). We characterized the insertion properties of 84mm samples with a range of diameters (100-430μm) with and without the coating utilizing an agarose brain phantom model and a nm-precision stage. For probes with a 230μm diameter, we observed 1.4 +/- 0.5 degrees deflection in the coated samples compared to 6 .2 +/- 0.3 in the control, indicating a surgically acceptable insertion accuracy at decreased cross-sectional area. We further characterized these insertion properties through MRI following a realistic surgery in porcine brain tissue.

These results suggest that incorporating a thin (<50nm) friction-reducing coating into a neural probe delivery device can enable an overall reduction in probe cross-sectional area, and therefore the expected dead zone during insertion. Such insertion devices could enable the translation of neural probe technologies from mouse brain models to complex primate systems by effectively delivering electrodes to target areas with minimal damage. In particular, we envision shape memory polymer based electrode deployment from the tip of this device, enabling long-term recording outside of any minimized dead or encapsulated zone.

3D Neural Microphysiological Systems—Opportunities for Materials Innovation Michael J. Moore[1,1,2]; [1]Tulane University, United States; [2]AxoSim, Inc., United States

Microphysiological systems, also called organs-on-chips, are rapidly being adopted as advanced *in vitro* tools for modeling disease, development, and injury, and as high-throughput preclinical drug screening devices. Modeling the nervous system using such devices presents unique challenges owing to its complex hierarchical structure and organization, and its unique physiological role in information transmission and processing. Past designs of neural microphysiological systems based on microfabricated chip-based platforms and 3D neural organoids have limitations in their abilities to recapitulate appropriate cell-cell interactions, morphology, and functionality seen *in vivo*. Microfabricated platforms can provide specified tissue organization, but typically restrict cell biology to 2D configurations, which can alter cellular physiology. Conversely, self-assembling 3D neural organoids provide a more physiologically-relevant microenvironment but fail to represent macroscale tissue organization. Our laboratory has sought to advance neural organ-on-a-chip platforms that balance simplicity and complexity to recapitulate neural physiology for scientific discovery and drug screening. We developed and commercialized a 3D peripheral nerve-on-a-chip for drug screening that enables both physiological and histological evaluation in manners analogous to clinical evaluation. We have further developed relatively simple methods for assembling multiple neural tissue

types and shown the potential of this approach for modeling the transmission of physiological signals associated with pain. Recent efforts have been focused on the integration of these tissue systems with integrated microelectrode technology to enhance our ability to investigate the electrophysiological behavior of these model systems. In all of these endeavors, materials continue to serve as both enabling technologies and opportunities for innovation. Interestingly, these same model systems may serve as convenient platforms for testing novel neural interfacing materials and devices. In this presentation, I will highlight our advances in the development of neural microphysiological systems and discuss intersections with materials innovation.

5:40 AM *F.FL02.01.05
High-Performance Conducting Polymer-Based Direct Cellular and Tissue Interfaces for Electrical Stimulation and Recording Myung-Han Yoon; Gwangju Institute of Science and Technology, Korea (the Republic of)

Due to the trade-off between their electrical/electrochemical performance and underwater stability, realizing polymerbased, high-performance direct cellular interfaces for electrical stimulation and recording has been very challenging. We developed conductive direct cellular interfaces based on a water-stable, high-performance poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) film via solvent-assisted crystallization. The crystallized PEDOT:PSS exhibited excellent electrical/electrochemical characteristics, long-term underwater stability without dissolution/delamination, and good viability for primarily cultured neurons and cardiomyocytes over several weeks. Furthermore, the highly crystallized, nanofibrillar PEDOT:PSS networks enabled dramatically enlarged surface areas and electrochemical activities, which were successfully employed to modulate cardiomyocyte beating via direct electrical stimulation. Finally, the high-performance PEDOT:PSS was seamlessly incorporated into transparent microelectrode arrays and free-standing 3D fiber network-based interfaces for efficient, realtime recording of neuronal and cardiac tissue action potentials with a high signal fidelity. All these results demonstrate the strong potential of crystallized PEDOT:PSS as a crucial component for a variety of versatile bioelectronic interfaces.

5:55 AM F.FL02.01.06
Human Brain Mapping with Multi-Thousand Channels Reveal Functional Boundaries and Oscillating Wave Patterns at Submillimeter Resolution Youngbin Tchoe[1], Andrew Bourhis[1], Daniel Cleary[2], Karen Tonsfeldt[1], Brittany Stedelin[3], Ahmed M. Raslan[3] and Shadi A. Dayeh[1]; [1]University of California, San Diego, Korea (the Republic of); [2]University of California, San Diego (UCSD), United States; [3]Oregon Health & Science University (OHSU), United States

Clinical mapping of electrophysiological activity in the human brain is routinely used for delineating margins between functional and pathological tissue, for therapeutic applications and for brain-machine interfaces. Trade-offs between spatial resolution and cortical coverage, specificity in recording and contact impedance, conformity/compliance to brain curvature/movement and complexity of grid designs often limit the scalability and the potential use of brain mapping electrodes. In this work, we developed a scalable manufacturing process to realize human-compatible electrocorticography surface grids with thousands of channels. The 7” long cortical electrodes together with our sterilizable compact connector overcome challenges associated with the required large separation between the sterile surgical field and the non-sterile acquisition electronics enabling reliable intraoperative recordings from patients undergoing neurosurgical resections. The electrode diameter and pitch were adjustable providing a spatial resolution from micrometer scale to millimeter scale. Pt nanorod electrodes were used as contact materials and demonstrated low impedances at frequencies of interest for brain activity mapping.
The spatiotemporal recording capability of the electrode is investigated first with anesthetized rat model undergoing whisker air-puff stimulations using high-density 32×32 array electrodes with 150μm pitch and 4.8mm×4.8mm coverage. The spatial mapping of stimulation evoked high gamma activity (HGA) measured from the electrode clearly distinguished functional boundaries of individual whisker barrels at 150μm resolution.
We recorded from awake patients undergoing tumor resection while performing motor tasks with our grid placed on the motor cortex. The geometry of the array included a 46×44 array with multiple 30μm diameter contacts and 1.8mm spacing extending over an area of 8cm×8cm. Motion sensors and an accelerometer were attached to a glove worn by patients who performed finger flexion/contraction tasks between thumb and the other four fingers. The motion signals were time-locked to the recordings using our custom-made intraoperative monitoring system. Both local field potentials and broadband HGA showed distinctive neural correlates of fine-motor movements for different fingers when compared to baseline. Furthermore, we recorded phase reversal boundaries during motor mapping to precisely localize the central sulcus in sub-mm scale resolution. These results with our high-density grids offer an unprecedented view of the functional organization and coordination of motor function over large brain regions in the human cortex.

6:05 AM F.FL02.01.07
Scalable Penetrating Microwire Arrays with Flexible Substrate for Chronic Large Area Coverage Brain-Machine Interfaces Sang Heon Lee[1], Martin Thunemann[2], Keundong Lee[1], Youngbin Tchoe[1], Farid Azzazy[1], Anna Devor[2] and Shadi A. Dayeh[1]; [1]University of California, San Diego, United States; [2]Boston University, United States

We introduce sharp, needle-like Si-based neuronal probes on ultra-thin, biocompatible flexible substrates for penetrative, high-resolution, 3D mapping of brain activity. The flexible polyimide/parylene-C substrate carrier allows conformal adhesion to the cortical surface and embeds electrical leads for data streaming. We utilize optically transparent polyimide/parylene-C layer and Si substrates with conventional Si micromachining processes and double-side photolithography alignment in order to fabricate 3D Si micropillars on a flexible substrate. We report in this work two devices layouts. Device A consists of 32 individually-addressable, high aspect ratio pillars (wire-to-wire spacing of 400 μm, 6×6 array, L=100 μm and D=10 μm) on a sub-10μm thin flexible substrate. Electrode sensing sites at the tip of the pillars were engineered by coating Pt nanomesh structure which significantly increased the electrochemically active surface area of electrodes thus achieving sub-1MΩ electrochemical impedance in phosphate buffered solution (PBS). We demonstrated up to 196 days of reliable chronic implantation on mice and multimodal capabilities of the device with air puff stimulation-evoked activities from barrel cortex, optogenetically stimulated responses, and 2-photon intravascular imaging of the implant sites on the brain cortex. The scalability of this technology is shown by the preliminary recordings from Device B with 1024 microwire arrays (wire-to-wire spacing of 400 μm, 32×32 array, L=200-300 μm and sharp tips with sub-1 μm diameter) which holds the potential for large-scale, higher fidelity recordings for brain-machine interfaces.

6:15 AM F.FL02.01.08
Analysing the Cell-Electrode Interface—A State Space Time-Varying Model Towards 3D Geometrical Design Optimization Ugo Bruno, Anna Mariano and Francesca Santoro; Istituto Italiano di Tecnologia, Italy

The whole-cell patch-clamp technique is probably the most commonly used technique to record neuronal electrical properties. Although this approach provides maximum achievable quality for intracellular recordings, it does not provide a sustainable method for simultaneous recordings and it inevitably leads to cell dialysis and loss of the intracellular machinery that may be essential for the expression of certain biological functions. Neuronal *in vitro* extracellular electrophysiology, instead, commonly relies on recording techniques which monitor neuronal activity by means of electrodes placed in close contact with the cells at their extracellular domain [1]. Since the interface scenario between cells and electrodes clearly affects the quality of recordings, this interaction is classically investigated applying equivalent electrical circuit models. Although conventional modelling approaches provide insights on the role of multiple interface parameters, they yet limit the studied systems in specific conditions, thus producing numerical results that are valid only for a fixed set of variables [2], ultimately impeding the understanding of the interface mechanical dynamics. However, systems theory [3], as already employed to analyse biological systems [4] or to study the cell-electrode interface in the frequency domain [5], promises to overcome these limits providing a modelling platform for multiparameter dynamic analysis.
Moving from the base of classical electrical modelling frameworks to a novel interpretation of systems theory, a time-varying state-space model is presented, achieving a clear separation between non-linear spike-generation dynamics [6] and linear cell-electrode coupling, while also recovering interface dynamics. Here the systematic variation of multiple parameters allows to perform a simulated spike sorting and to follow a target recorded spike while changing the same coupling parameters over time. Hence, by screening different planar electrodes sizes, the recording detection limits for each specific situation are identified. Extending the approach to 3D electrodes, time-varying simulations are then exploited to highlight the effect of micro protrusions and shape-curvatures on the recorded signals. In this way, by continuously defining the electrical detection limits, a dynamic geometrical optimization is enabled during the electrodes 3D design.

Seeing the Sound—Mechanoluminescent Materials as a Deep-Tissue Light Source for Non-Invasive Optogenetics Guosong Hong; Stanford University, United States

Optogenetics, which uses light to control neurons genetically modified with light-gated ion channels, is revolutionizing neuroscience research by the precise deconstruction of neural circuits with neuron-type specificity. However, the poor tissue penetration of visible light has limited the application of optogenetics due to invasive craniotomy and intracranial implantation of obtrusive optical fibers or light-emitting diodes (LEDs). Here, we present a new form of deep-tissue light source based on mechanoluminescence nanoparticles, which can be delivered intravenously, recharged during circulation, and turned on and off by brain-penetrant focused ultrasound with millisecond precision. With this circulation-delivered nanoscopic light source, we have achieved non-invasive ‘sono-optogenetic’ stimulation of ChR2-expressing neurons in the intact mouse brain, successfully evoking hindlimb motion that was synchronized with the ultrasound pulses. Our approach provides an ‘inside-out’ light source anywhere and anytime inside the body at will, and we envisage that it can be used for any application that needs a light source deep in the body, such as in organs (e.g., spinal cord, heart and lungs) that are usually refractory to fiber implantation.

5:30 AM *F.FL02.02.03
Mirroring Action Potentials—Non-Invasive and Accurate Recordings of Action Potentials Francesco De Angelis; Istituto Italiano di Tecnologia, Italy

The recording of the action potentials in electrogenic cells plays a central role in many fields of research spanning from neuroscience to cardiology, cell biology and pharmacology. To this aim, many techniques have been developed both in research and in clinical applications. Broadly speaking they can be divided into two categories: direct electrical measurements performed with micro-electrodes (such as patch-clamp and multi-electrode arrays (MEAs)) and optical measurements collected from fluorescent reporters administrated to the cell cultures. However, regardless of the field of application some fundamental needs are still not met. For instance, methods based on electrodes can provide very accurate measurements but they require inserting the electrode inside the cell by porating the cell membrane. Hence, they are very invasive, thus reporting on a perturbed system. Furthermore, only a limited number of cells can be investigated (few cells for patch-clamp, thousands for MEAs). Even in the latest generation CMOS –MEAs, that aims to monitor hundreds of thousands of cells, the distances between the electrodes remain large with respect to cell size thus providing fragmented information. The latter issue can be overcome with optical methods which can record a million points on multiple scales with no fragmentation. However, dyes are well known to be cyto-toxic. Even if nontoxic, fluorescent dyes may bind to membrane receptors altering the response of the cells to the administered treatment in unpredictable ways. These are serious issues in many applications, for example to investigate compound toxicity in pharmacology. In this regard, cardio-toxicity and brain-toxicity of potential drug-compounds account for 60% of rejection cases during trials. This massive rejection rate significantly contributes to making the drug development process extremely expensive (now exceeding 2 billion per drug on

average) and extremely long (13 years on average). This example, as with many others in neuroscience and cell biology, necessitates **the need for developing new technologies providing non-invasiveness and large spatial scalability combined with accurate monitoring. Namely, the possibility of measuring both shape and duration of the action potential with precision approaching the one achieved in patch-clamp (intracellular).**
In this talk, we will show a radically new concept for monitoring action potentials in human cells that overcomes all of the mentioned limitations. It bases on the concept of "mirror charge" in classical electrodynamics: electric charges placed in proximity of a conductor affect its spatial charge distribution thus generating mirror charges into the conductor itself. Hence, by monitoring the dynamics of the mirror charges one can monitor the dynamics of the "source charges" and the related electric potential, i.e. the action potential. The latter can be done by using charged dyes whose dynamics can be monitored by conventional optical methods. However, being the dyes placed in microfluidic chip, separated from the cell culture, the cells are subjected neither to dye contact, nor to direct light illumination, but are in a perfectly unperturbed physiological state. Remarkably, the optical signal perfectly resembles an action potential (AP) even without the need of cell membrane poration as for conventional electrical recording. We reported a set of experiments on human-derived cardiomyocytes that uniquely support our statements.
The working principle can be extended to other nanostructures such as Quantum Dot or plasmonic particles. More in general, this new approach based on "mirror or virtual cells" paves the way toward a new family of in-vitro bio-devices that can lay a new milestone in the field of electrophysiology. Such an innovative configuration could inspire a new disruptive class of electro-optical sensors or hybrid devices for optical computing.

5:45 AM *F.FL02.02.04
Listening to Molecules—Functional Optoacoustic Neuro-Tomography for Scalable Brain Recording Daniel Razansky[1,2]; [1]ETH Zürich, Switzerland; [2]University of Zurich, Switzerland

Optoacoustic imaging is increasingly attracting the attention of the biomedical research community due to its excellent spatial and temporal resolution, centimeter scale penetration into living tissues, versatile endogenous and exogenous optical absorption contrast. State-of-the-art implementations of multi-spectral optoacoustic tomography are based on multi-wavelength excitation of tissues to visualize specific molecules within opaque tissues. As a result, the technique offers unmatched capacities for simultaneous visualization of structure (e.g., vascular anatomy, organ structure), function (total hemoglobin, oxygen saturation, blood flow, pH, metabolic rate of oxygen consumption), and molecular information (intrinsic bio-chromes, targeted agents, genetic reporters, sensors) from living tissues. Our recent work has established ultrafast functional optoacoustic neuro-tomography (FONT) technology to enable acquisition and visualization of spectroscopic information from the rodent brain at video rates. In this way, bulk changes in multiple hemodynamic parameters can be monitored non-invasively in whole mouse brains. We were also able to optoacoustically track neural dynamics using genetically encoded calcium indicators, thus overcoming the longstanding penetration barrier of optical microscopy in scattering brains. FONT captures hemodynamic responses and calcium fluxes as true three-dimensional information across the entire brain with 10 ms temporal and 100 μm spatial resolution, thus enabling large-scale neural recording at penetration depths and spatio-temporal resolution scales not covered with the existing neuroimaging techniques. Several hybrid imaging solutions have further been developed to support concurrent acquisition of various combinations of functional optoacoustic, ultrasound and fluorescence data as well as concurrent ultrasound stimulation of the brain.

5:00 AM F.FL02.04.01
Laser-Assisted Synthesis of Ceramics for Biointerface Studies Aleksander Prominski and Bozhi Tian; The University of Chicago, United States

Ceramics find many applications in electronics, optics, energy storage, and medical implants. Synthesis of ceramic materials conventionally requires hours long processing time in a furnace. While this classic technique allows for large scale fabrication, it is not suitable for high throughput screenings necessary for efficient material discovery. New methods, such as flash sintering, rapid thermal annealing, and ultrafast high-temperature annealing, have been developed to address this issue. These methods rely on fast energy transfer to achieve uniform heating within the substrate, provide stable synthetic conditions, and speed up the processing time. However, all these approaches provide relatively standard synthetic conditions and do not enable new phases and structures.

Laser processing can enable new materials, increase research throughput, and allow for the instant prototyping of new devices. Here, we developed a modified laser processing to produce an intense photothermal effect over an elastic matrix, which allows the fast ceramics formation with a laser power as low as 10 mW. Out-of-equilibrium nature of the process and complex strain relaxation at the synthetic interface between the soft substrate and hard ceramic product create hierarchical anisotropic micro-structuring of the material on the scale from nano- to micrometers. Beyond understanding the fundamental principles of this laser-assisted synthesis, we have also explored their applications as diverse biointerfacing materials.

5:10 AM *F.FL02.04.03
Electrodeposition of Platinum-Iridium Alloy on Carbon Fiber Electrodes James Weiland, Elena della Valle, Cynthia Chestek and Elissa Welle; University of Michigan, United States

Next-generation brain-machine interfaces may use thin-film metals or non-metallic materials (e.g. carbon) for electrical connection to the brain. However, thin-films are not robust to electrical stimulation and carbon does not form a low impedance electrode interface with neural tissue. Thus, improving the electrical and mechanical stability of carbon fiber microelectrodes is a major challenge facing this promising technology. Surface roughening can improve interface properties, while maintaining small geometric area for targeted recording and stimulation of local neural populations. A platinum–iridium electrodeposition process has been developed for carbon fiber microelectrodes to improve the interfacial properties. We study the coating effect on impedance as well as morphology and composition of the deposited film. Carbon fiber electrodes (6.8 micron diameter) with parylene insulation and an exposed tip of approximately 10 microns were coated with a film of platinum-iridium. Accelerated soak test in a heated (T = 50 degrees C) saline solution showed impedance variation of less than 8 % after 36 days (89 equivalent) of soaking. Compared to uncoated fibers, impedance modulus of carbon fibers coated with platinum-iridium was decreased (on average) by 96% at 10 Hz, 89% at 1 kHz, and 13% at 1 MHz, due to the high surface roughness of the platinum-iridium film. Loss of platinum-iridium film was noted in 3 of 43 electrodes after soaking. The small decrease in impedance at 1 MHz indicates that geometric area was maintained. SEM analysis confirmed that deposition was confined to the area with exposed carbon. Energy dispersive X-ray spectroscopy (EDS) quantified the percentages of platinum and iridium as ~ 70% Pt, ~30 % Ir on the surface and the film appeared uniformly deposited. Focused ion beam was used to cut the coated microelectrode for cross sectional analysis. The film was about 400 nm thick and mostly continuous with some cracks. EDS was performed on the cross section using scanning transmission electron microscopy. As with the surface analysis, the cross-sectional analysis showed a homogeneous distribution of platinum and iridium with relative percentages similar to the surface measurements. Electrodeposition of platinum iridium is a feasible approach to decreasing the impedance of carbon fiber electrodes.

Maleimide-Functionalized PEDOT Copolymers for Chemical and Biological Sensing Samadhan Nagane, Peter Sitarik, Yuhang Wu, Michael Boeri, Quintin Baugh, Junghyun Lee, Shrirang S. Chhatre, Vivek Subramanian and David C. Martin; University of Delaware, United States

We continue to investigate the design, synthesis, and characterization of functionalized poly(3,4-ethylenedioxythiophene) (PEDOT) for use in a variety of applications including neural interfaces, as well as chemical and biological sensors. Here, we will present our recent results focused on maleimide-functionalized PEDOT variants that provide us a wide range of novel opportunities for post-polymerization modification with particular biomolecules. These copolymers can be precisely deposited onto electrodes using oxidative electrochemical deposition methods. Of particular current interest to us are the development of new materials that show specific responses to such biological and chemical agents as proteins, peptides, neurotransmitters, and opioids. We examine the morphology of our materials with optical and electron microscopy, as well as X-ray and electron diffraction. We examine the physical chemistry with UV-Vis, FTIR and Raman spectroscopy. Information about electrical transport is obtained by CV, electrochemical impedance spectroscopy, four-point probe, and transconductance measurements.

Minimally Invasive Neuromodulation Through an In-Body Curing Injectable Electrode Kip Ludwig[1,2]; [1]University of Wisconsin-Madison, United States; [2]Wisconsin Institute for Translational Neuroengineering, United States

Stimulation of the peripheral nervous system through implanted devices, often referred to as bioelectronic medicines, electroceuticals, or neuromodulation therapies, is increasingly being used to treat a variety of diverse conditions including FDA approvals for pain, overactive bladder, obesity, sleep apnea, migraine, essential tremor, and hypertension. Unfortunately, the availability of neuromodulation therapies is usually limited to patients that have failed conventional treatments. This is largely due to the need for invasive implantation procedures and resulting surgical risk. we have developed a minimally invasive method for stimulating the peripheral nervous system through a syringe-injectable electrode which is delivered as a pre-polymer composite material and cures *in vivo,* with the goals of reducing surgical risk, increasing the availability of neuromodulation therapies, and enabling the development of novel therapeutic strategies,. This electrode, referred to as the Injectrode, can conform to complex target structures and is orders of magnitude less stiff compared to conventional neural stimulation electrodes.
This talk will cover our work developing the Injectrode, validating the material properties of the Injectrode, and our ongoing progress towards non-invasively interfacing with the Injectrode through a transcutaneous interface. This will include microscopic and electrochemical testing to assess the material properties most relevant to electrical stimulation of the nervous system mimicking FDA pre-clinical test requirements, as well as a comparison to clinical vagus nerve stimulation electrode. Dr. Ludwig will present a finite element model of the transcutaneous Injectrode concept, validated in a swine cadaver model, to investigate a method for non-invasively coupling to the Injectrode without use of an implantable pulse generator. Lastly, Dr. Ludwig will present feasibility studies in rats a swine showing stimulation of complex peripheral nerve anatomy, comparisons to a clinical nerve cuff electrode, and *in vivo* non-invasive coupling to the Injectrode. The ability to deliver the Injectrode through a minimally invasive procedure - as well as non-invasively couple to it without the need for an implantable pulse generator - will lead to reduced surgical risk and the potential for fewer failure points. As such, this technology fits an unmet need for less invasive stimulation systems and could lead to novel and more widely applicable neuromodulation therapies.

5:15 AM *F.FL02.05.02
Biodegradable Materials and Devices for Neural Interfaces Lan Yin and Liu Wang; Tsinghua University, China

Biodegradable devices represent an emerging type of electronics that can degrades in physiological environments and can therefore eliminate a second surgery for device retraction and minimize associated infection risks. Such devices could play a critical role in many therapeutic and diagnostic processes at neural interfaces, including promoting tissue regeneration, probing neurotransmitters, monitoring neural signals, etc. Herein, we introduce novel materials strategies and fabrication

schemes that enable a biodegradable and self-powered device for peripheral nerve regeneration. Successful nerve regrowth and motor functional recovery are realized in rodent models. Approaches detecting neurotransmitters and neural signals will also be discussed. These works will provide new insights for modulating and probing neural activities.

5:30 AM F.FL02.05.03
Flexible CMOS Neuroelectrode Thread Kyung Jin Seo[1], Mackenna Hill[2], Jonathan Viventi[2] and Hui Fang[1]; [1]Northeastern University, United States; [2]Duke University, United States

Techniques to study brain activities have been evolving tremendously, yet challenges remain in acquiring high throughput of simultaneous electrophysiological recordings. Here, we developed a soft neuroelectrode array that is on-site multiplexed. This novel array achieved up to 256 channels on a thin flexible substrate in only $2.3\times0.3mm^2$ area, enabled by on-site multiplexing from Si thin film transistors, and with the electrode size of only $238\mu m^2$, which is capable of measuring single-unit neuronal activity. The array showed high electrical performance of average SNR of ~71 dB with over 91% yield. Mechanical bending test of 10,000 cycles proved great robustness of the device. We used 1 transistor current sensing method to reduce aliased white noise and multiplexer charge injection of the active electrodes. Acute auditory experiments in mice successfully validated in vivo use of this array. Together, these results demonstrate the promise of this on-site multiplexed, soft, penetrating neuroelectrode array for neuroscience and neural engineering.

5:00 AM F.FL02.06.01
High Density Subdural Spinal Cord Microelectrode Arrays for Neuromonitoring and Neuromodulation Samantha Russman[1], Daniel Cleary[2,2], Andrew Bourhis[2], Joel Martin[2,2], Youngbin Tchoe[2], Sang Heon Lee[2], Joseph Ciacci[2] and Shadi Dayeh[2]; [1]University of California, San Diego, United States; [2]University of California San Diego, United States

Intraoperative neuromonitoring is a standard clinical practice in spinal cord surgeries as it is a detection method for neurological injury and helps limit postoperative impairments. Neuromonitoring is conducted by recording motor evoked potentials (MEPs) or somatosensory evoked potentials (SSEPs) via pulsed peripheral nerve or transcranial electrical stimulation (TES). These recordings are accomplished with electroencephalography (EEG) or electromyography (EMG), which require the use of large stimulation amplitudes (up to 1kV in TES and 60mA with peripheral nerve stimulation). Direct recordings from the spinal cord can reduce the stimulation thresholds required to detect neurological activity and provide another avenue for neural interface devices in the recovery from spinal cord injury. When performed with high channel count electrodes, direct recordings from the spinal cord can help to better localize pathologic spinal tissue. Standard clinical electrodes cannot provide intimate contact with spine and their spatial resolution is not suitable for these types of recordings.

Here we report and discuss the applicability of thin-film conformal and low impedance microelectrodes with hundreds of channels for neuromonitoring during spinal cord surgical resection and the potential translation of this technology to neuromodulation after spinal cord injury (SCI). We recorded from the pial surface of the spinal cord from patients undergoing an intramodular tumor resection during both transcranial and peripheral nerve stimulation. We recorded evoked potentials at subclinical threshold currents (as low as 4mA) for peripheral nerve stimulation compared to thresholds amplitudes (16mA) for clinical detection in these patients. The subdural placement permitted us to record activity that was otherwise missed with standard clinical and even high-density epidural electrodes. With the high channel count, we observed well-defined spatial variability depending on stimulus type: sensory versus motor and upper versus lower limb. Using these patterns, we investigated the applicability of our electrodes for neuromodulation after SCI via a brain-spine interface (BSI) by classifying sensory and motor events in the spinal cord. We took the first steps in performing such classification by using a supervised learning model to classify the applied stimulus type based on the spatiotemporal features of a single-trial recorded response. Taken together, these advances highlight the potential applicability of thin-film microelectrode arrays to transform neuromonitoring and to develop a soft subdural spinal cord implant for a BSI.

Structured Metallic Glass-Based Multimaterial Fibers for Efficient Neural Stimulation and Recording Wei Yan[1,2], Nicholas D. James[3], Inès Richard[1], Güven Kurtuldu[4], Giuseppe Schiavone[5], Jordan Squair[3], Reinis Ignatans[6], Stephanie P.

Lacour[5], Vasiliki Tileli[6], Grégoire Courtine[3], Jörg F. Löffler[4] and Fabien Sorin[1]; [1]École Polytechnique Fédérale de Lausanne, Switzerland; [2]Massachusetts Institute of Technology, United States; [3]École Polytechnique Fédérale de Lausanne, University Hospital of Vaud, and University of Lausanne, Switzerland; [4]Laboratory of Metal Physics and Technology, Department of Materials, ETH Zurich, Switzerland; [5]Bertarelli Foundation Chair in Neuroprosthetic Technology, Laboratory for Soft Bioelectronic Interfaces, Institute of Microengineering, Institute of Bioengineering, Centre for Neuroprosthetics, École Polytechnique Fédérale de Lausanne, Switzerland; [6]Institute of Materials, École Polytechnique Fédérale de Lausanne, Switzerland

Recent advances in techniques and methodologies for dissecting complex neural circuits are poised to unravel the function of neural networks and the underlying causes of neurological diseases[1]. Electrical stimulation of neural tissue and recording of neural activity play critical roles for our understanding of information transfer and processing within the nervous system. The traditional strategy for this purpose mainly exploits metal-based microwires that are mechanically and biologically incompatible with tissue. Recently, thermally-drawn multimaterial fibers that integrate electrodes and other modalities have emerged as promising tools for deciphering the neural circuitry in a unique way[2-4]. The development of in-fiber electrodes with low impedances, small feature sizes, arbitrary geometries and excellent electrochemical properties that allow for efficient both electrical stimulation and recording, however, remains challenging. Here we, for the first time, achieve such capability via thermal drawing of a peculiar material system — metallic glasses (MGs) — that is metallic yet exhibits disordered atomic-scale structure within a polymer matrix[5]. Thanks to the control over the interplay between fluid instabilities and crystallization dynamics, we are able to fabricate ultra-long MG electrodes spanning a wide size range from a few micrometers to around 40 nm. Designing the structures in a macroscopic scaled-up preform enables the fabrication of structured MGs with arbitrary transverse geometries previously unachievable. The electrochemical characterization reveal that these novel MG electrodes surpass in all accounts typical in-fiber electrodes including metallic or polymeric electrodes found in state-of-the-art fiber probes. The charge storage capacity is superior compared to typical metallic electrodes such as commercialized Pt and PtIr. The electrochemical stability is demonstrated by the long-term cyclic voltammetry and voltage transient cycles, is even on par with that of the state-of-art carbon nanotube and graphene fibers[5]. These merits can be attributed to the intrinsic microstructural homogeneity and isotropy of structured MGs. We demonstrate the unique applications of these fiber probes integrating multiple MG conductors embedded in a biocompatible polymer, and microfluidic channels for electrical stimulation and recording plus localized pharmacological manipulation in the deep brain of animals. Specifically, chronic experiments in rats show the ability to elicit robust behavioral responses when delivering electrical neurostimulation in deep structures, to record neuronal activity during unconstrained locomotion, and to deliver pharmacological agents to manipulate local circuits. Our MG probes are implantable, miniaturized and fully functional to form stable brain-machine interfaces in freely moving animals paving the way towards innovative long-term, multi-functional neuro-probes.

Miniaturized Ultrasound Transducers for Neuromodulation Hyunjoo J. Lee; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Neuromodulation of the central nerve system (CNS) and periphery nerve system (PNS) is promising next-generation therapeutics for many neurological disorders. Direct physical stimulation such as electrical, magnetic, optical, and acoustic is an alternative approach to a pharmaceutical approach. Among various modalities, ultrasound is an attractive modality that offers distinct advantages, such as high spatial resolution, in-depth targeting, mature technology on beam-forming, and substantial data on biosafety of ultrasound on human. However, as neuromodulation based on ultrasound is in the early stage of development, further investigations on neuromodulation mechanism, therapeutic effects, and optimum neuromodulation protocols are still required. Thus, many new technological advancements such as miniaturized devices based on

microelectromechanical systems (MEMS) technology have been recently introduced for the specific purpose of neuromodulation. In this talk, these new neurotools which are essential to uncovering the fundamental mechanisms of ultrasound brain stimulation and essential to developing an effective therapeutic means for brain disorders will be discussed. Specifically, this talk will discuss the development of miniaturized ultrasound transducers for small animal experiments and also our research efforts to achieve higher spatial resolution. The functionalities and potential applications of our systems will also be discussed. This research was supported by the Brain Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Science and ICT (2016M3C7A1904343).

5:35 AM F.FL02.06.04
Establishing Electrochemical Safety Limits for Clinical Stimulation Using Depth and Strip Electrodes in the Pig Brain Ritwik Vatsyayan, Daniel Cleary, Joel Martin and Shadi A. Dayeh; University of California, San Diego, United States

Clinically, the safety thresholds for electrical stimulation have long been empirically established by the Shannon's equation. The Shannon's equation models the charge injection needed to produce tissue damage but does not take into account the electrochemical safety limits for the stimulating electrodes. In this work, we investigated the electrochemical safety limits for bipolar current clamped electrical stimulation using Platinum based depth and strip macroelectrodes in pig cortical tissue. We contrasted these limits against those established by benchtop testing and investigated the observed differences.
To characterize these limits, we first measured the tissue impedance using a 4-electrode setup. This allows us to isolate the electrode-tissue impedance, which can be subsequently modeled in terms of resistive and capacitive circuit elements and used to analyze the voltage drop across each. We subsequently performed cyclic voltammetry measurements to establish the water window both in saline and *in-vivo*. In bipolar stimulation, the electrochemical safety windows are larger than the traditionally established -0.6V and 0.8V and is dependent on the geometry of the electrode.
We measured the voltage transients for both types of electrodes, using different current amplitude levels and pulse widths. This allows us to study the variation of the Charge Injection Capacity (CIC) for each individual electrode as a function of the pulse width. Our results show that the CIC is much lower in the brain, as compared to that calculated from benchtop testing. This is a consequence of the higher tissue-electrode impedance *in-vivo*. We developed basic circuit models that capture the complete electrochemical interface and can reproduce the experimental results with good accuracy. We compared these results with the clinical levels used for stimulation, especially those determined from the Shannon's equation, and found that the electrochemical safety limits established are lower than those used in clinical stimulation. These electrochemical limits are found to be lower than the reported tissue damage thresholds. We argue that the electrochemical limits and currents established experimentally in this study should therefore be considered the upper bounds for clinical stimulation.

Developing Next-Generation Coatings for Implantable Chemical and Electrical Interfaces for Neuromodulation Nathalia Peixoto; George Mason University, United States

For the last several decades the neural engineering community has developed biocompatible interfaces for modulating the central and peripheral nervous systems. Related to such development there has been an enhanced design for reliability and robustness in implantable devices. The impacted areas range from retinal implants to electrode coatings. In this talk I will focus on those two devices and designs. From finite element modeling that leverages experimental results and merges electrochemical data (impedance and cyclic voltammetry) to device testing in chronically implanted animals, I will present results from our lab that show how materials can be combined in order to achieve impedance matching for applications in stimulation or recording of neural activity.
The sensorial prostheses designed for human use have gone through several design cycles. In this talk I will present a background of both epiretinal and subretinal designs for implants, and how materials were adapted for such objectives. Not only deep brain stimulators took advantage of platinum and iridium metal coatings, also retinal implants provided valuable experimental and modeling data to guide further designs. One critical example, which I will discuss in detail, is how the impedance of different layers of the retina makes it impossible to specify a single cell when stimulating using epiretinal or subretinal implants, and how the recording is impacted by this same feature of layered brain structure. I will discuss options to overcome such limitations based on engineering design. Novel combinations of materials designed to match Young's

modulus of the target tissue or to bio-dissolve over time after implantation.
The second topic to be discussed in detail is the effectiveness of coatings to enhance robustness and reliability of chemical, optical, and electrical implantable interfaces such as electrodes and sensors. For example, combining high surface area with several coating materials allow us to keep electrode micrometric size while increasing the charge delivery and guaranteeing biocompatibility of the device.
Finally, I will present possible future developments in engineered devices for immediate applications in biomedical engineering, specifically in combining multimodal sensors and hybrid systems with electronics embedded.

5:15 AM F.FL02.07.02
Electrochemical Characterization of Nanotube Coating on Silicon-Based Microelectrodes Nathaniel Keri, Ian Sands, Pejman Ghelich, Libo Zhou, Wuxia Zhang, Nicholas Nolta, Will Linthicum, Bryan D. Huey, Yupeng Chen and Martin Han; University of Connecticut, United States

Microelectrodes can treat injuries and disorders such Parkinson's disease through electrical stimulation, and can be used as powerful tools to help us learn more about neurological functions through neural recording. However, the foreign body response (FBR) can contribute to microelectrode failure over long implant durations. After insertion, glial cells eventually surround the implant, decreasing neural adhesion. The inflammatory environment may also inhibit neural function. As published previously, Janus base nanotubes (JBNTs) are synthetic molecules with a double ring mimicking DNA G^C bases and a lysine side chain. They present a potentially greater degree of biocompatibility than many microelectrode materials, eliciting fewer negative responses from the body. This project involves applying these nanotubes to the surfaces of microelectrodes, while avoiding negatively impacting the electrochemical properties of the microelectrode itself. Other chemical and medicinal coatings have also been shown to elicit positive physical responses but tend to disrupt the electrochemical properties of microelectrodes.

Initial tests of JBNTs have been conducted on developed microelectrodes. The microelectrodes have 2.5 mm long silicon shanks, gold/platinum/titanium traces, plasma-enhanced chemical vapor deposition (PECVD) silicon nitride and silicon dioxide insulation, and electrode sites with areas 2000-4000 μm^2 made of iridium. The microelectrodes were coated with RNTs through dipping, and SEM was used to examine the nanotube distribution on the electrode surfaces.

The tubes aggregated on the surfaces of the electrode sites, forming bundles around the edges. Electrochemical testing showed charge injection values remained largely unchanged, as did the impedances at 1 kHz. The cyclic voltammograms showed similarly consistent results, indicating the nanotubes did not contribute to a significant alteration of the microelectrodes' electrochemical characteristics. Additional electrochemical testing is ongoing, with electrodes of different sizes and materials. We expect that someday, JBNTs may be demonstrated as an important component of highly biocompatible, long-lasting neural microelectrodes.

5:25 AM F.FL02.07.03
Implantable Aptamer Field-Effect Transistor Neuroprobes Towards *In Vivo* Monitoring of Serotonin in Mice Chuanzhen Zhao, I-Wen Huang, Zhixin Xie, Kevin M. Cheung, Hanxiang Wu, Wenfei Liu, Nako Nakatsuka, Hongyan Yang, Yan Cao, Paul S. Weiss, Qibing Pei, Harold G. Monbouquette and Anne M. Andrews; University of California, Los Angeles, United States

Monitoring neurotransmitters in vivo necessitates sensors that approach the spatiotemporal resolution of neuronal communication, while differentiating similarly structured neurochemicals with high selectivity. We have developed biosensors based on aptamers, coupled to ultra-thin In_2O_3 (~3-nm thick) field-effect transistors (FETs). These biosensors show high sensitivity and selectivity for serotonin and dopamine with femtomolar detection limits *in vitro.* To enable *in vivo* measurements*,* we miniaturized our sensor architecture to fabricate neuroprobes with arrays of aptamer-field-effect transistors. The initial prototype for an implantable microprobe is fabricated using micro-electro-mechanical systems (MEMS) technologies on silicon (150-µm thick). Each neuroprobe has lithographically patterned interdigitated gold electrodes deposited atop ultrathin, semiconducting indium oxide channels, where the shank is of 150-µm wide and 150-µm thick. Functionalization of the exposed semiconducting surfaces with neurotransmitter-specific aptamers facilitated electronic neurotransmitter sensing. Reducing individual FET footprints leads to an increase in the numbers of independent transistors on a single neuroprobe for multi-site/multi-target detection capabilities. We characterized target sensitivity ranges, detection limits, and sensor stabilities *in vitro* prior to conducting *in vivo* measurements. We assessed the biofouling of neuroprobes using *ex vivo* measurements in brain tissue homogenates. We also fabricated flexible neuroprobes using polyimide as substrates instead of rigid Si to reduce immunological responses. Shuttle devices were used to assist the implantation of flexible polyimide neuroprobes. We are now working on shuttle-free flexible neuroprobes with temperature-responsive

polymers, which are hard at room temperature for implantation and soft in the brain after implantation. Implantable aptamer-field-effect transistor-neuroprobes, including additional designs on flexible polymers, will enable *in vivo* detection of neurotransmitters in the brain with high spatial resolution and selectivity.

5:35 AM F.FL02.07.04
Development of a Microfluidic Neural Interface for Drug Delivery to the Brain Yoo Na Kang and Sohee Kim; DGIST, Korea (the Republic of)

Implantable neural interfaces can record neural signals and electrically stimulate neurons. Several neural interfaces integrated with additional functions such as optical stimulation and drug delivery have been introduced recently. Among various neural electrodes, needle-type neural electrodes, for example, the Utah electrode arrays, have been widely used in non-human primate (NHP) and clinical studies. However, drug delivery function for the needle-type neural electrodes has not been implemented yet because of their structural characteristics. We previously developed a neural interface based on a flexible penetrating microelectrode array (FPMA), which is a needle-type neural electrodes array. Here, we propose a microfluidic flexible interconnection cable (μFIC), which is capable of delivering drugs to the FPMA, resulting in drugs delivered to the implant site. The neural signal recording was performed while delivering drugs to the brain *in vivo* experiments using the fabricated neural interface. The KCl-evoked excitation signals of neurons in the rat brain were recorded during the KCl solution delivery. Approximately 50% of the electrodes detected an elevation of the number of spikes and amplitude.

5:45 AM F.FL02.07.05
Integrated Neural Implant with Transdermal Ionic Communication Zifang Zhao, Georgios Spyropoulos, Claudia Cea, Jennifer Gelinas and Dion Khodagholy; Columbia University, United States

High-density neural interfaces are continuously progressing towards seamless integration of brain and electronics. As more effort has been dedicated to implantable devices, effective and non-invasive data communication between the implant and outside electronics becomes a critical unresolved issue. Although radio-frequency (RF)-based communication can provide a wireless link with high bandwidth, RF circuits suffer from high power consumption, complex rigid circuitry for signal transmission, and wave reflection that limit their capacity for prolonged used inside biological tissue. There is a tremendous need for a safe, low consumption, high-bandwidth wireless communication method for use in neural interface devices. Here we propose a fully integrated, conformable, high-channel count neural interface device equipped with a high-speed ionic communication (IC) link. We implanted the device in rodents and validated its performance in acquiring chronic in vivo electrophysiological data from freely moving animals without any tissue extruding components. To achieve this, we first designed a conformable ionic communication circuit for transmitting and receiving ion based signals. We then characterized the performance of this ion-based communication in terms of its bandwidth, depth of propagation, and capacity for parallel transmission at different operating frequencies. Next, we designed and tested IC transmitter and receiver pairs with various geometries to better understand the key parameters defining bandwidth and stability of the ionic link. Lastly, we were able to integrate the optimized configuration of each subsystem into a compact, fully implantable device. The proposed ionic communication scheme and the resulting devices demonstrate concrete steps toward a high performance, fully implanted neural interface system with prolonged effective operation time in vivo.

Bioresorbable Materials in Temporary Implants for Neurostimulation, Sensing and Drug Delivery John A. Rogers; Northwestern University, United States

Bioresorbable electronic materials serve as the basis for emerging classes of biomedical implants with operational lifetimes designed to match those of transient biological processes. These devices provide important functionality during a relevant timeframe and then naturally disappear within the body, thereby eliminating the need for surgical extraction. This talk presents our latest work in this area, with emphasis on materials aspects of (1) platforms for wireless neuromuscular electrical stimulation, with demonstrations of alleviated muscle atrophy resulting from denervation in rodent models via multiple episodes of the distal nerve engagement and (2) devices for programmable release of drugs from multiple, independently

addressable reservoirs, with illustrations in insulin and lidocaine delivery in animal models for control of blood glucose concentrations and pain responses, respectively.

5:15 AM *F.FL02.08.02
Miniaturized Neural Implants Using Magnetic and Optical Biohybrids Jacob Robinson; Rice University, United States

Neural interfaces promise to deliver more effective treatment for conditions affecting the brain and body by improving the specificity and timing of therapies. While miniaturization in key to improve biocompatibility and safe deployment of these technologies, we must also improve the specificity of devices that sense and actuate biological signals. In this talk, I will describe on-going work to co-design genetically engineered cells and miniature magnetic/optical devices. These biohybrid technologies combine the speed and programmability of electronics with the biochemical specificity of synthetic biology. Specifically, we will describe how magnetoelectric and magnetothermal biohybrids enable rapid and precise actuation of cell activity, while planar imaging devices combined with computational reconstruction algorithms enable high-resolution measurement of biological activity. Together these technologies can enable future minimally and minutely invasive links between the body and external electronic devices.

5:30 AM F.FL02.08.04
The Windansea Probe—A Composite Surface/depth Electrophysiological Electrode and Multiphoton Interrogation for 3D Brain Mapping Keundong Lee[1,2], Martin Thunemann[1], Lorraine A. Hossain[1], Youngbin Tchoe[1], Jihwan Lee[1], Sang Heon Lee[1], Yun Goo Ro[1], Gyu-Chul Yi[2], Anna Devor[3] and Shadi A. Dayeh[1]; [1]University of California, San Diego, United States; [2]Seoul National University, Korea (the Republic of); [3]Boston University, United States

One of the grand challenges in neuroscience is to understand how neuronal activity is orchestrated to produce function. Single modality technologies offer either high spatial or high temporal resolution and with varied degrees of coverage. Multimodal approaches that can probe the brain's activity from the surface, at depth, and with high spatiotemporal resolution are believed to yield results that may complete our understanding of behavior and function. We report the seamless integration of the electrical and optical modalities for comprehensive and interactive 3D probing and manipulation of cortical neuronal activity and optogenetic (OG) stimulation/inhibition. Our "Windansea" technology, named after the famous Windansea beach in La Jolla, will replace the current cranial glass windows providing measurements of the extracellular local field potential (LFP) and multiunit activity (MUA), as well as a see-through optical access. The Windansea allows us to obtain depth-resolved LFP/MUA information, which can be used for estimation of spiking and synaptic activity in specific cortical neuronal populations, while simultaneously sampling electrical neuronal activity from the cortical surface and implementing single/multiphoton optical imaging and optogenetic stimulation/inhibition in behaving animals.

We leveraged microelectromechanical systems (MEMS) surface micromachining techniques to developed the hybrid surface-depth electrode. The depth electrode can be maintained inside the cortex chronically and does not block optical access. Therefore, both the depth and surface electrodes are flush with the cortical surface: The integrated depth e;ectrode in our device utilizes an inserter with a small neck-region (narrow-constriction) of SU8 that is sheared (thermally or mechanically) to separate the handle from the implanted portion of the depth electrode so that a chronic transparent cranial window can be placed on the cortical implant. The device was implanted chronically in mice for several weeks and we recorded electrophysiological signals and obtained single/multiphoton optical images in awake animals.

5:40 AM F.FL02.08.05
Flexible and Transparent Sensor Materials Toward a Fully Implantable Brain-Measurement System Teppei Araki[1], Shusuke Yoshimoto[1], Hiroki Hamanaka[2], Yuki Noda[1], Takafumi Uemura[1], Toshikazu Nezu[1], Shuichi Tsuruta[1], Masayuki Hirata[1] and Tsuyoshi Sekitani[1]; [1]Osaka University, Japan; [2]National Institute of Information and Communications Technology, Japan

A telemetric methodology can be used for conducting efficient and effective preclinical research in small nonhuman primates during free movement. In this study, we propose a fully implantable brain-measurement system using stretchable components and a small measurement instrument that wirelessly records brain potentials, stimulates neural activities, and recharges its own battery. When the integrated system was fully implanted in a marmoset, simultaneous measurements of the cortical and local field potentials were successfully performed during free movements. Even after a month of the implantation, the marmoset remained in good health and displayed activity equivalent to the amount before implantation. The results confirm that the proposed system is minimally invasive.

A sheet-type stretchable electrode fabricated using Au/Au core/shell nanowire (AgNW/Au) was used to measure the

somatosensory-evoked potentials after a few months of implantation. Antithrombogenic polymer treatment was introduced in the electrode to stabilize the monitoring, thus preventing the growth of granulation tissues that could interrupt access to the targeted neuron [1]. Furthermore, the sheet-type stretchable electrode showed mechanical durability at 60% strain and optical transparency over 80%. The multifunction simultaneously realized an optogenetic stimulation and in vivo brain ECoG monitoring. The integrated system is equipped with a micro-LED light irradiation system and is compatible with the optogenetic stimulation, which could contribute to brain–machine interfaces with a feedback sensation for diagnoses and therapy of patients suffering from intractable diseases [2,3,4].

5:50 AM F.FL02.08.06
Stretchable, Fully Integrated Organic Circuits for Chronic *In Vivo* Monitoring of the Developing Brain Claudia Cea, Georgios Spyropoulos, Jennifer Gelinas and Dion Khodagholy; Columbia University, United States

Investigation of neural circuits in the immature brain is critical to understand how brain functions emerge and can be disrupted. The developing brain undergoes significant structural and molecular changes postnatally, some of which are experience-dependent. Mice provide one of the most common and accessible methods to model the human brain and its disorders. However, longitudinal monitoring of high spatiotemporal resolution neural activity in small, fragile mouse pups as they develop from newborns to adults is currently not possible. Here, we propose a flexible, stretchable neural interface device that allows chronic *in vivo* acquisition of neurophysiologic signals during postnatal development. The high biocompatibility, conformability and ultralow thickness of the device allow it to be hosted in the body for a duration of at least 15 days without inducing tissue reactions. The probe is sufficiently flexible to match the low elastic modulus of the tissue and designed in a stretchable configuration to expand with the pup's growth via serpentine-shaped interconnects. An electrocorticography array (NeuroGrid) is placed on the cortical surface and each electrode is connected to a net of internal ion-gated organic electrochemical transistor (IGT)-based voltage amplifiers. The high speed and transconductance of the IGTs along with their independently gated activation create a scalable integrated circuit that amplifies and multiplexes the recorded signals. The interconnects elongate inside the subcutaneous space of the pup's back, and electrical contact pads placed on the back of the animal are sutured through the tissue to the backend electronics via conductive PEDOT:PSS fibers. This approach will enhance knowledge of brain development in health and disease.

6:00 AM F.FL02.08.07
Multifuncional Fiber-Based Probes as a Three-Dimensional Deep Brain Interface Shan Jiang[1], Dipan Patel[2], Jongwoon Kim[1], Shuo Yang[1], Williams Mills III[2,1], Yujing Zhang[1], Kaiwen Wang[1], Ziang Feng[1], Suijith Vijayan[1], Rebecca Cai[1], Anbo Wang[3], Yuanyuan Guo[3], Ian Kimbrough[1], Harald Sontheimer[2,1] and Xiaoting Jia[1]; [1]Virginia Tech, United States; [2]VTC Fralin Biomedical Research Institute, United States; [3]Tohoku University, Japan

Complex interactions between neurons in different brain regions have been studied using a variety of technologies including microwires, silicon-based multielectrode arrays, and electrode arrays with flexible substrates. Such technologies have been shown to provide high-resolution electrophysiological recordings with high signal-to-noise ratio. However, with single implantation, the physical properties of these devices limit their access to one, small brain region. To overcome this limitation, we developed a platform that provides three-dimensional coverage of brain tissue through multifunctional polymer fiber-based neural probes capable of interfacing simultaneously with neurons in multiple sites. A scaffold with helix hollow channels is employed to achieve the 3D expansion of the multifunctional fiber probes in the deep brain while a femtosecond laser micromachining technique is utilized to expose electrode recording sites, microfluidic channel openings, and waveguide windows along the single fiber branch. By using our 3D fiber probes, we have obtained chronic endogenous neural activities with single-unit resolution from the wild type mice and captured optically stimulated neural signals with chemical modulation from transgenic mice expressing channelrhodopsin-2demonstrate. Furthermore, varying electrographic brain activities from different brain regions of interest were detected by our customizable multisite 3D fiber-based neural probes in a mouse model of epilepsy, suggesting the potential of using these probes for the investigation of brain disorders such as epilepsy. Ultimately, we envision that this 3D multifunctional neural interface can bring new insights for deciphering complex brain functions and dynamics in the near future.

Off-Stoichiometric-Thiol-ene Epoxy Polymers for Soft Implantable Electrode Array Eleonora Borda, Marta Airaghi Leccardi and Diego Ghezzi; École Polytechnique Fédérale de Lausanne, Switzerland

Implantable electrode arrays have been widely used to treat neurological disorders such as Parkinson's disease, epilepsy, hearing loss, and chronic pain by applying electrical stimulation and/or recording neural activity. One of the main requirements for these devices is the ability to evoke minimal inflammatory tissue response to guarantee the long-term use of integrated functions. However, this can be limited by a mechanical mismatch between the implant, very stiff, and the tissue, very soft, inducing neural damages and leading to glial scar formation. So far, the most common materials used for fabrication of such neural interfaces are PI and PDMS. On one hand, thin-film microfabrication techniques allow the fabrication of flexible miniaturized and highly integrated stimulating or recording arrays in PI. However, the Young's modulus of PI is about a few GPa. On the other hand, PDMS because of its low Young's modulus (approximately 1 MPa) and its elastic behaviour leads to less damage to the neural tissue, but it presents challenging steps in the microfabrication process, especially for the encapsulation of the active sites. Off-Stoichiometric-Thiol-ene Epoxy polymers (OSTE+) were developed firstly for rapid prototyping of microfluidic chips because they are less permeable to gas. OSTE+ materials are a good compromise between PI and PDMS. In fact, by adjusting the stoichiometry of the constituting monomers, the Young's modulus of OSTE+ can be decreased down to a few MPa at physiological temperature. The preparation of OSTE+ consists of two curing steps in which (1) thiol-ene photopolymerization allows to pattern the polymer surface and remove the non-polymerized areas before (2) thermal curing. Thus, it is possible to encapsulate the electrode array simply using photolithographic techniques. Taking advantage of these properties, we fabricated OSTE+ implantable multielectrode arrays with Pt serpentines in monolayer and bi-layer. The functional characteristics of these arrays have been tested by electrochemical characterization and recordings.

F.FL02.09.02
Parylene-Based Double-Faced Electrode Array for Retinal Prosthesis Namju Kim, Heewon Seo and Sohee Kim; Daegu Gyeongbuk Institute of Science & Technology, Korea (the Republic of)

Retinal prostheses require high-density electrode arrays to attain high spatial resolution in vision. However, the transmission lines panning out in the same layer with electrodes may hamper achieving high-density electrodes. Double-faced electrode arrays may circumvent this problem, in which the electrodes and bonding pads are arranged face-to-face and the transmission lines are absent. The electrodes can be connected with stimulation drivers such as photovoltaic cells directly through bonding pads. Here we present the fabrication of a flexible and transparent parylene-based double-faced electrode array and the method of integrating it with the stimulation driver IC.

F.FL02.09.03
Transparent and Flexible Ultrathin Gold Microelectrode Arrays Using Layer-by-Layer Coated Polyelectrolytes for Electro-Optical Neural Interface Woongki Hong, Yujin Hwang, Junil Kim, Hyuk-Jun Kwon, Jae Eun Jang and Hongki Kang; DGIST, Korea (the Republic of)

In recent years, neural interface technologies have been focused on flexible and transparent neural electrodes for high spatiotemporal resolution mapping of neuronal activities using electro-optical measurements. There had been several new material suggestions for the transparent, flexible neural electrodes such as ITO, graphene, conductive polymer, or patterned metal (nanowires, mesh patterns).**[1, 2]** However, these materials have shown several limitations such as high processing temperature, limited mechanical/electrical reliability, fabrication complexity and incompatibility with conventional microfabrication processes etc. To resolve these problems, in this work, we developed a flexible microelectrode array (MEA) using polymer-metal hybrid structures for high optical transparency and good electrical conductivity.
We used layer-by-layer assembly of polyelectrolytes as a nucleation inducing coating layer on transparent substrates (glass, polymer) to realize highly conductive vacuum deposited gold film at sub 10 nm thickness. We optimized the electrical and optical properties of the ultrathin gold electrodes, showing sheet resistance as low as 7.24 Ω/sq at 8 nm thickness and electrical conductivity of 1.327×10^6 S/m. Despite the opaque characteristic of typical thick gold film, the ultrathin film of gold in this work still showed optical transparency of 77% at 550 nm, which is comparable to or better than most of

transparent neural electrode materials. In addition, excellent mechanical stability is also demonstrated with bending radius down to 1 mm for at least 500 times of bending. We further measured the baseline noise properties of our ultrathin 40-µm diameter gold MEA for *in vitro* neural recording setup. We have confirmed that it shows low RMS noise level of 9.62 ± 2.24 μV_{rms} (n=60, bandpass filtered in 200 Hz – 3.5 kHz). These results confirm that the polymer-metal hybrid structure based MEA we developed in this work can be used for simultaneous extracellular electrical neural recording and optical neural recording such as calcium imaging.

F.FL02.09.04
Bioresorbable Endovascular Neural Interface for Minimally Invasive Neural Stimulation and Recording Adele Fanelli, Laura Ferlauto and Diego Ghezzi; EPFL, Switzerland

Neural signal recording and direct stimulation of the brain have been widely used to mitigate neurological disorders, such as epilepsy and Parkinson's disease. Current available techniques in this field commonly require invasive surgery potentially entailing both transient and permanent complications. A promising strategy designed to overcome these risks involves the exploitation of the cerebrovascular system as access route to the neural tissue. Cardiovascular stent technology, exceptionally designed for a minimally invasive procedure and maximum adherence to the vessel wall, represents an optimal scaffold for the recording/stimulating system. Moreover, given the versatility of this type of implant, peripheral nervous system could also be targeted for neural stimulation aimed at relieving intractable pain or supporting motor rehabilitation. Therefore, our goal is the development of a stent-inspired device, with electrodes embedded on its surface facing the vessel walls, for minimally invasive active and passive interaction with the surrounding neural tissue. In order to reduce the possibility of chronic local inflammation and delayed endothelialization, commonly occurring with metallic implants, our device has been fabricated using only biodegradable and biocompatible soft polymers such as poly-ε-caprolaptone (PCL) and (3-glycidyloxypropyl)trimethoxysilane-doped poly(3,4-ethylenedioxythiophene) : poly(styrenesulfonate) (GOPS-doped PEDOT:PSS), for encapsulation and electrodes respectively. Electrochemical properties of the prototypes have been tested in both static and dynamic conditions, with the latter simulating the vascular environment and its pulsatile flow. Degradation analysis in vitro has been performed as well to define the device durability. The promising results open the doors to further investigation of the potentialities of this innovative device, able to replace invasive systems currently used for neural recording and stimulation. Its development will have a huge impact in the treatment of neuropathological conditions related to both central and peripheral nervous system.

F.FL02.09.07
Enhanced Antioxidant Activity of Cerium Oxide Nanoparticles by Surface Modification and Their Potential Application for Mitigating Foreign Body Response in Implantation of Active Chronic Medical Devices Yue Hu, Vicki L. Colvin and Vivian Ling; Brown University, United States

There are roughly 175,000 different medical devices in the US market. The global market for medical devices grows fast yearly, it reached nearly $521.2 billion in 2017 and should reach $674.5 billion by 2022, at a compound annual growth rate (CAGR) of 5.3% for the period of 2017-2022. Some relevant examples include joint replacements, cardiac pacemakers, hernia meshes, subcutaneous real-time glucose sensors, and neural recording devices. An important and growing subset of these devices termed here 'active' implants, require electrical contact to tissues. Their function demands that they have long-term electrical contact to host tissue; perhaps the most widely known example is cardiac pacemakers now found in over 235,000 people in the US alone. Important emerging disease treatments, however, also rely on active medical devices including subcutaneous glucose sensors and neural recording devices. In the case of glucose sensors, the real-time information can drive both dietary choices and mitigate Type 2 diabetes or be part of an automatic insulin delivery system that frees patients with Type 1 diabetes from self-administered insulin injections. In these cases, the implant must stay functional and non-changing in their tissue interactions for years.
Every medical device that is implanted in a person encounters the body's foreign body response (FBR) which in short results in the body physically walling off an object from its physiology. Initially discovered in the 1970s, this multi-stage process is initiated by the innate immune system upon the introduction of foreign material. After injury and implantation, FBR activated by blood/material interaction, followed by protein adsorption, immune cells adhesion, activation, and differentiation. The whole process undergoes acute inflammation, chronic inflammation, the generation of granulation tissue and end up with the

fibrous encapsulation generated by FBGCs. Foreign body response (FBR) triggered by the implantation of medical devices limits the lifespan of devices.
One of the widely used solutions is to suppress the immune system response to medical devices. Reactive oxygen species (ROS) generated during the FBR process play a key role in immune responses to implantation. ROS are generally linked to aging, cancer, and nervous system diseases. Anti-inflammatories and antioxidants, such as nonsteroidal anti-inflammatory drugs (NSAIDs), dexamethasone, masitinib, and resveratrol have been combined with implantable devices in local delivery to fight against FBR. However, molecular antioxidants are facing several problems, such as short lifetime, instability in micro-environment, and ineffectiveness induced high doses, limiting the chronic efficiency of implanted devices. Nanoparticles, well known with their high surface to volume ratios, are widely used in biomedical engineering these days. Cerium oxide nanoparticles exhibit recyclable antioxidant properties due to facile electron transfer between Cerium (III) and Cerium (IV). Recent studies reveal that ceria nanoparticles with diameters of 5 nm are non-toxic and efficient for quenching ROS in vivo. We developed a PEGylated polymeric ceria nanoparticle which is stable and biocompatible. We also observed that the antioxidant activity of cerium oxide nanoparticle is enhanced by this PEGylated surface modification which can be widely used in vivo to control the ROS levels at the implant site and relief FBR.

Nanomaterials for Large Area Flexible Electronics and Small Area Ultra-Compact Microdevices Oliver G. Schmidt; Leibniz IFW Dresden, Germany

Nanomaterials in the form of nanomembranes are thin, flexible, transferable and can be shaped into unique 3D micro and nanoarchitectures. This makes them attractive for various scientific disciplines ranging from «Electronic Soft–Wear» to «Microrobotic Hard–Ware». This talk explores the underlying science of nanomembranes and discusses the fascinating application potential of this particular class of nanomaterials ranging from integrated microelectronic skin [1] and self–assembled 3D microelectronics [2] to medical microbots [3] and the world's smallest self–propelled microelectronic systems [4].

Flexible Inkjet-Printed Nanoparticle-Based Supercapacitors—Effect of Substrates, Printing and Materials Maxim Shkunov and Pavlos Giannakou; University of Surrey, United Kingdom

Inkjet printing is highly promising fabrication technology for electronic devices, including energy storage systems, due to the fact that is an industrially mature, readily scalable, low-cost, digital, contactless and mask-free method with roll-to-roll capability, minimal processing steps and minute quantity of material waste. Solution-processing of nanomaterials in printed electronics via ink-jet allows for very efficient integration of different types of nanoparticles in electrochemical energy storage devices. However, it is important to address the challenges associated with the variation in printed layers properties and to investigate the effects of printing including substrates, materials, printing and processing on the electrochemical performance and response of the devices.
In this work, we have fabricated and characterised flexible, fully solution processed, co-planar, NiO-nanoparticle-based, micro-supercapacitors through inkjet printing. Cyclic voltammetry studies were performed to investigate the effect of substrate and printing resolution, different types of current collector silver inks, sintering temperatures and carbon residues in electrodes, different types of electrolytes, including liquid and gel electrolytes, binders and other organic compounds in electrolytes, and the effect of electrode gaps on the electrochemical response and capacitance of supercapacitors. The devices were prepared on flexible polyethylene terephthalate (PET), polyimide Kapton substrates and photographic paper. Two types of silver nanoparticle inks have been used as the current collectors in the devices. A NiO nanoparticle ink was developed and has been used in different concentrations as the active electrode material in the devices. Aqueous solutions of sodium hydroxide (NaOH), sodium nitrate ($NaNO_3$), lithium hydroxide (LiOH), potassium hydroxide (KOH) and saturated magnesium perchlorate aqueous solution (SMPAS) have been used as electrolytes, either in liquid or gel form at different concentrations. The devices were scanned at voltage a window from 0 to 1 V, at scan rates from 10 to 1,500 mV/s. Capacitance has varied significantly depending on the substrate, printing resolution and the use of electrolyte and scan rate. Some of the highest capacitance values of 117 F/cm^3 at 10 mV/s were obtained on PET substrates. XPS measurements of carbon residues in active layers have been correlated with sintering temperatures and supercapacitors performance.
Highly flexible, inkjet-printed supercapacitors, with a particular focus on wearable applications, are finally demonstrated as epidermal printable supercapacitor, water-transferred on the skin of a human subject, to potentially serve as the power source for wearable health systems.
We will discuss the summary of results on the effects of substrates, printing, sintering, choice of materials on microsupercapacitors performance and outline how these results can be extended to flexible electronics, realised through printing fabrication processes, including wearable devices, batteries and energy generation-and-storage systems.

5:25 AM F.FL03.01.04
Printing Conformal 5G Antennas and Waveguides—A Material and Design Analysis Bradley J. Pothier, Katherine Berry, Eric Brown, Edward Kingsley, Craig A. Armiento, Alkim Akyurtlu, Gary Walsh and Corey Shemelya; UMass Lowell, United States

With today's fast-paced research environment, a need is being established to bring new form-factors to new and existing technologies. One such technology RF antennas, systems and components. For this reason, it is beneficial to examine communication components and adapt their design paradigms for advanced manufacturing techniques; in this case to develop 5G antennas and waveguides in a flexible or 3D printed form factor. Our work at PERC has extended state-of-the-art printed electronic technologies beyond simple circuits, and into RF antennas and sub-systems; while also allowing IC integration with conformal/flexible designs. RF devices such as Bluetooth boards, conformal RF antennas, and planar phased array systems, have been fabricated using printed electronic technologies to allow everything from wireless external communications to phased array tracking systems [1,2].
This project investigates additively fabricated conformal 5G (6 GHz) antenna designs and their performance when printed on the conformal surfaces. Design factors such as antenna type, orientation, and RF properties are considered. Here we analyze waveguide designs such as grounded co-planar, co-planar, and microstrip for conformal single-layer and multi-layer designs. As such, we explore multiple printable material systems including: silver nano-inks, thin-flexible laminate boards, and Kapton polyimide films, in order to determine potential systems that satisfy both functionality and manufacturability requirements. Our initial designs utilize direct-write micro-pen dispensing systems in order to develop a tool-box for printed material systems which can then be applied to the Optomec 5X 5-axis direct-write system. All antenna designs (planar and conformal) are simulated in ANSYS HFSS to ensure printed, conformal layer thickness and feature sizes produce an optimal antenna response. Additionally, this work investigates potential antenna performance characteristics in relation to system longevity and durability. For example, the adhesion between printed layers to potential end-use conformal material systems, as well as the effectiveness of RF-transparent polymeric layers for ruggedization. As such, all designs are modeled to incorporate spray-coatable fluoropolymer coatings. This work describes problems that reside in conformal RF applications

such as retaining printing accuracy and compensating for the rounded shape and functional properties of the surface.

5:35 AM F.FL03.01.05
The Large-Area Printing of Bending-Insensitive Pressure Sensors Achieved by Monodisperse Carbon Particles with Flower-Like Superstructures Naoji Matsuhisa[1,2,3], Stephen J. O'Neill[2,4], Huaxin Gong[2], Shucheng Chen[2], Hanul Moon[2,5], Hung-Chin Wu[2], Xianfeng Chen[4], Xiaodong Chen[3] and Zhenan Bao[2]; [1]Keio University, Japan; [2]Stanford University, United States; [3]Nanyang Technological University, Singapore; [4]The University of Edinburgh, United Kingdom; [5]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

We demonstrate a bending-insensitive pressure sensor with extremely high sensitivity (2×10^5 kPa^{-1}) by the simple blade coating of a composite containing carbon flowers. To date, highly sensitive pressure sensors have been fabricated by molding microstructures such as pyramids and domes. The printing of conductive particle:elasotmer composites does not require any molds, and can simplify the fabrication. However, composite based pressure sensors have suffered from poor flexibility and large-area uniformity. This is because the percolation-based sensing mechanism can be easily influenced by the composite thickness, requiring a considerable thickness for high sensitivity. Our composite is made of an SEBS elastomer and monodisperse carbon particles, which have flower-like superstructures and can be synthesized at very low cost (carbon flowers) [1]. The unique structural properties of carbon flowers enable a contact-based pressure sensing mechanism to achieve extremely high sensitivity which is insensitive to the printed thickness. The active layer can be as thin as 13 μm thickness, which to our knowledge is the thinnest among printed pressure sensors. The capability of pressure sensing was investigated under several bending radius down to 5.5 mm and showed consistent characteristics, although most previously reported pressure sensors have only been tested in a flat state after bending. Furthermore, we printed a pressure sensor over a substantial area (1 m × 2 cm), over which the sensors showed significantly uniform pressure sensing characteristics. This is achieved by the contact-based sensing mechanism that is robust against thickness variation across the large area printed composites. Our sensor demonstrates both high pressure sensing performance and high scale-ability, which is extremely suitable for applications in human-machine interfaces, healthcare, and Internet of Things (IoTs).

5:45 AM F.FL03.01.06
Digital 3D Printing for the Fabrication of Integrated Mechanical Sensors within Soft Personalized Wearables Ryan van Dommelen[1], Marco Riccardo Binelli[2], Yannick Nagel[3], Gilberto De Freitas Siqueira[3], André R. Studart[2] and Danick Briand[1]; [1]École Polytechnique Fédérale de Lausanne, Switzerland; [2]ETH Zürich, Switzerland; [3]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

The ultimate autonomous smart wearable device is one in which all parts are seamlessly integrated. One of main benefactors of these devices is the health sector. As currently the tools available for the evaluation of a patient’s recovery are limited to either bulky stationary equipment, or non-customized wearable devices. Therefore, with the recent strong progress in the field of 3D printing it is now more than ever possible to 3D print completely customized objects on the fly. Especially due to the digital nature of the fabrication tools used, wherein the overall process is called digital manufacturing, it is possible to adapt a general device layout for a patient's needs. Especially of interest here is that these 3D printed, and custom-tailored devices could be worn to continuously monitor the gait and joint motions of a patient during recovery. Currently this is something that often can only be measured in a specialized room within an hospital. Furthermore, the usage of 3D printing tools allows for the fabrication of more complex geometries, and functional layers not possible to produce with more conventional methods. These advantages can be exploited to introduce smart features into other 3D printed objects as well.

One of the key challenges for the full exploitation of these technologies is the integration of the printing of functional layers within a repeatable process chain. The main bottleneck being currently that the range of 3D printable materials is often limited to either hard or non-flexible materials, let alone functional ones. Therefore, we have developed and are continuously improving an elastomeric material system that is fully printable using Direct Ink Writing (DIW). Our material system is created by making use of natural cellulose based fibers to be able print self-supporting soft structures. This system thus makes it an ideal candidate to produce truly three dimensional and fully soft wearable devices with a high degree of comfort. In parallel, we are exploiting the use of a custom made 5-axis multi-tool printing platform to be able to directly print multiple materials on curved surfaces. This platform is driven by software that allows for on the fly modifications to the input model,

which has resulted in a early stage approach towards personalization of our sensing devices. With the multi-tool capability, it allows us to perform all production step within the platform.

Accompanying this, we have so far investigated the fabrication of piezoresistive, capacitive and triboelectric mechanical sensors made from our materials system. These sensors have been tested in both ideal circumstances, using mechanical test benches to compress and bend the sensors, as well as by actual human motions. We will present their evaluation by means of simulated and non-simulated human motions. The simulated evaluations were performed using static compression tests, up to 1000 kPa, and dynamic compression tests, up to 2 Hz. The hysteresis characteristics of the sensors were also found using the mechanical test benches.

At this stage, we are exploiting these results to integrate the sensors into a wearable demonstrator. By using our 3D printing technologies, we also show that we can print structures in three dimensions to create geometries which are not possible or unfeasible with conventional technologies. This approach, which uses our material's inherent self-supporting ability, allows for the miniaturization of 3D printed structures. Using this we can create more compact sensors with improved responses, as well as enable multi-modal sensing. All these factors combined allow for the fabrication of truly novel fully 3D printed sensors. Since these sensors are produced in a completely digital fashion, they can be fully personalized for each person, while using the same printing infrastructure.

5:55 AM F.FL03.01.08
Inkjet Printing Electronic Materials on Polymeric Platforms for Flexible and Wearable Electronics Inhwan Kim, Ying Zhou and Jesse S. Jur; North Carolina State University, United States

Inkjet processing is a promising method for printed electronics for flexible and wearable electronics, allowing for nano- to micron-scale films with low temperature processing. In this work, we explore process engineering of inkjet printing electronic films and textiles (e-textiles) with the application of multi-layered conductive, dielectric, and semiconductor materials. Considering fluid characteristics and jetting parameters, electronic inks were formulated based on common inkjet processing conditions of low viscosity (<25cP) and 25-50 dyn/cm of surface tension. Particle-free reactive silver inks based on silver carboxylates ($Ag^{+}{-}O_2C{-}R_1$) and aqueous ammonia ligand ($-NH_2/-NR_2H$) was processed both on films and textiles. The quality of the patterns was able to be controlled by the drop spacing variation (5-200 μm) with consideration of a single drop size (~50 μm). After low-temperature annealing process (150°C), the low sheet resistance of <0.5 Ω/sq was achieved by print resolution of 1693 dpi (15 μm drop spacing) - 2540 dpi (10 μm drop spacing) with only one print pass. The dielectric ink was formulated by the equal mass ratio of poly(4-vinylphenol) (PVP) and poly(melamine-co-formaldehyde) (PMF) in propylene glycol methyl ether acetate (PGMEA) solvent. Cross-linking process with UV and thermal annealing (150°C) after the inkjet process of the PVP/PMF dielectric ink as an insulator of the conductive silver layer. The inkjet processed reactive silver ink on the dielectric layer kept the dielectric layer compatible, showing potentials as the insulating materials for capacitors and transistors. In addition, p-type semiconductor ink with 6,13-bis(triisopropylsilylethynyl)-pentacene (TIPS-Pentacene) and polystyrene blend in tetralin was able to be inkjet printed on the flexible substrates to demonstrate the compatibility with the conductive and dielectric inks within the multi-layer device architecture via inkjet processing. Our study highlights viability of fully-inkjet processed flexible electronics in wearable technology applications.

6:05 AM F.FL03.01.09
Printing of Dielectric Particle Enhanced Textiles for Antenna Designs Ying Zhou[1], Braden M. Li[1], Chunxu Mao[2], Yuhao Wu[2], Inhwan Kim[1], Henry Soewardiman[1], Douglas Werner[2] and Jesse S. Jur[1]; [1]North Carolina State University, United States; [2]The Pennsylvania State University, United States

Printing methods are rapidly being developed for the improvement of fabrication efficiency in electronic devices, particularly in the field of electronic textiles (E-Textiles) of particular interest has been the formation of high efficiency antenna devices that provide a means for body area networking and data transfer. This work details a novel fabrication process for flexible textile antenna by a combination of the direct writing printing to enhance the dielectric properties of the textile. Using a direct write process, an ink consisting of a UV curable monomer with 4 wt.% 200 nm barium titanate nanoparticle loading is embedded within fabrics to enhance the dielectric constant of the naturally air porous textile architecture. This method is demonstrated to be universal for all kinds of the fabric, include nonwoven, woven, and knit fabric types. By controlling the spray parameters (time and translation speed) of the ink, the dielectric constant can be increases to 1.4 - 1.6 without significant blockage of the air gaps in the fabric. In this way, the flexibility and air permittivity of the fabric has minimal change. As a demonstration, the dielectric ink is applied to enhance the permittivity of a jersey knit fabric panel, allowing for a simplified manufacturing process for these traditionally complex e-textile systems. Combinations of nonwoven and knit layering through heat lamination is shown to provide the necessary structure for the antenna device with a conductive Ag

screen print active and ground layers with a conductivity of 1.3 *10^6 S/m. The methods explored are extended to a novel dual-port textile antenna aimed at 2.45 GHz with a low height profile and enhanced bandwidth for wearable applications, exhibiting a working bandwidth of 2.32 -2.45 GHz.

6:15 AM F.FL03.01.10
Thermoresistive Properties of Vapor Printed PEDOT-Cl Coated Fabrics Linden K. Allison and Trisha L. Andrew; University of Massachusetts at Amherst, United States

Fabric-based circuits are an important component of developing wearables. Thermistors have proven to be a difficult factor to measure accurately using a fabric. Temperature sensing is an important part of health monitoring, as abnormalities could signal conditions such as fevers, infections, or heatstroke. Early detection of these temperature deviations can lead to more effective treatments. Currently, methods of monitoring body temperature are either invasive or inaccurate, since accurately measuring the temperature of the body's core is difficult to do from the surface of the skin. Additionally, temperature sensing could prove useful in other forms of health monitoring when paired with other types of sensors, such as humidity sensors. Herein, we demonstrate a technique to produce an all fabric, wearable thermistor. Using reactive vapor deposition (RVD) we produce a thermoresistive coating of PEDOT-Cl on a variety of commercially available fabrics. We show that the thermistive properties and sensitivities of the coatings can be tuned by using different weave porosities, fabric thicknesses, and fabric materials. We further explore the response of the PEDOT-Cl fabrics when subjected to varying humidity, or the hygro-resistivity, and how this can influence the thermo-resistivity of the coated fabrics. Additionally, we utilize these coatings to create a wearable device, capable of sensing body temperature. By measuring the temperature of several key locations on the body, the temperature of the core can be monitored. This work provides a platform to monitor body temperature in a non-invasive and comfortable way. We also use the PEDOT-Cl coated fabric to demonstrate how the thermo-resistive and hygro-resistive responses can be combined to measure breathing when incorporated into a face mask.

6:25 AM F.FL03.01.11
Continuous Pilot-Scale Production of High-Performance Multifunctional Paper Based Sensors for *Internet of Things* Applications Sheila Goodman and Anthony Dichiara; University of Washington, United States

The growing demand of wearable technology has caused a resurgence of paper-based flexible electronics, offering a biodegradable and low-cost alternative to petrochemical substrates. In this research, "smart" papers were produced from renewable pulp fibers using a pilot-scale web former operated at 4 m/min. The surface of bleached softwood fibers was modified *in situ* by electrically conductive carbon nanotubes pre-adsorbed with cellulose nanofibrils during the papermaking process. The interfacial properties were tailored based on a layer-by-layer nanoassembly method, enabling good retention and uniform distribution of nanofillers in the sheet even at high content (up to 15 wt%). The as-produced multifunctional smart papers were employed as an inexpensive and sustainable alternative for various chemical and physical resistive sensing applications. An Internet of Things (IoT) device was fabricated utilizing an affordable microcontroller and simple circuit to rapidly and reliably detect variations (temperature, pH, chemical presence) in aqueous media for over thirty response cycles, with a maximum relative resistance increase of ~12,000%. This device was able to detect the presence of small volumes of water, as low as 0.5 µL, and the presence of water in organic solvents as low as 0.10 wt%, allowing for immediate signaling in circumstances where high water contents are intolerable. Electrical resistance changes remained stable and reversible in impure aqueous solutions, including tap water, and across a range of saline water concentrations which varied from 0.1 to 1 wt% NaCl. As-produced smart papers were successfully implemented as a piezoresistive device which demonstrated a wide sensitivity range (6 Pa~500 kPa) and low detection limit, with applications in gait and respiratory sensing. The versatility and efficacy of as-produced smart papers allows for a low-cost and biodegradable replacement for petrochemical substrates in multifunctional sensing applications.

6:35 AM F.FL03.01.12
Late News: Electrowetting Valves for Sweat-Based Microfluidics Aditi Naik[1], Brenda Warren[1], Andrew Burns[2], Ralf Lenigk[2], Jeffrey Morse[1], Azar Alizadeh[2] and James Watkins[1]; [1]University of Massachusetts Amherst, United States; [2]General Electric Global Research Center, United States

Skin-compatible microfluidic valving systems with on demand sweat capture are necessary to understand the temporal variation of chemical biomarkers. Here, we demonstrate solution-based electrowetting valves with rapid actuation integrated into a flexible microfluidic sweat collection patch. The valve is produced by inkjet-printing a pair of silver electrodes with spacings of 0.2 to 2 mm and modifying the downstream electrode with a hydrophobic self-assembled monolayer. To complete the valve, a microfluidic channel is fabricated from laser ablation of adhesive layers and pressed over the silver electrodes. Artificial perspiration is driven by capillary action within the channel until stopped by the electrowetting valve. A

low voltage is applied to the electrodes, altering the hydrophobic monolayer, and allowing the fluid front to continue through the microchannel. Statistical analysis demonstrates that applied voltage and not electrode spacing influences valve actuation time, with 17±8 s for 4 V and 40±16 s for 1 V. Inkjet-printing conditions were also optimized to achieve a valve fluid retention time of 9 hours. Using four electrowetting valves, an integrated wearable device is designed for artificial perspiration collection through valve actuation at distinct time points over 40 min. Finally, these inexpensive, user-friendly, and disposable electrowetting valves offer exciting opportunities for non-invasive point-of-care sweat monitoring**.**

6:45 AM F.FL03.01.13
Late News: 3D Patterned Electronic Paper from Nanocellulose and PEDOT:PSS Makara Lay and Isak Engquist; Linköping University, Sweden

Printed electronic technology has become an important tool for the production of low-cost flexible electronic devices. However, due to the limited thickness of printed materials, they have a limited electric current capacity and cannot be used for applications that need high power.
This work aims to fabricate a 3D conductivity patterned paper from nanocellulose and PEDOT:PSS based materials using syringe injection and 3D printing methods. Unlike the usual concept of electronic papers, comprising conductive ink on a paper substrate, these 3D patterned papers integrate the conductor patterns in the bulk of paper, while non-conductive sections are used as support to form free-standing papers. Two different inks, non-conductive and conductive, were derived. The non-conductive ink consists of cellulose nanofiber (CNF), microfibrillated cellulose (MFC), glycerol, and alginate in different concentrations for syringe injection and 3D printing, respectively. CNF, PEDOT:PSS, glycerol, and ethylene glycol were used to prepare the conductive ink. Both inks were deposited on a substrate using syringe injection or 3D printing, creating 3D patterned papers that can be peeled off from the substrate. The patterned papers are flexible, conformable, wearable, and strong. The conductive parts show electrical conductivity of up to 202 S/cm, current capacity above 0.7 A, and the full patterned papers have a tensile strength of 25 MPa. The non-conductive sections have some ionic conductivity, making it possible to use the conductor patterns as electrodes, and the non-conductive patterns of the same paper as electrolyte for simple supercapacitor devices. This successful 3D patterning of electronic paper will pave the way for manufacture of paper-based power transistors, supercapacitors, wearable devices or smart packaging.

6:55 AM F.FL03.01.14
Printable, Flexible and Fully Tissue Equivalent X-Ray Detection Using Polymer Nanosensors with Ultralow Operating Bias and Tuneable Radiolucency Matthew Griffith[1], Jessie Posar[2], Sophie Cottam[3], Joshua Stamenkovic[3] and Marco Petasecca[2]; [1]The University of Sydney, Australia; [2]The University of Wollongong, Australia; [3]The University of Newcastle, Australia

Research interest in new materials for X-ray detection is rapidly growing, driven by demand from diverse applications such as medical imaging, radiotherapy, space exploration, security and defence, and personal wearable dosimeters.[1–2] Current detectors use inorganic semiconductors such as silicon, selenium or cadmium zinc telluride. However, X-ray detectors fabricated from these materials are expensive to manufacture, and cannot be easily fabricated into flexible sensors or large-area pixelated arrays.[4] Furthermore, these semiconductors are composed of heavier elements, which exhibit much stronger X-ray attenuation than the lighter elements in human tissue. Consequently, use of these materials for medically relevant dosimetry faces two major challenges:

1. Allowing X-rays through the detector without altering carefully calibrated beam intensity.
2. A requirement for complex and often unreliable calibrations to produce a response equivalent to the human body.

Here we report the development and characterisation of printable, flexible and fully tissue equivalent X-ray detectors fabricated from solution-processable organic conductors. The photodetectors are composed of donor polymer P3HT and two different acceptors: fullerene derivative PCBM and non-fullerene acceptor o-IDTBR. We show these organic electroactive inks are uniquely capable of both tissue equivalent X-ray attenuation and electrical conductivity. The non-fullerene acceptor material shows both higher charge carrier mobility and a greater radiation hardness, which we establish is due to greater crystallinity and improved nanoscale morphology using synchrotron-based scanning X-ray transmission microscopy. We systematically characterise the optical-to-electrical conversion efficiency of the photodetectors with a range of steady state and transient optoelectronic techniques, demonstrating that the photodetector performance of these nanoscale systems can be tuned to exhibit higher values than any other reported printable organic systems by varying the fabrication parameters.

X-ray nanosensors fabricated by coupling the photodetectors with a plastic scintillator can operate without the need for

external bias, a key feature of wearable electronics. The X-ray performance is shown to be energy independent between 50 keV and 6 MeV by testing with clinical orthovoltage or medical linear accelerators, providing versatile materials for use across a wide range of applications without additional calibrations. We show the X-ray detection sensitivity can be tuned to match that of state-of-the-art inorganic semiconductors or slightly reduced to provide almost completely radiolucent devices for wearable radiation dosimetry. The X-ray nanosensors were fabricated into pixelated arrays using inkjet printing to provide spatial resolution that matches state-of-the-art medical detectors. The organic nanosensors fabricated with o-IDTBR also exhibited remarkable temporal responses, detecting a pulsed X-ray source with microsecond resolution that was indistinguishable from a silicon PIN photodiode. Furthermore, the device exhibited excellent radiation hardness, withstanding a radiation dose that represents a 5-year working lifetime.

The new materials science and flexible devices we report here are an exciting breakthrough, providing the first stable, printable, flexible, and fully tissue equivalent X-ray detectors with functionality that is tuneable for optimized X-ray attenuation, or high radiolucency for applications such as radiotherapy, where simultaneous monitoring and transmission of the X-ray absorbed dose to the human body is a required.

SESSION F.FL03.02: Flexible Materials and Manufacturing—Liquid Metal and Composite Structures
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-FL03

5:00 AM F.FL03.02.01
Fabrication of Orientation-Controlled Carbon-Nanotube/Polymer Composite Ribbon for Flexible Charge/Heat Conductors Manish Pandey, Maireyee Bhattacharya, Naofumi Okamoto, Ryo Abe, Yuki Sekimoto, Yasuo Okajima, Kotaro Nishioka and Masakazu Nakamura; Nara Institute of Science and Technology, Japan

Carbon nanotubes (CNTs) possess tremendous potential applications owing to their excellent mechanical, electrical and thermal properties. Although isolated CNTs possess excellent anisotropic physical properties, their bulk ones are, in general, significantly restricted by the highly random networks. Therefore, bulk fabrication of aligned CNT films is expected to be important for many applications to get anisotropic and high thermal/electrical conductivity along the CNT orientation direction. Various attempts have been made in the past to increase the degree of CNT alignment to realize their theoretical properties using different methods such as cutting, electrophoresis, melt processing, using crowding effect, chemical vapor deposition, templated growth, solid spinning of CNT forest, magnetic field to induce alignment, flow coating, and mechanical stretching. However, few techniques are suitable for the fabrication of highly conducting and flexible strings. In this presentation, we report a novel method to fabricate ribbon-like films of CNT/polymer composite containing highly aligned CNT networks using a robotic dispenser [1]. This method can easily produce a uniform ribbon-like film with oriented CNTs along the drawing direction of the ribbon. We prepared 400–2000 μm wide oriented ribbon of CNT/polymer films that can be used for roll-to-roll processing in length scale. CNTs were found to be aligned along the drawing direction as confirmed by polarized Raman mapping and scanning electron microscope images. Dependence of the electrical and thermal conductivities on the degree of CNT orientation will be also discussed.

5:10 AM F.FL03.02.02
Mechanically Robust Polymer-Perovskite Composite Solar Cells Blake Finkenauer and Letian Dou; Purdue University, United States

Self-healing semiconducting materials have had limited successes due to the tradeoff between excellent electronic properties and suitable rheology properties. This is because high performance inorganic semiconductor materials have a crystalline

structure, unlike fluidic and amorphous polymers which use secondary bonding forces to heal. However, hybrid inorganic-organic halide perovskites are high performing semiconducting materials with crystal-liquid-like behaviors. Their fluidic crystal lattice features a large combination of secondary bonding interactions, giving perovskites their remarkable electronic properties, defect tolerance, and low formation energy. Here, we discuss our investigations in creating the first mechanically self-healing hybrid inorganic-organic halide perovskite semiconductor. A molecularly tailored self-healing polymer is coupled with fluidic methylammonium lead iodide perovskite to form bi-continuous composites capable of healing mechanical damage through synergistic grain growth and solid diffusion processes at slightly elevated temperatures. These self-healing composites are demonstrated in solar cell devices with power conversion efficiencies reaching ~10% with improved thermal and mechanical stability. This pioneer research showcases the concept of joining perovskite and organic materials to create a unique composite with first-of-its-kind functionalities.

5:20 AM F.FL03.02.03
Polymer Nanocomposite Fabrication Using One Step *In Situ* Exfoliation of Two-Dimensional Layered Materials and Their Use as Flexible Multifunctional Sensors Ali Ashraf, Elizabeth Chang, Francis Farmer, Nikhil Jani, Suyeon Lee and Jennifer Lynch-Branzoi; Rutgers, The State University of New Jersey, United States

Polymer nanocomposites with two-dimensional (2D) nanofillers like graphene (Gr) and hexagonal boron nitride (hBN) have found widescale acceptance in healthcare, automotive, aerospace, energy storage, filtration, and military applications due to their exceptional mechanical, electrical, chemical, optical and thermal properties. However, the commercial use of this class of material is hindered due to problems with the nanomaterial fabrication and composite formation process-namely impurity incorporation, agglomeration, use of chemicals harmful to the environment, multi-step processes and cost. Here, we present one step innovative method to directly incorporate Gr and hBN to thermoplastic (polysulfone) and silicone elastomer (Ecoflex®, Dragon skin®) by in-situ exfoliation of bulk precursors (e.g. graphite) within the polymer. Unlike other conventional methods, this technique does not require use of solvents or harsh chemicals for preparation of nanomaterials, which additionally minimizes the probability of inadvertent impurity introduction during processing. Additionally, nanomaterials are exfoliated directly inside the polymer, providing pristine surface to form strong covalent bonds with the polymer matrix, resulting in significant material property enhancement[1, 2]. These flexible smart materials have high conductivity of ~1.8 S/cm and were used as wearable health monitoring sensors (pulse, breathing, speech, muscle movement), mass sensors that can detect mass as small as ~3 mg, chemical sensors that can differentiate between droplets of solvents (acetone, hexane, ethanol, water), temperature sensors that can detect temperature in the range from 10-80 C (sensitivity factor of 12), and as strain sensors for structural health monitoring (gauge factor of 50 at 0.5% strain). Due to external stimuli (temperature, chemical infiltration-based swelling, strain), the distance between graphene flakes and the dimension of the polymer matrix changes, leading to change in electrical resistance path, which is utilized for sensing. The hBN nanomaterial was added as a second filler, which acts as an effective dispersion aid for Gr in the nanocomposite. The composite structure, bonding with nanomaterials and influence of fabrication parameters were investigated with scanning electron microscopy, X-ray photoelectron spectroscopy, differential scanning calorimetry, X-ray diffraction, tensile, flexural and impact testing, Raman spectroscopy and Rheometry. Moreover, mid infrared based thermography technique with micro scale imaging capability was utilized to determine the dispersion of nanomaterials within these composites[3]. Our one-step, in-situ, low cost process is compatible with manufacturing techniques like injection molding, 3D printing, screen printing, soft lithography, and therefore, has the potential to be a commercially viable production technique for flexible multifunctional sensors with high sensitivity.

High-Resolution 3D Printing of Liquid Metals for Wearable Electronics Jang-ung Park[1,2]; [1]Yonsei University, Korea (the Republic of); [2]Institute for Basic Science (IBS), Korea (the Republic of)

Recent progress in optoelectronic devices for wearable electronics, bioelectronics, and soft robotics demands their outstanding physical deformability for versatile systems in daily life. However, the reliability of devices is often severely

restricted by concomitant failure, especially when excessive strains are applied beyond mechanical withstanding limits. Therefore the formation of stretchable interconnects with both high conductivity and high resolution is essential for providing conventional electronic systems an extra degree of deformability with high device integrity. This talk presents a high-resolution, reconfigurable 3D printing using liquid metal alloys and its application for wearable electronic devices with stretchable integrations. A minimum line-width of 2 μm can be reliably formed using direct printing through a nozzle, and these printed patterns can be successively reconfigured into diverse free-standing 3D structures, while maintaining pristine resolutions. Furthermore, the high-resolution printing of 3D coil antennas and interconnects with wearable biosensors and displays represents substantial progress toward next-generation electronics.

5:45 AM F.FL03.02.07
Liquid Metal Inks for Stretchable Electronics Christopher E. Tabor[1], Carl Thrasher[1], Michelle Yuen[1], Zachary Farrell[1,2], Nicholas J. Morris[2,1], Alex E. Flynn[1] and Alexander Watson[1,2]; [1]Air Force, United States; [2]UES, Inc., United States

Low melting point metals and alloys such as those utilizing gallium and bismuth have garnered significant attention in flexible electronics due to their ability to provide highly repeatable electrical performance under elongation, compression, and other harsh mechanical conditions. While these properties have been demonstrated in the lab to impressive degrees, the ability to process these materials and package them in order take advantage of their highly attractive mechano-electronic properties within textiles has been limited due to difficulties of processing the bulk material and the need to retain the liquid in pre-defined areas. Through taking advantage of the increased implementation of additive manufacturing to develop wearable electronics, a printable liquid metal ink has been developed in our lab which fully sinters without the need for high temperatures, providing flexible and strain tolerant liquid electronics. The key enabler of this ink is our ability to chemically tether each particle to its neighbor, creating a polymerized Liquid Metal Network (poly-LMN). The polymerized network forms a self-supporting framework that retains the liquid ink as deposited until full encapsulation is performed, allowing for high definition features (<30 um linewidth) and the autonomous formation of an internal tortuous conductive path that provides strain insensitivity to the circuits up to at least 700% strain. Applications of poly-LMNs range from wearable power distribution, physically deformable antennas, and stretchable resistive heaters.

6:00 AM F.FL03.02.08
Microstructured Liquid Metal Transmission Lines for Sensing of Multimodal Deformations in Electronic Textiles Andreas Leber, Chaoqun Dong, Rajasundar Chandran, Tapajyoti Dasgupta, Nicola Bartolomei and Fabien Sorin; Ecole Polytechnique de Federale Lausanne, Switzerland

The sensing of diverse deformations is an important functionality in soft electronics and wearable devices intended for use in health care, Internet-of-Things, or soft robotics. Current approaches usually rely on intricate arrays of sensors, which have no spatial resolution and cannot distinguish between different types of deformation. An alternative strategy toward distributed and multimodal sensing is electrical reflectometry in transmission lines. However, to create sensitive mechanical probes, the transmission lines must be built entirely with soft materials and feature a controlled microstructure over extended lengths. Here, we report the scalable fabrication of soft and stretchable transmission lines, composed of tens of liquid metal microchannel conductors meticulously arranged within an elastomer dielectric.[1] The interrogation with time-domain reflectometry converts the soft transmission lines into effective probes of deformation, enabling the detection of the mode, intensity, and location of multiple pressing and stretching events that are simultaneously applied. Additionally, the dynamically responsive line conductors yield a pressure sensitivity that is increased by a factor of 200 compared to conventional hard lines. Integrated within a larger fabric, an individual soft transmission line with a single interface port can decipher convoluted mechanical stimulation, bringing a new paradigm to sensing in functional textiles and robotic skins.

6:15 AM F.FL03.02.09
Nanoscale Dewetting Based Direct Interconnection of Micro-LEDs (30 μm × 60 μm) for Flexible, Wearable Electronics JuSeung Lee and Tae-il Kim; Sungkyunkwan University, Korea (the Republic of)

In the last few decades, the evolution of electronic devices has shown unprecedented progress, due to various discoveries of advanced materials, and improvements in fabrication technologies. Much more complicated tasks can be dealt with by miniaturized devices, such as smart wearable systems, which seemed impossible in the past. Electronic devices will become smaller and smaller in the future for multifunctionality, high performance, and power saving purposes, and will be densely

integrated and interconnected on limited areas. In particular, wearable devices that are deformable, and mountable on skin, need to be monolithically integrated on a single substrate for multifunctionality and miniaturization of devices. However, as electronic components, such as light emitting diodes (LEDs), transistors, and various sensors become smaller at microscale, there are some limitations on integrating them on the proper substrate by a general assembly method. Metal wiring, metal soldering, and anisotropic conductive film (ACF) are the most common integration method for electronics. However, metal wiring and metal soldering suffer from size limitation, significant reduction of the overall throughput yield, and poor mechanical stability. The ACF bonding requires high pressure of 2 – 5 MPa (20 -50 bar) and high temperature of 200 °C simultaneously for successful bonding. This process could be expected that the integration of a large number of microscale electronics needs significantly higher force to form electrical interconnect, which potentially raises assembly failure. Recently, research has been conducted to improve the fine pitch capability of interconnection by applying various methods, such as metal-coated polymer ball, multi-layered ACF and non-conductive film (NCF), sidewall insulation, and silver nanoparticle ink with eutectic gallium indium (EGaIn) liquid metal. But they still display multiple limitations such as size limitation and poor mechanical stability.
Here, we introduce a facile electrical interconnection method driven by selective dewetting of polymer adhesive that is applicable to a deterministic microelectronics assembly for flexible electronics. The interconnection system consists of polymer adhesive with nano-sized metal particles, or on protruding structured electrodes, so it can be used by a simple coating process, like spin-coating and jetting. As the stability and interfacial potential of thin polymer adhesive depend on the materials of substrate and adhesive, and the thickness of adhesive, the wettability and dewetting phenomenon of polymer adhesive could be controlled by modulating the condition of the coated polymer adhesive, and the size of nanoparticles (or morphology of the structured electrode). The minimum feature size for assembling microdevices is 30 μm × 60 μm for microscale inorganic LED with 20 μm × 15 μm electrode size and pitch. The transfer printing yield in terms of devices operation was ~99.9 %, so that thousands of micro LEDs can be printed at high throughput on a substrate with gold circuits. This interconnection of the microelectronics was strictly confirmed by harsh industrial levels under dramatic temperature change (-40 – 85 °C for 5 min, ramping rate: 25 °C/min) over 300 cycles, and high humidity and temperature environment (85 °C, 85 % relative humidity) for 300 hours. In addition, the theoretical calculation for the dewetting phenomenon is revealed.

6:30 AM F.FL03.02.10
Late News: Flexible Laser Scribed Graphene Dual-Function Integrated Device for Supercapacitor and Strain Sensor
Guangyuan Xu[1,2], Fangshuai Chen[3], Yanan Chen[3], Yinji Ma[1,2] and Xue Feng[1,2]; [1]AML, Department of Engineering Mechanics, Tsinghua University, China; [2]Center for Flexible Electronics Technology, Tsinghua University, China; [3]Department of Material Science and Engineering, Tianjin University, China

An extensive range of nanocarbon, such as 0D fullerene, 1D carbon nanotubes and nanofibers, 2D graphene and graphene oxide, and 3D carbon aerogels have attracted significant attention from the scientific society. Because of its excellent properties and outstanding performance, nanocarbon has been demonstrated successfully in the application of fabricating electrodes towards wearable electrochemical energy storage and sensing devices. Graphene, being a well-studied and outstanding electrode material has already been evidenced by its performance for manufacturing supercapacitors and skin electronics. The direct laser writing was reported to be an innovative and efficient methodology that enabled to fabricate graphene electrode patterns within a single-step. Inspired by the dual-functions of piezoresistive and electrochemical properties offered by laser-scribed graphene (LSG), the LSG can be fabricated as the integrated flexible device with both functions of strain sensor and supercapacitor. In this work, we have demonstrated the LSG utilized in the integrated supercapacitor-sensor system for the first time. When two LSG electrodes were used as a supercapacitor, its current density was improved from 0.02 to 0.6 mA/cm^2 with the rising scan rate from 10 to 200 mV/s. The highest capacitance was calculated as 18 mF/cm^2 at the consistent current density at 0.02 mA/cm^2. Also, the LSG supercapacitor showed excellent cycling stability after 5000 cycles. When the single electrode from the LSG supercapacitor was adopted as a strain sensor, the LSG electrode enabled to detect the phalangeal joint's motion by its resistance changes while bending up and down. The single LSG electrode could detect the strain signals simultaneously when charging and discharging the LSG supercapacitor. The integration strategy has permitted the possible promises for developing self-powered intelligent sensory, flexible, wearable, and healthcare electronics.

Organic Optoelectronic Devices for Wearables Hyeonwoo Lee, Taehyun Kim, Eungjun Kim, Junho Kim, Hanul Moon and Seunghyup Yoo; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Organic electronic devices are regarded as promising for wearables because the deposition of organic semiconductors is compatible with various substrates with a low thermal budget. This key benefit can allow for the realization of devices with versatile form factors such as flexible, foldable, and conformable devices that are considered desirable particularly for wearable applications. However, form factors are not the only advantage of organic electronic devices from the perspectives of wearable devices. Many of the organic semiconductors have rich optical properties, the strength of which has already been well recognized by the success of displays based on organic light-emitting diodes (OLEDs) and by the impressive progress recently made for organic solar cells. In this talk, we discuss what we can and what we need to do to unlock the full potential of organic optoelectronic technologies for wearable devices. The first part of the talk is dedicated to introducing some of our key efforts to make OLEDs ultra-flexible, stretchable, and more efficient. The second part then presents a case study where some of the inherent benefits of organic optoelectronic technologies are employed to realize organic wearable health-monitoring sensors with far less power consumption than that of conventional commercialized sensors with maximized photon utilization.

5:15 AM *F.FL03.03.02
Flexible Organic Solar Cells and Integrated Systems for Wearable Electronics Kenjiro Fukuda[1], Ruiyuan Liu[1], Zhi Jiang[1,2], Kilho Yu[1] and Takao Someya[1,2]; [1]RIKEN, Japan; [2]The University of Tokyo, Japan

The power conversion efficiency of organic solar cells has been significantly improved over the past decade. The certified power conversion efficiency (PCE) of single-junction organic solar cells exceeded 17%. In addition to a high PCE and excellent operational stability, good mechanical durability is also important to wearable/textile applications to ensure continuous operation under various moving conditions. It is possible to reduce the thickness of organic solar cells by using an extremely-thin (<10 um) polymer substrate. Owing to their extreme light-weight, improved bending stability, good conformability, and improved stretchability, these types of ultrathin solar cells cause minimal discomfort when integrated with textiles. Such ultrathin organic solar cells expand the applicability of flexible organic solar cells as power solutions for wearable electronics or for soft robots in the society of internet-of-things (IoT) in which numerous sensor devices need to be used. Recently, some integrated devices with these cells—such as conformable sensor systems—have been reported and used as power sources.
In this talk, we show our recent progress of flexible organic solar cells and integrated systems for wearable/textile electronics. First, we introduce how we improve the PCE and stability of ultra-thin organic solar cells [1]. Then the strategies to achieve good stability including air[2], high-temperature [3], water [4], and light illumination conditions [5][6] are discussed. Finally, we show some examples of integrated systems with charging devices [7], actuators [8], and sensors [9].

5:30 AM F.FL03.03.03
Ultra-Stretchable Conductive Polymer Complex with Repeatable Autonomous Self-Healing Ability Towards Wearable Sensors Yang Lu[1,2], Ju-Won Jeon[3] and Evan K. Wujcik[1]; [1]The University of Alabama, United States; [2]Georgia Institute of Technology, United States; [3]Kookmin University, Korea (the Republic of)

Wearable strain sensors are essential for the realization of applications in the broad fields of remote healthcare monitoring, soft robots, immersive gaming, among many others. These flexible sensors should be comfortably adhered to skin and capable of monitoring human motions with high accuracy, as well as exhibiting excellent durability. However, it is

challenging to develop electronic materials that possess the properties of skin. The presented skin-like electronic material exhibits ultrahigh stretchability, repeatable autonomous self-healing ability, quadratic response to strain, and linear response to flexion bending. This conductive polymer system, under ambient conditions, synergistically constructs a regenerative dynamic polymer complex crosslinked by hydrogen bonds and electrostatic interactions, which enables these unique properties. Sensitive strain-responsive mechanisms owing to the homogenous and viscoelastic nature provide omnidirectional tensile strain and bending deformations. Furthermore, this material is scalable and simple to process in an environmentally-friendly manner, paving the way for the next generation wearable sensors.

5:40 AM F.FL03.03.04
Stretchable and Fully Conjugated Donor-Acceptor Terpolymers with High Performance and Elasticity Jaewan Mun, Yuto Ochiai and Zhenan Bao; Stanford University, United States

Several strategies have been developed to impart stretchability to polymer semiconductors, which can be divided into two categories: 1) chemical structure modification, and 2) post-modification. However, altering chemical structures often results in reduced mobility, whereas post-modification of semiconducting polymers easily suffers from batch-to-batch variation. Here, a conjugated donor-acceptor terpolymer design is used to control microstructures of diketopyrrolopyrrole-based polymeric chains, which significantly improves stretchability of the polymers without any mobility and elasticity compromise. Analysis on the microstructures of the terpolymers confirms that they show well-maintained short-range ordered aggregates, while their crystallinity is significantly reduced. More importantly, the terpolymer films retain most of their ordered domains even under strain, which leads to record high mobility under strain. Fully stretchable transistors fabricated with our newly established semiconductor films exhibit one of the highest mobilities after repeated strain. All of the above results indicate that our simple molecular design is an effective way to achieve high-performance and stretchable semiconductors.

5:50 AM F.FL03.03.06
Intrinsically Stretchable Organic Light-Emitting Diodes for Next Generation Stretchable Displays Jin-Hoon Kim and Jin-Woo Park; Yonsei University, Korea (the Republic of)

Stretchable electronics are emerging technologies that develop devices with the ability to conform to nonplanar and dynamic surfaces such as a human body. Especially, stretchable light emitting devices (s-LEDs) could be potentially applied to tactile displays and biomedical devices. Several approaches based on geometrical designs such as mechanical buckling and island interconnect have been used to fabricate s-LEDs. However, geometrical designs possess several limitations. For instance, s-LEDs based on mechanical buckling approaches have high surface roughness, which prevents conformal contact with human body. Also, s-LEDs based on mechanical buckling were only uni-axially stretchable, not bi-axially stretchable. Very complicating fabrication processes were required for s-LEDs based on island interconnect, also an areal density of s-LEDs was highly limited to be stretchable. Hence, a demand for s-LEDs consisting intrinsically stretchable (*is*-) constituent layers continues to increase. However, the researches of *is*-LEDs are still largely in its infancy. Most works related to *is*-LEDs were mainly focused on the development of the stretchable and transparent electrodes. Hence, development and in-depth investigation of other *is*-constituent layers have not been performed yet. In this work, we reported *is*-organic light emitting diodes (*is*-OLEDs) which constituent materials are all highly stretchable. To accomplish this objective, all constituent layers including anode, hole transport layer (HTL), emission layer (EML), electron transport layer (ETL), and cathode were carefully modified to be highly stretchable. For anode and cathode, hybrid materials between organic and low-dimensional inorganic nano-materials were used. To make HTL and EML mechanically stretchable, surfactant and polymer blending induced nano-structure modification method was applied. This unique method enabled realization of *is*-functional layers with superior mechanical and electrical properties. The resulting *is*-OLEDs can emit light when exposed to strains as large as 80%. The turn-on voltage is as low as 8 V, and the maximum luminance is 4500 $cd \times m^{-2}$ on both the anode and cathode sides. It can also survive repeated stretching cycles up to 200 times, and small stretching to 50% is shown to significantly enhance its light-emitting efficiency. These results showed that the *is*-OLEDs superior mechanical stretchability compared to previously reported *is*-LEDs. Also, owing to the versatility of our approaches, *is*-OLEDs with various colors including red, green, and blue were successfully fabricated, which is essential in the realization of the stretchable displays. We expect that our works would be a milestone for development of *is*-optoelectronic devices by offering a general platform for *is*-optoelectronic devices.

Tuning Mechanical Properties of Polymer Semiconductor by Modulating Hydrogen Bonding Interactions Yu Zheng[1],

Minoru Ashizawa[2] and Zhenan Bao[1]; [1]Stanford University, United States; [2]Tokyo Institute of Technology, Japan

Polymer semiconductors have gathered much interest for their potential in next-generation deformable and wearable electronics applications. The optimum conjugated polymer film morphology for efficient charge transport consists of crystalline domains and effective inter-domain connections. Unfortunately, such a film morphology usually suffers from device failure under small strain deformation. Thus, it remains challenging to design polymer semiconductors that can maintain good electronic properties under mechanical strain.

The field of stretchable polymer semiconductor has witnessed rapid growth in recent years. Various strategies have been reported, including: (1) adding a secondary component and (2) molecular structural modification. The general design principle is to decrease the overall crystallinity of polymer semiconductor film, providing energy dissipation mechanisms from polymer conformation change during stretching. More design principles need to be investigated, to expand the tunability of polymer semiconductor mechanical properties and even imparting more functionalities.

Dynamic bonding has been widely incorporated into elastomers and hydrogels to enhance their mechanical properties. However, this strategy has not been used extensively to develop stretchable semiconductors. Our group reported that introducing 2,6-pyridine dicarboxamide (PDCA) H-bonding unit into a conjugated polymer backbone helped maintain its electrical performance under strain. The breakage of H-bonding between PDCA units was one of the mechanisms responsible. However, the structure-property relationship regarding H-bonding interactions and strain energy dissipation in polymer semiconductors needs to be further understood.

In this study, conjugation breakers (CBs) with different H-bonding chemistry and linker flexibility are designed. Two structural parameters need to be considered: (1) chemistry of H-bonding unit, and (2) linker between π-conjugated backbone and H-bonding unit. First, we choose urea, amide and urethane. They have structural similarities and can serve as fair comparisons in terms of H-bonding strength. Second, we use alkyl-chain or ether-chain as the linker. Choosing different linkers will influence the packing order of these H-bonding units, thus providing the possibility to tune H-bonding domain size and distribution.

After these H-bonding CBs are incorporated into a Diketopyrrolopyrrole (DPP)-based conjugated polymer backbone, the effects of H-bonding interactions on polymer semiconductor morphology, mechanical properties and electrical performance are systematically investigated. We observe that CBs with H-bonding self-association constant >0.7 or denser packing tendency are able to induce higher polymer chain aggregation and crystallinity in as-casted thin film, resulting in higher modulus and crack on-set strain. Additionally, the rDoC (relative degree of crystallinity) of the stretched thin film with the highest crack on-set strain only suffers a small decrease, suggesting the main energy dissipation mechanism is the breakage of H-bonding interactions. By contrast, other less stretchable polymer films dissipate strain energy through the breakage of crystalline domains, indicated by drastic decrease in rDoC. Furthermore, we evaluate their electrical performance under mechanical strain in fully stretchable field-effect transistors. The polymer with the highest crack on-set strain has the least degradation in mobility as a function of strain. Overall, these observations suggest that we can aptly tune the mechanical properties in polymer semiconductors by modulating intermolecular interactions, such as H-bonding chemistry and linker flexibility. Such understanding provides molecular design guidelines for future stretchable semiconductors.

6:10 AM F.FL03.03.09

Fabrication Strategies for Large-Area, Flexible Magnetic Nanoparticle Arrays Guinevere Strack[1], Yassine Ait-El-Aoud[2], Dennis Slafer[3], Richard M. Osgood[2] and Alkim Akyurtlu[1]; [1]University of Massachusetts Lowell, United States; [2]US Army Combat Capabilities Development Command Soldier Center, United States; [3]MicroContinuum, Inc., United States

Two-dimensional metasurfaces comprised of ordered nanoparticle arrays can be tailored to obtain desired electromagnetic properties, which depend on the size, shape, composition, and spacing of the nanoparticles. Potential applications of these materials include active and lightweight textiles, e-textiles, smart fibers, signature management, power/energy harvesting, encryption, and identification capabilities. These ‘real world’ applications typically require magnetic nanoparticle (MNP) arrays on flexible substrates; therefore, there is a need for research that addresses the fabrication and performance of these materials in the context of flexible, wearable platforms.

Traditional fabrications strategies for MNP arrays require costly equipment and highly trained personnel. For example, e-beam lithography has been used to fabricate such arrays; however, this technique is not feasible for large-area samples. In addition, the majority of MNP arrays are fabricated on Si wafers, which provide an ideal, flat, surface, but do not readily translate to flexible platforms or roll-to-roll processes. In this presentation, we will discuss fabrication strategies for large-

area MNP arrays on flexible substrates, along with the resultant optical and magnetic properties. The fabrication strategies are based on nanosphere lithography (NSL) and nanoimprint lithography (NIL). In the NSL strategy, polystyrene spheres (PS) are packed in a monolayer on the selected substrate and used as a template to produce ordered particle arrays. The size and spacing of the MNP array can be controlled by the size of the PS beads and other fabrication parameters. Several NSL methods can be used to produce the MNP array—the method depends on the desired MNP array dimensions and the substrate material. In the NIL strategy, a 3D mold is used to form the desired pattern in a UV curable polymer on the selected substrate. Working NIL molds are made from a single master template using e-beam lithography, which enables formation of precise structures in a wide range of geometries with dimensions down to tens of nanometers. There patterns can be used to either contain MNPs or the patterns can be formed from MNPs. NIL techniques lend themselves to large-area, cost-effective manufacturing using roll-to-roll technology.

Understanding the optical and magnetic properties of MNP arrays enables future design strategies for flexible, wearable, multifunctional optical and electronic devices. For example, total integrated transmission and spectral scattering were measured using a spectrophotometer with an integrating sphere accessory to account for scattering characteristics of the nanostructured arrays on flexible substrates. Nanometric Co films and MNP arrays on Kapton were subjected to Superconducting Quantum Interference Device (SQUID) magnetometer measurements. Finally, obtained hysteresis loops (magnetic moment vs. applied magnetic field) were used to determine the saturation magnetization, M_s, and magnetic coercivity, H_c, of Co films and MNP arrays.

Late News: Three-Dimensional Optoelectronics Formed by Origami Transformation of a Plasticized Polymer Substrate Gi-Gwan Kim, Yeongmin Kim, Seonggwang Yoo, Hun Soo Jang and Heungcho Ko; Gwangju Institute of Science and Technology, Korea (the Republic of)

The tremendous development of flexible electronics seems to pave a way to develop the three-dimensional optoelectronics, including hemispherical and polyhedral image sensors, and curved display system, which offers low optical aberration and wide field of view, from planar membrane-type electronics. Regarding optoelectronics, there are critical issues for 2D to 3D transformation. First, the devices require a transition of rigidity, soft for transformation, but rigid in the final shape. In the case of using membrane-type electronics, its flexibility allows the former but does not allow the latter, which naturally requires a supportive framework. Second, in order to minimize the optical path from or to the devices, the device layer should be placed on the top surface of the supportive framework; this effort naturally causes out of the neutral mechanical plane. In this case, during the deformation into either inward or outward curvature, the stress on the device naturally suffers from compressive or tensile tension. Third, In order to allow the pixel matrix design with common column and row connection lines, the Kirigami approach, which cuts off some areas, should be avoided. Fourth, removing the blind area is also important to enrich the visual information. The strategy uses the acrylonitrile-butadiene-styrene (ABS) framework that can support a membrane-type electronic layer and can undergo plasticized by using small molecules such as acetone and *N*,*N*-dimethylformamide (DMF). Sorption and desorption of the plasticizer in a controlled manner allows a dramatic decrease of elastic/hardening moduli of ABS by a thousand times of magnitude, with increased fracture strain up to 240%, which prevents mechanical failure from the deformation. Notably, a viscoplastic reflow of the ABS substrate can reduce stress/strain on the device layer, even in the case of placing the device layer on the top surface of the ABS substrate. Moreover, confining the plasticizing region within a microfluidic channel allows extreme folding of the ABS framework, and thereby a nondisruptive tucking-based origami to form a polyhedral optoelectronic device without cutting the connection lines. As an application, we demonstrate a tetrahedral image sensor for an omnidirectional camera[1] and double-sided/holographic/ hexahedral LED arrays.[2]

This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea Government (MSIT) (No. 2018R1A2B2005067).

6:30 AM F.FL03.03.12
Late News: Vertically-Stacked Complementary Inverter Based on Oxide-TFTs on Flexible Polymeric Foil Substrate Shu-Ming Hsu, Wei-Chen Lin, Hao-Lin Yang, Dung-Yue Su, Feng-Yu Tsai and I-Chun Cheng; National Taiwan University, Taiwan

With the increasing demand for wearable devices, realization of high-performance flexible electronic circuits becomes an important topic. Some oxide-semiconductor-based thin-film transistors (TFTs) have exhibited good operational stability and can be fabricated with a mass production compatible technology at low substrate temperatures. Therefore, they have been considered as potential candidates for flexible on-plastic circuits. Three-dimensional integrated circuit technology has been widely used in memories, image sensors, and logic circuits. The vertical integration of electrical components can enhance the device density. So far, only a few flexible oxide-TFT-based complementary inverters have been reported. In this work, we successfully demonstrate vertically-stacked complementary inverters by monolithically integrating n-type bottom-gated zinc oxide (ZnO) TFTs and p-type top-gated tin monoxide (SnO) TFTs on polyimide foil substrates. The ZnO TFT shows a linear field-effect mobility of 0.6 $cm^2V^{-1}s^{-1}$, subthreshold swing of 0.31 $Vdec^{-1}$, and on/off current ratio of $>10^7$. The corresponding values for the SnO TFT are 0.7 $cm^2V^{-1}s^{-1}$, 1.5 $Vdec^{-1}$, and 10^4, respectively. The vertically-stacked complementary inverter exhibits a static voltage gain of 36 V/V at a supply voltage of 10 V. To investigate the influence of mechanical strains on the electrical performance, the devices are evaluated when bent to various curvatures outwardly and inwardly. There is no significant change in the voltage gain and noise margins when the inverter is subjected to a tensile or a compressive strain. However, the stability against gate-bias stress for the SnO TFT deteriorates when a mechanical strain is applied, which may be mitigated by introducing an encapsulation layer to reduce the distance between the device and mechanical neutral plane.

SESSION F.FL03.04: Energy Harvesting for Wearables
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-FL03

5:00 AM *F.FL03.04.01
Flexible Piezoelectric Devices for Energy Harvesting and Ultrasonic Imaging Tianning Liu, Veronika Kovacova, Ajay Dangi, Sri-Rajasekhar Kothapalli, Kyusun Choi, Chris Rahn, Thomas Jackson and Susan E. Trolier-McKinstry; The Pennsylvania State University, United States

High quality piezoelectric thin films are typically crystallized at temperatures above 500°C, so integration in a flexible form factor can be challenging. In this work, two approaches will be described: films on metal foils for energy harvesting applications, and transferred films on polyimide substrates for ultrasound applications. For energy harvesters, $Pb(Zr,Ti)O_3$ (PZT) and $(K,Na)NbO_3$ (KNN) based harvesters using the piezoelectric compliant mechanism design, with resonances at 20, 40 and 70 Hz. Energy harvesting with the compliant design is more than twice as much efficient as for the simple cantilever beam. At 70Hz, the measured power densities corresponding to PZT and KNN are 113.9 and 3.1 $\mu W/cm^2$ respectively. The power density ratio between PZT and KNN is of the same magnitude as the ratio of their respective Figures of Merit. For ultrasound applications, PZT films were released from a high-temperature-compatible substrate by dissolution of a ZnO release layer. This enabled the design and fabrication of flexible ultrasonic transducers using 1 μm thick PZT on 5 μm thick polyimide substrates. The transducers were patterned single elements of PZT bar-resonators operating in width extension mode with center frequencies in the 8-80 MHz range. Pitch-catch was demonstrated with two 100 μm × 1000 μm neighboring elements respectively transmitting and receiving against an aluminum reflector at 1.5 cm distance. The element in receive detected a 0.2 mV pre-amplified signal for a driving frequency of 9.5 MHz.

5:15 AM F.FL03.04.02
Ultrathin Stretchable Piezoelectric Generator with Ultrahigh Power Density Heeyong A. Huh, Siyi Liu, Taewoo Ha and Nanshu Lu; The University of Texas at Austin, United States

Skin-conformable and mechanically imperceptible wearable electronics, a.k.a. epidermal electronics, is one of the trending fields in personal and biomedical device research. Although ultrathin, ultrasoft biometric sensors have been widely developed, most of them are dependent on rigid and bulky batteries for power, which is still limited in energy capacity. Wearable energy harvesters hence emerged as a non-depletable power source. However, ultrathin generators with ultrahigh power output are yet available. We introduce a stretchable and wearable piezoelectric generator made of 28-μm-thick polyvinylidene fluoride (PVDF) serpentine ribbons. Through analytical and numerical modeling, the serpentine shape and electrode coverage has been optimized to yield a power density of 0.24 $\mu W/cm^2$ at 50% applied strain under a frequency of 0.5 Hz. The combined thinness, high stretchability, and high power density qualify our generator as one of the top wearable energy harvesters. We have applied this stretchable generator at the crook of the human arm as a wearable energy harvester.

We demonstrate that it was able to support the reading and storage of temperature every 10 minutes without battery. All the stored data can be read through an NFC-enabled cell phone whenever the cell phone approaches the e-tattoo.

5:25 AM F.FL03.04.03
Establish a Self-Sustainable Wearable Multi-Modular Bioenergy Microgrid System Lu Yin, Kyeong Nam Kim, Jian Lyu and Joseph Wang; University of California, San Diego, United States

Despite the fast development of various energy harvesting and storage devices, their judicious integration into efficient, autonomous and sustainable wearable systems has not been widely explored. Here, we introduce the concept and design principles of microgrids to the world of wearable electronics by demonstrating the operation of a multi-module bioenergy microgrid system. Unlike earlier hybrid wearable energy systems,a bioenergy microgrid relies solely on human activities to work synergistically and autonomously, harvesting biochemical and biomechanical energy using energy harvesters such as sweat-based biofuel cells and triboelectric generators, and regulating the harvested energy via wearable energy storage modules such as batteries and supercapacitors. Through careful energy budgeting and performance pairing, the system can offer features like fast-booting, extended-harvesting, and smart energy management to efficiently power various wearable electronics. Implementing the “compatible form factors, commensurate performance and complementary functionality” design principles, the flexible, wearable bioenergy microgrid offers attractive prospects for the design and operation of efficient, sustainable and autonomous wearable systems.

5:35 AM F.FL03.04.05
Photonic Curing for High-Throughput Fabrication of Flexible Perovskite Solar Cells Weijie Xu[1], Robert Piper[1], Trey Daunis[1], Kurt Schroder[2] and Julia W. Hsu[1]; [1]The University of Texas at Dallas, United States; [2]Novacentrix, United States

Next-generation photovoltaics provide important energy sources for flexible devices. Among them, perovskite solar cells (PSCs) stand out for their high performance and low cost that is associated with solution processability. However, the critical bottleneck in commercializing PSCs is the processing speed. Thermal annealing is widely used in research labs as the post-deposition processing method for transport layers and active layers of PSCs. These minutes or even hours of processing time are incompatible with high-throughput manufacturing methods, e.g. roll-to-roll processes. At web speeds of 30 m/min, a typical 20 min annealing time would translate to an impractical 600-m-long oven. Additionally, thermal annealing is an equilibrium heating method, i.e. substrates and the surrounding environment are heated up together with the films, incurring large energy usage and inducing mechanical failure due to coefficient of thermal expansion mismatch between different layers. Consequently, eliminating thermal annealing steps is the key to achieve high-throughput, flexible PSCs. In this work, we have successfully utilized a pulsed light irradiation approach, photonic curing, to anneal both NiO and mixed cation perovskite (CsFAMA) films on Willow® Glass substrates. We substantially reduced the total processing time of p-i-n PSCs. The processing time for sol-gel NiO is below 0.5 ms, which is 10^6 times shorter than thermal annealing (0.5 ms vs. 45 min). The processing time for CsFAMA is 20 ms, which is a 10^5 reduction as well. The materials properties, including optical absorption, crystallinity, surface morphology, and work function, as well as device performance are compared between thermally annealed and photonically cured films. Successful fabrication of PSCs using photonic curing will establish it as a viable path forward to realizing high-throughput manufacturing of flexible PSCs.

5:45 AM F.FL03.04.07
3D Printed Flexible Triboelectric Nanogenerators—Functional Fibers and Stretchable Mechanosensors Yuxin Tong, Ziang Feng, Jongwoon Kim, John Robertson, Xiaoting Jia and Blake N. Johnson; Virginia Tech, United States

Triboelectric generators and sensors have great potential as self-powered wearable devices for energy harvesting, biomedical monitoring, and recording human activity. Here, we report a process for 3D printing highly flexible functional fibers, stretchable membranes, meshes, and hollow 3D structures using elastomeric (silicone) metal (Cu)-core extrudates to produce triboelectric nanogenerators (TENGs). The triboelectric performance of single 3D-printed functional fibers and 3D-printed membranes is quantified by cyclic loading tests, which showed maximum power densities of 31.39 and 23.94 mW m^{-2}, respectively. The utility of the flexible silicone-Cu TENG fibers and the 3D printing process is highlighted through various applications to wearable mechanosensors for organ and human activity monitoring. The use of machine learning algorithms for classification of sensor response is also discussed. Overall, this work expands the conductive and functional materials palette for 3D printing and encourages the use of 3D-printed triboelectric devices for self-powered sensing applications in biomanufacturing, medicine, and defense.

5:55 AM F.FL03.04.08
Triboelectric Nanogenerator for Self-Powered and Multi-Functional Tactile Sensors Seung-Rok Kim and Jin-Woo Park;

Yonsei University, Korea (the Republic of)

With the rapid development of the multi-sensing electronic skin (E-skin) imitating human skin by converting the external stimuli into electrical signals, the needs for maintenance-free operation of E-skin have been triggered. To bridge the E-skin of the users and their surrounding environment, the sensors are core components with their functions, such as detecting the physiological signals of a person or noticing the hazardous surroundings. As the number of the sensors and the functions increases, the needs for the external power supply like batteries are still unsolved with the problems of recycling, health and environmental hazards, and miniaturization. Recently, to fabricate the power sources operating the many sensors light-weighted and miniaturized, various kinds of nanogenerators converting mechanical, chemical, thermal, or solar energy into electricity have been developed. Among those power generators, the triboelectric nanogenerators (TENGs) have attracted massive attention for scavenging the energy from the mechanical motions. By contact electrification and electrostatic induction at the interface of the TENG and the touching object, TENG has been used as a touch sensor. Using the impedance matching property of the TENG to the sensor (passive electric element), we could expect the self-powered sensing without any other power supply. In this study, we successfully fabricated the multifunctional tactile sensor using the gel polymer electrolyte capacitor. Additionally, we utilized electrospun P(VDF-TrFE) nanofibers for supplying enough energy to operate the multifunctional tactile sensor with recognizing the initiation of the touch. Embedding the nanofibers in the PDMS elastomer, we can fabricate an efficient, flexible, and transparent TENG. For sensing temperature and pressure in the single sensing component, we exploited P(VDF-TrFE-CTFE) relaxor nanofiber and temperature-responsive [EMIM][TFSI]/P(VDF-HFP) gel polymer electrolyte. Porous structure made by the relaxor nanofibers can induce the polarization and be the channels for the ion transfer. Those transferred ions are the factors for the capacitance increases by pressure and temperature stimulus. Our multifunctional tactile sensor showed the characteristic pressure response of the wide sensing range (0~100 kPa) with ~0.05 /kPa sensitivity and the temperature response of the high sensitivity up to 0.283 /ºC compared with other wearable temperature sensors. The multifunctional sensor is integrated with the TENG expecting that sensor can transduce the generated signals at the outer touching surface depending on the pressure and the temperature. Using a self-powered multifunctional sensor, we could successfully map the pressure and the temperature at the same time without any extra power supplier.

6:05 AM F.FL03.04.09
Fabrication of Energy Harvesting Textiles Based on Fiber-Based Organic Photovoltaics Siddhant Iyer, Nelaka Govinna, Zhiyu Xia, Lian Li, Claire Lepont, Ravi Morsukal, Jayant Kumar and Ramaswamy Nagarajan; University of Massachusetts Lowell, United States

Fiber-based organic photovoltaics (OPV) offer the advantages of low-cost, rapid fabrication, ease-of scale up, high flexibility and versatility of tailoring properties through molecular design of the active materials. We explore a solution-coating process to fabricate fiber-based OPV comprising of a working primary electrode (polished 316LVM stainless steel wire) coated with a titanium dioxide electron transport layer, followed by a nanostructured phenyl-C61/71-butyric acid methyl ester: Poly(3-hexylthiophene) (PC61BM:PC71BM:P3HT) active layer and a poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) hole transport layer, which is wrapped around by a secondary counter electrode (silver-plated copper wire), for extraction of dissociated charge carriers. The device is encapsulated in an exfoliated mica (e-mica) reinforced modified epoxy based UV-curable cladding for imparting oxygen and moisture barrier properties. Individual wire specimens yielded a power conversion efficiency (PCE) of 3.4 ± 0.4% and an output power density of ~ 1.5 × 10-4 W/cm2. Multiple weaving configurations of the energy harvesting textiles based on fiber-based OPV was explored on a thread controller 2 (TC2) digital Jacquard loom to yield 10 × 10 in2 OPV modules. The PCE, effective series resistance (Rser),), fill factor (FF), open-circuit voltage (Voc), short-circuit current density (Jsc) and maximum power output of this energy harvesting textiles will be reported.

6:15 AM F.FL03.04.10
Late News: Study the Mechanical and Electrical Properties of Electrospun P(VDF-TrFE) and P(VDF-TrFE-CTFE) Nanofibers Chia-Yin Ma[1], Tu-Ngoc Lam[1], Wen-Ching Ko[2], Yi-Fan Chen[3], Chung-Kai Chang[4], Po-Han Hsiao[1] and E-Wen Huang[1]; [1]National Chiao Tung University, Taiwan; [2]Industrial Technology Research Institute, Taiwan; [3]National Central University, Taiwan; [4]National Synchrotron Radiation Research Center, Taiwan

P(VDF-TrFE) poly(vinylidene fluoride-trifluoroethylene) is a well-known piezoelectric electroactive polymer (EAP) with high crystallinity. If the third monomer (CTFE) is introduced to form P(VDF-TrFE-CTFE) poly(vinylidene fluoride-trifluoroethylene-chlorotrifluoroethylene), the ferroelectric domains will be fragmented into a relaxor ferroelectric domains which is nano polar region with high dielectric constant. In this study, we fabricated electrospun nanofibers of P(VDF-TrFE) and P(VDF-TrFE-CTFE). We conducted wide angle x-ray diffraction (WAXD) to study the impact of lattice structure and

crystallinity on the mechanical and piezoelectric properties.The mechanical and electrical properties of the copolymers and terpolymers were compared.

SESSION F.FL03.05: E-Textiles—Design Factors

5:00 AM *F.FL03.05.01
Textiles and Functional Apparel Design for a Soft Wearable Robotic Glove Diana Wagner, Diogo S. de Lucena, Kristin Nuckols, Christina Glover, Maxwell Herman, Cameron J. Hohimer, Will Moyo and Conor J. Walsh; Harvard University, United States

Soft wearable robotics is an emerging field which looks at methods of enabling functional, powered support to assist human movements using lightweight, low-profile, and flexible materials. Textiles hold great promise in establishing a platform to develop assistive devices that fit and feel like regular clothing. A diverse team of researchers in the Biodesign Lab at the Harvard School of Engineering and Applied Sciences are exploring the use of inflatable soft wearable robotics that leverage the functional properties inherent in textiles to provide mobility assistance for people with hand weakness through a soft robotic glove.

Hand weakness limits a person's ability to perform common activities of daily living such as eating, drinking and writing that can be the result of many conditions including stroke, ALS and spinal cord injury. For stroke survivors, hand function rehabilitation is one of the most important aspects to improve their quality of life and independence. Access to therapy is a key factor in a person's ability to perform rehabilitation exercises and recover motor function, however most stroke survivors do not receive the amount of therapy they need due to budget, time, and mobility constraints. Furthermore, achieving the high amount of repetitive hand movements required for successful rehabilitation is a major challenge in conventional methods of therapy.

The aim of our research is to show the viability of using a soft robotic glove to perform home-based hand rehabilitation for stroke survivors. The soft robotic glove facilitates high dosage repetitive stretching, active movement, and functional task training exercises through the use of comfortable, textile-based inflatable chambers that gently straighten and bend the fingers while an engaging digital interface guides the user through their exercises with motivating games.

Soft wearable robotic devices present a promising approach to hand rehabilitation due to their lightweight, compliant, and low-cost design. This talk will explore the development of the soft robotic glove through the lenses of functional apparel design and will present the human-centered design methods used in the collaborative development process.

5:15 AM *F.FL03.05.02
A Textile-Centric Approach to Wearable e-Textiles Tricia B. Carmichael, Yunyun Wu and Sara Mechael; University of Windsor, Canada

The future of textiles is electronic, with new wearable devices integrated into "smart clothing" systems that will incorporate sensors to detect biometric data, light-emitting devices to display data, and integrated wiring and power sources. At present, e-textiles can be made by sewing discrete, rigid elements like light-emitting diodes (LEDs), optical fibers, or bulky "black box" battery packs into clothing, which reduces softness, stretchability, and wearability. The next generation of e-textiles are being made from functional materials seamlessly integrated into the textile itself, while maintaining softness and stretchability. The challenge with this integration is the porous, 3D structures of textiles that are obviously different from the flat and rigid surfaces conventionally used for device fabrication. Textiles present a non-planar surface for fabrication and readily absorb and wick solutions of functional inks. Approaches that planarize the textile surface using polymer layers lose the softness and stretchability of the original textile. In this presentation, we show that instead of masking textiles with planar polymer layers, the textile structure itself can be exploited to form the basis for a new, textile-centric design approach. As an example of this approach, we discuss how the open structure of a low-denier nylon and spandex ultrasheer fabric can be used as a framework for highly stretchable transparent electrodes in wearable and stretchable light-emitting devices. We furthermore discuss how the tufted structure of a velour fabric forms the basis for an architectural engineering approach to protect brittle functional materials from strain and demonstrate this approach by fabricating stretchable textile-based lithium-

ion batteries.

5:30 AM *F.FL03.05.03
Textile-Integrated Wearable Technologies—Best Practices, Applications and Open Challenges Brad Holschuh; University of Minnesota, United States

This talk will focus on textile-integrated wearable technologies. I will discuss current best practices related to textile and garment integration of sensors, actuators, and circuitry, providing examples of work by the University of Minnesota Wearable Technology (WTL) Laboratory and other leading research institutions. I will highlight the specific advantages, challenges, and applications of garment-integration of these types of technologies, and will discuss future directions in this space where innovation can have significant impact, ranging from aerospace/military scenarios to medical, athletic, and commercial applications.

5:45 AM *F.FL03.05.04
Creating Smart Textiles Shu Yang; University of Pennsylvania, United States

Wearable technology is poised to explode in the next decade. As flexible electronic devices have begun to be incorporated into clothing, there are pressing needs to turn responsive materials into fibers and yarns to create smart textiles that will response to environmental changes and report personal health information.

Here, I will present our work on fabrication of polymer fibers and meter-long yarns with embedded chemical receptors and selective wettability. The yarns can be knitted, embroidered or weaved into various wearable fabric prototypes. By control of surface chemistry of the fibers, we demonstrate selective wettability of the yarns, which wicks aqueous solutions, and change colors in response to humidity, pH, and electrolytes. By selective embedding of functional yarns into different geometries, we create multi-sensors and "blooming" flowers that can response to UV light intensity, temperatures, and electrical fields.

6:00 AM *F.FL03.05.05
Wearable Textile Electronics for Personalized Health Care Jun Chen; University of California, Los Angeles, United States

Abstract:
There is nothing more personal than healthcare. Health care must move from its current reactive and disease-centric system to a personalized, predictive, preventative and participatory model with a focus on disease prevention and health promotion. As the world marches into the era of Internet of Things (IoT) and 5G wireless, technology renovation enables industry to offer a more individually tailored approach to healthcare with more successful health outcomes, higher quality and lower costs. However, empowering the utility of IoT enabled technology in personalized health care is still significantly challenged by the shortage of cost-effective and wearable biomedical devices to continuously provide real-time, patient-generated health data. Textiles have been concomitant and playing a vital role in the long history of human civilization. In this talk, I will introduce our current research on smart textiles for biomedical monitoring and personalized diagnosis, textile for therapy, and textile power generation as an energy solution for the future wearable medical devices.

Influence of Textile-Based Armband Form Factors on Wearable ECG Monitoring Performance Braden M. Li, Amanda Myers, Tashana J. Flewwellin, Jacklyn L. Herzberg, Azin Saberi Bosari and Jesse S. Jur; North Carolina State University, United States

Wearable technologies exist in a variety of form factors to accommodate a broad range of health sensing applications. Textile-based form factors are among the most enticing because they enable the creation of large-area sensing networks with sensing modalities such as ECG, EMG, and EEG. But, multiple form factor design considerations need to be accounted for to ensure the full wearable system exhibits exceptional sensing ability. In this talk, we explore the key form factor design parameters affecting ECG sensing performance of an Electronic textile (E-textile) armband worn on the upper left arm. The E-textile armband is integrated with screen-printed dry electrodes arranged in a three-lead sensing configuration. We identify the optimal electrode location needed to achieve high-quality ECG signals at low measurement frequencies on the upper left arm, without sacrificing the practical assembly of the armband. Our analysis reveals that the armband diameter plays a crucial role in dictating contact pressure against the upper arm and the resulting ECG signal quality. We also develop a predictive contact pressure model based on the mechanics of thin-walled cylindrical pressure vessels. Our model provides a framework to predict the contact pressure and ECG signal quality as a function of armband diameter. The fundamental design principles discussed in this presentation lay the groundwork for creating future E-textile form factors that enable efficient sensing capabilities.

Extensible 3D Hierarchical Woven Materials Widianto P. Moestopo[1], Arturo J. Mateos[1], Ritchie Fuller[2], Julia R. Greer[1] and Carlos Portela[3,1]; [1]California Institute of Technology, United States; [2]Independent Artist, United States; [3]Massachusetts Institute of Technology, United States

Most architected materials to date have enabled properties such as extreme stiffness and strength, at levels unattainable independently by their constituent materials, with few works focusing on the compliant, extensible regime pertinent to flexible electronics. While exceptional mechanical properties such as extreme resilience and high deformability have been realized in many three-dimensional (3D) architected materials using beam-and-junction-based architectures, stress concentrations and constraints induced by the junctions limit their mechanical performance. Compliant architected materials that overcome these limitations, in combination with conductive components or constituent materials, could help enhance the performance of wearable electronics.

We present a new hierarchical design concept for flexible 3D architected materials in which fibers are interwoven to construct effective beams, such as the ones in classical monolithic-beam lattice architectures. Via in situ tension and compression experiments of additively manufactured polymeric woven and monolithic lattices at the microscale, we demonstrate the superior ability of woven architectures to achieve high tensile and compressive strains (>50%)—without failure events—via smooth reconfiguration of woven microfibers in the effective beams and junctions. Cyclic compression experiments reveal that woven lattices accrue less damage compared to lattices with monolithic beams. We employ numerical studies of woven beams with varying geometric parameters to present new design spaces for the development of architected materials with tailored compliance that is unachievable by similarly configured monolithic-beam architectures. This woven hierarchical design offers a pathway to make traditionally stiff and brittle materials more deformable by introducing a new building block for 3D architected materials, with complex nonlinear mechanics, applicable to flexible electronics applications.

Human-Interactive Sensing Displays with Field-Induced Electroluminescence Cheolmin Park and Euihyuk Kim; Yonsei University, Korea (the Republic of)

Development of stimuli-interactive sensing display capable of spontaneously visualizing various external human sensible inputs has been of great interest and tremendous efforts are devoted to the visualization of nonvisible human senses such as touch, smell, taste, and sound. Field-induced electroluminescence under alternating current (AC) has been extensively studied and its unique device architecture in which an emitting layer is separated with an insulator from electrode offers a new platform for designing and developing emerging stimuli-interactive displays. In this presentation, we present 3 different types of interactive sensing displays. First, we demonstrate that simultaneous sensing and visualization of the conductive substance is achieved when the conductive object is coupled with the light emissive material layer on our novel parallel-type device. Second, a novel interactive skin display with epidermal stimuli electrode (ISDEE) is demonstrated, allowing for the simultaneous sensing and display of multiple epidermal stimuli on a single device. The ISDEE is directly mounted on human skin, which by itself serves as a field-responsive floating electrode of the display, allowing for displaying a variety of physiological skin factors, such as the temperature, sweat gland activity, and pressure. Finally, an interactive sensing memory platform is demonstrated, capable of sensing, monitoring, and storing the information of various liquids. Our platform utilises sound arising from liquid-interactive ferroelectric actuation, which is dependent upon the polarity of the liquid, allowing for facile liquid sensing and identification. Moreover, our device successfully monitored the flow of a human serum liquid passing through channels and determined its velocity. Mechanically flexible and optically transparent tube-type LIFS AC devices allow for in situ analysis of the flow of a liquid in terms of sound.

A Bimodal Soft Electronic Skin for Tactile and Touchless Interaction in Real Time Jin Ge[1], Xu Wang[1], Michael Drack[2], Oleksii M. Volkov[1], Mo Liang[1], Gilbert Santiago Canon Bermudez[1], Changan Wang[1], Shengqiang Zhou[1], Jürgen Fassbender[1], Martin Kaltenbrunner[2] and Denys Makarov[1]; [1]Helmholtz-Zentrum Dresden-Rossendorf e.V., Germany; [2]Johannes Kepler University Linz, Austria

The transformative emergence of smart electronics, human-friendly robotics and supplemented or virtual reality will revolutionize the interplay with our surrounding. The complexity that is involved in the manipulation of objects in these emerging technologies is dramatically increased, which calls for electronic skins (e-skin) that can conduct tactile and touchless sensing events in a simultaneous and unambiguous way. Integrating multiple functions in a single sensing unit offers the most promising path towards simple, scalable and intuitive-to-use e-skin architectures. However, by now, this path has always been hindered by the confusing overlap of signals from different stimuli.
Here, we put forward the field of soft, flexible electronics by developing a compliant magnetic microelectromechanical platform (m-MEMS), which is able to transduce both tactile (via mechanical pressure) and touchless (via magnetic field) stimulations simultaneously and discriminate them in real time [1]. For the first time, the electric signals from tactile and touchless interactions are intrinsically separated into two different regions, allowing the m-MEMS, a single sensor unit, to unambiguously distinguish the two modes without knowing the signal history.
Owing to its intrinsic magnetic functionality, our complaint m-MEMS platform is able to discriminate magnetic vs. non-magnetic objects already upon touchless interaction. With this intrinsic selectivity, we address the long-standing problem in the field of touchless interaction – namely, the issue of interference with objects, which are irrelevant or even disturbing the interaction process. In addition, the interaction process is programmable. The sensitivity of the two interaction modes could be tuned by adjusting the magnetic field of the objects able to meet the requirements of different interaction tasks.
By using tactile and touchless sensing functions simultaneously, our m-MEMS e-skins enable complex interactions with a magnetically functionalized physical object that is supplemented with content data appearing in the virtual reality. We demonstrated data selection and manipulation with our m-MEMS e-skins leading to the realization of a multi-choice for augmented reality through three dimensional (3D) touch. Beyond the field of augmented reality, our m-MEMS will bring great benefits for healthcare, e.g. to ease surgery operations and manipulation of medical equipment, as well as for humanoid robots to overcome the challenging task of grasping.

A Closed-Loop Tactile Sensor Array Using ZnO Thin-Film Transistors with Ultra-High Spatiotemporal Resolution Hongseok Oh[1], Gyuchul Yi[2], Michael Yip[1] and Shadi A. Dayeh[1]; [1]University of California, San Diego, United States; [2]Seoul National University, Korea (the Republic of)

Closed-loop control system is critical in sophisticated object manipulations such as grasping and cracking a raw egg or flipping a note page, to avoid drop and slip. Human hands can perform such actions naturally even without watching the objects, because mechanoreceptors on hands can provide wide dynamic range tactile feedback on a variety of physical parameters such as shear forces to the brain for closed-loop control of hands. For robots to operate autonomously, similar tactile perception is needed to provide versatile manipulation of our everyday objects and fixtures. Furthermore, in majority of applications, a tactile sensitivity on flexible substrates is required for interaction with arbitrary geometries. Multiple modalities have been suggested so far to indirectly infer tactile information, but direct tactile sensation with shear force sensitivity is important for high fidelity haptic feedback. The challenges for achieving high spatiotemporal resolution with shear sensing ability can be addressed by employing tactile sensors which can perform both transducing forces and multiplexing signals [1]. This approach circumvents the tradeoffs for density and performance, since no additional driving element is required in construction of the array. Additional structural engineering can allow them to sense shear forces with high spatiotemporal resolution, which can lead to achieve human-level tactile perceptions for robotics. Still, manufacturing challenges remain in the realization of flexible multi-functional tactile sensors with desired density and shear-force sensation, because only scalable techniques are are suitable for industrial applications.
Here, we report scalable flexible tactile sensor array with ultra-high spatiotemporal resolution including shear force sensation and real-time closed-loop grip adjustment for robotic android fingers and beyond [2]. We leveraged the flexible display technology and fabricated advanced dual-gated piezoelectric zinc oxide (ZnO) thin-film transistors (TFTs) on thin and flexible polyimide substrate. We attached a 3D Polydimethylsiloxane (PDMS) pillar array on the fabricated TFT arrays which exhibited excellent normal and shear force sensing over a broad range of forces, in both dry and wet environments. An individual ZnO TFT can intrinsically transduce the force and multiplex the signal, which allows integrating hundreds of elements with uniform sensitivity. The array composed of 256 TFTs achieved maximal spatial resolution of 100 μm and maximal frame refresh rate of 100 Hz, which to the best of our knowledge is the highest spatiotemporal resolution reported to date. The TFTs were reliably operational under curved environments with bending radius of 5 mm, or after 10000 bending cycles. Closed-loop control of robotic fingers showed rapid slip-detection and grip adjustment using feedback exclusively from the tactile sensor array, enabling autonomous robotic tactile perception. Other novel applications such as water-proof operation and flow detection are also demonstrated.

Wearable Kirigami-Based Sensor Patch for Rehabilitation of Shoulder Joint Injuries and Sports Performance Analysis Erin Evke, Amani Alkayyali, Rachel Menge, Alanson Sample and Max Shtein; University of Michigan–Ann Arbor, United States

Fitness activity trackers and health-monitoring devices are becoming increasingly prevalent in everyday life. Motion trackers constitute a class of wearable devices, with numerous applications, including physical therapy (PT) and analysis of sports performance, in which monitoring of the angular positions of joints can accelerate rehabilitation and improve performance. The shoulder joint is notoriously difficult to track, as it exhibits more degrees of freedom and greater articulation than most joints in the human body. Many traditional methods, as well as other wearable sensors used to record limb and shoulder movement remain quite limited in versatility or scalability.

We created a wearable patch from a flexible *kirigami* substrate, enabling a planar sheet with embedded circuits to conform to the three-dimensional shape of the shoulder. Upon deformation, the localization of stress near saddle-points in the kirigami structure is related to the degree of curvature, determined through finite-element modeling and experimental measurements, and assessed as a function of the sheet material and cut parameters. Strain gauges are strategically placed on the platform based on the stress distribution, creating a sensing device that corresponds to a standardized 19-camera motion tracking system, and can differentiate between many types of motion, including running, shrugging, arm circles, etc., in real time. The combination of electrical sensing elements and closed-shape kirigami structures demonstrated by this work enable a highly wearable, garment-integrable, inexpensive joint motion monitoring device that can be used for rehabilitation, athletic

training, feedback control for augmented mobility, robotics, and other applications.

5:45 AM F.FL03.06.06
Graphene Nanocomposite Kinesiology Tape for Human Motion Assessment Yun-An Lin[1], Yujin Park[1], Long Wang[1], Wei-Hung Chiang[2] and Kenneth J. Loh[1,1]; [1]University of California San Diego, United States; [2]National Taiwan University of Science and Technology, Taiwan

In recent years, wearable sensors have attracted considerable interest among the general public due to increased awareness in personal health. Technologies as such can be particularly beneficial to industries related to virtual reality, sports performance, military, and healthcare. However, most wearable sensors that are available today are still based on bulky, rigid, inconvenient, electronic devices. Furthermore, they are limited to discrete sensing at their instrumented locations. On the contrary, sensors in the form of patches are more conformable to the human body and are capable of distributed sensing. For this reason, the purpose of this study is to develop a flexible, skin-like sensor capable of continuous, real-time, human physiological monitoring. The approach was to integrate strain-sensitive graphene-based thin films with commercially available kinesiology tape (K-Tape) as the substrate. The strain and motion sensing properties of these Smart K-Tape were characterized using a load frame. Upon verifying their strain sensing properties, the wearable sensors were tested on individuals performing different activities and undergoing different types of movements. Data acquired from the wearable sensors were compared against post-processed recorded video of subjects performing different controlled motions. In addition, a network of these graphene-enhanced K-Tape could form a network of sensors for distributed motion monitoring. In general, repeatable and consistent sensing responses were obtained and confirmed, which demonstrated their potential applications for the development of next-generation human motion and physiological monitoring systems.

5:55 AM F.FL03.06.08
Computational Wrapping—A Universal Method Based on Computational Origami for Conformable and Wearable Devices Yuki Lee[1], Jyh-Ming Lien[2] and In-Suk Choi[1]; [1]Seoul National University, Korea (the Republic of); [2]George Mason University, United States

In this talk, we propose a novel method to make conformable devices on non-zero Gaussian surfaces, i.e. flexible devices that can be transformed into any complex 3-dimensional shape. We used computational polyhedral edge unfolding methods to obtain planar figures of arbitrary complex 3-dimensional shapes. It is well-known that 2-dimensional substrates cannot be attached on the non-zero surfaces without stretching, however, by computational approximation of 3-D surface and making it flat by algorithmic method, we could convert any 3-D shapes into a 2-D sheet. We can make devices having the programmed unfolded figures and return it to the original 3D shape. In this way, we could make electroluminescent lighting and primary battery which can conformably wrap diverse 3-D surfaces without failure. Shape programmable devices with computational wrapping design can cover anywhere on the 3-dimensional shapes including human skin and are able to be applied not only personalized wearable or skin attachable devices but also various industries, such as automotive design, clothing, and fashion accessories, medical services and so on.

6:05 AM F.FL03.06.09
Materials Selection Principles for Human Motion Detection via Textiles S. Zohreh Homayounfar, Ali Kiaghadi, Deepak Ganesan and Trisha Andrew; University of Massachusetts, Amherst, United States

The advancement of smart apparels capable of tracking human physiological signals and body locomotion has a great potential to revolutionize human performance sensing and personalized health monitoring through transforming daily life clothing into sensors. Quantitative evaluation of kinetic parameters of individual gait along with physiological signals can be employed in games and sports, as well as in the diagnosis of many diseases such as Parkinson's, Multiple Sclerosis, and sleep disorders. Among different methodologies in developing wearable sensors such as inertial measurement units, textile-based electromechanical sensors encompass the majority of widely adopted applications. Electromechanical sensors fall into three major categories based on their active mechanisms: piezoelectric sensors, triboelectric sensors, and piezoresistive sensors. Recently, different combinations of materials and designs have been reported to develop wearable sensors, each of which provides a unique window into a slightly different range of motion sensitivity. For example, some human signals and motions lie in the small-scale range of pressures such as those of a subtle touch, arterial pulses, and sound vibrations, while the other body movements lie in medium to a large range of pressures, such as joint movements, and locomotion during sleep and intense activities. The ability to design an unobtrusive wearable sensor being highly responsive in the required range of signals calls for getting an insight into the difference between the three mechanisms of electromechanical sensing and their corresponding responses under certain conditions.
Here, we introduced a set of materials selection principles which gives researchers an in-depth insight into how to design a

wearable electromechanical sensor when it comes to acquiring data from a specific source of motion. In order to achieve this goal, we performed a set of purposefully designed experiments on three types of wash-stable fabric-based electromechanical sensors that had already been introduced by our lab, i.e., triboelectric sensor, piezoelectric sensor, and piezoionic sensor as a subset of piezoresistive ones. These experiments explored the effect of impact pressure, bending angle and speed, frequency, presence of a base pressure, response time, breathability, and having a multi-layer structure on the performance and sensitivity of each type of sensors. For an instance, it turned out that the triboelectric and piezoelectric sensors are a more reliable sensing element for dynamic pressures, such as joint movements, with the former being failed in the presence of a base pressure. Piezoresistive sensors are the ones with the ability to sense both static and dynamic pressures, as well as being responsive under a base pressure. However, piezoresistive one would not be a choice when it comes to bending applications. Upon this comprehensive comparison, we demonstrated a conclusive map that can provide the researchers with distinguishing features of these three types of sensors to be used in corresponding niche applications.

6:15 AM F.FL03.06.10
Late News: Simulation and Fabrication of Pyramidal Microstructured PDMS Films for Capacitive Pressure Sensors Michael Facchini-Rakovich and Manisha Gupta; University of Alberta, Canada

Capacitive pressure devices have been used for different applications such as wearable health sensors, soft-robotics, and prosthesis. These devices can be designed as parallel plate capacitors with an elastomer dielectric film like polydimethylsiloxane (PDMS). When different microstructures are added to these elastomer films then the pressure range and sensitivity can be tuned. Here, we conducted simulation for pyramidal microstructures as they spread the force evenly and can be repeatably fabricated. We introduce a simple finite-element-method simulation model for determining the capacitance and sensitivity of these microstructured films. The model sees the PDMS films as consisting of parallel and series capacitors, and volumetrically solves for the total capacitance. COMSOL Multiphysics is used to generate various geometries. Key parameters, such as pyramid spacing, width and height are seen to influence the performance of sensors. We studied these parameters from the 10 to 100 μm range. We can modify the initial capacitance from 12.74 to 82.75 pF/cm2, and the sensitivity from 0.008 to 0.18 per kPa. As well, penetration into a lamination layer, and layer thicknesses are also studied. These are factors come into play during the moulding and bonding processes. Penetration was studied for 1 to 6 μm range, and layer thicknesses from 7 to 105 μm. These allow the control of capacitance from 12.15 to 27.9 pF/cm2, and sensitivity from 0.01 to 0.03 per kPa. Pyramidal structures can be fabricated via a moulding process of PDMS and bonding it to metalized plastic sheets. Moulds consist of square pyramidal arrays obtained by KOH etching of silicon wafers, and bonding can be performed by lamination to a thin PDMS layer. We will present the performance of devices in relation to these parameters and compare them with other mathematical models. Furthermore, we use the simulation to predict performance trends, and compare them with experimentally gathered data from fabricated devices. This simulation model may be used to predict the performance of new devices too by modifying the geometry. Doing so, devices can be tuned to obtain different ranges of pressure sensing and sensitivity for specialized applications. Ranging from monitoring pressure sores, with a necessary range up to 100kPa, to artificial skin with sensing below 1 kPa.

SESSION F.FL03.07: E-Textiles—Fiber-Based Processing
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-FL03

5:00 AM *F.FL03.07.01
The Rise of Fiber Electronics Huisheng Peng; Fudan University, China

Abstract : It is critically important to develop miniature electronic devices for a variety of emerging new fields, such as wearable facilities, smart textiles and internet of things. Here a novel family of energy and electronic devices with various functionalities, e.g., energy harvesting, energy storing, lighting, and sensing, in 1D fiber configuration are carefully discussed with unique and promising advantages such as lightweight and weaveable compared with the conventional planar architecture. The main efforts will be made to highlight the recent advance in the electrode material, device structure and property extension.

5:15 AM *F.FL03.07.02
Flexible Bioelectronics on a Thread Sameer R. Sonkusale; Tufts University, United States

This talk will explore the new realm of using textile threads as an ultimate platform for flexible and stretchable bioelectronics. Threads offer unique advantages of universal availability, low cost, material diversity and simple textile-based processing. Interestingly, threads also provide an ideal platform for passive microfluidic sampling and delivery of analytes. In this talk, I will report reel-to-reel fabrication of functional smart threads for variety of sensing and electronics application. I will report on nanomaterial-infused smart threads for sensing physical activity and temperature. Nano-infused threads will be presented for sensing pH, glucose, lactate, ammonium and other chemical and biological biomarkers directly in biological fluids such as sweat or wound exudate. Coloimetric washable threads that can sense both ambient and dissolved gases will be shown. Beyond sensing and microfluidics, I will present our recent work on making super-thin transistors and electronics directly on threads. This new toolkit of highly flexible thread-based microfluidics, sensors, transistors and electronics makes it possible to realize smart surgical sutures and flexible smart bandages for chronic wounds. Our recent work on using threads for closed loop spatiotemporal dosage controlled drug delivery will also be presented.

5:30 AM *F.FL03.07.03
Fiber-Based Sensors for Electronic Textiles Jordan Tabor, Ashish Kapoor and Tushar Ghosh; North Carolina State University, United States

Soft polymer-based wearable sensors as an integral part of textile structures have attracted considerable scientific and commercial interest recently because of their potential use in healthcare, security, and other areas. Electronic sensing capabilities can be integrated into textiles at fiber, yarn, or fabric level but unobtrusive integration of sensing capabilities while preserving all desirable textile qualities like comfort and flexibility can be better achieved by introducing the desired functions at the fiber level. In this research, we demonstrate a transformative sensing technology through the design of a multimodal and multifunctional woven sensor array by employing bicomponent fibers consisting of insulating and electrically conducting segments of unique cross-sectional shape, wherein each cross-over point in the woven fabric structure acts as a sensing pixel. To demonstrate the concept the fibers are initially fabricated using a benchtop coextrusion method. The insulating segments are formed using an ultraviolet curable poly(dimethylsiloxane) (PDMS) while the conducting segments are made from a conducting polymer composite containing PDMS and carbon black. The multimodal characteristic of the sensors is demonstrated through the measurement of capacitive and resistive responses while multifunctional capabilities are explored by measuring tactile (normal force), tensile, and shear deformations, as well as wetness and biopotential. As a potential biomedical application, these fiber-based sensing arrays are integrated into a prosthesis socket to monitor pressure within the inner socket environment of lower limb amputees. Also, a large channel sensor array is fabricated and its potential for contactless sensing of gestures is demonstrated as a potential textile-based human-machine interface. In order to demonstrate the scalability and commercial relevance of the concept, we have also fabricated the same sensory fiber using the tricomponent melt extrusion (TME) method. It is a process that involves the simultaneous extrusion of three distinct polymers to produce unique fiber shapes. Due to the complex nature of this process and the specialty equipment required, TME has rarely been utilized in research efforts and has not been explored for producing fiber-based sensors.
So far in this ongoing research, we have extruded the sensory fibers of the desired shapes using the TME process and explored the influence of the shape control parameters such as flow-rate and fractional throughput. We have characterized the fibers for their morphological, mechanical, and electromechanical properties. Initial results indicate that the micron-scale fibers can be produced at speeds of >100 m/min thus providing a scalable and commercially relevant method of producing fiber-based sensors for wearable technology.

5:45 AM F.FL03.07.04
Carbon Nanotube Yarn and Fabric for Wearable Electronic Textile Applications Md. Milon Hossain[1,2], Mostakima Lubna[1] and Philip Bradford[1]; [1]North Carolina State University, United States; [2]Khulna University of Engineering & Technology, Bangladesh

Individual carbon nanotubes (CNTs) have remarkable properties that are often hard to scale directly to macroscopic materials and devices. A tremendous effort has been made to assemble CNTs at the micro and macro scale in controlled methods to utilize their anisotropic material properties. Here we report a single-step method of assembling CNTs wrapped textile yarns for wearable electronic textile applications. The dry spinning method was used to fabricate CNT yarns from millimeter tall vertically aligned CNT arrays produced by the chemical vapor deposition method. Both pristine CNT and CNT wrapped textile yarns were produced and their structure-properties relationship were compared. This unique method of assembling CNTs with traditional textile yarns provides greater freedom to tailor the strength and conductivity of the yarns for desired applications. Surface morphology examination showed that CNTs were wrapped uniformly over the core textile yarn and have a similar diameter to those yarns suitable for producing highly flexible textile fabrics for body-worn applications. The CNT yarn showed very good mechanical properties and could withstand 1000 loading cycles at a 2% strain. The use of

polyurethane binder enhanced the mechanical stability of the CNT yarn and prevented the delamination and loss of CNTs from the core yarns during mechanical strain. The CNT yarn was knitted to produce a seamless 3D knitted structure for strain sensing and Joule heating applications. The produced knitted fabric could sense applied strain and successfully track the movement of the finger. When voltage was applied to the fabric, a highly stable heat was generated in seconds and the fabric can produce heat above skin temperature with as low as 3 volts applied. To realize the true potential of the CNT yarns for use in next-generation wearable electronics, the CNT yarn was subjected to an extensive wash durability study. It was found that the CNT yarn was extremely resistant to washing showing no significant changes in conductivity after 30 washing cycles. This yarn may also find uses in electromagnetic shielding and energy storage textile applications.

The integration of conducting architectures within thermally drawn thin and flexible fibers is emerging as a versatile platform for smart sensors and imaging systems, robotic surgery, biological and neural probes, and advanced textiles[1-3]. The fabrication of conductors with nanoscale feature sizes, large aspect ratios, complex transverse geometries and excellent conductivity within thermally-drawn fiber electronics, however, remain unresolved. Here we, for the first time, address this challenge via the thermal drawing of metallic glasses (MGs), a material system that is metallic yet with a disordered atomic structure compatible with controlled thermal deformation[4]. The high viscosity during drawing, combined with a viscous interface provided by a thermoplastic matrix surrounding MGs domains allows us to control fluid instabilities that are normally detrimental for molten crystalline metals. This fabrication strategy enables the production of ultra-long, highly uniform and well-ordered nanoscale MG domains with arbitrary cross-sectional geometries within flexible polymer fibers. In terms of integrating metallic electrodes within flexible fibers, catheters, capillaries or textiles, the figure of merit we can achieve, that can be defined as the ratio of the conductivity to feature sizes, significantly surpasses existing strategies. Beyond using MG components as electrodes, we further show that they can be monolithically integrated with other functional materials, forming novel all-in-fiber flexible devices and smart textiles. Specifically, optoelectronic fibers that integrate MG ribbons serving as highly conductive electrodes and a semiconducting selenium core serving as a photodetector are fabricated. The device exhibits a unique combination of excellent responsivity and sensitivity that compares favorably with other reported nanoscale planar devices. Moreover, the flexibility and form factor of the polymer cladding enable to weave the fiber into different types of textiles. Our work brings, for the first time, extreme miniaturization of highly conducting metal-based electrodes, paving the way towards the integration of more complex functionalities and devices in flexible electronics, fibers and fabrics.

Full-Area Textile Displays with All Organic Light-Emitting Diode Fibers Young Jin Song, Ha-Young Song and Sung-

Min Lee; Kookmin University, Korea (the Republic of)

As an emerging format of wearable electronics, the electronic textile (e-textile) display devices consisting on emitting fibers have been actively studied for substantiating 'in-cloth' information displays. Several technical issues have to be resolved to create fiber-based e-textile displays, such as high electroluminescence performance of luminescent fibers, solid passivation systems, and interconnectable configuration of pixel elements in fibers for the two-dimensional matrix-addressing. Recently, we successfully demonstrated a class of the e-textile displays by weaving interconnectable organic light-emitting diode (OLED) fibers with conductive fibers. This OLED e-textile display could be operated by the passive matrix addressing scheme due to perpendicularly aligned woven fiber network with interconnectable OLED fibers and conductive fibers that were served as scan and data lines, respectively. Moreover, it was reliably operated even in the water owing to the chemically/mechanically sturdy but electrically conductive passivation system formed on each OLED pixel. Despite the noticeable proof-of-concept, the reported devices could exploit a half area over the available entire textile area at the most due to the nature of woven network that OLED pixels placed alternately along the conductive fiber, which limited the imaging resolution. In this regard, here we present a strategy to achieve matrix-addressable e-textile OLED displays throughout the entire textile area by weaving only OLED fibers that can support the scan and data lines at the same time. To create the united functional fibers, phosphorescence OLED pixels are regularly deposited on the common indium tin oxide (ITO) electrode coated on one side of the rectangular-shaped polyimide (PI) fiber. The conductive metal bus electrode that can work as a data line in the matrix addressing scheme is thermally deposited on the opposite side of the PI fiber except the defined emitting spots. As the OLED pixels exist at every cross points of interlaced perpendicularly arranged OLED fibers, full-area OLED e-textile displays can be achieved, where high-resolution images are produced by the passive matrix addressing process.

High-Throughput Cleanroom-Free Fabrication of Thread Based Transistors Tanuj Kumar, Rachel E. Owyeung and Sameer Sonkusale; Tufts University, United States

In the past few decades, applications such as wearable electronics, biosensing, and flexible displays have led to advances in flexible electronics.[1,2] Textile threads are a highly suitable substrate for truly flexible and biocompatible electronics. Recent works have demonstrated thread-based transistors (TBTs), but their methods were not scalable to manufacturing more than a few transistors.[3,4] To realize complex large-scale thread-based circuits for wearables, diagnostics, and flexible displays, a high throughput fabrication method of TBT is required.

In this work, we present a low-cost, high-throughput, and cleanroom-free fabrication process for ionogel gated, poly(3-hexylthiophene)-based organic TBTs. This lithography-inspired approach involves the use of a flexible Ecoflex "mask" that threads are pierced into, to fabricate the active channel area gap. Then, conductive carbon ink is painted or drop cast on to fully coat the exposed threads, and when dried, the threads are removed to reveal the active channel area of the transistor. Notably, the flexibility of the mask is paramount for easy insertion of threads when stretched and provides a tight seal around each thread when relaxed to inhibit electrode ink seepage.

In our preliminary experiments, we achieved a density of 1 TBT fabricated per cm^2 of Ecoflex mask; we demonstrate fabrication of close to 50 TBTs in a mask of approx. 50 cm^2. After correcting for some geometrical variations from manual effort, we show consistent device performance among all TBTs with a threshold voltage of (1.48 ± 0.11) V, an operating region of 0 to -3V, and an ON/OFF ratio of the order of 10^2. These results prove the feasibility of this new approach for batch fabrication of several TBTs which with automation, holds potential for even higher areal densities of fabricated TBTs and much tighter tolerances. What we have proposed will address the key bottleneck in scaling up threads as a substrate for very large-scale electronics on thread with applications in wearable devices, flexible displays, and diagnostic toolkits.

6:25 AM F.FL03.07.10
Late News: The Effect of Cellulose Nanocrystals (CNCs) on the Conformation of Polyvinylidene Fluoride (PVDF) Nanocomposite Fibers and Triboelectricity of Textile Sensors Jung-Eun Lee, Hyejin Ju, Ga-Hyeun Lee, Ji Hyun Kim and

Han Gi Chae; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Polymers such as poly(vinylidene fluoride) (PVDF), and its copolymers with hexafluoropropylene (HFP), trifluoroethylene (TrFE) and chlorotrifluoroethylene (CTFE) are known to possess electroactive properties and have been studied for decades, enabling them one of the most promising candidates for wearable and smart textile applications. Nonetheless, the practical applications are still limited and are in the early stage of development because of poor mechanical integrity. Most of researches have focused on the form of film or electrospun mat (nanofiber) which showed weak mechanical properties to practically use. Since the high mechanical properties are the critical requirement to smart textiles because the resistance ability to external damage is related with the durability of textiles, the film and mat should be replaced with a stronger fibers. In the current study, PVDF and PVDF/cellulose nanocrystal (CNC) nanocomposite fibers were dry-jet wet spun at CNC concentrations of 0, 1, and 3 wt% with respect to the polymer. The high draw ratio (DR) of 8 and the interaction between PVDF matrix and CNC lead to superior mechanical properties and β phase fraction (F_β), which is beneficial for practical application in smart textiles. The behavior of various conformation of PVDF were also analyzed according to DR and CNC contents. All fibers showed increase in tensile properties and F_β as the polymeric chains become extended with increasing DR. Among them, the highest 298.0 MPa of tensile strength, 3.3 GPa of tensile modulus, and 69.1% of F_β were exhibited in fibers with the addition of 1 wt% of CNCs at DR 8 based on their active interaction with PVDF. To demonstrate the use of these PVDF-based fibers in wearable devices, the triboelectric textile sensors were fabricated through a conventional weaving method based on their high mechanical integrity. They can detect a broad pressure range of 980 Pa to 98 kPa, enabling diverse pressure-sensor applications.

Skin-Interfaced Wearable Sweat Biosensors for Personalized Healthcare Wei Gao; California Institute of Technology, United States

The rising research interest in personalized medicine promises to revolutionize traditional medical practices. This presents a tremendous opportunity for developing wearable devices toward predictive analytics and treatment. In this talk, I will introduce our recent advances in developing fully-integrated skin-interfaced flexible biosensors for non-invasive molecular analysis. Such wearable biosensors can continuously, selectively, and accurately measure a wide spectrum of sweat analytes including metabolites, electrolytes, hormones, drugs, and other small molecules. These devices also allow us to gain real-time insight into the sweat secretion and gland physiology. The clinical value of our wearable sensing platforms is evaluated through multiple human studies involving both healthy and patient populations toward physiological monitoring, disease diagnosis, and drug monitoring. This talk will also feature our very recent works on laser-engraved lab on the skin and biofuel-powered battery-free electronic skin toward metabolic/nutritional management as well as dynamic stress monitoring. These wearable and flexible devices could open the door to a wide range of personalized monitoring, diagnostic, and therapeutic applications.

Highly Compliant and Printable Giant Magnetoresistive Sensors for Human-Interactive On-Skin Electronics Minjeong Ha[1], Gilbert Santiago Canon Bermudez[1], Yevhen Zabila[2], Jürgen Fassbender[1] and Denys Makarov[1]; [1]Helmholtz-Zentrum Dresden-Rossendorf, Germany; [2]Institute of Nuclear Physics PAN, Poland

The highly-compliant and skin-conformal magnetic field sensors have been of great interest for the human-interactive on-skin electronics capable of position recognition and tracking gesture. To design such on-skin electronics, solution-processable printing technologies are attractive way due to simple, cost-efficient, and highly adaptable to various materials. Here we report printable giant magnetoresistive (GMR) sensors on ultra-thin films that can naturally comply with the skin. Thanks to the strong interfacial bonding of triblock copolymer in GMR paste, the printed GMR microflakes could be firmly adhered to the any substrates with excellent mechanical stability under 16 μm bending radius without any damage. The excellent percolation contacts among GMR microflakes coupled with 2nd antiferromagnetic maximum attribute the high sensitivity of 3 T^{-1} in low magnetic field ranges of 0.88 mT on the bending curvature of 16 μm, resulting in 3409 times higher figure of merits than current state-of-the-art printable magnetic field sensors. Since the fast quenching of binding matrix induced

random orientation of GMR microflakes rather than 2D stacks, the printed GMR sensors are omnidirectional magnetic field sensing capability regardless of angular change from 0 to 360º for freely locating GMR sensors on skin. With this performance, our printed GMR sensors on skin demonstrate a touchless control of virtual objects for the practical application in human-interactive wearable devices, artificial prosthetics, robotics, and internet of things.

5:25 AM F.FL03.08.04
Facilitating Hair Growth via Flexible Vertical Red µLED Jaehee Lee and Keon Jae Lee; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

A lot of people around the world have suffered from alopecia, which can lead to aesthetic issues, low selfesteem, and social anxiety. Therapeutic technology including thermal, electrical, pharmacological, and photo stimulation have been suggested to treat hair loss. Among them, laser stimulation to hair is a strong treatment, activating the proliferation of hair follicles without side effects. Particularly, periodically irradiating red light with a wavelength of 650nm in the hairless area can help efficient stimulation of hair follicles under the skin, because this light can penetrate deeper into the skin tissue than blue and green light with short wavelengths. However, this laser stimulation treatment has difficulty in high power consumption, large size, and spatiotemporal restriction. Recently, flexible micro-light-emitting diodes (µLEDs) have been a great attention for future biomedical devices, such as biosensors, pulse oximetry (SpO2) sensors, and optogenetic stimulators due to its high performance and outstanding stability. However, flexible µLEDs still have significant drawbacks in application to wearable phototherapeutic devices, such as high heat, low optical efficiency, and high energy consumption.
Herein, we report high-performance 30 × 30 AlGaInP fVLEDs fabricated with transfer-free monolithic method for a wearable phototherapeutic device. Ultrathin flexible µLEDs were fabricated by vertically interconnecting top and bottom electrodes. The red f-VLED arrays were conformally attached on a human wrist with high irradiance of ∼30 mW mm−2 and low forward voltage of ∼2.8 V. The red light with 650 nm wavelength deeply penetrate the skin and stimulate the hair follicles, which is located 2 mm under the skin. The thermal stability of the monolithic f-VLED was theoretically investigated by using finite element method (FEM) simulation and experimentally optimized by operating f-VLEDs on the skin. Mechanical stability of monolithic f-VLEDs was confirmed by harsh periodic bending/unbending motions, which is necessary for skin-attachable phototherapeutic devices. Finally, photostimulation in hairless region was performed to promote hair growth in a living depilated mouse via f-VLED array with thermal stability. Hair regrowth in the mice via f-VLED was verified by analyzing immunofluorescent and histological effects.

5:35 AM F.FL03.08.05
A Laser-Engraved Wearable Microneedle Array Based on Biopolymers Obtained from Food Residues Elvira Fortunato; Universidade NOVA de Lisboa, Portugal

Although many delivery systems have been proposed to improve drug permeation through the skin, all of them suffer from several limitations. This drives a continuous search for innovative systems that can provide safe and effective transdermal drug delivery solutions. In line with this, microneedle arrays (MNs), a hybrid combination of hypodermic injections and transdermal patches, have been proposed. MNs consist of micro-scale needles that can pierce the skin by a simple, minimally invasive and painless route, enabling the transport of drugs and macromolecules into the human body. This study reports, for the first time, the use of a bio-based, biodegradable and biocompatible polymer, poly(3-hydroxybutyrate-co-3-hydroxyvalerate), P(3HB-co-3HV), for the fabrication of a biopolymer-based MNs patch. Molds of poly(dimethylsiloxane) (PDMS) were prepared by direct laser writing technology, a low-cost and mask-less technology, and used to produce biodegradable P(3HB-co-3HV) MNs by a thermosetting process. The best results were obtained with a laser power of 30 W at 0.15 m/s, with a spiral model as a pattern. The obtained MNs had a length of 0.69 mm and a diameter of 0.33 mm, ideal for painless penetration of the skin. Additionally, the produced MNs had good mechanical properties and the ability to successfully impregnate fluorescent dye (Rhodamine 6G). These features render P(3HB-co-3HV) a promising material for the development of novel MNs with improved functionality

5:45 AM F.FL03.08.06
Ultra-Low-Noise Organic Biosignal Amplifier with Flat Stamp Parallel Printed Electrodes Takafumi Uemura[1], Tomoharu Kimura[2], Yayoi Shibafuji[2], Takeshi Suyama[2], Hiroyuki Ueno[2] and Tsuyoshi Sekitani[1]; [1]The Institute of Scientific and Industrial Research, Osaka University, Japan; [2]SCREEN Holdings Co., Ltd., Japan

The monitoring of microvolt-level biosignals such as electroencephalograms (EEG) requires the application of low-noise signal amplifier circuits, which, for single-use cases, must be fabricated for disposability using low-cost manufacturing techniques. In this study, we propose a scalable electrode printing process for organic transistors that can carry out precision measurement of EEG using a low-noise organic amplifier. In the transistor fabrication process, Ag electrodes are processed

via flat stamp parallel printing (FSPP), and fine-process optimization to minimize the charge-trapping effect enables a three-order reduction in transistor noise. The low-noise transistors were used to produce an organic pseudo-CMOS amplifier with a small noise level of 2.2 μVp-p at 10 Hz. The ultra-low-noise organic amplifier enables precision EEG monitoring in a close correlation with signals obtained using a commercialized measurement system.
Wearable biosensing equipment is a highly anticipated next-generation medical device technology for obtaining advanced personal healthcare and self-medication. A critical requirement for a wearable device is that it does not interfere with daily human activity, which means that it must be mechanically flexible and lightweight. Furthermore, to avoid motion-induced artificial noise and obtain higher-quality biosignals, the sensor device must be lightweight and remain in close contact with the surface of the human body. To meet these requirements, a number of sheet-type flexible biosensors have been recently developed [1-5]. A further requirement for wearable biosensor devices is disposability for single-use cases, which in turn requires the use of low-cost manufacturing processes. Also, the most critical circuit parameter in the development of biosignal detection circuits is transistor noise, which limits the minimum detectable signal level and quality of measurement. In this study, we demonstrate a low-noise printing process that minimizes transistor noise by optimizing the source-drain electrode stacking process. The device employs a bottom-contact, top-gate transistor structure in which source-drain silver electrodes are printed using the flat stamp parallel printing (FSPP) method. The FSPP is a type of reverse offset printing method that enables both the patterning of fine source-drain electrodes and a large-area biopotential input electrode. In the transistor stacking process, several improvements such as thinning the contact electrodes and insulator film and optimizing the chemical treatment process for the contact electrodes were conducted to evaluate their respective impacts on transistor noise. This process optimization resulted in improved mobility, reduced contact resistance, and reduced subthreshold slope and enabled the fabrication of a low-noise organic transistor, 2.3×10^{-11}/Hz, with improved transistor characteristics. Using the low-noise transistors, a pseudo-CMOS amplifier with an ultra-low output noise of 2.2 μVp-p at 10 Hz was successfully fabricated and enabled precision EEG monitoring. The scalable printing method for realizing low-noise organic amplifier is a useful fabrication method for a single-use daily personal healthcare system.

Fiber-Based Soft Electronic Sensors for Textile Electronics and *In Vivo* Bioelectronics Jaehong Lee; Daegu Institute of Science and Technology (DGIST), Korea (the Republic of)

Electronic devices with stretchable and wearable features have been attracting a huge interest because of their potential applications in wearable electronics, electronic skins, biomedical engineering, and in-vivo bioelectronics. Among various types of soft and wearable electronic devices, textile electronics which combine conventional textiles and electronic devices is one of promising fields because clothes are essential at all times for all humans regardless of age or gender. However, conventional planar electronic devices have been limited to being woven into flexible textiles or integrated onto complex nonplanar substrates. Such limitation has hindered their use in textiles electronics or advanced wearable electronics.[1] In this regard, stretchable and wearable electronic devices in fiber (1D) form, which can be directly integrated into daily clothes or textiles without any inconsistency are greatly promising for future wearable electronics. In addition, the fiber-based electronic devices can successfully overcome practical limitations (e.g. structural mismatching, suturability. etc.) of previous planar soft electronics in *in-vivo* applications.[2]
In this talk, fiber-based (1D) soft pressure and strain sensors based on metallic nanomaterials, which can overcome the existing limitations of previous 2D electronic devices, are presented. The research starts with the development of stretchable conductive fibers with outstanding conductivity (>20,000 S/m), stretchability (>450%) and stability over 10,000 stretching cycles using metallic nanoparticles.[3] Based on the conductive fibers, various fiber-based mechanical sensors such as pressure, strain, and multimodal sensors are fabricated for smart textile and wearable applications.[3,4,5] In addition to their successful demonstrations in wearable applications, this research is also focusing on considering practical issues in current implantable electronics which is important for clinical applications but have been barely considered so far.[2]

A Bioinspired Ion Channel for Wearable Electronic Skin Joo Sung Kim, Vipin Amoli, Yoon Sun Chung, Yunah Kim, Hanbin Choi, Hyukmin Kweon and Do Hwan Kim; Hanyang University, Korea (the Republic of)

Creating artificial sensory skins that shows the tactile-sensing capability of human skin has been a big challenge in wearable skin electronics. In particular, biomimetics has emerged as a burgeoning area in the field of deformable tactile sensor skins that has led innovations in material designing and device structure manipulation with the aim of imitating sensing mechanism of human skin, intelligently.
In this talk, inspired by the sophisticated physiological ion dynamics of living cells, we describe a uniquely designed deformable ion channel consisting of artificial ions confined into well-designed hybrid interface. Novel bottom-up strategy employed here resulted into supramolecular polymer networks through non-covalent interactions between poroelastic artificial ions and viscoelastic polymer chains or through hydrogen-bonding triggered ion dynamics, which endows effective ion drift under mechanical stimuli, simultaneously. This design allows for high-performance synaptic plasticity as well as ultrasensitive mechano-transduction over a wide spectrum of pressure, which can serve next neuromorphic tactile platform for highly interactive human-machine interface.

6:20 AM *F.FL03.08.10
Wearable Smart Sensor System Youfan Hu; Peking University, China

The development of electronic devices that offer biointegration capabilities is of interest in various clinical and biological applications, where they could be used for monitoring, diagnosis and therapy. In general, an intimate interface is required between the device and the biological material, so the devices need to be built in a flexible form. At the same time, the increasing demand for portability restricts the allowable power dissipation of any device. Here we show several examples of wearable smart sensor systems for human body monitoring, including triboelectric nanogenerator-based self-powered sensors for respiratory and pulse monitoring, ultrasensitive flexible pressure sensors based on wrinkled microstructures for vocalization recognition, general 3D adjustable sensor platforms conformable to curved biological surface by utilizing kirigami art to extend 2D structures into 3D ones, and integrated smart sensor systems on ultrathin plastic foil with in-situ signal processing capability based on high-performance carbon nanotube complementary electronics. These cases show the great possibility of next-generation wearables for personal health care.

Monitoring of Human Diseases with Smartphones Through Soft, Smart Contact Lenses Eunkyung Cha and Jang-Ung Park; Yonsei University, Korea (the Republic of)

In order to diagnose and monitor the human disease, it is essential to continuously and periodically monitor the biomarker related to the disease. In a human body, eyes can act as sites that have the potential to provide various information about one's health condition including chemical and physical biomarkers. In particular, smart contact lenses have been studied as

the wearable medical device to diagnose and monitor diseases noninvasively, detecting biomarkers from the eyes. However, there has been no clear study regarding the correlation between the signals obtained from the eyes and the actual state of the disease. Smart contact lenses can have actual effects only when these two factors are established whether they are correlated. To address this problem, we studied the correlation of diseases using our smart contact lenses. One of the biomarkers that can be monitored by smart contact lenses is tear glucose level, which is related to diabetes. We fabricated the smart contact lens which includes electrochemical glucose sensor, antenna, and NFC chip, enabling its operation only with the smartphone. By applying this smart contact lens to the *in-vivo* test using live animals, we demonstrated that the tear glucose level is correlated with the blood glucose level. Accordingly, we verified that the smart contact lenses detecting tear glucose concentration can be used to diagnose and monitor diabetes. Another bio-signal that can be obtained from the eyes is the IOP(intraocular pressure), which can act as the indicator of glaucoma. To detect the IOP, we integrated the IOP sensor, transparent and stretchable antenna, and NFC chip onto the smart contact lens. We successfully measured human IOP with a smartphone by wearing this smart contact lens onto a human eye, presenting the feasibility of smart contact lens monitoring the state and progress of glaucoma.

6:45 AM F.FL03.08.13
Absorbent, Flexible and Transparent Substrate for Wearable Bioelectronic Devices Dhruv R. Seshadri[1,2], Christian A. Zorman[1,2,1] and Kath M. Bogie[1,2,1]; [1]Case Western Reserve University, United States; [2]Louis Stokes Cleveland Veterans Affairs Medical Center, United States

Epidermal electronics that conform to the irregular topography of the skin enable non-invasive monitoring and measurement of biomechanical, physiological, and biochemical parameters relevant to monitoring human health and performance. Materials such as polydimethyl siloxane (PDMS), polyethylene terephthalate (PET), and polyimide (PI) are routinely used as substrate materials; however, such materials are not absorbent thereby limiting their utility for applications that necessitate the wicking of large volume bodily fluids when placed on the open skin, such as for wound healing applications. Polyvinyl alcohol (PVA) has been routinely used as a sacrificial layer in fabricating epidermal electronics; however, its utility as a standalone material for substrates or flexible electrodes has not been extensively studied. The biocompatibility, relative ease of fabrication, cost, absorbing capabilities, and scalability render it an ideal material for wearable bioelectronic devices. The objective of this study was to develop an absorbent, flexible, transparent, and inexpensive substrate (herein referred to as *AFTIDerm*) for use in wearable bioelectronic applications that necessitate the aforementioned material properties. PVA solutions were created with varied glycerol concentrations (1 wt%, 3 wt%, 5 wt%, 7 wt%, and 10 wt%) and drop cast in 9 mm plastic dishes and cured overnight at room temperature for subsequent use. The absorbent capabilities of the substrate were assessed in phosphate buffer saline solution (PBS), pH 7.4 (mimicking a chronic wound environment), over a one-week period with samples assessed daily. An inverse relationship between the varied glycerol concentrations and percent mass increase was observed. The high variability among the 1% glycerol samples over the one-week period compared to the other glycerol concentrations (~ greater than 300% difference in mass increase over one week) suggest a potential percolation threshold at or below this level. The 5% glycerol samples demonstrated greatest stability (~120% mass increase) over the one-week period. Previous work by our group found that ~10% of individuals are sensitized to current commercial adhesives that are included in substrates today often resulting in erythema. Incorporation of silicone-based adhesives (compared to currently utilized acrylate-based adhesives) deposited in pre-defined geometries on the *AFTIDerm* substrate enable long-term adhesion to the skin without deleterious reaction. When placed over the wound in a porcine chronic wound model following a 4 mm biopsy, the 5% glycerol *AFTIDerm* substrate with the silicone adhesive absorbed exudate from the wound without swelling over a one-hour period. Mechanical stability of the *AFTIDerm* substrates was evaluated under cyclic loading over a strain range of 0 to 2.5% for 50 cycles. Data from each glycerol concentration suggest that the AFTIDerm substrates undergo a short burn-in period for less than 10 cycles before stabilizing. The 5% glycerol samples demonstrated the largest tensile stress of ~800 KPa over this duration with an increase in tensile stress noted over the initial burn in period, which was opposite to the decrease observed for the other PVA-glycerol samples. Overall, the measured tensile stress of the *AFTIDerm* substrate was significantly greater than that of Tegaderm™ (~50 KPa), which served as controls for all benchtop studies. Further elucidation of the mechanical properties of the PVA-glycerol substrate through pre-clinical and clinical testing will provide first-hand assessment of the utility of the *AFTIDerm* substrate for use in bioelectronic devices. Doping of the AFTIDerm substrate with conductive elements will assess the utility of the substrate as a platform for flexible electrode technologies.

6:55 AM F.FL03.08.15
Resettable Skin Interfaced Microfluidic Sweat Collection Devices with Chemesthetic Hydration Feedback Jonathan Reeder; Northwestern University, United States

Recently introduced classes of thin, soft, skin-mounted microfluidic systems offer powerful capabilities for continuous, real-time monitoring of total sweat loss, sweat rate and sweat biomarkers. Although these technologies operate without the cost, complexity, size, and weight associated with active components or power sources, rehydration events can render previous measurements irrelevant and detection of anomalous physiological events, such as high sweat loss, requires user engagement to observe colorimetric responses. Here we address these limitations through monolithic systems of pinch valves and suction pumps for purging of sweat as a reset mechanism to coincide with hydration events, microstructural optics for reversible readout of sweat loss, and effervescent pumps and chemesthetic agents for automated delivery of sensory warnings of excessive sweat loss. Human subject trials demonstrate the ability of these systems to alert users to the potential for dehydration via skin sensations initiated by sweat-triggered ejection of menthol and capsaicin.

A Printed Flexible Graphene Transistor-Based Biosensor for Real-Time Monitoring of Biomarkers Niazul I. Khan, MD Shaad Mahmud and Edward Song; University of New Hampshire, United States

Flexible and wearable electronics have become a rapidly emerging technology and are continuously finding new applications in the commercial world. The use of wearables has expanded far beyond being just a fashionable gadget and is now being recognized as a critically important and essential technology. In particular, the potential benefit it offers in the healthcare industry could revolutionize the field as it enables real-time continuous monitoring of biomarkers in a non-invasive manner without interrupting the user's daily activities. The use of nanomaterials in biosensors has shown to be very effective because of their high surface-to-volume ratio, enhanced reactivity, and in some cases, biocompatibility (Geim & Novoselov, 2007). Especially, 2D nanomaterials such as graphene show promising results in this regard. It not only offers highly sensitive detection of biomarkers due to its monolayer structure, exposing each carbon atom of the lattice to the sensing environment, but also provides flexibility in terms of its mechanical bendability which make them an unparalleled candidate for flexible wearable biosensors. As a result, its application as a channel material in field-effect transistors (FETs) offers numerous advantages in terms of mass-scale production, integration, power consumption as well as miniaturization. Graphene-based FETs (GFETs) have been shown by our group (Ghosh et al., 2018; Khan et al., 2020) and others (Wang et al., 2018; Zuccaro et al., 2015) to be effective in detecting biomarkers with high sensitivity. However, these devices developed for rigid substrates are not well-suited for the wearable platform requiring flexibility and stretchability. Recently, a flexible and stretchable GFET-based biosensor was developed for its potential use in wearable and implantable applications (Wang et al., 2019). However, the electrodes were deposited with metal evaporation and patterned with conventional photolithography and thus making the fabrication process expensive and complex. A viable alternative approach to manufacturing a wearable GFET device is the printing of conductive inks. The advantages of this method include rapid prototyping, low cost, and flexibility in the printed patterns among others. In this work, we investigate the feasibility of using a printed circuit board (PCB) printer with a polymer-based flexible substrate such as Kapton or polyethylene terephthalate (PET) film to develop a GFET biosensor. A Commercially available Voltera V-One PCB printer was used to pattern an electrode with conductive silver ink. A minimum feature size of 200 μm was achieved. Afterwards, the fabricated flexible GFET device was used to monitor biomarkers commonly present in human sweat sample (such as Dermcidin, a breast cancer biomarker) to test its feasibility as a wearable sweat-based biosensor.

Breathable Dry Electrode Designs for Bioelectronic Sensing Amanda Myers, Elizabeth Cobarrubias and Jesse S. Jur; North Carolina State University, United States

The ongoing improvement of human health and increased accessibility to wearable electronics has created new garment-based platforms for continuous health monitoring. Additional innovation in sensor design for long-term use is necessary for these smart textiles to be comfortable and accurate. Wet electrodes traditionally used in biopotential monitoring cannot be used in these platforms due to a limited shelf life and the potential to cause skin irritation. Dry electrodes can be used in smart

textiles, but also face considerable comfort and sensing challenges such as breathability, application pressure, noisy bioelectronic signals, and motion artifact. This study investigates the effect of dry electrode design on bioelectronic signal quality. Dry electrodes were designed with varying surface areas and vacancies in the conductive ink and polyurethane layers to test moisture vapor transmission rate and application pressure and to correlate those effects to bioelectronic signal quality. Results showed that electrode design influenced its conformability where an increased number of holes increased the pressure exhibited. The increased number of vacancies also improved electrode breathability. Electrodes were sewn into an armband to evaluate electrocardiogram (ECG) sensing performance where the ECG signal to noise ratio was compared to the dry electrode surface area and vacancy designs. There is a notable trade-off between breathability, skin-electrode impedance, and ECG signal quality attributed to the electrode design. These results demonstrate that an optimal balance between electrode design and contact area can be achieved to realize increased user comfort while retaining desired biopotential electrode properties for potential long-term wearability of e-textiles.

Versatile Micro Nano Fibre Printing Technique Towards 3D Sensing Architectures and Bio-Interface Devices Wenyu Wang, Yan Yan Shery Huang, Karim Ouarus, Alexandra Rutz and George G. Malliaras; University of Cambridge, United Kingdom

Fibrous structures and materials widely exist in nature and have played an important role in our daily life and industry. Thanks to the high aspect ratio, low bending stiffness, flexibility and transparency, fibres possess unique physical and optical properties that are usually inaccessible with conventional planer structures. Combining with functional materials and polymers, such as piezoelectric, conducting polymers and biocompatible materials, novel fibre-based devices and textiles could open up possibilities for emerging applications. Such prospects could range from transparent textile-based sensors to biointerfacing architectures. However, challenges largely remain with the current fibre fabrication techniques, in which the synthesised fibres are usually deposited to a surface substrate. Thus, the optomechanical properties of the planer substrates would largely compromise the advantageous properties of the fibres. Moreover, conventional fibre printing techniques usually suffer from inefficient functional material usage (*e.g.* blending functional material with passive polymer), and this could lead to an overall reduced performance in the final products.

Herein, we present two original fibre printing techniques, which are especially developed to efficiently print substrate-free functional fibres with different fibre dimensions and applications. First, the dynamic near field electrospinning is developed to fabricate *in situ* poled piezoelectric nanofiber mesh, with high visible light transparency (> 97%) and air permissiveness. Such suspended nanofibre mesh harnesses the physical merits of spider web in its high acoustic sensing ability and broad active bandwidth. Combined with piezoelectric polymers, such spider-web inspired acoustic sensor has a broad sensitivity bandwidth covering 200–5000 Hz at hearing safe sound pressure levels. Second, inflight fluidic fibre printing, which integrates conducting fibre production and fibre to circuit connection in a single step is developed to produce metallic (silver) or organic (PEDOT:PSS) fibres with 1-3 μm diameter. Using PEDOT:PSS fibres as a cell-interfaced impedimetric sensor and a moisture sensor, we show that even a single fibre component can achieve complex functions or outperform conventional film-based devices. The capability to design suspended fibres and networks of homo-, hetero- cross-junctions, paves the way to applications including flow-permissive devices, and 3D optoelectronic and sensor architectures. Overall, we demonstrate the versatility and scalability of novel fibre printing methods that could pave way for the next-generation fibre-based devices that could fully harness the potential of the physical merits of fibres and the functional performances of advanced materials.

Late News: Thermal-Free, Wireless Patch-Type Tissue Oximeter with Radiative Cooling Structure Minhyung Kang, Gil Ju Lee, Joon Hoon Lee, Min Seok Kim and Young Min Song; Gwangju Institute of Science and Technology, Korea (the Republic of)

For emerging skin-integrated electronics/optoelectronics, thermal management should be achieved for reliable signal acquisition as well as thermal comfort. However, the current layout of skin-integrated devices has limited their use to indoor settings, because of solar energy gain outdoors, particularly strongly in oximeters. Various approaches have been reported to release accumulated heat in the skin-integrated device, such as a thin metallic heat sink to dissipate the concentrated heat and a copper/paraffin bi-layer acting as a heat sink based on phase variation. However, metallic layers hinder wireless communication between the receiver and transmitter, and phase shift materials function irreversibly at high temperatures of ~ 50 °C. In particular, in conventional wearable oximeter reported in the literature, since black encapsulation layer is adopted to block ambient light, using the conventional layout in outdoor environment considerably exacerbates device heating owing to solar energy absorption. Previous works could not provide an obvious solution for these challenges.

Here, we introduce a new platform of radiatively cooled wearable optoelectronics that is free from heat and light concerns, which enables assessing athletic performance in outdoor environments under direct sunlight. To maximize the radiative cooling performance, a nano-/micro-voids polymer (NMVP), a nonmetallic and flexible radiative cooler, is realized by applying bi-layer layout of two perforated polymers (*i.e.,* polymethylmetacrylate (PMMA) and styrene-ethylene-butylene-styrene (SEBS)), which are optically and mechanically optimized for wearable optoelectronics. The NMVP boasts near-unity reflectivity and emissivity in the solar spectrum and atmospheric window (i.e., 8-13 μm-wavelength) with flexible feature. As a result, the optimized NMVP exhibits sub-ambient cooling of 6 °C in daytime under various conditions such as scattered/overcast clouds, high humidity, and clear weather. Additionally, the integration of the optimum NMVP with the device enables maintaining temperature of ~ 34 °C on the skin under sunlight, whereas the normally used, black encapsulated device shows over 40 °C owing to solar absorption. The heated device exhibits an inaccurate tissue oxygen saturation (StO_2) value of ~ 60 % compared with StO_2 in a normal state (i.e., ~ 80 %). However, our thermally protected device presents reliable StO_2 of ~ 80%. This successful demonstration provides a potential of thermal management in wearable devices for outdoor applications.

Late News: Wearable Humidity Sensor Based on Rhenium Disulfide (ReS2) for Respiration Monitoring Vivek Adepu, Naveen Bokka and Parikshit Sahatiya; BITS-Pilani, Hyderabad Campus, India

Due to the immediate requirement of accurate control of humidity in various industries such as agricultural development, life and health, etc. the humidity sensors based on two-dimensional materials have provoked much attention because of their exceptional properties (i.e. high surface to volume ratio, large exposed surface area, tunable semiconducting properties, etc.)[1]. Rhenium disulfide (ReS_2), being less explored transition metal di-chalcogenide (TMD) has unusual but exciting physicochemical properties[2]. Herein, ReS_2 film was deposited on a flexible cellulose paper substrate using a vacuum filtration technique and was further applied as a humidity sensor. The 2D ReS_2 humidity sensor demonstrated elevated sensitivity (~115%), faster response time (~15 seconds), and enhanced long-term stability[3]. In particular, the electropositivity of the transition metal plays a key role in humidity sensing. Compared to tungsten, molybdenum, and other well explored transition metals of TMDs rhenium has higher electropositivity, which indicates that ReS_2 has more surface energy to capture water molecules and attach to the substrate[4]. The structural and compositional characterization of pristine ReS_2 showed a hexagonal phase with the P63/mmc space group. Further, to demonstrate a real time application, the fabricated ReS_2 humidity sensor was utilized as a respiration sensor to sense normal, slow, and fast breath patterns. The frequency and amplitude of the sensor current peaks were utilized to differentiate between various breath patterns which hold potential applications in non-invasive healthcare. The successful demonstration of scalable, cost-effective ReS_2 based humidity sensor on flexible and decomposable cellulose paper offers exciting applications in flexible and wearable electronics.

Developing of Ultraflexible Organic Photovoltaics with Reduced Angular Dependence Masahito Takakuwa[1,2], Kenjiro Fukuda[2], Shinjiro Umezu[1] and Takao Someya[2]; [1]Waseda University, Japan; [2]RIKEN, Japan

Ultraflexible OPVs are expected to be used as a flexible energy harvester for wearable devices such as wearable textiles. Wearable devices would be easily changed and deformed according to the movement of the body. Assuming such usage, angle of incident lights to ultraflexible OPV is always changing, and along with this, power conversion efficiency (PCE) of ultraflexible OPV is also changing. Thereby the suppression of angular dependence is important to get a stable power generation. One of the major reflection losses happened at the substrate surface, between air and a substrate because of the large difference of refractive index [(1)]. Therefore, controlling the surface reflection by fabricating nanostructure to substrate is one strategy to reduce the angular dependence. A previous work reported flexible OPVs with nanostructured substrate is exhibited 1.3 times less angular dependence than OPVs with flat substrate [(1)]. However, a 1-μm-thick ultrathin substrate for ultraflexible OPV takes a susceptible to damage by conventional high energy patterning methods like laser carving method [(2)] so that it is hard fabrication process of nanopatterning to its.
This research shows the developed low energy patterning method for ultrathin substrate and the effect of reducing the angular dependence of the nanopatterning ultrathin substrate. Generally, ultrathin substrate is fabricated by evaporating the polymer materials onto glass applied fluorinated polymer. The fluorinated polymer is fabricated by spin coating as a decreasing the surface energy between the substrate and delaminating it easily. Therefore, we focus on the undried fluorinated polymer layer. Nanostructures are fabricated onto the low energy surface of the fluorinated polymer by optimizing the condition for the drying process of it like temperature and drying time with placing nanopatterned polydimethylsiloxane mold on undried fluorinated polymer. These nanostructures of fluorinated polymer layer are traced onto ultrathin substrate surface by evaporating the polymer materials onto nano patterned fluorinated polymer layer. Valid point of this method does not require the extra heating process or ultraviolet curing process for the nanopatterning. Therefore, the nanopatterned ultrathin substrate is fabricated with avoiding damage to it by this method. OPV with nano line patterns ultrathin substrate which has 760 nm of pitch and 100 nm of height was exhibited low angular dependence compare with OPV with flat ultrathin substrate. The performance of OPV was measured with changing incident light angle 0 degree to 70 degrees, every 10 degrees. For all angles >10 degrees, the difference of performance appears due to nanopattern ultrathin substrate, especially, maximum reduction of the angular dependence of 5.7% being observed at 50 degrees [(3)]. Furthermore, the surface reflection rate upon the ultraflexible OPV suppress due to the reduction of the light interference effect by using nanopatterned ultrathin substrates. As a result, ultraflexible OPV with nano patterned ultrathin substrates was exhibited higher short current density of 2.1% compared with ultraflexible OPV having flat ultrathin substrate [(3)].

Radiative Cooling Textiles for Personal Thermal Management Yucan Peng, Jun Chen, Lili Cai, Po-Chun Hsu, Alex Song, Peter Catrysse, Shanhui Fan and Yi Cui; Stanford University, United States

Thermal comfort is essential for health and productivity. However, it consumes enormous energy to maintain thermal comfort through space heating and cooling, due to energy waste in the vast empty space of the entire building. Here, we propose the personal thermal management strategy focusing on temperature regulation of only the human body and its local environment, and present a passive personal thermal management textile system via engineering the thermal radiation property of textiles to reduce building energy consumption and improve the quality of human life.

F.FL03.09.04
Wearable Biodiagnostics via Skin Volatile Emission Detection Using Colorimetric Sensors Melissa Finnegan, Emer Duffy and Aoife Morrin; Dublin City University, Ireland

The focus of this research is to develop and apply new and existing soft responsive materials capable of responding to target biomarkers on the body emitted from the skin. One of the approaches being investigated is the use of responsive colorimetric dyes to track volatiles being emitted from the skin. Specifically, the acidity of the volatile emission is being assessed using pH-responsive dyes. Early evidence from the group has shown that the total volatile fatty acid emission (C8-C16) correlates well with skin surface pH as measured by a glass pH ion-selective electrode. This early study used a headspace-solid phase microextraction (HS-SPME) approach to sample the skin volatiles which were then analysed by GC-MS. This project aims to exploit this correlation of acidic volatile emissions with skin pH to develop a non-contact, skin pH sensor. Aldehyde emissions from the skin are also being examined.

A range of responsive colorimetric dye spots are being tested in this work to understand their response to the skin volatile

emission. pH, solvatochromic and metalloporphyrin dyes being used in the sensor array are immobilised as spots to flexible cellulose substrate. A sol-gel encapsulation matrix is used to allow the soluble dyes be converted into nanoporous pigments which are insoluble. The durability and stability of the dyes is improved by using this encapsulation method.[1] The response of each dye spot was recorded by imaging the sensor array before and after exposure to skin volatiles and the net colour response quantified. A host of different skin sampling methods have been examined including gauze sampling, swab sampling, tape stripping and also direct application on the skin incorporating a wire mesh spacer between the sensor array and the skin. This presentation will highlight some of the results from this research to date.

F.FL03.09.05
Evaluation of a NaPc/TCNQ Complex Structure for Flexible Diode Applications Leon Hamui; Universidad Anahuac, Mexico

This work is related to the progress on the implementation of sodium phthalocyanine for flexible organic diodes. A NaPc/TCNQ structure was deposited on TCO/PET for the electronic device and silver contacts were used to determine the optoelectronic properties. HV Thermal evaporation of small molecules and spin coating processes were used for device deposition. The Characterization of the electronic device was conducted using FTIR, AFM, UV-Vis, IV characteristics for chemical, structural, morphological, opto-electrical properties. FTIR measurements confirm an efficient transfer for the device to the PET flexible substrate with a smooth and homogeneous surface topography. A direct transition bandgap of 2.5 and 2 eV were obtained for different the NaPc deposited thicknesses. Diode type characteristics were obtained with threshold voltages of ~1.5 V and ~15 microAmpers current across the device at 6 V. IV characteristics were measured with different incident led light colors showing a variation of the curves on the NaPc-TCNQ flexible device which gives evidence of the device and interfaces quality for diode applications.

F.FL03.09.06
3D Printed Polymer-Based Multiferroic Nanocomposites for Electronics Application Bedanga Sapkota and Vijaya K. Rangari; Tuskegee University, United States

Flexible polymer-based magnetoelectronics with an organized structure are most desirable in the field of memory, energy storage, sensing, and harvesting devices. In this work, we have developed flexible nickel ferrite (NiFe203)-PVDF nanocomposite films. The obtained composite films show excellent magnetoelectric coupling at room temperature, making them good candidates for improved ferroelectric devices. The nanocomposite films were prepared by the solution casting and 3D printing method, wherein the nickel ferrite nanoparticles with different weight percentage (5, 10, 15, 20, and 30%) were incorporated in the ferroelectric PVDF polymer matrices. The structural, morphological, mechanical, electrical, magnetic, and thermal properties of the nanocomposites were studied by X-ray diffraction, FTIR, scanning electron microscope, nanoindentation, DSC, TGA, and SQUID.

F.FL03.09.07
Macro-Scale Graphene-Based Tactile Pressure Sensor Array Sheet Seiji Wakabayashi[1], Takayuki Arie[1], Seiji Akita[1] and Kuni Takei[1,2]; [1]Osaka Prefecture University, Japan; [2]JST PRESTO, Japan

Macroscale flexible and stretchable pressure sensor enables to monitor pressure distribution on a variety of nonplanar objects such as infrastructure, vehicles, and humans if very thin flexible pressure sensor arrays can be realized. In fact, many types of flexible tactile pressure sensors have been studied. For the macroscale flexible sensor sheet, one important parameter is device cost. To realize economical sensor sheets, printing, transferring, and laser ablation methods have been widely proposed. As one of the potential economical process, this study proposes a simple and scalable fabrication process to form a very thin macroscale flexible tactile pressure sensor array.
Fabrication process is briefly explained. First, laser-induced graphene (LIG) was formed by exposing CO_2-based laser over polyimide film. The LIG layer was then transferred into a polydimethylsiloxane (PDMS) elastomer film. In parallel, silver electrodes were screen-printed on a polyethylene terephthalate (PET) film. After the formations, PDMS and PET films were laminated. The total thickness of the device is ~300 μm. The sensing mechanism of tactile pressure is to measure contact resistance change between the LIG embedded in the PDMS and the silver electrodes on the PET films as a function of applied pressure.
Resistance change at an applied pressure was characterized. Due to the observation of contact area change between two

conductive materials, at low pressure range less than 30 kPa, resistance change is large while the resistance change gradually decreases by increasing the applied pressure. The maximum sensitivity is ~0.84 %/kPa at 28.3 kPa, and the sensitivity at 566 kPa is ~0.1 %/kPa. The response time is relative fast to be <0.1 s. Importantly, this sensitivity and response speed are independent with the device bending even under 1 cm curvature radius. After confirming the fundamental properties of very thin flexible tactile pressure sensor, uniformity, stability, and reliability were tested. The uniformity in terms of initial resistance and sensitivity at 56.6 kPa of the sensor are 1062±62Ω and ~0.6±0.3 %/kPa, respectively. The sensor can measure the pressure precisely more than 4500 cycles for a long time.
Finally, as a proof-of-concept, pressure distribution was measured by using an integrated 4×4 array sheet. We confirmed that this sensor array sheet can monitor the finger position on a pen covered by the sensor sheet. Furthermore, by covering this sensor sheet surrounding a roller, pressure distribution of the roller under rolling onto a floor is successfully monitored in real time. These demonstrations depict that this very thin flexible sensor sheet can detect the pressure distribution regardless of the surface shape without changing the object shape drastically.

F.FL03.09.08
Supercapacitive Polymer Hydrogel Electrode via Pure PEDOT:PSS Hydrogel Printed on Laser-Induced Graphene for DC Stimulation Applications Sebastian Shaner[1], Monsur Islam[2], Jan Korvink[2] and Maria Asplund[1]; [1]Universität Freiburg, Germany; [2]Karlsruhe Institute of Technology, Germany

Bioelectronic interfaces rely on intimate contact with tissue to establish efficient signal exchange between electrodes and the biological target structure. Mechanically soft and ion conducting materials are beneficial in this context, in particular for semi-dry interfaces such as electrodes contacting skin. Typical natural (e.g. alginate, collagen, agar) and synthetic (e.g. polyacrylamide, polyethylene glycol, polyvinyl alcohol) hydrogels used for biomedical implementation are not inherently electronically and/or ionically conductive, wherefore development of conducting hydrogel systems is highly relevant. We demonstrate here how a supercapacitive polymer hydrogel whose network is entirely comprised of conducting polymer poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) nanofibril interconnections can be combined with laser-induced graphene (LIG) on a flexible substrate (i.e. polyimide). This results in a bioelectronic interface which easily conform and connect to skin and can support both recording and electrical stimulation. The PEDOT:PSS hydrogel precursor can be printed (i.e. direct ink writing) or dip-coated onto laser pyrolyzed polyimide (e.g. Kapton) film. The LIG and PEDOT:PSS hydrogel electrode was shown to have a high charge storage capacity (up to 1500 mC/cm^2), electrochemical stability (retains more than 85% of the original charge storage capacity over 500 cycles) and ability to deliver long term biologically-relevant electric fields (10-1000 mV/mm). In short, via affordable technology, we were able to make devices that outperform previous technology based on noble metals. Thereby we pave the way for disposable bioelectronics as well as DC stimulation of cells and tissues at levels relevant for regenerative therapy.

F.FL03.09.10
Upcycling CDs into Soft Bioelectronics Matthew S. Brown, Louis Somma and Ahyeon Koh; SUNY Binghamton, United States

Soft bioelectronics are an emerging class of wearable electronics for point of care (POC) applications; however, fabrication processes for these stretchable devices have relied on time-consuming, expensive, and complicated microfabrication techniques. The required active materials (e.g., gold) present expensive deposition or complicated galvanization methods, for developing thin films of metals for stretchable electronics, which limits the transcendence of rapid, one-time devices. Of note, electronic CDs generate a large amount of electronic waste and contribute to the fast growing global problem of landfill waste. To solve critical challenges in the rapid fabrication of soft bioelectronics and environmental challenges, we have developed a fabrication method for upcycling gold compact discs into transient, fibrous, and permeable devices.

The reflect metal layer from compact discs (CDs) can be recycled for rapid, low cost development of thin gold films. Following the removal of the CD's protective layer, it can be easily cut to a feasible size for harvesting the gold layer. Utilizing water-soluble tape, the pickup at the optimal peel velocity highlighted the transfer efficacy, due to the stronger adhesion forces produced between the gold and tape rather than the gold and adhesive layer. Intricate patterns can be realized onto the gold film by laser engraving, capable of transforming the rigid constituent into fully flexible form factors. We present feature sizes of about 700 µm that are contingent on the laser resolution with the drawback of sacrifice the gold's durability after patterning. Electrospinning synthetic polymers were further deposited onto the patterned gold film to increase durability and stretchability. With this fabrication method, a wide range of fibrous polymeric systems, including biodegradable and natural polymers, can apply to soft, mesh type bioelectronics. The mechanical and electrical properties of the developed bioelectronics have been systematically analyzed to confirm its conformality. Further, the devices were demonstrated in application as electrocardiography (ECG) electrodes.

F.FL03.09.12
Development of Nanofiber-Based Sunscreen with a Portable Electrospinning System Byeongjun Lee, Hyunwoo Lee, Chan Park, SungUk Hong, Hyunsuk Jung, HyongUk Kim, CheolJeong Park, JungMin Kim, YeonDo Jeong, Younghyeon Song, JeongBeom Kang, HaRan Lee, Jongwon Yoon and Seong Jin Cho; Chungnam National University (CNU), Korea (the Republic of)

Recently, as the harmfulness of ultraviolet rays (UV) is widely known, protecting skin from UV rays is attracted attention. However, the current use of liquid or stick sunscreen can cause skin problems due to the toxicity of chemicals and poor water resistance, it has a short durability, so there is inconvenienced to apply regularly. This study report a new type of sunscreen, nanofiber-based sunscreen, which is chemical-free, high water-resistance, dust resistance and gas breathability, and novel portable electrospinning system to apply it. The nanofiber-based sunscreen use biocompatible polymers and can be quickly applied by the portable electrospinning system. Nanofiber-based sunscreen consist of nanofiber-matrix structures, the fiber was solidified and chemically stable. Owing to its nature, the nanofibrous sunscreen does not dissolve in sweat or water and block micro dusts while allowing air and vapor to pass through. Also, skin trouble can be prevented due to the sterilizing effect of TiO_2 nanoparticles contained in nanofiber-based sunscreen. Due to its flexibility and stretchablity, it can coated on skin conformably and be able to stretch and relaxed repeatably along the skin without falling. Finally, the nanofiber-based sunscreen can be easily detached from skin without residue unlike liquid-type sunscreens. We believe our nanofiber-based sunscreen can be used in daily life and professional medical such as patients with organ transplants or skin diseases that are vulnerable to UV rays.

F.FL03.09.13
Design of a Scalable, Flexible and Durable Thermoelectric Cooling Device for Wearable Applications Zoe Rosenberg, Nathan Weiner, Hasan Shahariar, Jennifer Peavey, Amanda Myers and Jesse S. Jur; North Carolina State University, United States

There is growing interest in flexible thermoelectric cooling devices to provide personal thermal regulation to alleviate energy demands of current HVAC systems as well as to provide safety to workers in uncontrollable outdoor environments. Here we demonstrate flexible thermoelectric cooling devices, utilizing a foam substrate, that can be integrated into wearable products. Our flexible thermoelectric devices utilize commercially available materials and scalable processing techniques to improve the manufacturability. Thermoelectric legs were embedded in a foam substrate to provide flexibility, and kirigami-inspired cuts were patterned within the foam to mimic drape found in textile materials. In total, nine different configurations, three different fill factors, and three different kirigami cut patterns, were created and tested. The devices were assessed for thermal performance, mechanical durability, flexibility and drape. The results from this characterization show that adding kirigami patterns can increase the durability of the device, improve the flexibility, decrease the drape coefficient, and have <1% of impact on cooling performance at higher fill factors, reaching temperature differences up to 4.39 ± 0.17°C. These thermoelectric cooling devices show great promise for the future of wearable cooling devices considering both the manufacturing scalability and its' familiar drape and feel, which will allow for easy integration of the devices into products.

F.FL03.09.14
Reverse Engineering of E-Textile Products for Design and Material Evaluation Caitlin Knowles, Amanda Myers and Jesse S. Jur; North Carolina State University, United States

E-textile design heavily relies on the human use case as well as factors such as price point and emphasis on sustainable material use. The e-textiles market is in its early years of commercial establishment, so there are few standards when it comes to material and design choices and product validation. This lack of standards makes designing new products difficult and when benchmarking against existing products, makes identifying areas for innovation challenging. This research examines the use of reverse engineering principles based on the disassembly, characterization, and analysis, of popular commercial e-textile products, allowing for both an analysis of the products disassembled and providing a framework of best practices for future designs. Using a reverse engineering framework, commercial products were evaluated based on their system block diagram and materials characterization, relating each to understanding the design criteria employed for their construction. Products with similar use cases are compared and evaluated for functionality, performance, and sustainability. This research ultimately provides a framework to better understand design criteria and material selection in order to improve future product designs.

Use Case Scenarios and Characterization Methods for Textile-Based Piezoelectric Energy Harvesting Beomjun Ju, Braden M. Li and Jesse S. Jur; North Carolina State University, United States

Textile-based structures exhibit inherent properties such as flexibility, stretchability, breathability, and high durability under severe mechanical deformations. These properties make textiles an ideal platform to create conformable wearable electronics that rely on flexible circuitry. However, current wearable power supplies are not suitable for textile-based wearable platforms or smart textiles since they utilize functional materials that are rigid, heavy, and exhibit negative environmental impacts. Therefore, researchers have turned to harvesting energy resources from the human body that would have otherwise been wasted, as an alternative power supply solution for smart textiles.
In this work, we review the possible forms of harvestable mechanical energy from various human motions (i.e. Running, Bending Arms, etc) using piezoelectric polymers integrated into textile-based structures. Piezoelectric polymers such as polyvinylidene fluoride (PVDF) and poly(vinylidene fluoride-co-trifluoroethylene) (PVDF–TrFE) are ideal for smart textiles due to their high throughput, low-temperature processing capabilities and larger range of deformations compared to piezoelectric ceramics. We introduce the state of the art in textile-based piezoelectric energy harvesters using PVDF and PVDF-TrFE with regards to the hierarchical levels of textile structures (i.e. fiber -> yarn -> fabric). We categorize these textile energy harvesting devices as either *in-situ* or *ex-situ* based on their fabrication method and structural design of their electrodes. Then, we suggest standardized testing methods based on this in-situ/ex-situ classification system to accurately characterize energy output for various mechanical stimuli and working harvesting areas. Lastly, we create a framework based on the challenges and exciting opportunities for practical use case scenarios of these textile-based piezoelectric energy harvesters.

F.FL03.09.16
High Conductivity in Thin, Flexible and Stretchable Inter-Connect with Polymer Composite in a Sandwich Structure Mayukh Nandy, Todd K. Houghton and Hongbin Yu; Arizona State University, United States

Flexible conducting materials has been in the forefront of a rapidly transforming electronic industry focusing on wearable devices for a variety of applications in our world today. Over the past few decades, bulky, rigid devices have been replaced with a surging demand for thin, flexible, light weight, ultra-portable yet high performance electronics. But the inter-connects available in the market today only satisfy a few of the desirable characteristics, making it necessary to compromise one feature over another. Materials like thin copper foils provide metallic conductivity but cannot be stretched or bent repeatedly over the lifetime of the product owing to bending fatigue and ultimately mechanical deformation leading to electrical failure. On the other hand, stretchable metal polymer composite structures previously explored by researchers in this industry failed to achieve high conductivity to compete with metal counterparts.
We present a method to prepare a thin, flexible, and stretchable inter-connect with much improved conductivity compared to what has been achieved before. It also satisfies most mechanical and electrical conditions desired in the wearable electronics industry today. The composite prepared with the widely available, low cost silicon-based organic polymer - Polydimethylsiloxane (PDMS) and Silver (Ag) is sandwiched between two cured PDMS layers. These two protective layers improve the mechanical stability of the inter-connect. The stretchability of the material is enhanced by over 100% by laser cutting it into a serpentine structure without compromising its electrical stability. The structure, less than 500 um thick, can be integrated into thin electronic packaging. The synthesis process of the composite material, along with their electrical, mechanical and corrosion resistive properties will be presented in detail.

F.FL03.09.17
Intrinsically Stretchable Biosensor Detecting Sweat Based Multi Analytes and ECG Using Ag Nanocomposite Electrode with Photo Patternable Ecoflex Seungwan Kim[1], Wonryung Lee[2], Joohyuk Kang[1], Injun Lee[1] and Byeong-Soo Bae[1]; [1]KAIST, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Fusion of physical and chemical sensing onto a single platform cannot only provide information for physical parameter such as Electrocardiogram (ECG) but also offer more insightful and comprehensive chemical parameters from biofluids such as sweat [1]. From monitoring glucose and lactate level with ECG, biosensor could prevent the exerciser from hypoglycemic shock during intense exercise.
In this work, intrinsically stretchable electrode is fabricated to monitor biochemical and biophysical information using elastomeric composite comprised of Ag flake and photo-patterned Ecoflex [2,3]. Direct pattening of the Ecoflex benefits

from convenient fabrication process. Furthemore the encapsulation of Ecoflex improves the conductivity of Ag nanocomposite when it is stretched. That is induced by an efficient strain energy dissipation at an inteface between the conductor and the encapsulation layer.
Since Ag electrode could be readily oxidized in biological circumstance and leach out the Ag ions to human tissue, the stretchable conductor consisting of Ag nanocomposite is limited to bioelectronics. To enchance the biocompatibility of Ag, the electrode is modified to form Pt and Au nanoparticles onto counter electrode and working electrode respectivly by galvanic replacement process [4]. Various functional materials for multisensor are electrodeposited on to Au modified working electrodes. A pH sensor is perfomed via Polyanilne showing the 100mV/pH sensitivity stretched up to 50%. Glucose and Lactate sensors are opreated *in vitro* showing 3nA μM^{-1}, 260nA μM^{-1} sensitivity respectively. Finally intrinsically stretchable multi biosensor *in vivo* are successfully monitoring a variation of analytes concentration of glucose and lactate in sweat before and after meal and exercise simultaneously with electrical signal.

Methodology for Binary Detection Analysis of Inkjet Printed Optical Sensors for Chemical Detection Li-lin Tay and John Hulse; National Res Council Canada, Canada

Development of sensors for early warning and protection against chemical and biological agents is a priority for front line first responders as well as military personnel. We have developed inkjet-printed surface enhanced Raman spectroscopy (SERS) sensors that is specifically designed to work with field portable Raman analyzers for the detection of chemical and biological agents. These SERS sensors are inkjet-printed on filter paper or fabric substrates. Ink formulation are carefully optimized colloidal silver or gold nanoparticle solutions synthesized in house. They are flexible, lightweight and provides point-of-sampling capabilities that other rigid planar SERS substrates lacks. These sensors can be integrated with the wearable gear of the first responders. These flexible and wearable sensors are designed for qualitative detection such as binary detection of either positive or negative presence of certain chemical/biological agent. Conventionally, performance of a SERS substrate is characterized by its enhancement factor which is defined as the ratio of the normalized SERS to normal Raman intensity. This is an inadequate measurand for a chemical/biological sensor. The performance of a chemical/biological sensor is best characterized by its sensitivity, probability of true positive detection, false positive rate and its response time. The sensors receiver operating characteristics (ROC) captures the performance trade-off between all these factors. It is meaningless to specify sensitivity without the confidence level of detection expressed as the probability of detection and the false positive rate. Although ROC has been used commonly for assessing chemical/biological sensors, it is not trivial to adapt it for SERS detection. In this presentation, we will present a new methodology developed specifically for the binary analysis of the SERS sensors using the receiver operating characteristic concept. This can be applied for all SERS sensors but we will focus its use with the printed SERS sensor.

F.FL03.09.19
ZnO Thin Film-Based Flexible Biosensor for the Continuous Monitoring of Glucose Levels in Sweat Fahmida Alam, Shahrzad Forouzanfar, Ahmed H. Jalal and Nezih Pala; Florida International University, United States

Diabetes is one of the significant causes of fatality throughout the word in the present day. The deficiency of insulin and hyperglycemia is caused by the metabolic disorder of diabetic patients. This disorder promotes high risks of kidney failure, heart attack, chronic liver diseases, and blindness. Thus, constricted day-to-day monitoring of glucose concentration is a demand for the diagnosis and treatment of diabetes. Also, fast, accurate and continuous monitoring of glucose concentration is of great importance. As a successful consumer product of wearable biosensors, it is important to demonstrate reliability, multiplexed functionality and ease-to-use noninvasive monitoring of glucose from the body fluids, such as sweat. Sweat is easy to analyze and is considered as one of the most widely used body fluids having significant medical information. However, the introduction of nanomaterials allows many new signal-transduction technologies results improved the sensitivity of different biosensors. ZnO thin film-based biosensors are promising to determine the glucose levels in sweat with better sensitivity, reliability, continuously, and in a noninvasive manner. ZnO itself has exclusive chemical and physical characteristics to enhance chemical stability in physiological environments. Moreover, it has highly catalytic activity, biocompatibility, and higher isoelectric point (IEP). ZnO nanoflakes (ZnO-NFs) exhibit several unique advantages compared to bulk materials. For example, polarized (0001) plane orientation enhances enzyme immobilization which improves sensing

performance. A high isoelectric point (9.5) of ZnO NFs enhances the immobilization of any biomolecules which eliminates the necessity of an additional binding layer. This elimination of additional layer and immobilization of enzyme offer a steady and shorter pathway for quick electron transportation increasing the electron transfer rate. A single step sonochemical approach was developed to synthesize a thin layer of ZnO-NFs virtually on any substrate. This technique is fast, catalyst-free, less expensive, and ecologically benign. The rate of reaction of the sonochemical approach is 100 times faster than conventional hydrothermal procedures, which enables a well-oriented growth on polyethylene terephthalate (PET) over an extensive range. The temperature for the process is low enough to permit the application of different materials, for example, fabrics, paper, and polymers.
In this study, an electrochemical glucose biosensor was fabricated by immobilization of glucose oxidase on ZnO nanoflakes with a thickness of 20nm, synthesized on Au-coated stretchable PET. The results demonstrated a fast response within 5s. The sensor was tested in the range of 10 pM – 20 mM, which covers the entire physiological range and capable of detecting as low as 1 μM of the glucose concentration. The sensitivity of the sensor was determined by 4.53 μA/decade/cm^2. Moreover, the sensor performed repeatable characteristics having with average standard deviation (S.D.) of 0.14 μA. Furthermore, in our experiment, the fabrication process is simple, and the thin film-based nano-biosensor provides excellent performance in stability, selectivity, sensitivity, and reproducibility.

Copper-Coated Reduced Graphene Oxide Fiber Mesh-Polymer Composite Films for Electromagnetic Interference Shielding Mingxin Li, Kun Yang and Jie Lian; Rensselaer Polytechnic Institute, United States

Expected to become mainstream in the electronics industry, flexible electronics still face major challenging issues. For polymeric-based flexible electronic substrates in particular, these challenges include a lack of electromagnetic shielding capability and poor heat dissipation. Here, we report a highly flexible and thermally conductive macroscopic polydimethylsiloxane (PDMS) polymer film embedded with a copper-coated reduced graphene oxide (rGO) fiber mesh. The rGO fibers are assembled into 3D fiber meshes and electroplated with micrometer-thick copper coatings, displaying excellent electrical and thermal conductivities. Oriented in the horizontal and perpendicular directions within the PDMS polymeric matrix, the fiber mesh serves as a highly electrically and thermally conductive backbone through the in-plane direction. Meanwhile, the fiber mesh also effectively shields electromagnetic interference in the X-band without causing thermal damage. The macroscopic film remains electrically insulated in the through-plane direction. Utilizing both the favorable thermal and electrical properties of the graphene fiber-based mesh and the flexibility of the PDMS matrix, our film may exhibit potential for flexible electronics applications such as wearable electronic thermal management and flexible microwave identification devices.

F.FL03.09.24
Thermoelectric Ultrafine Fibers for Temperature Regulation and Power Generation Elena Ewaldz, Morgan McLeroy and Blair Brettmann; Georgia Tech, United States

Thermoelectrics are materials consisting for an electron conductor (n-type) and a hole conductor (p-type) that are connected electrically in series and thermally in parallel. They work through both the Seebeck effect (power generation) and the Peltier effect (refrigeration). Through the Seebeck effect, a heat gradient causes current to flow generating electricity. Through the Peltier effect, a current flow generates a heat gradient leading to one side of the material being actively cooled. Traditionally inorganic materials are sued that have a low natural abundance, high costs, and are rigid and brittle. Polymeric thermoelectrics or organic thermoelectrics (OTEs) overcome the limitations of conventional materials as they are low cost and flexible; though they typically have lower conductivity so they require enhanced designs such as high surface fibers. OTEs cannot readily be made into fibers as they are low molecular weight and have strong molecular interactions and high conductivity that alter fiber formation. In this work, we use electrospinning to prepare composite ultrafine fiber mats of organic based n- and p-type conductors enabling close contact between fibers. Electrospinning is a solution processing technology that creates nonwoven ultrafine fibers (diameter ~100nm-2um). Ultrafine fibers have very high surface area allowing for many close contact points between fibers. PEDOT:PSS, a p-type conductor, is able to be electrospun with an insulating polymer at amounts up to 56wt%. NiETT, a n-type conductor, is made by forming a PVA-nickel salt complex through electrospinning then polymerizing the final fibers. These materials can then be layered to create a soft, flexible, wearable, electronic device.

Controlled Light Scattering Over LWIR in Polyethylene Films Yassine Ait-El-Aoud[1,2], Ihsan Uluturk[1], Elizabeth Welsh[1],

Michael Okamoto[1], Sean R. Dinneen[1], Alkim Akyurtlu[2] and Richard M. Osgood[1]; [1]U.S. Army Combat Capabilities Development Command Soldier Center, United States; [2]University of Massachusetts Lowell, United States

Recently [1-3], polyethylene (PE) has gained significant interest by the textile fiber/film industry and opened up new advanced textiles for personnel thermal management with simple structures and unique optical properties. Controlling these optical properties in the long wave infrared (LWIR) spectral range could have a strong effect on cooling and heating the body and per consequence it could be a solution to obtain a textile with enhanced radiative cooling/heating for passive releasing/trapping of human body heat and this is not found in conventional textiles. Moreover, PE is a durable polymer, scalable, cost-effective and lightweight materials.
In this study, we have demonstrated both the effect of polymer chain alignment and integration of inorganic particles into ultrahigh molecular weight polyethylene (UHMWPE) polymer on the optical properties of UHMWPE films. We have seen that the total transmittance of the films increases with higher the draw ratios while the scattered light can be controlled over LWIR by introducing a small percentage of inorganic particles where the forward scattering was found to be preferred over backward scattering. The high transparency of the films could be explained by the film thickness reduction on one side and the surface morphology of the film on the other side. In addition, the stretched films become thinner which allow more light comes through the film whereas the surface morphology of the films become one hand smoother and aligned and on other hand the films crystallinity increase significantly. Most importantly, we have seen that the intensity of the scattered light in the forward direction can be controlled by addition of additives into the pure UHMWPE film. The integration of inorganic nanoparticles into the pure UHMWPE polymer allows both the properties from inorganic nanoparticles (higher refractive index and higher forward scattering) and UHMWPE polymer (higher transparency) to be combined and enhanced the optical properties of films, particularly, in the LWIR regime. By preferentially scattering in the forward direction, these novel textile materials, in thin films, could release heat from an overheated body (eg. the human or warm equipment) better than if there is significant backscattering.
In this talk, the following will be presented and discussed : the fabrication process of highly oriented and transparent PE films, the heat-releasing data of PE films collected by a simulated device for skin temperature that operates at constant power output to produce the human skin temperature and lastly the controlled light scattering measurements in PE films over LWIR spectral range.

Keywords:
Polyethylene film, forward scattered light, backward scattered light, LWIR, UHMWPE, thermal management, thermal radiation, textiles.

Testing Mechanical Durability and Electrical Stability of Conducting Materials for Flexible and Stretchable Inter-Connects Mayukh Nandy, Todd K. Houghton and Hongbin Yu; Arizona State University, United States

Over the past decades, foldable electronics have become a major area of research in the electronics industry. Our devices are getting smaller, more portable and the need for flexible electronics is booming for various applications. While a major part of the research is being performed on high performance flexible and foldable batteries, the longevity of the materials used as the interconnects has remained under-explored. The thin metal sheets available in the market today is an ideal choice for such applications owing to their high conductivity. Researchers have also explored conducting composite polymer interconnects for improved stretchability and flexibility despite their reduced conductivity. The lifetime and mechanical stability of these materials are most important before considering them for integration into flexible electronic packages.
In this paper, we propose testing methods and results for mechanical and electrical stability over extensive flexing and stretching cycles. The materials put into test are copper foils, copper coated polyimide (PI), aluminium coated Polyethylene terephthalate (PET) and conductive Silver (Ag) - Polydimethylsiloxane (PDMS) composite in a sandwich structure.

Laser Writing of Flexible Silicon Carbide-Based Devices for Bioelectronics Aleksander Prominski, Vishnu Nair, Menahem Rotenberg and Bozhi Tian; The University of Chicago, United States

Laser-assisted production has increased in popularity due to their low cost and ease of use for general prototyping. In the context of materials science, laser-produced composites have the potential to increase the research throughput and enable unique complex phases. Recently, graphene-based conductive materials have been obtained in the process of laser ablation from the polyimide substrate and were efficiently applied for electrochemical biosensing. We sought to expand this synthetic framework with a platform that allows for the production of semiconductor-based structures and harness a plethora of electronic, electrochemical, photoelectrochemical, and photothermal properties for their application in bioelectronics.

Here, we show that laser writing can be used to synthesize semiconductor materials. We used polydimethylsiloxane (PDMS) as a precursor to silicon carbide (SiC) based materials. The doping and internal structure of the materials can be controlled with varying the processing parameters, which allowed us to synthesize both oxygen- and nitrogen-doped, glassy and crystalline materials, including rare SiC polytypes. A variety of doping levels and patterns create materials with tunable electronic properties. Synthesis of the material directly in the insulating elastomer matrix yields ready-to-use bioelectronic devices in which electrical and electrochemical properties can be used for cardiac pacing and muscle cell stimulation. Our results show the great potential for direct fabrication of semiconductor-based devices for tissue- and organ-modulation as well as building platforms for organoid research.

F.FL03.09.31

An Artificial Cochlear Stimulation Model Using 3D Printing and Neural Network Iek Man Lei[1], Chen Jiang[1], Chon Lok Lei[2], Simone d. Rijk[1], Yu Chuen Tam[3], Manohar Bance[1] and Yan Yan Shery Huang[1]; [1]University of Cambridge, United Kingdom; [2]University of Oxford, United Kingdom; [3]Emmeline Centre for Hearing Implants, United Kingdom

Cochlear implants are widely recognised as a solution for patients with profound hearing loss. The implant restores auditory sensation by electrically stimulating nerve, remarkably improving patients' quality of life. Despite overall successful outcomes, the main problem with the present cochlear implants are their imprecise stimulation causing frequency dispersion and 'blurring' of the perceived sound. Traditional testing platforms, such as animals and cadavers, are impractical for studying the intra-cochlear potential distribution evoked by electrical stimuli. Animal models have different anatomy and electrical properties compared to human cochleae, and the limited availability of cadavers greatly restricts its popularity in cochlear research. It is also difficult to instrument them to measure electrical spread. Therefore, this study has developed a novel methodology that exploits 3D embedded printing and a neural network approach to create an artificial stimulation model of human cochleae for replicating the intra-cochlear potential distribution evoked by electrical stimuli.

We fabricated the model by embedded 3D printing a sacrificial cochlea-shaped structure inside a support bath. Our

fabrication method offers two key innovations – tuneable geometry and tuneable resistivity. With 3D embedded printing, our model can replicate the general geometric features of human cochleae and the large variation in the shape of human cochleae. By structuring a conductive network in the support bath, the resistivity of our model can be tuned over 2 orders of magnitude from 0.19 kΩcm to 22 KΩcm. This wide range of resistivity, which covers the reported resistivity of human cortical bone, cannot be replicated easily with the existing printable materials, such as thermoplastics and hydrogels.

To evaluate the ability of our model to replicate the physiological intra-cochlear potential distribution evoked by cochlear stimulation, we compared the electric field imaging (EFI) profile of our model and the patients' EFI profiles. EFI is a clinical method that measures how the intra-cochlear potential is distributed across the electrode array of a cochlear implant in patients' cochleae. Our results show that our model can replicate the mean intra-cochlear potential distribution in patients' cochleae. By fabricating a wide variety of models with different matrix resistivity and cochlear shapes, a dataset of EFIs is obtained. We then deployed a neural network (nn) approach to build a computational model that predicts the trend in the EFI resulting from different matrix resistivity and different cochlear shapes. Our nn model correctly predicts the EFIs within the dataset with over 85% accuracy. It can determine how fast the voltage decays in a particular cochlear shape and resistivity.

This study presents a simple workflow in modelling the intra-cochlear potential distribution evoked by electrical stimuli using 3D printing and neural network. Our model could potentially serve as a screening model for developing new cochlear implants, or a tool to predict patient-specific clinical outcome after cochlear implantation. Our methodology is general and can be readily adapted to other anatomical sites of electronic implants.

Late News: Self-Signal Processing Pressure Sensor by Controlled Sensing Band and Its Response Curve Chanho Jeong and Tae-il Kim; Sungkyunkwan University, Korea (the Republic of)

Resistive-type pressure sensor, which are mainly utilized in industry, are easy to manufacture and are not significantly affected by external electromagnetic fields, unlike capacitive type. However, the produced signal is not linear, and it is also difficult to measure a wide range of pressures using such a sensor. Therefore, before being utilized, the extracted nonlinear data from them need to be modified and re-processed for a specific target use. Here, we presented resistive-type pressure sensors whose response characteristic can be freely adjusted without the need of any additional computer processing. Five different types of introducing sensors performed different functions by the sensors themselves and they were manufactured by only modifying their electrodes: normal pressure sensor, linear pressure sensor, on/off switch sensor, high-pressure band sensor, and low-pressure band sensor. The operating mechanism of the sensor is the electron shortcut pathway in a designated electrode circuit from the contact area change of the deformed conductive elastomeric lenticular pattern. Sensors fundamental properties such as sensitivity and measurable range(~4 MPa) could be also controlled by selecting the polymer or controlling the electrode slope.

F.FL03.09.36
Late News: Effects of Molecular Structures on Electrochemical Doping and UV-Vis/NIR Absorption in Thin Films of Conjugated Polymers Onyu Bae, Taemin Kim, Yaena Na and Felix S. Kim; Chung-Ang University, Korea (the Republic of)

Conjugated polymers have been studied for developments of novel lighting devices, electronic components, and energy conversion and storage systems. The electronic energy levels and bandgaps of the conjugated polymers can be studied by photoelectron spectroscopies, electrochemical redox potentials, and UV-Vis-NIR absorption spectroscopies. In this work, we prepared thin films of polythiophene derivatives and investigated their electrochemical doping processes and UV-Vis-NIR absorption spectra. Polymer films were laminated with a gel electrolyte and electrodes and electrical potential was applied at the electrodes. Because the molecular structures of polymers govern their electronic and macroscale properties, we observed distinct spectral changes of the polymers caused by redox of the materials. The polymer films in a neutral state showed absorption in a visible range. When electrochemically activated, the absorption bands of pristine polymers decreased and strong NIR absorption bands evolved. We tried to link the observed spectral phenomena with performance of the electrochemical devices.
This work was supported by the research programs (2019M3F3A1A03079821 and 2019R1A2C1087234) through the National Research Foundation of Korea (NRF). This research was also funded in part and conducted under "the Competency Development Program for Industry Specialists" of the Korean Ministry of Trade, Industry and Energy (MOTIE), operated by Korea Institute for Advancement of Technology (KIAT), with the project No. P0012453, Next-generation Display Expert

Training Project for Innovation Process and Equipment, Materials Engineers.

Late News: Electrospun Polyurethane-Polyvinylidenefluoride Nanofiber Webs Based Hybrid Pressure Sensor Mohammad S. Reza, Kap Jin Kim and Hongdoo Kim; Kyung Hee Univ, Korea (the Republic of)

Recently, polymer-based pressure sensors have drawn much attention due to the importance of sensing device for soft robotics, wearable or/and health monitoring device etc. However, electrospun polyurethane (PU) nanofiber webs having very high amount of nano-sized open cell can be used as a piezo-capacitive sensor for monitoring both static and dynamic pressures due to excellent electrospinnability and very good elastic properties that has been reported in our previous study [1]. In contrast, electrospun Polyvinylidene fluoride (PVDF) exhibits high β-crystalline phase content and superior piezoelectricity [2]. Consequently, in this study, the mixture solution of PU and PVDF was electrospun under controlled compositions to obtain PU-PVDF hybrid nanofiber webs. Their physico-mechanical and piezo-responsive behaviors were investigated. When the dynamically changing force was applied to this hybrid sensor, dynamic pressure could be measured through the electric current generated by the orientational change of C-F dipoles in the PVDF part of the composite nanoweb as a function of time. When the static force was applied to this hybrid sensor, static pressure could be measured through the increasing capacitance value caused by the decreasing thickness of the composite nanoweb rather than the piezoelectric current. The piezoelectric and piezocapacitive properties of this hybrid sensor could be measured simultaneously using a piezoelectric amplifier and an LCR meter, respectively. Overall, 25~50 wt.% addition of PVDF in PU greatly enhanced the piezoelectric output signal as well as reduced pressure-capacitance hysteresis and higher capacitance change with the applied pressure due to the rubbery PU of this hybrid sensor. Moreover, $AgNO_3$, which acts as a precursor of silver nano-particle (AgNP) formed in the electrospun PVDF nanoweb, was added into the PU-PVDF electrospun solution to get enhanced piezoelectric performance of the hybrid sensor caused by the preferential formation of β-phase of PVDF

F.FL03.09.38
Late News: Chemical-Free Atomic Force Microscope Mechanical Bilayer Lithography—A Water Based Process to Fabricate Advanced Flexible Devices Yu Shu and Harish Bhaskaran; University of Oxford, United Kingdom

Both polymer flexible substrates and two-dimensional materials (2DMs) have highly strict nanomanufacturing requirements that they should avoid using strong chemicals and minimize exposure to radiation damage. The current fabrication method for flexible 2DMS based devices mainly relies on transferring the devices prefabricated on rigid substrates by electron beam lithography or photolithography onto polymer substrates. This fabrication process is time-consuming and expensive, which restricts this method to a limited number of applications. Here, a water based technique, atomic force microscope mechanical bilayer lithography was proposed to improve this fabrication process by directly building devices on flexible substrates without introducing any hazardous chemicals during fabrication. It has been demonstrated to be suitable for both SiO_2/Si and flexible polyethylene terephthalate (PET) substrates. The mechanical force applied on the AFM tip can be controlled flexibly without risk of substrate damage or pattern loss. It has also been proved to be effective to build MoS_2 photodetector on flexible PET substrates, which brings more opportunities to directly construct flexible 2DMs based devices.

Late News: Sterically Stabilized Multilayer Graphene Nanoshells for Inkjet-Printed Resistors Michael D. Orrill[1], Dustin Abele[2], Michael Wagner[2] and Saniya LeBlanc[2]; [1]NextFlex, United States; [2]The George Washington University, United States

Printable resistive materials are as important for printed electronic devices as highly conductive materials, but they are not investigated as widely, nor are they as commercially available. Of the few demonstrations of printed resistors, most require a variable component geometry to achieve different resistances. This requirement presents challenges for circuit layout as spare board space is often scarce and valuable.

Here we present ink synthesis and printing results for variable resistance patterns that are inkjet-printed with a novel and sustainable carbon nanomaterial—multilayer graphene nanoshells, the byproduct of a biofuel synthesis process from biomass[1]. The dispersed multilayer graphene nanoshells are stabilized with a surfactant (Triton X100). The optimal surfactant dosage achieves sufficient particle coverage without leading to agglomeration. Here, the optimal dosage is determined with a surface tension-based adsorption analysis technique, whose results suggest adsorption is driven primarily by hydrophobicity of the anchoring group in the surfactant molecule. The conformation of adsorbed surfactant molecules is explained by a geometric model. The difference in efficacy between sterically and electrostatically stabilized particles is demonstrated by comparing the energetic interparticle potentials between approaching particles stabilized by either mechanism.

Resistive patterns are inkjet-printed and electrically characterized. We find the resistivity of printed patterns can be varied by adjusting the solid-loading and the number of printed layers. We also discover that for few-printed layers, the presence of residual steric stabilizing material enhances the electrical conductivity of resistive patterns. This finding challenges the paradigm around the necessity of stabilizing material removal post-deposition and suggests some potential nascent and unique functionality for stabilizing materials. The multilayer graphene nanoshell inks demonstrated here present a promising new pathway toward practical and sustainable printed resistors that can achieve variable resistances within a constant areal footprint without a post-process.

Late News: Flexible Broadband (UV-Vis-NIR) Photodetector Based on All MoS2 0D/2D Mixed-Dimensional Unipolar Heterojunctions Venkatarao Selamneni, Sankalp Koduvayur Ganeshan and Parikshit Sahatiya; Birla Institute of Technology and Science, Pilani, Hyderabad campus, India

With the recent advances in the field of electronic information technology, optoelectronic devices have become an indispensable part of the society and are widely used for various applications. Among them, photodetectors are extensively studied. Commercial photodetectors with active materials such as Germanium, Silicon, GaAs are rigid, which hinders their application in wearable electronics technology and further, these photodetectors are not responsive to a wide extend of electromagnetic range [1]. Hence, novel semiconductor materials which can easily be integrated with flexible substrates need to be researched for future flexible broadband photodetectors. In recent years, the research on two-dimensional (2D) materials and their heterostructures based photodetectors has tremendously increased, due to their tunable bandgap, high carrier mobility and high specific area for sufficient light harvesting [1-3]. Large number of reports published on MoS_2 based photodetectors [4], which shows the tremendous application prospects of MoS_2 in the next generation photodetectors. Pristine MoS_2 appears to show strong absorption in the NIR and visible region of the electromagnetic spectrum but not in UV locale [2,4]. The range of absorption of pristine MoS_2 in the electromagnetic spectra needs to be further increased which limits its applicability for far reaching applications. One of the possible ways to overcome this problem is by fabricating heterostructures with higher bandgap semiconducting materials such as quantum dots (QDs) [5]. QDs engineering the 2D materials by constructing 0D-2D heterostructures is an effective strategy to assist the dissociation of photogenerated electron-hole pairs by forming heterojunctions, along with increasing the range of absorption.

In this work, flexible broadband photodetector based on novel MoS_2QDs/MoS_2 on a cellulose paper substrate was fabricated, wherein MoS_2 QDs and MoS_2 flakes were synthesized by one-pot hydrothermal method. The resultant MoS_2 flakes were deposited on paper substrate using facile and scalable vacuum filtration method and thereafter, MoS_2 QDs solution was drop-casted on MoS_2/paper to form the unipolar heterostructures. Physico-chemical characterizations such as X-ray diffraction analysis, UV-vis spectroscopy, X-ray photoelectron spectroscopy, Transmission electron microscopy, Raman spectroscopy and photoluminescence spectroscopy reveals the formation, morphology and optical properties of MoS_2 and MoS_2 QDs with good stoichiometry.

The formation of heterostructures at the interface of MoS_2 QDs and MoS_2 flakes resulted in the improved responsivity and broadband photoresponse range from UV to NIR. The discretely decorated MoS_2QDs on MoS_2 flakes not only enhances the sensitivity in the UV region but also create localized electric fields that help in the efficacious separation of the generated electrons and holes upon illumination of light. Further, the metal contacts for the device were taken from MoS_2 flakes, so as to reinforce the collection of the photogenerated carriers. The fabricated device exhibited good photodetection performance with a responsivity of 3.94 mA/W, 12.82 mA/W, and 7.55 mA/W and under NIR, visible, and UV light illumination, respectively. This work provides guidance for the development of large-area and flexible paper based broadband photodetectors using mixed dimensional 0D/2D heterojunctions that finds potential applications in the field of wearable electronics.

Late News: Wearable, Tactile Pressure Sensors Based on 1T MoS2 Nanosheets Coated Porous Sponge for Real-Time Healthcare Monitoring and Human-Machine Interface Devices Melih O. Cicek, Mustafa C. Gorur, Mete Batuhan Durukan and Husnu E. Unalan; Middle East Technical University, Turkey

Following their promising demonstration in various fields such as real-time healthcare monitoring, tactile information systems, gesture recognition and so on, there is an ever-increasing demand for flexible, lightweight and wearable sensors. To address this demand, various strain sensing mechanisms have been introduced and investigated. In this work, we fabricate a wearable tactile pressure sensor using a commercially available sponge decorated with conducting 1T phase of MoS_2 nanosheets and a very thin layer of elastomer. Solution based preparation of 1T phase of MoS_2 allowed scalable and cost-effective fabrication of the wearable tactile pressure sensors. MoS_2 nanosheets were decorated onto the sponge using a simple dip and dry method. Thanks to highly porous structure of the sponge, fabricated pressure sensors possessed high flexibility, favorable sensitivity (~ 0.5 kPa^{-1}) and a wide working pressure range from 10 Pa to 100 kPa. A very thin layer of elastomer overcoat improved the stability of the sensors under cyclic compression and bending tests, while preserving its electromechanical properties. Finally, we demonstrated the use of tactile pressure sensors for real-time body motion monitoring and human-machine interface device. Results provided herein proves that the fabricated sensors hold strong potential as wearable sensors.

F.FL03.09.43
Late News: Monolithic, Highly Sensitive, Parallel Plate Capacitive Sensors for Body-Motion Monitoring Melih O. Cicek, Doga Doganay, Mete Batuhan Durukan and Husnu E. Unalan; Middle East Technical University, Turkey

Significant research efforts have been spent on capacitive pressure sensors due to recent developments in wearable electronics. However, the fabricated sensors still have some problems yet to be solved. Due to the additional electrode layers, most of the reported parallel plate capacitive pressure sensors suffer from excessive weight, lack of air permeability and washing stability, all of which are directly related with the user comfort. To overcome these issues, a parallel plate capacitive sensor with monolithic structure was demonstrated. In this work the monolithic capacitive pressure sensor was fabricated using 3-D masking technique, using a commercially available sponge with silver nanowire (Ag NW) electrode layers and a very thin protective layer of polydimethylsiloxane (PDMS). Finite-element analysis revealed the differences in deformation mechanisms between the classical parallel plate design and the monolithic design. More homogeneous stress distribution was obtained for the investigated monolithic system. Benefitting from these unique features, the developed monolithic capacitive sensors are light, have high sensitivity (up to 1 kPa^{-1}), fast response/recovery times, very low-pressure sensing ability (< 1 Pa) and high mechanical stability. Finally, fabricated sensors were used to demonstrate real-time body motion monitoring.

F.FL03.09.44
Late News: Printed and Nanostructured Breath Sensors Guojun Shang, Shan Yan, Dong Dinh, Behnaz Malaei, Shan Wang, Shiyao Shan, Jin Luo, Mark Poliks, Susan Lu and Chuan-Jian Zhong; Binghamton University, The State University of New York, United States

There is a rising interest in the development of wearable sensors for monitoring human performance and health. One type of promising sensors is breath sensor that detects breath volatile organic compound (VOC) as biomarkers of certain diseases such as cancer and diabetes. However, a major challenge is the limited sensitivity and poor selectivity for many of the current breath sensors. This presentation describes recent results of an investigation of nanocomposite-structured materials as chemiresistor array sensing interfaces to enhance the sensitivity and selectivity of breath sensors. Results from both experimental testing and theoretical simulation of sensor arrays for detecting the VOCs will be discussed, revealing excellent agreement of the experimental data with the theoretical modeling. The fabrication of nanoparticle-printed chemiresistor devices on paper substrates and the formulation of the nanocomposites as printable sensing films will also be discussed. Implications of the findings for the design of advanced sensing materials and breath sensors will also be discussed.

F.FL03.09.45
Late News: Surface-Mediated Interconnections of Nanoparticles Towards Multi-Functional Fibrous Sensors Richard J. Robinson, Shan Yan, Shan Wang, Kevin Lee, Virginia Krause, Omar Lezcano, Serena Tycko and Chuan-Jian Zhong; State University of New York at Binghamton, United States

Fibrous materials serve as an intriguing class of 3D materials to meet the growing demands for flexible, foldable, biocompatible, biodegradable, disposable, inexpensive, and wearable sensors and the rising desires for higher sensitivity, greater miniaturization, lower cost, and better wearability. The use of such materials for the creation of a fibrous sensor

substrate that interfaces with a sensing film in 3D with the transducing electronics is however difficult by conventional photolithographic methods. This presentation will describe a highly effective pathway featuring surface-mediated interconnection of metal nanoclusters (NCs) and nanoparticles (NPs) in fibrous materials at ambient conditions for fabricating fibrous sensor substrates or platforms. Bimetallic gold-copper and silver-copper alloy NCs and NPs are used as a model system to demonstrate the semiconductive-to-metallic conductivity transition, quantized capacitive charging, and anisotropic conductivity characteristics. Upon coupling SMI of NCs/NPs as electrically conductive microelectrodes and surface-mediated assembly of the NCs/NPs as chemically sensitive interfaces, the fibrous chemiresistors function as sensitive and selective sensors for gaseous and vaporous analytes. This strategy has significant implications for manufacturing high-performance fibrous platforms to meet the growing demands of the advanced multifunctional sensors and biosensors.

SESSION Tutorial F.MT01: Advanced In Situ Characterization of Materials Kinetics (TEM and Synchrontron X-Ray)
Session Chairs: Chengjun Sun, Huolin Xin and Hua Zhou
Sunday Afternoon, November 29, 2020
F.MT01

12:30 PM *
Electron Microscopy Huolin Xin; University of California, Irvine, United States

The instructor will introduce the most advanced analytical transmission electron microscopy and data science application in the field. The application of the advanced (S)TEM techniques will be discussed for solving materials problem in *operando* conditions. Deep learning is beginning to make major inroads within physics, chemistry and materials sciences and hold considerable promise for accelerating the discovery of new theories and materials. Prof. Xin will introduce deep convolutional neural networks and how they can be applied to the computer vision problems in transmission electron microscopy and tomographic imaging. At the end some perspectives on the future integration of analytical TEM characterization and spectroscopy techniques will be given.

2:00 PM BREAK

2:15 PM *
Synchrotron X-Ray Hua Zhou; Argonne National Laboratory, United States

The instructor will firstly guide the audience through a brief survey of the evolution of light sources from the earliest sealed tubes to electron storage rings and free-electron lasers, the global competition on modern synchrotrons and LINACs, and

pressing coherent X-ray techniques emerged from them. In the following, he will demonstrate a set of fresh science cases in the exploration of advanced multifunctional materials for information and energy applications enabled by applying these powerful X-ray toolkits, such as atomic mapping of an oxide heterostructure by phase retrieving coherent Bragg rods and structural motifs responsible for a strongly correlated perovskite fuel cell, and capturing field-driven material perturbations and defect flows in an emerging memristor device for neuromorphic computing.

3:45 PM BREAK

4:00 PM *
Advanced X-Ray Spectroscopy Techniques Chengjun Sun; Argonne National Laboratory, United States

The instructor will discuss the advanced X-ray spectroscopy techniques at APS, and their applications for investigating in the materials research. The in-situ/operando characterization on advanced battery materials, and other ex-situ characterization on various materials will be covered in this lecture too. In addition, the new opportunities with APS_U and some future challenges will be discussed as well.

Moreover, the correlation between the electron microscopy and synchrotron x-ray characterizations will be briefly discussed as an open question to highlight the importance of multimodalities of materials characterization.

SESSION F.MT01.09: Live Panel Discussion: Advanced In Situ TEM for Material Science
Session Chairs: Yuzi Liu and Yugang Sun

MeV-UED—A Platform for *In Situ* Studies of Material X.J. Wang; SLAC National Accelerator Laboratory, United States

MeV-UED has led to a new paradigm in ultrafast electron scattering: higher electron beam energy means stronger diffraction and significantly reduces space-charge effects hence leads to atomic spatial-temporal resolution [1-3]. Furthermore, MeV electrons experience less multiple-scattering,possess “real” flat Ewald-sphere and favourable sample enviroments; MeV-UED is a unique platform for *in situ* studies of material.MeV-UED has enabled broad scientific opportunities in material science and chemical dynamics, such as revealing the energy flow in superconductor [4] and atomic movie of light-induced structural distortion in the perovskites solar cell [5].

I will present two examples in capturing metastable states of functional material using MeV-UED: topological properties & charge density wave controlled by light[6-7]**.** Recently *in situ* charterization oftransient state during the electrically-triggered insulator-metal transition was sucessfuuly realized at SLAC MeV-UED [8]. Future development of nano-probe at SLAC MeV-UED will open new window to probe metastable state and dynamics in spatially heterogeneous systems and in *in-situ* device geometries.

5:45 PM *F.MT01.07.02
Advances in *In Situ* and Ultrafast Electron Microscopy for Materials Characterization Ilke Arslan; Argonne National Laboratory, United States

With recent advances in in-situ microscopy, a new era in microscopy has arrived that allows for the dynamic imaging of materials under reaction conditions in the (scanning) transmission electron microscope. To better understand the structure/property relationships of materials, it is essential to get closer to the conditions in which the material will be used, such as high/low temperature, liquid environments, gas environments, or a combination thereof. Within these environments, moving beyond “real time” imaging to ultrafast imaging can provide yet another level of fundamental understanding of nanomaterials. Further, combining an in-situ or ex-situ experiment with electron tomography is a very powerful method for materials characterization as this provides the 3-D morphology of the (nano)materials under more relevant conditions. This talk will focus on newer developments such as in-situ heating in liquid, and the future of ultrafast transmission electron microscopy at the Center for Nanoscale Materials.

6:15 PM *F.MT01.02.04
Nanoscale Crystal Growth on van der Waals-Bonded Materials as Seen with *In Situ* Microscopy Techniques Frances M. Ross; Massachusetts Institute of Technology, United States

Two-dimensional materials provide exciting opportunities as substrates for the growth of three-dimensional nanocrystals. The difference in the nature of the bonding at the 3D nanocrystal / 2D material interface, compared to the situation for conventional epitaxy, is expected to generate interesting and potentially useful new growth modes and interfacial structures. It is well known that deposition of gold and other metals onto certain van der Waals-bonded materials produces faceted nanocrystals that can be aligned with the substrate lattice. Here we describe the use of several *in situ* microscopy techniques to explore the principles governing epitaxial growth in a broader range of nanocrystal / van der Waals substrate combinations. An unusual feature of the *in situ* experiments is that substrate preparation and materials deposition can be carried out under ultra high vacuum conditions in chambers that are connected to the microscope, while materials deposition is also possible while the sample is under observation within the microscope. These multiple capabilities are helpful in allowing flexibility and experimental robustness. Furthermore, for these particular experiments, a UHV environment (low 10^{-10} Torr base pressure range) allows reactive materials such as niobium or germanium to be deposited and examined without oxidation. We will describe nanocrystal growth on suspended 2D materials using a UHV-TEM that has integrated capabilities for heating, laser cleaning, metal evaporation, and semiconductor chemical vapor deposition. Post-growth observation using scanning transmission electron microscopy yields atomic level compositional information as well as movies showing nanoparticle motion and annealing phenomena. We will also describe complementary measurements performed in a multi-probe, UHV *in situ* scanning tunneling microscope. This instrument provides opportunities to examine the atomic and electronic structure as well as to measure the transport properties of the nanocrystal / van der Waals material interface. We apply these techniques to evaluate nanocrystal morphology, orientation relation and interfacial structure and properties as a function of deposition parameters. We discuss strategies for morphological control and describe nanocrystal coalescence events and the patterning of the 2D substrate to control nucleation sites. We finally consider the formation of epitaxial alloy and heterostructure islands via sequential deposition. The eventual aim of the *in situ* experiments is to

understand the relationship between the interfacial structure and morphology in a nanocrystal / van der Waals-bonded material combination and the electronic properties that are required for its applications.

6:45 PM *F.MT01.04.02
Observation of Topological Transformations of Ferroelectric Vortices Kai Du and He Tian; Zhejiang University, Chile

Topological structures based on controllable ferroelectric or ferromagnetic domain configurations offer the opportunity to develop microelectronic devices such as high-density memories. Despite the increasing experimental and theoretical insights into various domain structures (such as polar spirals, polar wave, polar vortex) over the past decade, manipulating the topological transformations of polar structures and comprehensively understanding its underlying mechanism remains lacking. We successfully developed a technique to realize domain structures modulation and take an atomic resolution observation simultaneously. This atomistic observation of dynamic evolution reveals the potential of modulating ferroelectric domain patterns in ferroelectric nano-devices. Here we systematically investigate the real-time topological transformations of polar structures in PbTiO3/SrTiO3 multilayers at an atomic level. The procedure of vortex pair splitting and the transformation from polar vortex to polar wave and out-of-plane polarization are observed step by step. Furthermore, the redistribution of charge in various topological structures has been demonstrated under an external bias. These findings advance the current understanding of topological structures transformation manipulated by the external field and its origination in multilayers; it would ultimately enable the design of nanostructured materials to realize their potential applications in microelectronics.

Interfacial Self-Assembly and Engineering of Hierarchically Structured Nanocrystals with Photocatalytic Activity Hongyou Fan; Sandia National Laboratories, United States

Design and engineering of the size, shape, and chemistry of photoactive building blocks enable the fabrication of functional nanoparticles for applications in light harvesting, photocatalytic synthesis, water splitting, phototherapy, and photodegradation. Here, we report the synthesis of such nanoparticles through a surfactant-assisted interfacial self-assembly process using optically active porphyrin as a functional building block. The self-assembly process relies on specific interactions such as π–π stacking and ligand coordination between individual porphyrin building blocks. Depending on the kinetic conditions, resulting structures exhibit well-defined one- to three-dimensional morphologies such as nanowires, nanooctahedra, and hierarchically ordered internal architectures. At the molecular level, porphyrins with well-defined size and chemistry possess unique optical and photocatalytic properties for potential synthesis of metallic structures. On the nanoscale, controlled assembly of macrocyclic monomers leads to formation of ordered nanostructures with precisely defined size, shape, and spatial monomer arrangement so as to facilitate intermolecular mass and energy transfer or delocalization for photocatalysis. Due to the hierarchical ordering of the porphyrins, the nanoparticles exhibit collective optical properties resulted from coupling of molecular porphyrins and photocatalytic activities such as photodegradation of methyl orange (MO) pollutants and hydrogen production. The capability of exerting rational control over dimension and morphology provides new opportunities for applications in sensing, nanoelectronics, and photocatalysis.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

4:00 PM F.MT01.05.01
***In Situ* X-Ray Investigation Underpins Roles of Water on Improving Crystallinity and Stability of Organohalide Perovskite** Hua Zhou[1], Zhiyuan Ma[1,2], Hsin-Hsiang Huang[1,3], Wei Chen[1,3] and Zhang Jiang[1]; [1]Argonne National Laboratory, United States; [2]China University of Petroleum, China; [3]The University of Chicago, United States

Emerging organolead-halide-perovskite-based materials and devices have recently received tremendous attention due to their extraordinary photonic and optoelectronic performance and potential low production costs. Many physical and chemical properties beyond light harvests have erupted. Despite the rapid development of perovskite materials and devices, the impact of environmental factors on different stages of materials synthesis and device fabrication still remains unclear. Moisture or humidity is widely recognized as one of the major lethal factors in perovskite devices degrade or decompose after fabrication. However, recent reports have shown that moisture could be crucial to obtain high-performance perovskite films in a suitable moisture of ~35% relative humidity. Although a few attempts have been made to investigate the morphological evolution of organohalide perovskite films, a comprehensive understanding of the environmental influence in the process of thermal annealing is not achieved yet, as it is critically important to further improve the optoelectronic device performance.

By taking advantage of synchrotron-based grazing incident wide-angle x-ray scattering (GIWAXS), we *in situ* monitor the transformation of organohalide perovskites from precursors to final films upon thermal annealing at different relative humidity. *In situ* GIWAXS reveals the formation of crystalline perovskite materials over relevant time and moisture scales to decipher the effect of humidity on both phase transition and crystal structures during annealing. These *in situ* measurements demonstrate that moderate humidity accelerates the formation of organohalide perovskites and improves the orientation of the film, but more than 50% realtive humidity retards the formation of perovskites and destructs their crystal structures. Furthermore, the highly orientated films obtained at optimized relative humidity are observed which could be attributed to the hydration of precursors. The beneficial influence of moisture content in the crystalline structure formation process on the operation stability of the resulting devices will also be discussed.
These findings clearly elucidate the influence of moisture environment in annealing process of organohalide perovskites and, in turn, allow us to correlate the improved performance of organohalide perovskite matrials and devices to structural features in terms of environmental effects.

4:15 PM TOWN HALL DISCUSSION

5:00 AM *F.MT01.01.01
Microscopic Kinetics of Crystallization in Graphene Nanocapillaries Revealed by *In Situ* TEM Lifen Wang; Chinese Academy of Sciences, China

Graphene liquid cell was used for *in situ* electron microscopy because the single atom thickness, extraordinary mechanical strength and high conductivity of graphene allows the study of material in pristine stages with atomic resolution[1]. Using high-resolution transmission electron microscopy and electron energy loss spectroscopy, we show that BeO and NaCl follows unclassical crystallization process in graphene liquid cell. BeO in nature has a wurtzite structure and crystallizes in the sp^2-coordinated, layered structure in liquid cells formed by sheets of graphene. We further reveal that the layered crystals can be thicker than the thermodynamically determined ultra-thin limit, beyond which the layered phase is energetically unfavored. The discovery counters a long-held dismissal and calls for a reevaluation of the possible existence of sp^2-coordinated, layered polymorphs of octet compounds beyond the ultra-thin limit[2]. Sodium chloride has long been a classical crystallization model. Here we used time-resolved transmission electron microscopy to monitor crystallization of sodium chloride nanoparticles with atomic resolution in and out of graphene cell. The *in situ* observations, combined with large-scale reactive molecular dynamics simulations, reveal the details of the non-classical crystallization of sodium chloride nanoparticles via a nanoscale Wulff construction i. e. hexagon shape selection as they grow in a two dimensional confined system. Visualization of hexagon crystal growth strongly suggests the prominence of 2D confinement effect and allows us to quantify the effect on surface energy. Understanding the growth mechanism inside 2D confined system provides new revenue to rational design of nanomaterials with controlled properties.

5:15 AM F.MT01.01.02
Understanding Temperature-Dependent Nanoscale Electrochemistry Using Liquid Cell Transmission Electron Microscopy Serin Lee[1], Nicholas Schneider[2], Kate Reidy[1], Shu Fen Tan[1] and Frances M. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]Nicholas Schneider, United States

The technique of liquid cell transmission electron microscopy (LC-TEM) provides exciting information by applying the unique capabilities of electron microscopy to imaging and controlling nanoscale phenomena in liquid media. The liquid cell itself is a microfabricated enclosure that is hermetically sealed from the vacuum of the microscope and is filled with a liquid sandwiched between two electron-transparent membranes. LC-TEM provides a unique combination of spatial and temporal resolution for nanoscale liquid phase processes. However, a general limitation of LC-TEM has been the challenge of controlling and quantifying key aspects of the experimental conditions.
Here, we are particularly interested in processes that require simultaneous temperature and electrochemical control. These are important for designing batteries that must operate reliably over a range of environmental conditions or for understanding corrosion processes at elevated temperatures. We observe temperature-dependent electrochemistry using custom-fabricated microfabricated liquid cells that combine electrodes with an electrically isolated heater strip. Here we will discuss, using simulation tools, three key questions that must be understood in order to obtain quantitative information from these experiments.
We first calculate the spatial distribution of temperature in the liquid cell chip. Our setup controls temperature by Joule heating a Pt strip heater embedded within one of the electron transparent windows. We model the heater as an electrothermal system and solve for the temperature profile for a given potential difference, incorporating the temperature-dependent resistance change of the heater material. We also model two common experimental situations that can change the temperature and hence reaction kinetics within the imaged region: misalignment of the top and bottom chips and window bulging due to pressure differences. We show that the strip heater creates temperature gradients in three dimensions, discuss the dependence on experimental conditions, and propose changes in heater chip geometry to allow more precise temperature control. We next calculate the effect of the electron beam on the liquid (radiolysis) as a function of temperature. In TEM, radiolysis is modeled by including the rate at which incident electrons transfer energy to water and create radiolysis species and the subsequent diffusion and interactions of these species with each other and with other molecules present. All steps of this process are temperature-dependent, and we highlight the effects most relevant to our electrochemical experiments. We finally model the

temperature-dependent kinetics of an electrochemical reaction in the case where only part of the electrode is heated, as in our experiments. We focus in particular on Cu deposition under galvanostatic conditions, aiming to understand the role of spatially-dependent diffusion in determining how the deposited morphology evolves under simultaneous control of heat and electrochemical conditions. We are excited by the opportunities of LC-TEM in quantifying temperature-dependent electrochemical processes for a range of practical applications in energy storage, catalysis and corrosion.

5:25 AM F.MT01.01.03
Visualizing Ligand-Mediated Bimetallic Nanocrystal Formation Pathways with *In Situ* Liquid Phase Transmission Electron Microscopy Synthesis Mei Wang and Taylor J. Woehl; University of Maryland, United States

Organic capping ligands play accompanying roles aside from controlling the size and shape of nanocrystals. For instance, heteronuclear ligand-metal complexes have been shown to facilitate alloying of colloidal bimetallic nanoparticles; however, the mechanism by which this occurs remains unclear. Here we utilize liquid-phase transmission electron microscopy (LP-TEM) to demonstrate the roles of metal thiolate complexes and thiol ligands in controlling the formation pathways of bimetallic AuCu nanoparticles. Direct visualization of AuCu nanocrystal under dose-rate controlled LP-TEM conditions shows that polyethylene glycol thiol (PEG-SH) capping ligands modulate the rates of inter-metal electron transfer and metal atom aggregation reactions by forming metal thiolate complexes and kinetically trapping random alloy structures *via* strong, rapid surface capping. Systematic LP-TEM experiments varying dose rate established imaging conditions that minimized electron beam induced nanoparticle aggregation and phase separation and produced alloyed bimetallic nanoparticles of similar structure to benchtop flask-based synthesis. Kinetic simulations of the reactions between ligands and electron beam produced radicals revealed that thiol functional groups were oxidized to disulfide groups and organic radicals. At sufficiently high levels of ligand oxidation (high electron beam fluxes), weak ligand capping by disulfide groups leads to nanoparticle aggregation and metal phase separation, while at low levels of capping ligand oxidation spherical alloyed nanocrystals are formed. Taken together, our results indicate that thiol ligands play a dual role in facilitating alloyed nanoparticle formation by confining metal species within metal-ligand precursor complexes, which promotes simultaneous chemical reduction of metal ions and minimizes inter-metal electron transfer reactions that cause phase separation, and strongly and rapidly capping nanoparticles to prevent phase separation during crystallization.

Graphene—A Promising Electrode Material in Liquid Cell Electrochemistry Shu Fen Tan[1], Kate Reidy[1], Serin Lee[1], Julian Klein[1], Nicholas Schneider[2], Haeyeon Lee[1] and Frances M. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]Renata Global, United States

Two-dimensional (2D) materials such as graphene and transition metal dichalcogenides (TMDs) are potential candidate materials for electrodes due to their exceptional intrinsic properties including their high specific surface area, high electrical charge mobility and good thermal conductivity and mechanical strength. Graphene in particular shows tuneable structures and electrocatalytic activity, excellent conductivity, good chemical resistance and mechanical flexibility, as well as the ease and low cost of production. Graphene-based composites have been explored as next generation electrode materials for electrical and optical devices, supercapacitors, organic electronics and dye-sensitized solar cells and graphene itself is considered a promising electrode material for applications ranging from photocatalysis and solar cell to optoelectronic devices. In electron microscopy, graphene is used in a different way: its remarkable mechanical and scavenging properties make it ideal for graphene liquid cells[1] where liquid is encapsulated between two graphene sheets for high-resolution imaging. However, the transfer method of graphene to fabricate high quality graphene liquid cells and the reproducibility of making liquid pockets with sufficient volume, exact chemical content and well-defined thickness are key experimental challenges with graphene liquid cells. Recent studies circumvent leakage issues by using a liquid cell that is a hybrid of SiN_x and graphene to form leak-proof liquid confinement.[2] Furthermore, separating top and bottom graphene windows with a thin layer of hexagonal boron nitride (hBN) enables more control over liquid thickness and can provide a two-fold improvement in resolution[3] compared to conventional graphene liquid cells. Despite these and other advances in engineering 2D materials into liquid cell design, the full functionality associated with microfabricated liquid cells, such as addition of electrochemical, heating or flowing and mixing capabilities, are generally still absent.
Here we focus on the opportunities arising from the use of 2D materials in liquid cell electrochemistry. To establish whether 2D materials can indeed evolve into a reliable electrode material for both electroanalytical chemistry and electron microscopy, we need to develop a reproducible protocol in transferring 2D materials onto microfabricated liquid cell chips to achieve reliable electrical contact and mechanical robustness. We describe liquid cells equipped with 2D material electrodes and show results aimed at understanding the interplay of kinetics and thermodynamics during electrochemical deposition, measuring parameters such as the shape, size and epitaxy of electrochemically deposited nanoparticles. We discuss the effects of external parameters such as the thickness and nature of the 2D materials and the deposition potential and we

consider beam damage of these 2D materials. Exploring the possibility of 2D materials as electrode materials potentially opens up new opportunities for investigating a wide range of problems pertaining to energy storage and electrocatalysis.

Graphene Liquid Cell for High-Resolution *In Situ* S/TEM Imaging to Study Nucleation and Growth of Nanomaterials Walid Dachraoui, Trond R. Henninen and Rolf Erni; Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Understanding the chemical and the physical processes of nanomaterials (NMs) in liquid media is a crucial challenge and of fundamental interest to modern materials science, chemistry and biology [1]. For example, observing the initial steps of nucleation and the growth of solids is of highest importance for the development of novel materials. This requires techniques allowing the study of NMs in their liquid environments with the corresponding resolution necessary to observe the formation and evolution of clusters at atomic-scale. The most attractive and unique capabilities of a scanning/transmission electron microscope (S/TEM) is its high-resolution, enabling to study materials at the atomic-scale. Nevertheless, a key limitation of this technique is the need of high vacuum conditions to analyse samples. In recent years, a new frontier in the field of transmission electron microscopy has emerged to observe specimens in liquid environments instead of high-vacuum conditions, by separating the liquid sample from the vacuum column using thin impermeable/electron transparent membranes [2]. Recent advances in microfabrication technology has led to a number of commercially available liquid cell TEM holders, where the liquid cells are made of two micro-fabricated silicon nitride (Si_xN_{1-x}) electron transparent thin films. The cell thickness can be controlled by spacers ranging from 50 nm to 5000 nm. Since the thickness of the encapsulating material is one aspect that negatively affects the resolution, the commercial cells are not optimized around achieving the highest spatial resolution including atomic resolution. Graphene-based liquid cell electron microscopy (GLC-EM) have demonstrated a better imaging resolution [3].
In this study, we optimized graphene-based liquid cells to realize in real time atomic-scale observations of nucleation and growth of gold (Au) nanoparticles in liquid mode, using high-spatial resolution S/TEM. The cell shows excellent imaging capabilities compared to conventional Si_xN_{1-x} liquid cells especially at higher-magnification. This work demonstrates that, using graphene to encapsulate small pockets of liquid, we were able to image and track in real time the very early stage of material growth at an interpretable atomic-scale resolution.

From Atoms to Particles—Hetero- and Homogeneous Nucleation of Sub-nm Pt Clusters Observed at the Atomic Scale in Liquid Trond R. Henninen, Debora Keller and Rolf Erni; Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

The formation of solid matter as modelled by the classical nucleation theory (CNT), assumes to be triggered by the generation of spherical nuclei. However, initially at sub-nm scale, non-spherical atomic clusters form with structures deviating from a bulk crystal. Understanding the atom-by-atom growth dynamics at this size, requires considering the individual atoms. Conventional liquid cell holders have enabled studying liquid systems in transmission electron microscopes, but are limited in spatial resolution by the thickness of the liquid and the encapsulating windows (in total 100-

1000 nm), making imaging at sub-nm resolution challenging. To further progress to atomic resolution, we use low vapour-pressure liquids, (glycerol or ionic liquids, such as 1-butyl-3-methyl imidazolium chloride).[1] The negligible vapour pressure makes such liquids directly vacuum compatible without windows, and enables atomic resolution in suspended nanofilms and supported nanodroplets (5-50 nm thickness). Furthermore, a melting point above room temperature enables adjusting the viscosity of the liquid, and thus reaction kinetics, by heating. In our liquid phase experiments, we can observe dispersed Pt atoms to nucleate into few-atom clusters, which further coalesce and grow into nanoparticles or disordered cluster agglomerates, or redissolve into the liquid. CNT tells us that the presence of a surface lowers the energy barrier of heterogeneous nucleation, compared to homogeneous nucleation in a liquid phase. In our liquid experiments, there is indeed a corresponding effect, where nucleation is rarely observed in the suspended liquid nanofilms, while easily observable at a high nucleation rate in the nanodroplets on a carbon surface. As the highly unstable sub-nm clusters nucleate and dissolve, increased stability is observed in clusters of ca 8-13 atoms, compared to smaller clusters. Indeed, nucleating clusters typically form directly into this size range, where various close-packed structures (such as fcc and icosahedral[2]) often can be observed. This indicates that the formation of close-packed, crystalline structures, already at the few-atomic scale, is an essential step of the nucleation process.

SESSION F.MT01.02: Advanced In Situ TEM for Material Science
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-MT01

5:00 AM *F.MT01.02.01
Plasmonic Nanostructures for Room Temperature Catalysis Renu Sharma and Wei-Chang Yang; National Institute of Standards and Technology, United States

In situ transmission electron microscopy (TEM) is now routinely used to measure the effect of external stimuli, such as temperature, gas or liquid environment, mechanical stress, etc., on the structure, chemistry, morphology and functioning of nanostructured materials. Here we employ in situ TEM to show that local surface plasmon resonance (LSP) energies can be used to initiate chemicals reactions that mimics photocatalysis.
The energy barrier for most of the chemical reactions is overcome by heating the reactants in the presence of a suitable catalyst, where the thermal energy provided by heat helps in surpassing the barrier that has been reduced by the adsorption of the reactant molecules. In recent years, the localized surface plasmon (LSP) resonance energy has been used to replace the thermal energy to initiate reaction at low temperatures, even at room temperature.[1,2] As most of the plasmonic materials, Au, Ag or Al, are not generally catalytically active, i.e. do not adsorb most of the gas molecules, but have been successfully combined with active catalysts such as Pt, Ni, Ru, etc., for harvesting their LSP resonance energies for low temperature reactions. So far optical methods have been used to generate and measure the LSP resonance energies. However, the low spatial resolution, of the order of 100 nm, achievable by optical methods, does not provide sub-particle level distribution of coupling efficiency of different modes. On the other hand, high energy electrons not only excite all LSP modes simultaneously, but also provide high spatial resolution in the nanometer range to resolve their energy loss probability that indicates the location-specific efficiency of coupling to the LSP modes at certain resonance energies on the plasmonic nanoparticle. Therefore, we use a monochromated electron source in an environmental scanning-transmission electron microscope (ESTEM), combined with metallic nanoparticle boundary element method (MNPBEM) and density functional theory (DFT) simulations, to characterize various LSP modes and their coupling efficiency distribution within the shape- and size-controlled nanoparticles of Au and Al. We demonstrate that the knowledge gained from low-loss and core-loss EELS measurements can be used to design catalyst-plasmonic particle combination for selected chemical reactions.

Probing Interfaces in Heterogeneous Catalysts via *In Situ* and 4D STEM Miaofang Chi; Oak Ridge National Laboratory, United States

Interfaces in catalysts are inherently dynamic - they often form under vigorous synthesis conditions and dynamically adapt their structures down to atomic scale to the specific reaction conditions. Depending on the synthesis conditions and the phase of the reactant, the active interfaces include those between solid-gas, solid-liquid, and triple-phase interfaces of solid-gas-liquid. Hence, in order to understand the catalytic reaction mechanisms, not only their initial structural and chemical configurations matter, but also their evolution under reaction conditions have to be clearly elucidated. In this talk, I will present our recent studies on understanding the synthesis and reaction mechanisms of precious metal nanoparticle based heterogenous catalysts, by using scanning transmission electron microscopy. Specifically, three examples will be given, including the understanding of the deposition and growth mechanisms of metal core-shell nanoparticles using *in situ* liquid cell electron microscopy, the probing of the dynamic evolutions of surface atomic structures of core-shell nanocubes *via* environmental cell STEM, and at last, the mapping of strong interactions between support and metal as a function of post-synthesis treatments using four-dimensional STEM.

***In Situ*, Site Specific and High Spatial Precision Electron Microscopy Studies for Correlation of Atomic Structure to Properties** Eva M. Olsson; Chalmers Univ of Technology, Sweden

In situ electron microscopy allows us to reveal the correlation between local atomic structure and properties with high spatial resolution. The effect of electric fields, light, mechanical strain and temperature on both structure and properties can be imaged and studied using spectroscopy. The obtained knowledge is used to tune the properties of advanced materials and devices. Catalytic activity of metal nanoparticles and electrical properties of semiconducting nanowires are examples where the strain induced effects have a strong influence on the properties and performances. High resolution annular dark field (ADF) scanning transmission electron microscopy (STEM) imaging can provide high resolution (better than 1 Å) and high precision (better than 1 pm) information about the local atomic structure [1]. In situ and correlative microscopy can be used to perform spatially resolved electrical, mechanical and optical studies [2]. In addition, dynamic electric field induced changes on the atomic scale can be studied using in situ microscopy [3]. The precision of the measurement and the quantitative information enable important and theoretical modelling on the same material systems. New aspects of material properties and mechanisms, not obvious from measurements on the macro scale are revealed using in-situ electron microscopy where interfaces, surfaces, geometries and defects affect the material properties on the macro, micro, nano and atomic scale. The knowledge is crucial for the understanding of the mechanisms active on the nano- and atomic scale, the effect of atomic structure on the properties and also for the design of materials and devices with tailored properties.

Nanoscale Crystal Growth on van der Waals-Bonded Materials as Seen with *In Situ* Microscopy Techniques Frances M. Ross; Massachusetts Institute of Technology, United States

Two-dimensional materials provide exciting opportunities as substrates for the growth of three-dimensional nanocrystals. The difference in the nature of the bonding at the 3D nanocrystal / 2D material interface, compared to the situation for conventional epitaxy, is expected to generate interesting and potentially useful new growth modes and interfacial structures. It is well known that deposition of gold and other metals onto certain van der Waals-bonded materials produces faceted nanocrystals that can be aligned with the substrate lattice. Here we describe the use of several *in situ* microscopy techniques to explore the principles governing epitaxial growth in a broader range of nanocrystal / van der Waals substrate combinations. An unusual feature of the *in situ* experiments is that substrate preparation and materials deposition can be carried out under ultra high vacuum conditions in chambers that are connected to the microscope, while materials deposition is also possible while the sample is under observation within the microscope. These multiple capabilities are helpful in allowing flexibility and experimental robustness. Furthermore, for these particular experiments, a UHV environment (low 10^{-10} Torr base pressure range) allows reactive materials such as niobium or germanium to be deposited and examined without oxidation. We will describe nanocrystal growth on suspended 2D materials using a UHV-TEM that has integrated capabilities for heating, laser cleaning, metal evaporation, and semiconductor chemical vapor deposition. Post-growth observation using scanning transmission electron microscopy yields atomic level compositional information as well as movies showing nanoparticle motion and annealing phenomena. We will also describe complementary measurements performed in a multi-probe, UHV *in situ* scanning tunneling microscope. This instrument provides opportunities to examine the atomic and electronic structure as well as to measure the transport properties of the nanocrystal / van der Waals material interface. We apply these techniques to evaluate nanocrystal morphology, orientation relation and interfacial structure and properties as a function of deposition parameters. We discuss strategies for morphological control and describe nanocrystal coalescence events and the patterning of the 2D substrate to control nucleation sites. We finally consider the formation of epitaxial alloy and heterostructure islands via sequential deposition. The eventual aim of the *in situ* experiments is to understand the relationship between the interfacial structure and morphology in a nanocrystal / van der Waals-bonded material combination and the electronic properties that are required for its applications.

6:00 AM *F.MT01.02.05
Investigating the Effects of Additives on Particle Nucleation and Assembly by Liquid Phase TEM James J. De Yoreo[1,2], Guomin Zhu[2,1], Zhaoming Liu[3,1], Maria Sushko[1], Zhisen Zhang[4], Benjamin Legg[2,1] and Ruikang Tang[3]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States; [3]Zhejiang University, China; [4]Xiamen University, China

Due to a unique combination of spatial and temporal resolution, liquid phase (LP) TEM has provided new insights into poorly understood processes of particle nucleation and assembly. Here we describe the results of studies on metals, oxides, and carbonates aimed at understanding the effects of additives, both as surface-bound ligands and dopants, on nucleation pathways and particle assembly. Investigations into hematite (Hm) mesocrystal formation from a ferrihydrite (Fh) precursor show that, in the presence of oxalate, isolated Hm particles rarely form. However, when they do, new Hm particles then repeatedly nucleate about 2 nm away from the new surfaces and immediately undergo oriented attachment to the growing aggregates of coaligned particles. Because nucleation rates are statistically deterministic and direction-specific, the resulting mesocrystals exhibit a constant shape irrespective of size. Results on Au nanoparticle formation in the presence of citrate reveal a similar outcome and comparison to natural and synthetic systems suggests such interface-driven pathways are widespread. Classical DFT analyses indicate that, for both Hm and Au, the surface-bound organics create interfacial chemical gradients that result in enrichment of cation species about a nm from the surface, though in the case of Au the species and degree of enhancement is pH dependent. Investigations of calcite formation from amorphous calcium carbonate (ACC) precursors in the presence of additives reveal a very different outcome. When carboxyl-rich organics are added, ACC transforms to crystalline phases via dissolution-reprecipitation, but at slower rates than in pure solution. However, when Mg is added, ACC initially exhibits low electron contrast, which increases over time absent any change in particle morphology. Diffraction and spectroscopic analysis show that the ACC transforms to Mg-calcite accompanied by loss of structural water. In combination with molecular dynamics simulations, the results imply Mg brings excess water into ACC, inducing structural fluctuations that enable transformation without the need to nucleate a separate crystal. These results highlight the opportunity that LP-TEM provides for deciphering underlying mechanisms of particle nucleation and assembly.

6:15 AM *F.MT01.02.06
2D Nanostructure Formation and Defects Evolution Revealed by *In Situ* Liquid Cell Transmission Electron Microscopy Haimei Zheng[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley,

United States

Two-dimensional (2D) materials have attracted significant attention due to their unique structure and properties. However, our understanding of their growth mechanisms, especially those in solution, is still limited. Using liquid cell transmission electron microscopy (TEM), we study the growth of 2D nanostructures and defects evolution with high spatial resolution in-situ. First, as an example, I will show the growth of 2D cobalt oxide and cobalt nickel oxide nanosheets. Our direct observation reveals that 3D nanoparticles are initially formed from the molecular precursor solution and they transform into 2D nanosheets. Ab initio calculations show that a small nanocrystal is dominated by positive edge energy, but when it grows to a certain size, the negative surface energy becomes dominant, driving the 3D nanocrystal transformation into a 2D structure. Uncovering these growth pathways, including the 3D-to-2D transition, provides opportunities for the future design and solution synthesis of novel materials. Second, I will also show the growth of 2D indium chloride nanostructures. The nucleation and growth of 2D nanosheets in solution are found through both classical and non-classical pathways. The growth kinetics at the low temperature is reduced compared to that at the room temperature. The fast growth induces high density of defects (e.g., nanotwins). In addition, our atomic structural analysis of the nanosheets and chemical mapping of the reaction front provides useful complementary information. These systematic studies allow us to develop an understanding of the growth mechanisms of $InCl_3$ 2D nanosheets and defect evolution. In conclusion, our development of high resolution liquid phase TEM opens opportunities for future study of many other nanomaterials growth and transformations.

6:30 AM *F.MT01.02.07
Machine-Learning Revealed Nanoparticle Dynamics from Liquid-Phase TEM Videos Qian Chen; University of Illinois at Urbana-Champaign, United States

In this talk, I will present my group's recent in using our customized analysis framework based on a machine learning model based on convolutional neural network in extracting quantitative information from liquid-phase TEM videos. We apply this framework to three typical systems of colloidal nanoparticles, concerning their diffusion and interaction, reaction kinetics, and assembly dynamics, all resolved in real-time and real-space by liquid-phase TEM. A diversity of properties for differently shaped anisotropic nanoparticles are mapped, including the anisotropic interaction landscape of nanoprisms, curvature-dependent and staged etching profiles of nanorods, and an unexpected kinetic law of first-order chaining assembly of concave nanocubes. These systems represent properties at the nanoscale are otherwise experimentally inaccessible. Compared to the prevalent image segmentation methods, our method shows a superior capability to predict the position and shape boundary of nanoparticles from highly noisy and fluctuating background—a challenge common and sometimes inevitable in liquid-phase TEM videos. We expect our framework to push the potency of liquid-phase TEM to its full quantitative level, and to shed insights, in high throughput and statistically significant fashion, on the nanoscale dynamics of synthetic and biological nanomaterials.

6:45 AM F.MT01.02.08
***In Situ* Imaging of Carbon-Coated Aluminum Nanoparticles via Low Energy Laser-Induced Heating in TEM** Chi-Chin Wu[1], Trevor Clark[2], Lily Giri[1], Rose A. Pesce-Rodriguez[1] and Khalid Hattar[2]; [1]U.S. Army Research Laboratory, United States; [2]Sandia National Laboratories, United States

Metallic nanoparticles such as nano-aluminum (nAl) are promising candidates as energetic additives for improved combustion and detonation effects in explosive/propellant formulations because of the high heat of combustion for aluminum and potentially rapid burning of nAl enabled by the high surface area to volume ratio. Various carbon-coated core-shell nAl were produced via atmospheric dielectric barrier discharge plasmas using commercial nAl (40-60 nm avg. diameter). Preliminary ex-situ characterization via transmission electron microscopy (TEM) has discovered the formation of γ-alumina (γ-Al_2O_3) crystallites that are both present in the organic coating and in the matrix of amorphous shell surrounding the Al core, presumably due to the phase transformation of the originally amorphous Al_2O_3 (a-Al_2O_3) induced by the plasma process. This work aims to investigate in-situ the coupled effects of transformed Al_2O_3 shell and organic coating on the dynamic behavior of nAl during heating experiments induced by a low-energy focused laser beam in TEM. The laser energy varied from ~1.5 W to 3 W with an incremental increase of 0.1 W every few minutes. The dynamic morphological and phase transformation during heating were investigated and captured through increasing numbers of hexagon-shaped γ-Al_2O_3 crystals floating on molten Al cores at a lower threshold laser energy than the as-received commercial nAl. The results from this paper directly revealed the real-time interactions among Al, a-Al_2O_3, γ-Al_2O_3, and carbon-coating for enhancing fundamental understanding of nAl at high temperatures. This paper also underscores the significance of exploiting advanced in-situ materials characterization to enhance in-depth understanding of reactive nAl composites possessing plasma-altered surface modifications for optimal controls of synthesis conditions and resultant structural and chemical properties.

6:55 AM F.MT01.02.09
Probing Thermal Expansion Coefficient of $SrTiO_3$ Grain Boundaries by *In Sit*u STEM-EELS Kun-Yen Liao, Kiyou Shibata and Teruyasu Mizoguchi; The University of Tokyo, Japan

In nanocrystalline materials, smaller crystallite size and increasing grain boundary (GB) volume may result in different physical properties from those of the bulk. Thermal expansion coefficient (CTE), as one of the important factors for materials selection, has been investigated extensively in several nanocrystalline materials [1-3]. Conventional approaches include the measurement of bulk CTE with varied grain size as well as the determination of lattice constants by scattering methods. However, the inconsistency of experimental findings has left the question on whether GBs contribute to the enhancement of CTE. Direct determination of CTE near GBs may require the dedicated measurement of temperature and volume in nano-meter scale and is still challenging issue for conventional methods due to the lack of spatial resolution.

In recent years, a nanoscale thermometry has been realized using valence electron energy loss spectroscopy (EELS) in scanning transmission electron microscope (STEM) [4]. Local temperature can be estimated by mapping the variation of plasmon energy. With this method, CTE of various 2-D materials has been successfully determined in nanoscale region with the support of theoretical calculation [5]. However, GBs contribution has not yet been discussed in the previous reports.

In this work, we attempt to probe the CTE of individual GBs by using in-situ valence EELS. Bicrystals of Σ5 and Σ29 strontium titanate ($SrTiO_3$) GBs were investigated in a temperature range from 300 to 873K. The GB structure was analyzed by high angle annular dark field (HAADF) image. The plasmon energy was mapped near GBs in each temperature and compared with the density functional theory (DFT) calculation. By carefully monitoring the shift of plasmon energy, we achieved to obtain local CTE near selected GBs. The relationship between CTE and GB structure was further analyzed by molecular dynamics (MD) simulation. The details will be shown in my presentation.

7:05 AM F.MT01.02.10
***In Situ* High-Resolution Transmission Electron Microscope on Atomic Scaled Friction** Xiang Wang, Yang He and Scott X. Mao; University of Pittsburgh, United States

Observing atomic-friction and revealing the friction mechanism at the atomic-scale are significant to understand macro friction behaviors and control wastage induced by the friction between contacts in microdevices. Here, by designing the atomic-scale contacts under transmission electron microscopy (TEM) observation, the real-time atomic friction process is captured. Friction between single tungsten asperities shows a discrete stick-slip behavior and in-situ TEM experiment revealed that the accumulation and release of the strain energy during friction is an asynchronized process. This work paves a possible way to realize in-situ atomic-friction research and enriches the understanding of the atomic-friction.

SESSION F.MT01.03: Advanced Synchrotron X-Ray for Materials Dynamics
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-MT01

5:00 AM *F.MT01.03.01
***Operando* Synchrotron X-Ray Studies of Metal Additive Manufacturing** Tao Sun[1], Cang Zhao[2], Niranjan Parab[3] and Sarah Wolff[4]; [1]University of Virginia, United States; [2]Tsinghua University, China; [3]Argonne National Laboratory, United States; [4]Texas A&M University, United States

Metal additive manufacturing (AM) refers to a group of disruptive technologies that build metallic three-dimensional objects by adding feedstock materials layer by layer based on computer models. AM not only unleashes the design freedom of engineers by allowing the build of geometrically complex parts, but also opens up tremendous opportunities for material

scientists to synthesize materials far-from-equilibrium and fabricate functionally graded architectures. While AM holds the promise for completely revolutionizing the way we make thing, building defect-free metal products with precisely controlled material microstructures and part performance remains challenging. Indeed, substantial fundamental issues associated with metal AM still need to be addressed before it can reach its full potential, and many new research areas need to be explored.

At the Advanced Photon Source, we have been applying *operando* high-speed x-ray imaging and diffraction techniques to probe a variety of metal AM processes since 2016. The superior penetration power of high-energy x-rays and the extremely high photo fluxes afforded by the 3rd-generation synchrotron facility allows the quantitative characterization of dynamic structural evolution in bulk metallic materials with unprecedented spatial and temporal resolutions. Many highly transient phenomena that take place during the energy-matter interaction in metal AM were investigated, and the mechanisms responsible for different types of defects were identified.

In the presentation, I will give a brief overview of the *operando* synchrotron studies of metal AM performed by our team and other scientists around the world. These metal AM processes include laser powder bed fusion, directed energy deposition, and binder jetting. The strength and limitations of different beamlines (i.e. source, detector) and *operando* AM systems will be elaborated. I will then introduce the new understanding gained from our synchrotron x-ray experiments, as well as their broad impact on the development of AM materials, technologies, and numerical models.

Multi-Scale and Multimodal X-Ray Microscopy and Applications Xianghui Xiao and Xiaojing Huang; Brookhaven National Laboratory, United States

Interactions between x-ray and matters carry the matters' property information, e.g. chemical species, chemical states, electronic structures, morphological structures, etc. In a complex heterogeneous sample system that has a hierarchical structure, multi-modal and multi-scale characterizations are necessary to reveal the system's properties. Various x-ray microscopy and imaging techniques are valuable tools in such applications.
X-ray micro-imaging with synchrotron sources has been successfully applied to study dynamic systems of large volumes at high spatial and temporal resolutions. Compared to radiography, tomography is capable to provide structural information in three dimensions that is crucial in studying heterogeneous systems. However, with tomography, it is challenging to pursue temporal resolution as high as radiography. On the one hand, a tomography scan needs to take hundreds to thousands of radiography images of a sample. On the other hand, the sample needs to rotate during the image acquisition that may induce disturbances to the sample system due to unavoidable centrifugal force under rapid spinning. In this presentation, a recent development aiming to overcome these limitations will be presented.
At higher spatial resolution, it is possible to integrate multimodal techniques onto the same imaging/microscopy platform. Transmission X-ray Microscopes (TXM) have been widely used in energy storage material e.g. battery researches. One uniqueness of TXM is fast spectro-imaging capability at tens of nanometer spatial resolution that provides complex chemo-mechanical interaction information at a single electrode particle level in battery systems. Such information helps not only to understand the electrode materials' behaviors but also to improve battery electrode engineering designs to mitigate the potential damages under charge/discharge conditions.
Although TXM is capable to provide correlative spectro-morphological imaging capabilities, other scanning nano-probe techniques are needed to pursuit even more modalities at higher sensitivity. At a state-of-art nanoprobe beamline, nano-diffraction, nano-fluorescence, and scanning imaging techniques can be integrated onto the same platform. Multimodal measurements with these techniques provide correlative structural information of the samples from different aspects. However, such measurements are slow, so it is not suitable for in situ and high throughput experiments. Combining TXM and nano-probe techniques overcomes each technique's limitations and provide deep insights into the measured system. Few examples of this approach will be discussed in the presentation.

5:30 AM *F.MT01.03.03
Dynamic and *In Situ* Characterization Using X-Ray Synchrotron Sources Michelle Mejía and Michael Behr; Dow, United States

High flux radiation sources where we have active research programs (APS, ALS, and NIST) enable the study of materials and material properties in non-ambient environments characteristic of their synthesis, processing conditions, and/or use in the field. The variety of sources allows for enhanced contrast mechanisms for the analysis of structure, composition, and phase behavior of a variety of systems across R&D from the atomic to near visible light scale. In-situ experiments, including thermal and mechanical, allow for in-depth understanding of mechanisms of energy transfer present in materials. This presentation will give an overview of the problem solving capabilities available to Dow as well as some case studies on in-

situ tensile/X-ray to examine energy absorbing mechanisms and in-situ DSC/X-ray to examine crystallization dynamics. Deformation and failure mechanisms of polyolefin blends are investigated by collecting X-ray scattering data during in-situ tensile experiments. By simultaneously collecting both WAXS and SAXS patterns during the tensile experiments various energy transfer mechanisms can be tracked/observed including changes in orientation, crystal breakup, microvoiding, and lamellar size and shape. It is the sequence, type, and magnitude of these mechanisms that dictate mechanical performance in a material. WAXS will reveal differences in orientation and crystallite size while SAXS will give insight into the presence of microvoiding as well as lamellar size and shape. By combining the X-ray data with the tensile data, we are able to track how the addition of propylene-based olefin block copolymer (P-OBC) compatibilizers of different composition to PE/PP blends affects the deformation mechanism present during strain.
Additionally, in-situ DSC/X-ray experiments were conducted in order to investigate the effect of P-OBC compatibilizers on the crystallization behavior of polyethylene. A change in temperature is observed in a static DSC experiment, however this test does not determine whether this change is caused by crystallization/nucleation of the P-OBC compatibilizer or microphase segregation of the P-OBC compatibilizer. In-situ experiments allows for this distinction and WAXS is used to track the crystallization and microphase segregation of these blends as a function of temperature.

5:45 AM F.MT01.03.04
Elucidating the Factors Governing the Cyclic Performance of MgO-Based Sorbents of CO_2 Using Time-Resolved *In Situ* XRD/PDF Techniques Margarita Rekhtina, Maximilian Krödel, Paula M. Abdala and Christoph Müller; ETH Zürich, Switzerland

The development and deployment of technologies for CO_2 capture and storage (CCS) is key to limit the global warming below the 2 °C target (Paris Agreement). One of the CCS techniques considered is the post-combustion capture of carbon dioxide with solid sorbents. In particular, MgO-based sorbents are highly promising due to their abundance and low cost, as well as their intermediate operational temperature range of 200–450 °C and high theoretical uptake of 1.09 g_{CO2}/g_{MgO}. However, an important disadvantage of MgO-based sorbents is their slow carbonation kinetics. To tackle this, promotion of MgO with molten salts, such as alkali metal nitrates, can drastically accelerate the rate of MgO carbonation. Nonetheless, it has been observed that over cyclic operation, the rate of CO_2 uptake in MgO-based sorbents can decrease considerably, leading to deactivation and representing a major issue for their industrial implementation. Thus, understanding the structural changes that occur during cyclic operation is crucial to advance sorbent design.
In this work, we use time-resolved (1 s) *in situ* synchrotron XRD to shed light onto the structural dynamics occurring during cyclic operation of MgO nanoparticles coated with $NaNO_3$ (MgO-$NaNO_3$). The *in situ* XRD study allowed us to determine the structural evolution of the material in the kinetically controlled regime over ten consecutive cycles of carbonation (315 °C, CO_2) and regeneration (450 °C, N_2). The high signal to noise ratio and the time resolution of the collected data allowed us to obtain the detailed information of the crystalline phases and their transformation with time and cycle number. To quantitatively describe the phase composition of the sorbent parametric Rietveld analysis was performed, allowing to quantify the phase composition and its dynamics with time on CO_2 stream. This information enabled us to perform a kinetic analysis of the rate of $MgCO_3$ formation (via $MgO+CO_2 \rightarrow MgCO_3$). The $NaNO_3$ promoter is molten during the entire cyclic operation, and was probed using Pair Distribution Function analysis.
Furthermore, the data recorded revealed the formation of small quantities of a crystalline Na_2CO_3 phase after the sorbent regeneration steps. We hypothesize that a partial decomposition of molten $NaNO_3$ into Na_2O occurs during sorbent regeneration in N_2 (likely through $NaNO_3 \rightarrow NaNO_2+0.5O_2$ and subsequently $2NaNO_2 \rightarrow Na_2O+N_2+1.5O_2$), followed by the reaction of Na_2O with CO_2 in the carbonation step to form Na_2CO_3. Na_2O is in an amorphous state or present as ionic species dissolved in the molten $NaNO_3$. In the beginning of each carbonation cycle, Na_2CO_3 rapidly (ca. 120 s) transformed into $Na_2Mg(CO_3)_2$, while $MgCO_3$ starts to form only after ca. 15 min on CO_2 stream. The rate of $MgCO_3$ formation was described with an Avrami-Erofeev model. The presence of $Na_2Mg(CO_3)_2$ drastically enhanced the carbonation rate in each cycle, possibly by increasing the number of nucleation sites. Both the formation of $Na_2Mg(CO_3)_2$ and $MgCO_3$ has been found to be reversible during the regeneration step, but Na_2CO_3 was not decomposed at any stage and its amount increased after each regeneration.
To conclude, we were able to show that the formation of $Na_2Mg(CO_3)_2$ via the decomposition of the promoter $NaNO_3$ enhances the carbonation rate and reduces the induction period for $MgCO_3$ formation. However, during cyclic operation the decomposition of the $NaNO_3$ promotor was found to be detrimental for the CO_2 capture performance of the sorbent.

5:55 AM F.MT01.03.05
Real-Time Coherent X-Ray Study of the Relationship Between Structure and Dynamics in Self-Organized Ion Beam Nanopatterning Peco Myint[1], Xiaozhi Zhang[2], Yugang Zhang[3], Lutz Wiegart[3], Andrei Fluerasu[3], Randall Headrick[2] and Karl Ludwig[1,1]; [1]Boston University, United States; [2]The University of Vermont, United States; [3]Brookhaven National

Laboratory, United States

Real-time coherent Grazing-Incidence Small-Angle X-ray Scattering was used to investigate the average kinetics and the fluctuation dynamics during self-organized nano-patterning of Silicon. Flat Silicon samples were bombarded by 1keV Ar^+ and Kr^+ at 65° polar angle, leading to the spontaneous formation of nanoscale ripples with 30 - 50 nm wavelengths. The temporal evolution of the average intensity shows the evolution of average kinetics, while the fluctuation dynamics is investigated by correlating speckles. At early times, the surface behavior can be understood within the framework of linear theory. The transition away from the linear theory behavior is observed in the dynamics through the intensity correlation function, which quickly evolves into a compressed exponential decay on length scales corresponding to the peak wavelength. On shorter length scales, the dynamics becomes stretched exponential in behavior. The correlation times are maximum at the ripple wavelengths while they are smaller at other wavelengths. This has notable similarities and differences with the phenomenon of de Gennes narrowing. Overall, this dynamics behavior is found to be consistent with the simulations of a nonlinear growth model by Harrison *et al.* (Phys. Rev. E, **96**, 032804). Following the formation of self-organized nano-ripples, they move across the surface. Homodyne X-ray alone cannot detect the motion, but because of the gradient of ion flux throughout the sample, there is a corresponding ripple velocity gradient that can be measured by cross correlating speckles and tracking their movements.
This work was supported by NSF grant DMR-1709380 (BU) and DOE grant DE- SC0017802 (UVM).

6:05 AM F.MT01.03.06
Theory-Guided *In Situ* X-Ray Absorption Spectroscopy Reveals Backbonding Contributions to Small Molecule Adsorption in a Cu^I-Containing Metal-Organic Framework Gregory Su[1], Han Wang[1], Brandon Barnett[2,1], Jeffrey Long[2,1], David Prendergast[1] and Walter Drisdell[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Nanoporous metal-organic frameworks are promising materials for gas capture, separation, and storage due to their high surface area and tunable chemistry, allowing these frameworks to selectively adsorb small molecules. The metal-organic framework Cu^I-MFU-4*l*, which contains coordinatively unsaturated Cu^I centers, can engage in backbonding interactions with various small molecule guests, enabling distinct binding energies for different adsorbates. Understanding these fundamental electronic interactions is needed to design tailored frameworks with targeted adsorption properties. We use *in situ* near edge X-ray absorption fine structure spectroscopy coupled with theory to examine several gases expected to bind to the open Cu^I sites in Cu^I-MFU-4*l* via different electronic interactions, including σ-donation, π-backbonding, and formal electron transfer. We show that *in situ* Cu L-edge X-ray absorption spectroscopy of Cu^I-MFU-4*l* in the presence of a gas can elucidate the π-backbonding contributions by directly probing excitations to unoccupied backbonding orbitals with Cu *d*-character, even for gases where other interactions, such as ligand-to-metal σ-donation, dominate. First-principles calculations based on time-dependent density functional theory reveal the backbonding molecular orbitals associated with these spectroscopic transitions. The energies of the transitions correlate with the energy levels of the isolated small molecule adsorbate, and the transition intensities are proportional to the binding energies of the guest molecules with Cu^I-MFU-4*l*. This definitive probe of the molecular and electronic structure origins of backbonding between metal-organic frameworks with electron rich metal centers and small molecule guests provides guidelines for molecular-level design of solid-state sorbents for energy-efficient industrially relevant separations processes.

6:15 AM F.MT01.03.07
***In Situ* Synchrotron Pair Distribution Function (PDF) Analysis to Monitor Synthetic Pathways Under Electromagnetic Excitation** B. Reeja Jayan[1], Nathan Nakamura[1], Laisuo Su[1], Jianming Bai[2] and Sanjit Ghose[2]; [1]Carnegie Mellon University, United States; [2]Brookhaven National Laboratory, United States

We experimentally demonstrate that the application of external electromagnetic (EM) fields influence ceramic nanoparticle synthesis via distortions introduced in the local atomic structure. Such distortions do not occur during conventional hydrothermal synthesis. Prior studies show that EM fields can promote rapid, low-temperature synthesis and atomic structures not replicable using conventional hydrothermal routes. However, the mechanisms promoting these changes are not well understood, despite decades of scientific investigations. A critical limitation of prior studies was the inability to monitor structural changes while the EM field was applied, resulting in a lack of information about dynamic, field-driven changes in local atomic structure. We address this knowledge gap through a custom-designed microwave waveguide reactor (Gerling Applied Engineering) enabling in-situ synchrotron x-ray pair distribution function (PDF) analysis. This configuration (implemented in beamline 28-ID-2 at National Synchrotron Light Source II (NSLS-II), Brookhaven National Laboratory, USA) allows us to monitor EM field-induced changes in atomic structure in real-time during synthesis.

PDF analysis is an ideal tool for such in situ structural studies, as it can quantitatively characterize changes in the local atomic structure which serve as precursors to phase transitions and crystalline phase formation. PDF thus contrasts with x-ray diffraction (XRD), which is applicable to well ordered crystalline materials and is limited in characterizing systems with structural disorder or nanoscale features. Specifically, we find that the enhanced growth of crystalline rutile SnO_2 nanoparticles during EM field exposure is predated by structural reordering of the oxygen sub-lattice. In contrast, nanoparticles synthesized under conventional hydrothermal conditions exhibit no such structural changes and experience limited particle growth compared with EM field-assisted conditions. Our studies thus establish a clear difference in the phase formation mechanisms under EM fields, which would not be observable using conventionally used XRD techniques and *ex-situ* studies.

The lack of mechanistic insight into EM field-assisted processes has limited their widespread application. Our demonstration of a change in the synthetic pathway under EM field exposure holds important implications for materials design and inspires future work towards manipulating external fields for atomic-scale design of local structure in nanomaterials. Additionally, by revealing that applied fields influence individual sub-lattices before and during crystallization, we contribute significant knowledge towards fully understanding the mechanisms surrounding EM field-assisted phase formation. We believe this work will thus help guide the design of novel nanoparticles with altered local atomic structure, which will have a significant impact on materials for energy storage, catalysis, and advanced sensors.

6:25 AM F.MT01.03.08
Liquid-Solid and Vapor-Liquid Phase Transformations in Laser-Melted Ti- and Ni- Alloys—A Multi-Modal, *In Situ* Synchrotron Study Rakesh R. Kamath[1], Ryan Heldt[1], Logan White[1], David Garcia[2], Rongxuan Wang[2], Zhenyu Kong[2], Kamel Fezzaa[3], Tao Sun[4,3] and Hahn Choo[1]; [1]University of Tennessee Knoxville, United States; [2]Virginia Polytechnic Institute and State University, United States; [3]Argonne National Laboratory, United States; [4]University of Virginia, United States

The capability to tailor the grain and defect structure of the final product is critical in realizing the full potential of metal additive manufacturing (MAM) technologies. With regard to fusion-based MAM techniques, a fundamental knowledge of the ensuing phase transformations (vapor-liquid, liquid-solid and solid-solid) is critical to establish a correlation between MAM process parameters and the key physical variables governing the build microstructure. A wealth of fundamental solidification and applied welding literature points to the thermal gradient across the liquid-solid interface (G) and the velocity of the liquid-solid interface (R) as being the key physical variables in the liquid-to-solid phase transformation.

Ex-situ microstructural characterization of AM Ti-6Al-4V (Ti-64) builds produced using different melt strategies (and therefore, different G and R) was performed using high-energy synchrotron x-ray diffraction (S-XRD). The analysis of the S-XRD patterns using Rietveld refinement revealed a distinct change in crystallographic texture type of the solidified β-BCC phase, preferred variant selection of daughter α-HCP and a higher phase fraction of retained β-BCC compared to the Ti-64 powder used for the build. The crystallographic texture of β-BCC phase was observed to go from a cube texture in raster/line melt to a rotated cube/fiber-type texture in spot melts. Ex-situ synchrotron x-ray tomography on the Ti-64 builds revealed that the spot melt strategies result in higher porosity (both gas and lack of fusion defects) compared to the raster melts.

Motivated by the findings made in the ex-situ studies, the present in-situ studies used a laser-AM simulator (developed at beamline 32-ID-B, APS, Argonne National Laboratory) to mimic the unit processes of spot and line melt strategies on Ti-6Al-4V and IN-625 alloy plates, along with varying the relevant process parameters namely laser power, line scan speed, spot dwell time, and temporal and spatial intervals between two consecutive spot melts. In-situ dynamic synchrotron x-ray radiography was used in tandem with the laser-AM simulator to obtain the interface velocity (R) of the liquid-solid interface with a state-of-the-art spatial resolution of 2 μm and temporal resolution of a few μs. Simultaneous thermal imaging was performed on the top surface of the melts during the laser melting experiments to obtain the thermal gradient (G) at the liquid-solid interface. Post-mortem, ex-situ SEM-EBSD characterization of the melt pools were used to correlate the measured G and R evolutions to the resulting microstructure, as well as indirectly estimating the thermal gradient (G) for comparison to the in-situ experiments.

The in-situ x-ray radiographs were also used to observe the fluctuations in the vapor-liquid interface to study the conduction-to-keyhole transition and defect formation/mitigation mechanisms. Furthermore, the characteristics of the vapor-liquid interface, along with the liquid-solid interface, were used to validate/develop existing heat transfer models used to describe MAM.

6:35 AM F.MT01.03.09

Mapping of Elastic Stress and Density of Domain Variants in Bulk Twinned Materials by Dark-Field X-Ray Microscopy Jan Schultheiß[1,2], Lukas Porz[2], Lalitha Kodumudi Venkataraman[2], Marion Höfling[2], Can Yildirim[3], Philip Cook[3], Carsten Detlefs[3], Semen Gorfman[4], Juergen W. Roedel[2] and Hugh Simons[5]; [1]NTNU Norwegian University of Science and Technology, Norway; [2]Technical University of Darmstadt, Germany; [3]European Synchrotron Radiation Facility, France; [4]Tel Aviv University, Israel; [5]Technical University of Denmark, Denmark

State-of-the art high-resolution in situ imaging techniques are limited to probing the surface of the material. This is an important drawback for the characterization of twinned materials as the strain state changes from biaxial at the surface to triaxial in the bulk, dramatically influencing the functional properties. One way around this is Dark-field X-Ray Microscopy, which allows to access structural information from the bulk. Its resolution, however, is determined by the optics of the lenses, which prohibits investigations on nano-sized domains common in complex twinned materials.

In this work, we overcome this limitation by using the full reciprocal-space intensity distribution, allowing to map nanosized domains highly localized in the bulk. Calculation of the local elastic stresses from measured raw data for a ferroelectric/ferroelastic $(Ba,Ca)(Zr,Ti)O_3$ model system as a function of the externally applied electric field demonstrates the power of our technique. We find that, for all electric fields, the local domain size is spatially coupled to the elastic stress. The electric field induced crystallographic texture narrows the distribution of the elastic stresses and reduces the mechanical elastic energies by 60%, while simultaneously increasing the domain size by 35%. The results pave the way towards in situ imaging of elasto-morphological correlations inside the bulk crucial for many scientific disciplines, ranging from complex oxides to other twinned systems, such as martensitic materials or high entropy alloys.

6:45 AM F.MT01.03.11
***In Situ* X-Ray Investigation Underpins Roles of Water on Improving Crystallinity and Stability of Organohalide Perovskite** Hua Zhou[1], Zhiyuan Ma[1,2], Hsin-Hsiang Huang[1,3], Wei Chen[1,3] and Zhang Jiang[1]; [1]Argonne National Laboratory, United States; [2]China University of Petroleum, China; [3]The University of Chicago, United States

Emerging organolead-halide-perovskite-based materials and devices have recently received tremendous attention due to their extraordinary photonic and optoelectronic performance and potential low production costs. Many physical and chemical properties beyond light harvests have erupted. Despite the rapid development of perovskite materials and devices, the impact of environmental factors on different stages of materials synthesis and device fabrication still remains unclear. Moisture or humidity is widely recognized as one of the major lethal factors in perovskite devices degrade or decompose after fabrication. However, recent reports have shown that moisture could be crucial to obtain high-performance perovskite films in a suitable moisture of ~35% relative humidity. Although a few attempts have been made to investigate the morphological evolution of organohalide perovskite films, a comprehensive understanding of the environmental influence in the process of thermal annealing is not achieved yet, as it is critically important to further improve the optoelectronic device performance.

By taking advantage of synchrotron-based grazing incident wide-angle x-ray scattering (GIWAXS), we *in situ* monitor the transformation of organohalide perovskites from precursors to final films upon thermal annealing at different relative humidity. *In situ* GIWAXS reveals the formation of crystalline perovskite materials over relevant time and moisture scales to decipher the effect of humidity on both phase transition and crystal structures during annealing. These *in situ* measurements demonstrate that moderate humidity accelerates the formation of organohalide perovskites and improves the orientation of the film, but more than 50% realtive humidity retards the formation of perovskites and destructs their crystal structures. Furthermore, the highly orientated films obtained at optimized relative humidity are observed which could be attributed to the hydration of precursors. The beneficial influence of moisture content in the crystalline structure formation process on the operation stability of the resulting devices will also be discussed.
These findings clearly elucidate the influence of moisture environment in annealing process of organohalide perovskites and, in turn, allow us to correlate the improved performance of organohalide perovskite matrials and devices to structural features in terms of environmental effects.

Magnetic Processes at the Nanoscale Observed Using *In Situ* Transmission Electron Microscopy Amanda K. Petford-Long[1,2], Frank Barrows[2,1], Vuk Brajuskovic[1] and Charudatta Phatak[1,2]; [1]Argonne National Laboratory, United States; [2]Northwestern University, United States

Understanding the behavior of nanoscale magnetic structures relies on being able to understand the complex interplay of the energy terms that control this behavior at a local scale. The relative contribution of these energy terms can be modified by parameters such as geometric confinement, interfacial effects and interactions between adjacent magnetic nanostructures. In addition, it is important to be able to explore how a magnetic nanostructure responds to an external driving force, such as temperature, and electric or magnetic fields. Our approach is to use Lorentz transmission electron microscopy (LTEM) or electron holography combined with in-situ magnetizing, heating and biasing experiments to elucidate the micromagnetic behavior at the sub-micron scale in nanomagnetic structures. Quantitative analysis of the LTEM data is carried out using the transport of intensity equation (TIE) approach, which we have extended to allow us to visualize the magnetic structure in three dimensions. By comparing the phase reconstructions of the magnetic induction obtained experimentally with the results of micromagnetic simulations, we are able to gain a detailed understanding of the way in which the various energy terms contribute to the behavior that we observe. We are interested in both geometrically-confined structures, for example arrays of nanomagnets patterned on lattices (artificial spin ice (ASI) arrays), in addition to nanomagnetic structures such as skyrmions and other topological spin structures that we create in thin films.

Our recent interest in artificial spin ices has focused on ASIs patterned on quasicrystalline lattices, in which the lack of translational symmetry and the varying coordination number at the vertices at which the magnetic bars meet leads to a heterogeneous energy landscape and to varying magnetic frustration across the lattice, even in the ground state. Our reconstructed magnetic induction maps allow us to determine the local magnetization configuration and we can then calculate the energy at each vertex motif for each possible magnetic configuration from simulations and thus determine which vertices play the largest role in influencing magnetic frustration and thus behavior in response to magnetic fields and to changes in temperature. Applied to magnetic skyrmions we used in situ LTEM to observe skyrmions in a Co/Pt multilayer film as a function of applied magnetic field, and by combining with simulations we were able to determine the strength of the Dzyaloshinskii-Moriya interaction.

5:15 AM *F.MT01.04.02
Observation of Topological Transformations of Ferroelectric Vortices Kai Du and He Tian; Zhejiang University, Chile

Topological structures based on controllable ferroelectric or ferromagnetic domain configurations offer the opportunity to develop microelectronic devices such as high-density memories. Despite the increasing experimental and theoretical insights into various domain structures (such as polar spirals, polar wave, polar vortex) over the past decade, manipulating the topological transformations of polar structures and comprehensively understanding its underlying mechanism remains lacking. We successfully developed a technique to realize domain structures modulation and take an atomic resolution observation simultaneously. This atomistic observation of dynamic evolution reveals the potential of modulating ferroelectric domain patterns in ferroelectric nano-devices. Here we systematically investigate the real-time topological transformations of polar structures in PbTiO3/SrTiO3 multilayers at an atomic level. The procedure of vortex pair splitting and the transformation from polar vortex to polar wave and out-of-plane polarization are observed step by step. Furthermore, the redistribution of charge in various topological structures has been demonstrated under an external bias. These findings advance the current understanding of topological structures transformation manipulated by the external field and its origination in multilayers; it would ultimately enable the design of nanostructured materials to realize their potential applications in microelectronics.

Voltage-Induced Periodic Domain Pattern in La-Doped $BiFeO_3$ Marvin J. Müller[1], Yen-Lin Huang[2], Eric K. Parsonnet[2], Ramamoorthy Ramesh[2,2], Morgan Trassin[1] and Manfred Fiebig[1]; [1]ETH Zurich, Switzerland; [2]University of California, Berkeley, United States

The ability to switch magnetism through application of an electric field holds great promise to launch a new era of energy-efficient memory and logic devices.[1,2] Tremendous progress has been achieved with the integration of magnetoelectric $BiFeO_3$ thin films into oxide electronics architectures.[3,4] The remaining energy gap towards the coveted attojoule switching can be bridged by the refinement of materials properties such as reduced electric coercivity and lower polarization value. Bringing $BiFeO_3$ close to the ferroelectric-paraelectric phase boundary via high La doping has emerged as a promising approach.[5,6]
Here, we evaluate the prospects of highly-La-doped $BiFeO_3$ for technological applications. Using optical second harmonic generation microscopy, we directly access the polarization of the films once integrated in technology-relevant capacitor heterostructures. We find that La-doping results in a drastic deviation of the ferroelectric domain architecture from the prototypical $BiFeO_3$ domain configuration. This leads to the loss of the net in-plane polarization in the films in the pristine state. We show, however, that the application of out-of-plane electric fields leads to a spontaneous ordering of the La-doped $BiFeO_3$ domains. In particular, our results demonstrate the electric-field-induced emergence of the stripe-like domain pattern, key ingredient in the $BiFeO_3$-based magnetoelectric switching. This suggests La-doped $BiFeO_3$ as an ideal candidate for integration into a new class of reduced-energy-consumption oxide memory and logic devices.

Interfacial Self-Assembly and Engineering of Hierarchically Structured Nanocrystals with Photocatalytic Activity Hongyou Fan; Sandia National Laboratories, United States

Design and engineering of the size, shape, and chemistry of photoactive building blocks enable the fabrication of functional nanoparticles for applications in light harvesting, photocatalytic synthesis, water splitting, phototherapy, and photodegradation. Here, we report the synthesis of such nanoparticles through a surfactant-assisted interfacial self-assembly process using optically active porphyrin as a functional building block. The self-assembly process relies on specific interactions such as π–π stacking and ligand coordination between individual porphyrin building blocks. Depending on the kinetic conditions, resulting structures exhibit well-defined one- to three-dimensional morphologies such as nanowires, nanooctahedra, and hierarchically ordered internal architectures. At the molecular level, porphyrins with well-defined size and chemistry possess unique optical and photocatalytic properties for potential synthesis of metallic structures. On the nanoscale, controlled assembly of macrocyclic monomers leads to formation of ordered nanostructures with precisely defined size, shape, and spatial monomer arrangement so as to facilitate intermolecular mass and energy transfer or delocalization for photocatalysis. Due to the hierarchical ordering of the porphyrins, the nanoparticles exhibit collective optical properties resulted from coupling of molecular porphyrins and photocatalytic activities such as photodegradation of methyl orange (MO) pollutants and hydrogen production. The capability of exerting rational control over dimension and morphology

provides new opportunities for applications in sensing, nanoelectronics, and photocatalysis.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

Amorphous Thin-Film Growth—Exploring Nanoscale Local Dynamics versus Average Kinetics Chenyu Wang[1], Christa Wagenbach[1], Jeffrey G. Ulbrandt[2], Meliha G. Rainville[1], Suresh Narayanan[3], Hua Zhou[3], Randall Headrick[2] and Karl Ludwig[1,1]; [1]Boston University, United States; [2]The University of Vermont, United States; [3]Argonne National Laboratory, United States

X-ray photon correlation spectroscopy (XPCS) provides kinetics and dynamics information about condensed matter by characterizing fluctuations at nanoscales. We have used the technique to study the growth of amorphous WSi_2 on SiO_2 templates by sputter deposition at room temperature in order to explore the average kinetics and real-time dynamics as a function of pressure. It's known that, as a consequence of kinetic behavior, there is a transition from smooth to rough growth surfaces with increasing pressure. It's observed that the speckle-averaged X-ray scattering intensity doesn't change after the film reaches a kinetic steady-state. Four timescale parameters were determined for each of the three pressure conditions (16mTorr, 10mTorr and 8mTorr). Peaks are found in intensity vs. time curves, and the corresponding timescale parameters at the intensity peak for each wavenumber $q_{//}$ represent the time when the local roughness is maximum at the length scale $2\pi/q_{//}$. Dynamic behavior is analyzed by means of two-time correlation functions at different $q_{//}$ values. Most of the time parameters show $q_{//}$ dependence. The time for local morphology to reach a steady state decreases most rapidly with $q_{//}$. Therefore, for high $q_{//}$ regions (i.e. short length scales), it is found that a kinetic end point may be reached before the dynamic steady state is reached. In other words, in these regions, an average local structure is stabilized while processes of nanoscale deposition, relaxation and coarsening have not yet reached a dynamic equilibrium. The timescales for reaching dynamic and kinetic steady states, and the correlation time of surface structure in the final dynamic steady state all decrease as growth pressure and final surface roughness increase. This work was supported by the National Science Foundation (NSF) under Grant No. DMR-1709380 and by the U.S. Department of Energy (DOE) Office of Science under Grant No. DE-SC0017802.

Accelerated Solid-State Diffusion During Cation Exchange in Nanocrystals Richard Robinson; Cornell University, United States

The phenomenology of solid-state transformations and diffusion at short length scales (where the interaction of point defects with free surfaces and interfaces is significant) remains poorly understood, is increasingly important for nanostructured devices that utilize the "nano properties" (quantum confinement, high surface-area-to-volume ratios, and short transport lengths), for applications utilizing nanoscale reactivity, and for understanding interfaces and defects responsible for mass transport through them. In this work, *via* in-situ synchrotron x-ray diffraction (XRD), we directly interrogate the structure and reaction kinetics of lead sulfide (PbS) nanocrystals transforming into cadmium sulfide (CdS) through cation exchange. The epitaxial relationship of zincblende CdS to rocksalt PbS breaks the overall symmetry of the core-shell nanocrystal without requiring the loss of unit cell symmetry, leading to anomalous peak shifts in the diffraction pattern. Conversion occurs in three stages: (1) surface exchange to form a metastable rocksalt CdS shell, (2) crystallization of this shell to zincblende, and (3) diffusive transport of ions through the completed shell. The interdiffusion coefficient, D, for ions diffusing through the shell follows the Arrhenius relationship with an activation energy of 160-180 kJ mol^{-1}, which exceeds that observed in many other experiments in diffusion in nanoparticles and is similar to values measured in bulk solids, suggesting the barrier to exchange is dominated by the energies of point defect formation rather than surface-bound reactions. However, the magnitude of D is larger by four orders of magnitude or more compared to the slowest diffusing species in our system (self-diffusion of Cd in CdS). This surprising result suggests interdiffusion is enhanced in nanocrystals, and possible mechanisms include high concentrations of induced extrinsic defects and/or increase in the diffusive jump length through high-diffusivity paths. Cation exchange illustrates that the distinction between chemical diffusion in a potential gradient and diffusion at thermodynamic equilibrium has not been fully appreciated. Acceleration of interdiffusion in core-shell nanoparticles due to large chemical potential gradients will be important for understanding for nanoscale heterostructure formation and stability.

Suppressing Co-Crystallization of Halogenated Non-Fullerene Acceptors for Thermally Stable Ternary Solar

Cells Sandra Hultmark; Chalmers University of Technology, Sweden

Solution-processed organic solar cells display inferior thermal stability largely because the nanostructure of the active layer blend changes upon heating. While photovoltaic blends based on non-fullerene acceptors such as indacenodithienothiophene-based ITIC derivatives are touted as more thermally stable than those based on fullerenes, they readily crystallize even far below their nominal glass transition temperature. We study two halogenated ITIC derivatives that readily co-crystallize upon mixing, which indicates that the use of an acceptor mixture alone does not guarantee the formation of a disordered mixture. The addition of the donor polymer to the acceptor mixture readily suppresses the crystallization which results in a fine-grained ternary blend with nanometer-sized domains that do not coarsen due to a high Tg ~ 200 C. As a result, annealing at temperatures of up to 170 C does not markedly affect the photovoltaic performance of ternary devices, in contrast to binary devices that suffer from acceptor crystallization in the active layer. Our results indicate that the ternary approach enables the use of high-temperature processing protocols, which are needed for upscaling and high-throughput fabrication of organic solar cells.

Grain Growth Suppression in Nanocrystalline Metal Oxides at High Temperatures via Excess Oxygen Content and Dimension Control Gyu Rac Lee[1], Hyeuk Jin Han[2], Eugene Cho[1], Judy Cha[2] and Yeon Sik Jung[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Yale university, United States

Nanoscale-engineered metal oxides have demonstrated improvement in device performance through enhancement in physical and chemical properties. Key factors in achieving the improved performances include high surface-to-volume ratios and high surface activities which are attributed to the decreased feature size by nanostructuring. Of the many variables that contribute to the performance enhancement, grain size is one feature, which plays an important role for improving the latent property of the material. For example, in catalyst and sensor applications, decrease in grain size increases the activity as a result of increased surface area. Furthermore, in sensors, decreasing the grain size to less than 10nm significantly increases sensitivity due to full depletion and accumulation of carriers in the sensing channels. Therefore, in terms of physical and chemical properties, nanostructures with nanosized grains can significantly improve the properties of high-performance devices. However, metal oxide devices commonly require an annealing process for crystallization and stabilization, which is usually accompanied by grain growth, particle agglomeration, and deformation of the nanostructure leading to degradation of device performance. Also, metal oxide nanostructures often operate at elevated temperatures and in chemically harsh environments, which induces structural change and gradual grain growth causing instability, sensor response and signal drift, and ultimately failure. Therefore, a strategy to maintain grain size and structure in metal oxide nanostructure during device operation is needed.
Here, we demonstrate a method to maintain grain size in crystalline metal oxide (i.e. tin oxide) nanowire through grain growth suppression by excess oxygen stoichiometry and nanoscale confinement control. Even at high annealing temperatures, grains with size below 10 nm retain their structural integrity and grain size. Grain growth dynamics and structural changes of the metal oxide nanowire during annealing were studied by in-situ and ex-situ TEM. Conditions such as temperature, nanowire diameter, annealing environment, and oxygen content were varied to understand the parameters needed for grain suppression. From the analysis, it was found that grain formation and growth are simultaneously affected by oxygen content in the nanowire and that suppression of grain growth occurs when the effect of oxygen inside the nanowire is maximized by controlling the diameter and stoichiometric oxygen ratio of the metal oxide nanowire. Grain growth suppression of nanosized grains in metal oxide nanowire provides an opportunity to fabricate structurally stable metal oxide nanostructures for high-performance gas sensor applications. By applying the parameters for grain suppression, a metal oxide nanostructure was fabricated by solvent-assisted nanotransfer printing. Consequently, the gas sensor built from the metal oxide nanowire accompanied by suppressed nanosized grains as the building block showed improved thermal and operation stability with high sensitivity toward ethanol gas. Our findings provide new insights into thermally stable nano-sized grains in metal oxide nanowire and suggest a novel material design for metal oxide based applications.

5:55 AM F.MT01.05.06
The Nucleation and Crystallisation of Calcium Sulphate Phases Stephen Yeandel[1], Helen Freeman[2], Rik Drummond-Brydson[2], Colin Freeman[1] and John Harding[1]; [1]University of Sheffield, United Kingdom; [2]University of Leeds, United Kingdom

The calcium sulphate phases (anhydrite, bassanite and gypsum) are industrially important due to their widespread use in plaster and as a cement additive. The $CaSO_4 \bullet xH_2O$ system displays easily reversible hydration/dehydration reactions between the different phases. In an aqueous environment it is known that bassanite ($CaSO_4 \bullet \frac{1}{2}H_2O$) is formed first, before the thermodynamically more stable gypsum ($CaSO_4 \bullet 2H_2O$). The bassanite then converts to gypsum, either by assembly into

elongated aggregates followed by transformation or by dissolution and reprecipitation[1].

This work uses molecular dynamics simulations performed using the LAMMPS[2] code and the potential model of Byrne et al.[3] to explore the crystal growth of $CaSO_4$ phases. In our work we compute the aqueous surface energies for bassanite and gypsum which have been used to predict equilibrium morphologies which are in good agreement with previous studies[4]. Simulations of the assembly of bassanite nanoparticles in aqueous solution have been performed and compared with the recent work of Stawski *et al.*[5] The modelling studies are complemented by experimental liquid cell TEM studies of the bassanite to gypsum transformation. The implications for a non-classical mechanism of the crystallisation of calcium sulphates are discussed.

***In Situ* High Temperature Dynamics of Surface Residues and Monolayer MoS_2 on Graphene Surface** Heena Inani[1], Dong Hoon Shin[2], Jun Hee Choi[2], Kimmo Mustonen[1], Min Hee Kwon[2], Clemens Mangler[1], Hyunjeong Jeong[2], Niall McEvoy[3], Sang Wook Lee[2] and Jani Kotakoski[1]; [1]University of Vienna, Austria; [2]Ewha Womans University, Korea (the Republic of); [3]Trinity College, Ireland

Low-dimensional materials and their hetero-stacked systems have shown potential for various applications. Due to their atomically thin nature, atomic scale modifications are possible under external stimuli, e.g., heating and particle irradiation leading to nanofabrication techniques. Here, we show through atomic-resolution in situ scanning transmission electron microscopy (STEM) experiments, that Joule-heated suspended graphene can be used as an atomically thin and electron transparent high temperature "hot plate". In these experiments, we apply continuous voltage pulses through graphene while observing dynamical changes in surface contaminants on top of graphene [1], as well as drastic structural changes in a mono-layer MoS_2 layer [2]. The highest temperatures of the graphene substrate were estimated to be above 2000 K. Specifically, we observe cleaning through evaporation of surface residues and hydrocarbon contaminants, as well as positional and rotational dynamics of residual particles on otherwise atomically clean graphene. In the MoS_2 structure, heating through the graphene substrate leads to increase in edge disorder and appearance of voids, accompanied by appearance of clusters on top of the edges. At the highest temperatures, the initially 2D MoS_2 structure breaks apart, and only independent 3D nanocrystals remain on graphene. The crystals have typically a hexagon-like shape with the 2H lattice. Our results show that graphene can be used as an efficient high-temperature substrate for in situ microscopy experiments and provide new insights into nanofabrication techniques for 2D materials for applications, for example, in catalysis.

Phase Transition-Driven Multiphysical Transformation of Vanadium Dioxide for Aerospace Applications Latha Nataraj; Air Force Research Laboratory, United States

Vanadium dioxide (VO_2) is a thermochromic material with thermally driven crystallographic transformation resulting in an insulator-to-metal transition [1]. The first-order monoclinic insulator phase to rutile metallic phase transition in VO_2 results in a fast reversible transition of
(i) electrical properties [1] - from electrically insulating properties at temperatures below the phase transition temperature (T_c) of 68 °C to conductive properties at temperatures above T_c,
(ii) optical properties [2]- from being transparent to infrared radiation (IR) below T_c to reflecting IR above T_c,
(iii) mechanical properties – with elastic anisotropy, significant increase in modulus along the transitioned rutile *c*-axis, and a pronounced phonon softening

(iv) magnetic properties [3] - from nonmagnetic below T_c to magnetic above T_c.

The electrical transition of VO_2 has potential applications in switching and sensing. VO_2 has also received renewed attention as a strongly correlated material for new ultrafast and microscopy techniques, ionic gating, and improved computational approaches. Our earlier work has exploited the magnetic and optical transitions for smart carbon fiber reinforced aerospace composites integrating them with micron-sized VO_2 particles [4]. In addition, mechanical actuation with large amplitude, fast response of ~10 ms, and long lifetime has been demonstrated combining the temperature dependent thermal expansion and actuation of vanadium dioxide (VO_2) and the excellent electrical conductivity of carbon nanotube (CNT) thin films [5]. Practical mechanical actuation will be investigated via trade studies on the film thickness, displacement, and energy associated with two-dimensional shape change.

We present the dramatic multiphysical transformation of VO_2 resulting from the thermally driven crystallographic transformation. The challenging VO_2 film growth, structural characterization of the thin film, electrical transition, the in-situ thermo-mechanical response and theoretical underpinnings for VO2-based actuation for aerospace applications will be discussed.

TEM *In Situ* Investigation of Size Effects on the Mechanical Properties in Aerospace-Grade Epoxy Raz Samira and Noa Lachman; Tel Aviv University, Israel

Epoxy polymers are often used as a base for composites in aviation and aerospace applications, owing to their light weight, good affinity to the fillers, excellent mechanical properties, and stability under chemical corrosion and high temperatures. Many studies previously demonstrated that reducing materials scales, such as thin films or nanotubes, provides significant increase in the mechanical properties compared to the bulk material. However, few studies have dealt with these size effects in epoxy resins, and none was able to validate a mechanism. We present here an in-situ flexural bending experiments of thin epoxy cantilevers (bellow 200 nm). A Picoindenter is combined within TEM in order to investigate size effects on the mechanical properties of epoxy. A real-time video of the fracture process is gathered with the corresponding mechanical data from force and displacement. Experiments show crack propagation within the elastic region until fracture, without a yield point. Furthermore, the nano-scale samples demonstrate a significant increase in the flexural strength and are impressively close to the theoretical strength of the material. The combination of mechanical measurements and morphological data enables deeper understanding of the mechanisms behind the mechanical behavior. This work can be further expanded towards potential application as thin inter-layer of matrix in reinforced composites or in MEMS applications.

Sequential Interfacial Reactions Govern Phase Evolution in Solid-State Ceramic Synthesis Wenhao Sun; University of Michigan, United States

Solid-state synthesis from powder precursors is the primary processing route to multicomponent ceramic materials. The black-box nature of the reaction vessel typically precludes an understanding of the solid-state reaction mechanisms that govern phase evolution, leading to trial-and-error approaches to synthesis. Here, we combine *ab initio* thermodynamics with *in situ* synchrotron X-ray scattering and TEM to build predictive theories for which non-equilibrium phases form during solid-state ceramic synthesis, and why. I will present examples from the ceramic synthesis of NaxMO2 (M = Co, Mn) layered oxides [1] and also the classic high-temperature superconductor YBa2Cu3O6+x (YBCO) [2]. We derive an interfacial reaction model to predict the first-phase-to-form between two powder precursors, which can consume a large fraction of the reaction energy and can topotactically template structural transformations to other non-equilibrium intermediates. When there are three precursors, such as in Y2O3 + BaO2 + CuO --> YBCO, we show how sequential pairwise reactions dictate the

multi-step phase evolution process towards the target multicomponent ceramic. Our insights can help guide the choice of precursors and parameters employed in the solid-state synthesis of ceramic materials, and constitutes a step forward in unraveling the complex interplay between thermodynamics and kinetics during materials synthesis.

Electrically Driven Phase Changes in the Superionic Conductor $Cu_{16}Rb_4Cl_{13}I_7$ Baoming Wang[1], Teodor Todorov[2], Nicholas Schneider[3], John Collins[2], John Ott[2], John Rozen[2] and Frances M. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]IBM T.J. Watson Research Center, United States; [3]Nicholas Schneider, United States

The highest room temperature conductivity of any solid electrolyte, 0.34 S/cm, was reported for the superionic conductor $Cu_{16}Rb_4Cl_{13}I_7$ [1]. The crystal structure of this material has been determined using single-crystal X-ray diffraction [2] and neutron powder diffraction [3, 4], allowing models to be developed for the conduction pathways within the structure. Due to its high conductivity and insensitivity to air and humidity, $Cu_{16}Rb_4Cl_{13}I_7$ is particularly interesting as a solid electrolyte for synaptic cells targeted for neuromorphic computing applications [5] and three-terminal, fast-switching memory elements have been developed. The operating principle of these devices is that a voltage applied to a control electrode causes Cu^+ to migrate through the solid electrolyte and deposit onto a channel, changing its resistivity as measured using two read terminals. It is important to understand the physical phenomena that underlie copper ion transport in this material in order to optimize properties of the devices such as the on/off ratio and the reliability. We have therefore developed an experimental design for transmission electron microscopy (TEM) to bias devices based on solid electrolytes *in situ* while imaging the structural changes that take place during operation.
We fabricated electron-transparent thin film samples on commercial TEM window chips with a copper control electrode and various materials for a channel placed several hundred nm to one side. The chips are accommodated in a Hummingbird TEM holder with biasing capability. The entire active area of the device is visible and the structural changes both within the electrolyte and at the electrodes can be correlated with current flow. Movies recorded during these experiments show a variety of interlinked, dynamic phenomena. At the channel, copper is deposited as whiskers or nuclei, with morphology depending on the electrode material. Within the electrolyte, an unexpected structural modulation appears when the current density exceeds a certain threshold. Diffraction analysis reveals a phase transformation initiated at the electrode, converting the electrolyte from a polycrystalline structure to a nanocrystalline phase with different atomic spacings. A distinctive bright stripe becomes visible at the phase boundary with contrast that is consistent with the local reduction in ion concentration. We suggest that depletion of copper ions, initiated at the electrode, drives the conversion to a CuRbClI phase of different stoichiometry. Furthermore, we suggest that the lower ion conductivity of the new phase is responsible for the formation of the bright contrast: finite element and Monte Carlo simulations show that a drop in conductivity cause local depletion. The interlinked nature of the phase change, conductivity change, and ion concentration then alter the voltage and current flow at the next current pulse, allowing the structural modulation to propagate across the electrolyte in a series of bright stripes. We suggest that the insights achieved by TEM in terms of the structural stability and phase changes in the superionic conductor $Cu_{16}Rb_4Cl_{13}I_7$ help to assess its capabilities as an electrolyte for neuromorphic devices and provide useful guidance for its other applications.

***In Situ* Microscopy Analysis of Thermodynamic and Kinetic Contributions to Stability in Nanocrystalline Alloys** William S. Cunningham[1], Wenbo Wang[1], J. Sebastian Riano[2], Sooyeon Hwang[3], Andrea Hodge[2,2] and Jason R. Trelewicz[1,1]; [1]Stony Brook University, United States; [2]University of Southern California, United States; [3]Brookhaven National Laboratory, United States

Despite their intrinsic instabilities, nanocrystalline metals have demonstrated improved properties relative to their coarse-grained counterparts. Targeted doping of grain boundaries to offset their energetic penalty has been pursued as a

thermodynamic pathway for increasing thermal and mechanical stability. However, as recently demonstrated in a number of systems, notably Cu-Ta, dopant species thought to produce thermodynamically preferred nanocrystalline structures instead contain features such as small nanoprecipitates that act to inhibit grain boundary migration through kinetic pinning forces. In this study, we use thermodynamic nanostructure stability models to select a model system – Mo-Au – for exploring the interplay between thermodynamic and kinetic contributions to thermal stability in nanocrystalline alloys. A unique starting microstructure containing nano-metallic multilayers was employed and thermally aged through in situ electron microscopy experiments to access evolving segregation states. A combination of imaging and analytical electron microscopy was used to map solute segregation to different microstructural features and corresponding phase transitions as a function of temperature. Our results demonstrate the microstructure initially evolved through a phase transformation at lower homologous temperatures (< 600°C) where Au solute atoms cluster and segregate to the underlying grain structure, consistent with predictions from thermodynamic stability models. With increasing temperature, grain boundaries are shown to migrate and produce an increase in grain size, which was accompanied by intermittent pinning events from solute-rich regions. This regime transpired at temperatures where the microstructure thermodynamically phase separated, thus demonstrating kinetic contributions to stability at higher homologous temperatures.

Late News: *In Situ* Observation and Modelling of High Temperature Nanoparticle Evaporation James Horwath[1], Peter Voorhees[2] and Eric Stach[1]; [1]University of Pennsylvania, United States; [2]Northwestern University, United States

Understanding the evolution of systems of supported nanoparticles is vital to the field of industrial catalysis - high reaction temperatures and harsh conditions drive the degradation of small, highly active catalytic nanoparticles, thereby reducing activity. While research aimed to describe coarsening and degradation processes has been undertaken for decades, the difficulty of *in situ* observation and the analysis of *in situ* experimental data has inhibited the development of a theory which comprehensively describes the evolution of supported nanoparticles.
Here, we present the results of *in situ* Transmission Electron Microscopy (TEM) experiments studying the development of a model catalyst system, gold nanoparticles on a silicon nitride support, at high temperatures. After heating the system and annealing in vacuum we observe global mass loss through sublimation of the solid nanoparticles. Using deep learning to aid image analysis, we are able to observe nanoscale changes in sets of hundreds of nanoparticles with high spatial and temporal resolution. After compiling data describing size and shape change of these nanoparticles, we are able to study the evolution of both the entire system, to understand the fundamental behavior with respect the environmental conditions, and small groups of particles, to recognize and study short-range interactions and stochastic mass-exchange processes. With these data in hand we develop a theoretical model based on thermodynamics and kinetics which closely describes the evaporation and surface diffusion of gold nanoparticles leading to a degradation of the model catalyst. By imposing physical constraints on our model, we can relate parameters to individual physical properties of a catalyst material. Based on this, we will demonstrate how materials and processing methods can be chosen to develop supported catalysts which resist degradation, and how environmental factors impact the mechanisms by which nanoparticles interact and evolve.

Fabrication of Ferroelectric Thin-Film Specimen for *In Situ* Electrical Biasing S/TEM Studies by Focused Ion Beam Alexander Vogel[1,2], Martin Sarott[2], Marco Campanini[1], Manfred Fiebig[2], Morgan Trassin[2] and Marta D. Rossell[1]; [1]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]ETH Zürich, Switzerland

Piezoelectric actuators, sensors, dielectric capacitors and memory devices are examples of applications of ferroelectrics in modern life. In data storage applications, ferroelectricity presents a unique alternative to ferromagnetism as it allows for more energy efficient and faster devices. Commercially ferroelectrics have been hindered by major reliability issues [1,2] such as retention loss [3], imprint [4], and fatigue [5]. Overcoming these issues requires a deeper understanding of the microscopic mechanisms of domain wall kinetics, nucleation and the role of various types of defects, such as oxygen vacancies. Even so, at present, there is a lack of dynamical data on the ferroelectric switching process at the atomic scale, which impedes further development in this field.
In this work, we report on the fabrication by focused ion beam (FIB) of ferroelectric thin film specimens for in-situ electrical

biasing experiments inside the transmission electron microscope (TEM). The specimens were fabricated on commercial micro-electro-mechanical system (MEMS)-chips that allow for ferroeletric switching over large areas of the film under a uniform electric field in the absence of external strains. A plate capacitor geometry was adopted to mimic the environment of industrial applications for ferroelectric capacitors. The bottom electrode of the capacitor consists of a conductive substrate, such as Nb-doped $SrTiO_3$, while Pt is used as the top electrode. The investigated ferroelectric thin films comprise $Pb(Zr_{0.2}Ti_{0.8})O_3$ (PZT) and $BiFeO_3$ (BFO) grown by pulsed laser deposition.
The specimen geometry was optimized to prevent the mechanical failure of the electrodes caused by the strain induced by the piezoelectric response of the ferroelectric. This allowed for stable PZT thin film specimens, with a film thickness of 100 nm, up to a biasing voltage of 20 V. The investigation of the currents passing through the capacitor in response to the applied voltage revealed a Schottky-diode like behaviour. Typical currents in the reverse-bias direction were on the order of 100 nA at a biasing voltage of 5 V. A thermal breakdown of the lamella occurred once the leakage currents exceed 1 μA. The characterization of the ferroelectric thin films by dark-field (DF) TEM, differential-phase contrast scanning TEM (DPC-STEM) and high-resolution high-angle annular dark-field (HAADF) STEM imaging was performed using a FEI Titan Themis microscope equipped with a probe CEOS DCOR spherical aberration corrector operated at 300 kV. DF-TEM allows for tracking the in-plane or out-of-plane domain distribution in the ferroelectric film, while in DPC- and HAADF-STEM imaging, the ferroelectric polarization is mapped on the atomic scale by combining time series averaging [6], probe deconvolution and atomic column fitting [7].
Our results provide the path to prepare highly stable ferroelectric thin film capacitor specimens for in-situ S/TEM observations. This shall enable future studies on the dynamic processes in ferroelectric thin films under an applied bias voltage, which are crucial for the practical implementation of these materials in data storage devices [8].

***In Situ* White-Light Interferometry for Early-Stage Uranium Oxidation and Hydride Characterization** Yaakov Idell, Wigbert Siekhaus, Kerri Blobaum and William McLean; Lawrence Livermore National Laboratory, United States

The corrosion of uranium by means of oxygen or hydrogen is a material degradation process that is a significant concern for long-term storage and disposal. Hydrogen can locally attack the uranium to form uranium hydride (UH_3), which has been shown to increase brittleness of the uranium and to produce less desirable properties of tensile strength, hardness, and elongation. Corrosion of uranium by hydrogen has typically been characterized by an initiation time followed by pitting corrosion; however, variability in the UH_3 initiation time, thought to be correlated to thickness of the coherent uranium oxide (UO_2) film, have made understanding of early-stage UH_3 growth quite difficult. We will introduce a novel characterization tool that can rapidly collect *in-situ* time-dependent 3-D spatial data using while-light interferometry and provides growth data for both the UO_2 film and UH_3 precipitates.

White-light interferometry is a non-destructive and non-contact optical surface profiling technique for materials characterization that offers μm-scale lateral and nm-scale vertical resolution. This optical profiling technique is based on interpreting a series of interferograms, a pattern of dark and bright lines, resulting from constructive and destructive interference caused by the optical path length difference between a beam interacting with a reference material and the sample of interest. The interferograms are individually processed using a frequency-domain analysis algorithm, which converts the vertical measurements interferometrically for each pixel in field of view creating a three-dimensional image of the sample surface.

The white-light interferometer is equipped with an environmental sample cell with flowing oxygen or hydrogen gas permitting *in-situ* heating experiments. Several experiments have been conducted at different temperatures ranging from 40 °C to 90 °C under oxygen and hydrogen gas flow will be presented. Becsuse a single measurement requires less than ten seconds, the spatial data will display the effectiveness of this rapid novel characterization tool for early-stage time-dependent oxide thickness and UH_3 growth kinetics. Furthermore, activation energies of oxide film and UH_3 growth will be reported and compared to literature. The spatial data provides visual features that improve the current understanding of the early-stage

growth mechanisms for UO_2 and UH_3.

Lawrence Livermore National Laboratory is operated by Lawrence Livermore National Security, LLC, for the U.S. Department of Energy, National Nuclear Security Administration under Contract DE-AC52-07NA27344.

Streamlining the Study of Materials Dynamics with an Integrated *In Situ* SEM Experimental Platform William Harris[1], Fang Zhou[2], Luyang Han[2] and Hrishikesh Bale[1]; [1]Carl Zeiss Microscopy, United States; [2]Carl Zeiss Microscopy GmbH, Germany

Recent hardware and software advances are ushering in a new paradigm in materials characterization, in which the direct observation of dynamics is revealing exciting new connections between material microstructures and properties. By directly observing the same specimen as it undergoes change or is exposed to service conditions, the *in situ* experimental approach helps remove the ambiguity and sparse statistics often associated with interpreting disparate samples extracted from different stages of the materials lifecycle. Doing so properly requires that *in situ* observations must be made with appropriate length scales, time scales, and modalities to observe the relevant phenomena of interest.
As a ubiquitous materials characterization tool, scanning electron microscopy (SEM) offers prime opportunities for such *in situ* experiments, impacting a broad range of research fields. But to date, achieving such results in a coordinated fashion is not a simple feat. Performing *in situ* SEM experiments is in no way a trivial task, often involving manual coordination of hardware and software distributed across numerous platforms and vendors (electron imaging, analytics acquisition, *in situ* stage control). Beyond coordinating an experiment, further complications arise in data interpretation, with the challenge of correlating results in space and time originating from multiple data streams. These technical barriers serve to restrict access to these techniques to the elite super-users who are able to dedicate substantial time and resources to developing their instrumentation, expertise, and workflows.
This contribution will present a fully integrated solution to mitigate these problems, combining a tensile-compression stage, heating unit, dedicated high temperature detectors, EDS/EBSD sub-units, and processing tools controlled from a unified software environment. The user can prescribe automated runs with multiple ROI's, implement automated feature tracking and autofocus, and define different imaging conditions or EDS/EBSD acquisition per ROI and load. Furthermore, integrated digital image correlation (DIC) can be built into the workflows for rapid interpretation of localized strain evolution within samples. Examples will be presented including copper, steel, and nickel alloy systems. The implementation presented serves several purposes including: 1) facilitating difficult and complex *in situ* SEM experiments in a routine manner, 2) improving consistency and repeatability, allowing for more samples and increased statistics, and 3) doing so in such a way that it brings the power of this approach into the hands of the average researcher, where the focus can be shifted onto the materials science and engineering rather than heavily relying on microscopy expertise.

5:30 AM F.MT01.06.04
Structures of Point Defects in Ceramic Oxides During Microwave Radiation-Assisted Synthesis Shuyan Zhang[1], Shikhar Jha[2], Jie Gong[1], Nathan Nakamura[1], Alan McGaughey[1] and B. Reeja Jayan[1]; [1]Carnegie Mellon University, United States; [2]Indian Institute of Technology Kanpur, India

Microwave radiation (MWR) is known to lower the temperatures required for crystallization of ceramic oxides by introducing changes in the local atomic structure. This structural disorder serves as a precursor to phase transitions and crystalline phase formation. To better understand these field-driven phenomena, structural changes during MWR-assisted synthesis of titanium dioxide (TiO_2) were studied using *in situ* synchrotron X-ray diffraction (XRD) conducted at beamline 6-ID of the Advanced Photon Source at Argonne National Laboratory. We observed anisotropic expansion-contraction of the lattice parameters, which differs from the linear increase of lattice parameters with increasing temperature that is observed conventionally. Such anisotropy can be attributed to the structure becoming disordered under microwave exposure. Our Raman spectroscopy and X-ray photoemission spectroscopy experiments support such increased defect generation. We then applied molecular dynamics (MD) simulations to test the hypothesis that MWR-assisted synthesis leads to defect generation, such as the nucleation of vacancy-interstitial pairs. The second-moment tight-binding charge equilibrium (SMTB-Q) variable charge potential was used to model the TiO_2 system. The mean square displacements (MSD) of the ions were calculated for different concentrations of titanium Frenkel defects, oxygen Frenkel defects, or oxygen vacancies to probe the influence of defects on atomic thermal vibration. The ionic translational mobility as the structures move toward equilibrium is enhanced as the defect concentration increases.

To more precisely understand the local disorder and defect structure under MWR, we combined MD simulations with pair distribution function (PDF) analysis, a powerful tool for studying atomic structures capable of quantitatively characterizing

both the long and short-range atomic order of a material. The X-ray PDF data of MWR-grown anatase TiO_2 and tetragonal zirconia dioxide (ZrO_2) was collected at the National Synchrotron Light Source II (NSLS-II) at Brookhaven National Laboratory (BNL). The local order of the samples was characterized by a real space Rietveld refinement using the defected phases as structure models. The increase of the atomic displacement parameters (ADP) obtained from the refinement were consistent with the MSD calculation. The results strongly suggest the presence of point defects within MWR-grown TiO_2 and ZrO_2. Utilizing *in situ* and *ex situ* characterization techniques and atomistic simulations, we provide evidence for the nonthermal field effect through defect generation. Our efforts to understand the fundamental mechanisms underlying electromagnetic field-assisted materials processing can help to realize low-temperature techniques to engineer ceramic and ceramic-polymer hybrid materials for energy storage, catalysis, and other electronics applications.

High-Throughput *In Situ* Tracking of Millisecond-Scale Metastable Phase Formation in Thin-Film Oxides Aine Connolly[1], Duncan Sutherland[1], Katie Gann[1], Max Amsler[1,2], R. B. Van Dover[1] and Michael O. Thompson[1]; [1]Cornell University, United States; [2]University of Bern, Switzerland

Most analyses of high-speed materials transformations and kinetics are limited to comparisons before and after synthesis, and thus often forced to infer the materials' behavior during processing. Laser spike annealing, or LSA, is a powerful exploration technique that has been shown to form and trap a broad range of metastable phases in thin film oxide materials. With a small spatial footprint and wide temperature range within each anneal, lateral gradient LSA has been highly effective in high-throughput combinatorial studies. These transient thermally induced structural transformations can be characterized through a range of techniques including optical imaging, reflectance spectroscopy, and direct X-ray diffraction. Furthermore, the temporal evolution of materials phases can be probed during LSA scanning using spatially resolved techniques by displacing the probe with respect to the localized heat source. A single 2D image can capture the entire temporal evolution as well as, with lgLSA, the behavior as a function of peak temperature. Key events during the thermal cycle (nucleation, phase conversions) can thus be identified for further analysis.
We demonstrate the power of this technique to understand the formation and evolution of metastable phase transformations in thin-film Bi_2O_3 and Ga_2O_3. In Bi_2O_3, as a function of dwell and temperature, the δ, β and α phases can be formed; using the *in-situ* tracking, the evolution dynamics for these phases were observed. Similarly, in analyzing metastable phases of Ga_2O_3, we gain insight into the mechanisms that give rise to the nucleating phase γ and its subsequent evolution to the thermodynamically stable β phase. This approach can be adapted to take advantage of various analytic techniques, including synchrotron source X-ray diffraction.

A Machine Learning Approach to Materials Characterization Xing Liu[1], Christos E. Athanasiou[1], Nitin Padture[1], Brian Sheldon[1] and Huajian Gao[1,2]; [1]Brown University, United States; [2]Nanyang Technological University, Singapore

Analytical and empirical solutions to engineering problems are usually preferred because of their convenience in applications, especially in materials characterization. However, they are not always accessible in complex problems. A new class of solutions, based on machine learning (ML) models such as regression trees and neural networks (NNs), are proposed and their feasibility and value are demonstrated through the analysis of fracture toughness measurements including single cantilever and pillar indentation splitting methods. It is found that both solutions based on regression trees and NNs can provide accurate results for the specific problem, but NN-based solutions outperform regression-tree-based solutions in terms of their simplicity. This example demonstrates that ML solutions are a major improvement over analytical and empirical solutions in terms of both reliable functionality and rapid deployment. When analytical solutions are not available, the use of ML solutions can overcome the limitations of empirical solutions and substantially change the way that engineering problems are solved. This ML solution has been employed in our fracture toughness measurements of rGO-reinforced ceramic nanocomposites.

***In Situ* Observation Thermoelastic Material Property Evolution in Ni-Based Concentrated Solid Solution Alloys Under Extreme Conditions** Cody A. Dennett; Idaho National Laboratory, United States

Directly observing the evolution of material performance *in situ* under extreme conditions remains a great challenge. Environments including high temperatures, high pressures, radiation fields, and others promote defect formation and microstructure evolution which may rapidly and drastically change the performance characteristics of metals and alloys. Emergent or transient behaviors in these conditions are often difficult or impossible to capture using property and microstructure characterization after the fact. In an effort to fill a gap in the ability to capture material performance

characteristics directly under extremes, transient grating spectroscopy (TGS), an all-optical photoacoustic methodology, has been implemented as an *in situ* diagnostic able to capture multi-property information while materials are exposed to the combined extremes of high temperature and ion beam bombardment. This non-destructive method returns elastic and thermal transport properties with second-scale time resolution. Here, recent work using this methodology to track the evolution of Ni-based solid-solution alloys using the *in situ* ion irradiation TGS (I^3TGS) beamline will be described. Tracking material property evolution during long exposure times (hours) provides a clear indication of performance degradation due to irradiation-induced void swelling. On short timescales (seconds to minutes), observing rapid changes in thermoelastic properties as defect generation is initiated allows a unique window into bulk transient defect populations which are otherwise difficult to observe. This presentation will demonstrate the utility of this powerful new *in situ* technology as well as provide insight into the kinetic behavior of this interesting class of chemically-complex alloys under extremes.

6:10 AM F.MT01.06.10
***In Situ* Reflection High Energy Electron Diffraction in Atomic Layer Deposition for Monitoring Epitaxial Transformations** Alexandra J. Howzen and Nick C. Strandwitz; Lehigh University, United States

The maximum amount of thermal energy available during atomic layer deposition (ALD) is generally determined by the decomposition temperature of the precursors and also sets the maximum temperature in the "ALD window". This maximum temperature in some cases limits the structural perfection and extent of crystallization in resulting films. Intermittent annealing during the film growth in between ALD chemical exposures has been explored previously and shown to increase density and quality of ALD films.[1] However, without direct monitoring of one or more of the physical properties of the films, it can be difficult to determine the nuances of film transformation, such as crystallization temperature, surface roughening, and dependence on gas ambient.

In this work we integrate reflection high energy electron diffraction (RHEED) into a home-built ALD system to monitor structural and morphological transformations during ALD growth and thermally-induced structural transformations. RHEED is a surface sensitive diffraction technique that utilizes high energy (> 10 keV) electrons at a glancing angle, and is most commonly utilized in molecular beam epitaxy and pulsed laser deposition systems. The relatively high pressures associated with ALD are incompatible with RHEED due to filament instability and resulting short electron mean free path within the chamber, necessitating either 1) differential pumping on the electron gun and a short path length between the electron gun and phosphor screen or 2) a pump down to high vacuum conditions. In addition to describing the system design, flow, and thermal modelling; we will show initial results of the deposition and annealing of ultrathin films (1-20 ALD cycles) focusing on transformations of polymorphic Ga_2O_3. The integration of RHEED with ALD offers a slow-motion picture of traditional epitaxial growth techniques by decoupling the deposition and crystallization steps with simultaneous monitoring of the surface structure.

Beyond the Thin-Film Limit, Extraction of Both Thickness and Optical Properties (n,k) with *In Situ* Ellipsometry to Monitor ALD Growth Florian Maudet[1], Soursih Banerjee[1], Hanno Kroencke[1], Veeresh Deshpande[1] and Catherine Dubourdieu[1,2]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Freie Universität Berlin, Germany

Spectroscopic ellipsometry (SE) is a powerful technique that is widely used to determine the thickness *d* of thin films as well as their dispersion law as a function of the wavelength l, composed of the refractive index *n(λ),* and of the extinction coefficient *k(λ)*. SE data interpretation relies on an optical model built to fit the measured psi and delta values in order to extract *n(λ)*, *k(λ)* and *d*. Given its sensitivity to small thickness variation, SE has also been applied *in situ* to monitor thin film growth in ALD reactors. However, in the case of very thin film (~1nm) the extraction of both optical properties and thickness is limited by the non-uniqueness of the solution (thickness, n) that prevents from determining both values with precision. Thus, in an *in situ* ALD measurement, a model with fixed optical properties is usually applied and only thickness changes are considered. This is problematic as the different steps during the ALD growth cycles will obviously lead to different optical properties of the thin film that will incorrectly result as thickness variations on the model.
In order to address this issue, an expansion of the three-phase equation (air, thin film, substrate), was applied in the thin film limit ($d<<\lambda$) [1]. This expansion leads to a disambiguation of *n*, *k* and *d* by measurements of the changes in the reflectance and in the complex reflectance ratio. By using this method, we were able to monitor the growth process of amorphous gallium oxide films and determine more reliably the thickness evolution than with classic interpretation of *in situ* ellipsometry. We were also able to evidence changes in the optical properties of the grown layer occurring during the different ALD cycles. We consequently evidenced the role of plasma exposure time in the minimization of absorbing defects

of the gallium oxide thin films.

Late News: *In Situ* Characterization of the Thermal and Elastic Behavior of Rectifier Diodes Under Working Conditions Sara Román-Sánchez[1], Aida Serrano[1], Adolfo del Campo[1], Israel Lorite[2], José Francisco Fernández[1] and Alberto Moure[1]; [1]Institute of Ceramics and Glass, Spain; [2]SEG Automotive Germany GmbH, Germany

A widely extended application in semiconductor-based technology is the use of rectifier diodes in vehicles alternators to convert part of the mechanical energy into electrical energy. The most common failures in electric alternators are due to the electrochemical corrosion of the diodes or to damages as a consequence of the high current that circulates through diodes, which causes a significant temperature increase. This temperature increase is one of the system weakness, affecting directly to the device operation parameters. The diodes show a multicomponent nature since they are built up by different materials: epoxies to provide mechanical resistance, metals to evacuate the heat and a silicon semiconductor part. All of them have different physical characteristics and, therefore, different behavior, which is responsible of the appearance of diverse damaging phenomena such as the mechanical stress generation in the device.
The aim of this project is to understand what happens in the interfaces between the different materials of the device during its performance, mainly in the silicon interfaces, since it is the active part of the diode. For that, a study of several diodes currently used in automotive alternators has been carried out under certain working conditions which can lead to system failures, as well as to some phenomena allowing to understand their working mode. Some techniques such as confocal Raman microscopy and infrared thermography have allowed an *in operando* study of the diodes in forward biased and reverse biased conditions. The results show the device behavior at the interfaces, the generated stress in the different components and some system failure modes.

Late News: How Planar Nanowires Grow—Kinetic and *In Situ* Studies Amnon Rothman[1], Vladimir G. Dubrovskii[2], Anna E. Kossoy[1], Ifat Kaplan-Ashiri[1] and Ernesto Joselevich[1]; [1]Weizmann Institute of Science, Israel; [2]St. Petersburg State University, Russian Federation

The bottom-up assembly of nanowires facilitates control of their dimensions, structure, orientation and physical properties. Surface-guided growth of planar vapor-liquid-solid (VLS) nanowires has been shown to enable their assembly and alignment on substrates during growth, thus eliminating the need for additional post-growth processes. However, accurate control and understanding of the growth mechanism of the VLS planar nanowires were achieved only recently (PNAS **2020**,117, 152). The new growth model presents two limiting regimes - either the Gibbs-Thompson effect controlling the growth of the thinner nanowires or surface-diffusion controlling the growth of thicker ones. Although the comprehensive growth model supported by post-growth and *ex-situ* characterization help understand the planar nanowire growth mechanism, it can only resolve the static morphology of the nanowire and is unable to provide a complete picture about the growth kinetics of the VLS growth. Recently, fundamental *in situ* studies of semiconductor nanowire growth using a transmission electron microscope (TEM) presented significant findings of the VLS growth kinetics. Unlike these studies whose precursor were supplied in the gas phase and therefore could be fed into the TEM chamber with no contamination issues, studying binary semiconductor nanowire as ZnSe and ZnS require solid-phase precursors. Here, we demonstrate the *in situ* observation of guided ZnSe and ZnS planar nanowires on sapphire substrate by environmental scanning electron microscope (ESEM). The ESEM chamber is used as a CVD system using solid-phase precursors, enabling the study of the nanowire growth mechanism. The study provides new insights during the nanowire growth process, such as nucleation and incubation times, the real growth rates, interaction between different nanowires and the evaluation of the final nanowire morphology. The experimental findings, combined with the suggested theoretical model, is an essential step in understanding the guided growth of planar nanowire phenomenon.

MeV-UED—A Platform for *In Situ* Studies of Material X.J. Wang; SLAC National Accelerator Laboratory, United States

MeV-UED has led to a new paradigm in ultrafast electron scattering: higher electron beam energy means stronger diffraction and significantly reduces space-charge effects hence leads to atomic spatial-temporal resolution [1-3]. Furthermore, MeV electrons experience less multiple-scattering,possess “real” flat Ewald-sphere and favourable sample enviroments; MeV-UED is a unique platform for *in situ* studies of material.MeV-UED has enabled broad scientific opportunities in material science and chemical dynamics, such as revealing the energy flow in superconductor [4] and atomic movie of light-induced structural distortion in the perovskites solar cell [5].

I will present two examples in capturing metastable states of functional material using MeV-UED: topological properties & charge density wave controlled by light[6-7]**.** Recently *in situ* charterization oftransient state during the electrically-triggered insulator-metal transition was sucessfuuly realized at SLAC MeV-UED [8]. Future development of nano-probe at SLAC MeV-UED will open new window to probe metastable state and dynamics in spatially heterogeneous systems and in *in-situ* device geometries.

Advances in *In Situ* and Ultrafast Electron Microscopy for Materials Characterization Ilke Arslan; Argonne National Laboratory, United States

With recent advances in in-situ microscopy, a new era in microscopy has arrived that allows for the dynamic imaging of materials under reaction conditions in the (scanning) transmission electron microscope. To better understand the structure/property relationships of materials, it is essential to get closer to the conditions in which the material will be used, such as high/low temperature, liquid environments, gas environments, or a combination thereof. Within these environments, moving beyond “real time” imaging to ultrafast imaging can provide yet another level of fundamental understanding of nanomaterials. Further, combining an in-situ or ex-situ experiment with electron tomography is a very powerful method for materials characterization as this provides the 3-D morphology of the (nano)materials under more relevant conditions. This talk will focus on newer developments such as in-situ heating in liquid, and the future of ultrafast transmission electron microscopy at the Center for Nanoscale Materials.

5:30 AM F.MT01.07.03
Liquid-Liquid Phase Transitions and Dynamic Crystallization Phenomena in Phase-Change Materials Probed by Single Shot Femtosecond Electron Diffraction Marc Zajac[1], Thies Albert[2], Aditya Sood[3], Mianzhen Mo[3], Peter Zalden[4], Marius Milnikel[2], Michael Kozina[3], Xiaozhe Shen[3], Daniel Krieg[5], Duan Luo[3], Anna Ziefuß[2], Shuai Wei[6], Peihao Sun[3], Martin Jerman[2], Antonowicz Jerzy[7], Ryszard Sobierajski[8], Jerome Hastings[3], Matthias Wuttig[6], Stephen Weathersby[3], X.J. Wang[3], Aaron Lindenberg[1] and Klaus Sokolowski-Tinten[2]; [1]Stanford University, United States; [2]Universitat Duisburg-Essen, Germany; [3]SLAC National Accelerator Laboratory, United States; [4]European XFEL, Germany; [5]Technische Universitat Dormund, Germany; [6]RWTH Aachen University, Germany; [7]Polish Academy of Sciences, Poland; [8]Warsaw University of Technology, Poland

Phase change materials (PCMs) are semiconducting alloys that rapidly and reversibly switch between an amorphous (or glassy) state and a crystalline (or ordered) state via electrical and optical pulses. The two phases have optical and electrical properties that vary by orders of magnitude, which means that they can be used in rewritable optical data storage media and in fast, non-volatile memory devices. For these memory device applications, PCMs need to have fast (on the order of nanosecond) crystallization times in order to write data quickly, and they need to be able to quench into a room temperature stable glassy state, in order to enable long-term memory storage. These application specifications require a pronounced temperature dependence of the kinetic properties. Recent X-ray studies at LCLS on AIST and GeSb [1] have provided evidence for structural changes that occur in the super-cooled state, namely a Peierls-distortion-driven liquid-liquid phase

transition (LLPT), which governs the kinetic properties. It has been argued that a liquid-liquid phase transition is also responsible for the anomalous liquid-phase properties of water, silicon, and germanium. To understand the role that the liquid-liquid phase transition plays in these systems and to understand its "universality", the single-pulse capabilities of the MeV Ultrafast Electron Diffraction (MeV-UED) instrument at the SLAC National Accelerator Laboratory were used to explore the transient structure and pair distribution function of laser-melt-quenched, strongly super-cooled PCMs, such as $Ge_2Sb_2Te_5$ (GST), $Ag_4In_3Sb_{67}Te_{26}$ (AIST), $Ge_{15}Sb_{85}$, and pure Sb at various thicknesses, as well as diamond-cubic structured semiconductors such as Ge and Si. Given the large momentum-transfer range of MeV-UED, the time-resolved pair-distribution functions are obtained at a high spatial resolution, which we use to explore interesting material dependent aspects of the liquid-liquid phase transitions.

Monitoring Energy Conversion in Photoexcited Gold Nanocrystals via Ultrafast Electron Diffraction Burak Guzelturk[1], James Utterback[2], Igor Coropceanu[3], Vladislav Kamysbayev[3], Marc Zajac[4], Nuri Yazdani[5], Ben Cotts[4], Suji Park[4], Aditya Sood[4], Ming-Fu Lin[6], Alex Reid[6], Xiaozhe Shen[6], Stephen Weathersby[6], Vanessa Wood[5], Alberto Salleo[4], X.J. Wang[6], Dmitri Talapin[3], Naomi Ginsberg[2] and Aaron Lindenberg[4]; [1]Argonne National Laboratory, United States; [2]University of California, Berkeley, United States; [3]The University of Chicago, United States; [4]Stanford University, United States; [5]ETH Zürich, Syrian Arab Republic; [6]SLAC National Accelerator Laboratory, United States

Gold nanocrystals exhibit attractive electronic, thermal and catalytic functionalities in response to light governed by dynamic energy conversion processes among photons, electrons and phonons. Although such processes have been typically investigated by optical methods, an understanding of the response of atomic structure following photoexcitation in nanocrystals has remained elusive to date. Here, we monitor energy conversion processes in gold nanocrystals from lattice point of view by resolving dynamic structural responses via femtosecond electron diffraction [1]. We uncover the effects of size and surface chemistry on the electron – phonon coupling and thermal relaxation. We show that smaller size leads to stronger electron – phonon coupling in these nanocrystals, which is associated with the reduced dielectric screening at the nanocrystal surfaces. In addition, we elucidate that surface ligands provide a tuning knob for the electron – phonon coupling. Particularly, thiol-based ligands slow down the cooling of hot carriers that are generated by surface plasmon polaritons. Overall, our findings provide new design principles to exploit dynamic energy conversion processes in gold nanocrystals in applications such as photocatalysis and thermoelectrics.

***In Situ* Dynamics During Heating of Copper-Intercalated Bismuth Telluride Using Electron Microscopy** Pralav P. Shetty and Matthew T. McDowell; Georgia Institute of Technology, United States

Layered materials are characterized by strong covalent bonding within each layer, while the layers themselves are held together by weak van der Waals forces. These materials have received considerable attention owing to their compatibility with other materials, and exceptional electronic, optical, thermal, mechanical, and thermoelectric properties. The presence of a van der Waals gap between individual layers enables the intercalation of several species which can be used for tuning these properties. However, intercalation of species can also be an unintended consequence of diffusion from patterned contacts on the layered materials. In either scenario, the introduction of intercalant species into a layered material may lead to unanticipated structural and phase transformations. These transformations can be further exacerbated at elevated temperatures, yet little is understood about the high-temperature dynamics that occur in intercalated layered materials. Here, we use *in situ* transmission electron microscopy to investigate temperature-dependent structural evolution of Bi_2Te_3, a layered material with well-known application as a thermoelectric, when Cu is intercalated within the van der Waals gap. As temperature is increased, the initially disordered Cu undergoes local ordering within the van der Waals gap, which is followed by high-mobility boundary motion, polycrystal growth, and anisotropic sublimation behavior. As the temperature is raised further, layered Cu_2Te crystals nucleate and grow with a crystallographic relationship to the Bi_2Te_3 lattice. The presence of Cu substantially alters both the transformation temperature of various phenomena, as well as the dynamic evolution of the crystals. These findings are consequential for the design of layered nanoscale devices and nanostructured systems where intercalants may intentionally or unintentionally alter the properties and stability of these systems.

Probing the Structure of Oil-Water Mixtures in Porous Media Using Dielectric Spectroscopy Abdullah AlShuaibi[1,2], Amen Hammami[1] and Emmanuel Giannelis[1]; [1]Cornell University, United States; [2]King Faisal University, Saudi Arabia

Oil-water interactions play a critical role in wettability alteration and enhanced oil recovery (EOR). In this work, we study the dielectric response of oil-water mixtures in calcite and analyze the observed behavior in terms of structural ordering and fluctuation of charge carriers. In the presence of water, the dielectric response gives the rise to anomalous low-frequency dispersion (ALFD). Which follows two power-law regions, separated by a transition frequency (ω_c). The response is rationalized in terms of hopping transport. Additionally, we measured the dynamic dielectric response on untreated and aged calcite pressed pellets in partially saturated conditions using brines with different salinities and compositions. In the presence of oil, the dielectric dispersion and their corresponding transition frequency were shifted to lower frequencies and lower susceptibility values. This suggests less connectivity between water clusters in rocks, where the trapped oil is preventing direct contact between water and calcite grains. We also demonstrated that the power-law exponents can be used to understand the fractal structure of the inclusions. Whereas untreated calcite followed the predicted behavior of single fractal clusters, aged calcite followed that of percolation of many-clusters. Interestingly, aged calcite mixtures in various electrolytes fall between the two distinct behaviors, indicating a mixed contribution.

Unraveling Shape Transformation of ZnO Nanostructures in Acid Solution by Correlative *In Situ* Microscopy Fangyuan Liu, Xingxu Lu, Zichao Bian, Xiaohui Song, Guoan Zheng and Pu-Xian Gao; University of Connecticut, United States

Understanding of ZnO nanocrystal morphology evolution during wet chemical etching process is crucial for constructing nanoscale structures with desired physical and chemical properties [1,2]. However, the dynamic shape transformation in etching process is less revealed and understood so far, although it holds a key to control the surface exposure regularity of the etched ZnO nanostructures [3-5]. Here, we directly observe the reaction of ZnO rod-like structures in HCl solution using a combination of *in situ* liquid cell transmission electron microscopy (LCTEM) and *in situ* optical microscopy. A crown-capped nanorod is captured as the intermediate structure. Microscopy images and calculations show that HCl attacks ZnO slowly to form a concave region of the crown base at each radial corner initially and exposes high index surfaces such as {11-2k}. The high atomic density and their semipolar nature of the high index planes of {11-2k} are suggested to be responsible for the stabilization in the concave crystal regions. Furthermore, when the new high index facets exposed outside during the etching, the surface energy and defects populate and lead to accelerating the etching rate of the crown cap. By using different acids with varied pH or temperature, the ZnO morphology can be readily controlled with different electronic and optical properties. These findings shed light on the understanding of wet chemical etching of ZnO and the future design of novel functional materials.

Ferroelectric Domain Switching in BFO/CFO Vertically Aligned Nanocomposites as a Function of Epitaxial Interface Proximity Luis Ortiz[1], Michael Martin[1], Jingfeng Song[2], Aiping Chen[2] and Bryan D. Huey[1]; [1]University of Connecticut, United States; [2]Los Alamos National Laboratory, United States

Self-assembled $BiFeO_3$-$CoFe_2O_4$ vertically aligned nanocomposites (VAN) are promising for their multiferroic functionality. In this work, we directly investigate interfacial-strain-controlled ferroelectric switching in the fully epitaxial BFO

nanostructures within a CFO matrix. By applying Tomographic Atomic Force Microscopy and its unique nanomachining capability, we achieved high fidelity PFM imaging sequences while minimizing imaging artifacts. This uniquely reveals interfacial strain effects on ferroelectric switching as a function of distance from the strained interface. Even a relatively low interfacial strain of 0.6% can significantly alter ferroelectric switching fields and especially domain nucleation behavior. Notably, ferroelectric domains along the BFO-CFO interfaces exhibit up to two times higher coercive voltages as well as diminished nucleation site densities. Such results from our new approach can provide critical insight into optimizing the properties of such laterally heterogeneous strain engineered functional materials systems.

Late News: Effect of pH on the Shear Modulus of Anion Exchange Membranes Amy Sharin[1], Sohan Shetty[2], Lindsay Wright[3], Emily Zhang[4], Aniket M. Raut[5] and Miriam H. Rafailovich[5]; [1]Lawrence High School, United States; [2]Half Hollow Hills High School East, United States; [3]Del Norte High School, United States; [4]General Douglas MacArthur High School, United States; [5]Stony Brook University, The State University of New York, United States

Anion exchange membranes (AEMs) are membranes with positively charged functional groups that enable the transport of anions and have been utilized for numerous purposes. AEMs may be used as membranes for hydrogen fuel cells, which have the potential for providing access to energy storage in hydrogen in an alkaline environment at lower operating temperatures with non-precious metals, which would dissolve in proton membranes and their solution. AEMs are also used in water filtration, including in the process of desalination whereby relatively fresh water is obtained from sea or wastewater by letting the water flow through the membrane. As more purposes are explored for AEMs it is important to determine and record their physical properties, such as shear modulus, that indicate qualities such as durability, strength, and ion conductivity for various uses and environments, such as changes in pH. A. Kisliuk et. al. determined that shear modulus specifically is correlated with increased barrier to ion conduction[1]. In this study, MTPN1-TMA membranes were soaked in potassium hydroxide solution of pH in the range of 8 to 14 for 1 hour before measuring shear modulus on an atomic force microscope. There were 6 trials conducted for each pH value and preliminary results reveal that the highest average shear modulus, 8.07, occurred at pH 9 and lowest average shear modulus, 1.84, occurred at pH 10. Changes in the measured shear modulus in response to the different pH environments could be due to changes in AEM surface roughness and the tendency for membranes to be hygroscopic when they are soaked in aqueous solution with KOH. Future characterizations of AEMs include zeta potential measurements, SEM, contact angle, and finally, shear modulus and durability measurements under other environmental conditions such as temperature and gas flow.

Probing the Structure of Oil-Water Mixtures in Porous Media Using Dielectric Spectroscopy Abdullah AlShuaibi[1,2], Amen Hammami[1] and Emmanuel Giannelis[1]; [1]Cornell University, United States; [2]King Faisal University, Saudi Arabia

Oil-water interactions play a critical role in wettability alteration and enhanced oil recovery (EOR). In this work, we study the dielectric response of oil-water mixtures in calcite and analyze the observed behavior in terms of structural ordering and fluctuation of charge carriers. In the presence of water, the dielectric response gives the rise to anomalous low-frequency dispersion (ALFD). Which follows two power-law regions, separated by a transition frequency (ω_c). The response is rationalized in terms of hopping transport. Additionally, we measured the dynamic dielectric response on untreated and aged calcite pressed pellets in partially saturated conditions using brines with different salinities and compositions. In the presence of oil, the dielectric dispersion and their corresponding transition frequency were shifted to lower frequencies and lower

susceptibility values. This suggests less connectivity between water clusters in rocks, where the trapped oil is preventing direct contact between water and calcite grains. We also demonstrated that the power-law exponents can be used to understand the fractal structure of the inclusions. Whereas untreated calcite followed the predicted behavior of single fractal clusters, aged calcite followed that of percolation of many-clusters. Interestingly, aged calcite mixtures in various electrolytes fall between the two distinct behaviors, indicating a mixed contribution.

Unraveling Shape Transformation of ZnO Nanostructures in Acid Solution by Correlative *In Situ* Microscopy Fangyuan Liu, Xingxu Lu, Zichao Bian, Xiaohui Song, Guoan Zheng and Pu-Xian Gao; University of Connecticut, United States

Understanding of ZnO nanocrystal morphology evolution during wet chemical etching process is crucial for constructing nanoscale structures with desired physical and chemical properties [1,2]. However, the dynamic shape transformation in etching process is less revealed and understood so far, although it holds a key to control the surface exposure regularity of the etched ZnO nanostructures [3-5]. Here, we directly observe the reaction of ZnO rod-like structures in HCl solution using a combination of *in situ* liquid cell transmission electron microscopy (LCTEM) and *in situ* optical microscopy. A crown-capped nanorod is captured as the intermediate structure. Microscopy images and calculations show that HCl attacks ZnO slowly to form a concave region of the crown base at each radial corner initially and exposes high index surfaces such as {11-2k}. The high atomic density and their semipolar nature of the high index planes of {11-2k} are suggested to be responsible for the stabilization in the concave crystal regions. Furthermore, when the new high index facets exposed outside during the etching, the surface energy and defects populate and lead to accelerating the etching rate of the crown cap. By using different acids with varied pH or temperature, the ZnO morphology can be readily controlled with different electronic and optical properties. These findings shed light on the understanding of wet chemical etching of ZnO and the future design of novel functional materials.

3D Morphology of Double Gyroid and Double Diamond BCP Tubular Networks Edwin Thomas and Xueyan Feng; Texas A&M University, United States

Block copolymers (BCPs) self assemble into a wide variety of periodic structures and elucidating their nano- and micro-structures has typically been accomplished by a combination of transmission electron microscopy and small angle xray scattering. Two of the more complex microdomain structures in BCPs are the double gyroid (DG) and double diamond (DD). We have developed a 3D reconstruction tool, slice and view scanning electron microscopy to create large volume tomograms of the DG and DD structures enabling detailed investigation of a host of supra- and sub- unit cell morphological characteristics. These include the nature of the curvature of the Intermaterial dividing surface (IMDS), the length and angle distribution of the network struts as well as distortions of the cubic unit cells into triclinic variants. In addition to the periodic structure, we have discovered and classified various point, line and surface defects. Because the minority component in the DG and DD phases are 3D continuous networks, defects lead to changes in topology. We find loop and bridging defects in the networks, as well as dislocation defects and sharp, coherent twin grain boundaries and wide non-crystalline grain boundaries. Such defects generally occur during nucleation and growth of the phase and are important for order-order phase transformations as well as for mechanical and transport properties.

Multiscale Strain Mapping and Mechanical Properties Determinations of 2024 Aluminum Alloys Using Transmission Electron Microscopy Techniques Florent Ravaux, Humaira Zafar, Cyril Aubry and Dalaver H. Anjum; Khalifa University of Science and Technology, United Arab Emirates

Lightweight aluminum (Al) alloys reinforced with a second phase are widely used in aerospace industry. Nanometer scale precipitates distributed in an aluminum matrix considerably change the mechanical properties of these alloys. The degree of coherency of those precipitates, their density, and material properties (such as Young's modulus) considerably change the bulk mechanical behavior of the alloys. Therefore, investigation of their properties is of great interest for improving alloy characteristics.
The structure-property relationships between the precipitates and Al matrix are complex and often require advanced characterization techniques for their analysis. The formation of the precipitates results in the outbreak of internal stress fields due to the lattice mismatch between precipitates and Al matrix. Strain mapping techniques using Transmission Electron Microscope (TEM) are proven to be a powerful technique for investigating the mechanisms leading to the formation of stress fields. Commensurately, the technique of Electron Energy Loss Spectroscopy (EELS) provides a complementary information on the Young's modulus (Y_m) through the analysis of the energies of bulk plasmons.
In this study, different TEM techniques are applied to characterize the influence of the Cu precipitates in an Al alloy. We focused on the characterization of a specific material namely 2024 Al alloy composed of Al-4.35 Cu-1.5 Mg-0.64 Mn-0.5 Si-0.5 Fe (wt.%). The samples are treated at 495°C followed by water quenching. Different aging processes are carried out to control and accelerate the formation of particular precipitates known as θ". Strain mapping techniques capable of generating results at different field of views are applied to get insights on the properties of θ" precipitates. Specimens are prepared with a

standard lamella process using Focused Ion Beam (FIB) scanning electron microscope and TEM experiments are performed using aberration corrected microscope of model Titan 80-300 ST from Thermo-Fisher Scientific.
Geometric Phase Analysis (GPA) is applied to high resolution STEM images in order to determine the strain in Al matrix around the θ" precipitates. This technique allows to determine at a very high spatial resolution the strain at the vicinity of the precipitates and their coherency. However, the field of view is limited to a 20 nm x 20 nm area. Nano beam diffraction (NBD) is used to determine strain at the microscale due to its higher field of view which allows to map mechanical deformation at the grain size scales. Due to the larger field of view (500 nm x 500 nm), this technique, combined with GPA, make the analysis of the strain inside grains possible and show the influence of the dislocations identified and localized with GPA.
Additionally, the determination of plasmon energies was carried out to evaluate the Y_m of the alloy at nanoscale. Moreover, the bulk modulus (B_m), and shear modulus (G_m) are established. Furthermore, the nano-indentation experiments and electron backscatter diffraction (EBSD) mappings are performed to correlate the bulk material properties to the nano and micro scale observations. In this way, a true structure property relationship of 2024 alloys has been investigated at bulk scales as well as at nanoscales.
In conclusion, the presented study shows that the employed techniques of TEM and EELS complement the results obtained by using the techniques of EBSD and nano indentation. Hence their combination enables to gather a deeper understanding of the strain relaxation mechanisms occurring in the alloy. This methodology resulted in the determination of a relation among (i) heat treatment, (ii) precipitates distribution and (iii) mechanical properties. In the end, the obtained results are used as inputs to propose a model for better prediction of mechanical properties of 2024 Al alloy.

Furthering the Resolution Limit of EBSD Jakub Holzer[1,2,3], Andrew Marshall[4,3], Pavel Stejskal[3], Chris Stephens[3] and Tomáš Vystavěl[3]; [1]Institute of Physics of Materials of CAS, Czechia; [2]Central European Institute of Technology of BUT, Czechia; [3]Thermo Fisher Scientific, Czechia; [4]The University of Surrey, United Kingdom

Electron Backscatter Diffraction (EBSD) has become an established crystallographic and microstructural characterization technique, particularly for metallurgical applications. The resolution of the technique is ultimately limited by the practical SEM probe size combined with the overlap of sampling interaction volumes. This spatial resolution is constrained further by the requirement to use high sample tilts to increase the diffraction contrast. As a result, certain applications often require the use of transmission Kikuchi diffraction, or other transmission electron microscopy (TEM) based techniques, which typically demand lengthy foil or lamellae preparation by focused ion beam. By utilizing an array of sensors capable of direct electron detection, mounted on a retractable arm around the microscope's objective pole piece, we are able gain several advantages compared to EBSD in a standard geometry. This tilt-free sample-to-detector geometry permits the collection of distortion free patterns from a well-defined area and the high sensitivity of the detector allows for pattern collection at lower incident electron energies. This enables a reduction of the sampling volume and has the potential for improved precision and physical spatial resolution with usable signal intensity. Here, we present an adapted methodology to determine the resolution of this tilt-free geometry together with the first experimental results on a molybdenum bi-crystal with a well-defined Σ3 boundary. By sampling perpendicular to the Σ3 boundary with 5nm step and evaluating the variation in the quality of the collected diffraction patterns, the physical resolution can be measured based on the full width at half maximum of the Gaussian curve fit of the pattern quality. Even with 5 nm step, the measured boundary on the indexed map is sharp. The EBSD results are further compared and validated by TEM measurements on lamellae prepared from the same specimen.

F.MT03.08.06
Multimodal Characterization of Hybrid Nanocomposite Materials—The Case Study of the Oleophilic Hydrophobic Magnetic (OHM) Sponge for Oil Spill Remediation Stephanie Ribet[1], Vikas Nandwana[1], Roberto dos Reis[1], Tirzah Abbott[2], Eric Roth[2] and Vinayak Dravid[1,2]; [1]Northwestern University, United States; [2]NUANCE Center, United States

There are significant intrinsic challenges to characterizing hybrid (hard-soft) materials due to the difference in properties between components of these structures. Nonetheless, establishing the structure-property relationships of these systems is an essential step in material design. Here we study the recently reported Oleophilic Hydrophobic Magnetic (OHM) sponge, a nanocomposite system that offers the ability to repeatedly adsorb 20-35 times its weight in oil. [1,2] The OHM sponge is synthesized by coating a polyurethane membrane with a nanocomposite, made of nanoparticles, such as Fe_3O_4, and graphite. In addition to the aforementioned challenge of distinguishing both the hard (nanocomposite) and soft (PU sponge) features,

this hierarchical material necessitates exploration at multiple length scales. Given the physically and chemically complex characteristics of this membrane, a correlative multimodal approach is needed to study the fundamental underpinnings contributing to the performance of this material. We apply a combination of SEM, S/TEM and Raman spectroscopy to probe the structure, morphology and chemistry of the OHM sponge including with *operando* techniques.

Preparing thin samples for electron microscopy of hybrid materials can be difficult due to the nonuniform mechanical properties of the system. Here, we embed the OHM sponge in resin at the sub-micron scale and use an ultramicrotome cross section approach to directly assess the nature of the coating. Scanning electron microscopy and spectroscopy techniques provide rich atomic and electronic information about the sponge both on the micro (SEM/Raman) and nano (S/TEM) scale. Using a combination of backscatter electron imaging (compositional contrast) and EDS, the spatial distribution of iron oxide nanoparticles can be explored. Additionally, by exploiting the distinct graphite sp^2 (π bond) EELS edge and Raman spectral signature, we map the graphite distribution of the sponge, distinguishing it from the other carbon-based materials in the sample. This correlative approach is used to provide a complete assessment of the nature of this material and can be more broadly be applied to other hybrid systems. Further, dynamic electron microscopy is a powerful tool to observe reactions as the progress in real time, and ESEM experiments, in particular, provide a pathway to characterize the solid-fluid interactions that contribute to the OHM sponge's performance.

The presentation will emphasize the holistic understanding of OHM sponge and other hierarchical, hybrid materials that can be attained through correlative and multimodal characterization methods.

Nanoscale Nonlinear Optical Spectroscopy with Electron Beams Andrea Konecna[1], Valerio Di Giulio[1], Vahagn Mkhitaryan[1], Claus Ropers[2] and Javier Garcia de Abajo[1]; [1]ICFO - The Institute of Photonic Sciences, Spain; [2]4th Physical Institute-Solids and Nanostructures, University of Gottingen, Germany

Electron energy loss spectroscopy (EELS) nowadays allows us to acquire information on excitations in nanostructures with high spatial and spectral resolution over a broad energy range covering vibrational, optical (valence-electron) and core-electron excitations [1, 2]. The possibility of nanoscale mapping of optical response beyond the diffraction limit has made EELS one of the leading techniques in characterization of nanophotonic structures. However, EEL spectra are typically dominated by linear optical response, as the nonlinear contributions are negligible due to weak interaction between electrons and sample, which prevents the use of EELS in studying the nanoscale behavior of nonlinear optical fields.

The interaction between electrons and optical excitations in a sample can be substantially increased if the sample is excited by external optical pumping. Such a scenario is possible in photon-induced near field electron microscopy (PINEM), where we can reach scattering probabilities of order unity, and obtain multiple energy quanta exchanges between the electron probe and the optical field [3, 4]. Additionally, high light intensities can also trigger substantial nonlinearities in the sample response, which should be reflected in measured PINEM spectra.

In our work [5], we suggest PINEM as a suitable technique for nanoscale mapping of nonlinear optical response. In particular, we show that the interaction of electrons with nonlinear optical fields introduces asymmetries in otherwise symmetric PINEM spectra, which we demonstrate on several realistic examples. First we focus on studying second-harmonic (SH) response of spherical gold nanoparticles. We show that the evanescent SH field, which cannot be probed by conventional nonlinear optical spectroscopies, gives rise to substantially asymmetric electron spectra under achievable illumination intensities. We further calculate SH field in gold nanorods and show that significant asymmetries in the PINEM spectra can be achieved for particular beam positions when the linear-field coupling is reduced. We envision that PINEM performed with variable illumination frequency and intensity could become a powerful technique for characterization of nonlinear optical response with unsurpassed combination of spatial and spectral resolution.

Observation of Crystal Grain Images by Using Multi-Segmented Back Scattered Electron Detector in Scanning Electron Microscope Yusuke Sakuda, Takeshi Otsuka, Mayu Ishino and Hiroshi Onodera; JEOL Ltd., Japan

The characters of a material depend on the crystal grain size and grain boundaries. Therefore, evaluation of crystals from a viewpoint of crystallography is extremely important. Various methods by using Scanning Electron Microscope (SEM) have been extensively developed for the evaluation of crystals because samples can be handled in a bulk state and observed in the region of μm to nm order. One common method is the Electron Channeling Contrast (ECCI) method[1)], which allows to obtain an image contrast corresponding to crystal grain boundaries by using the intensity difference of Back Scattered Electrons (BSEs) emitted from a bulk sample. The other common method is the Electron Backscatter Diffraction (EBSD) pattern method[2)]. The EBSD is possible to analyze crystal orientation distributions using diffraction patterns from a sample detected by a fluorescence screen. Those methods are quite useful for knowing grain distribution in the crystal as well. On the other hand, there are some issues in these methods of measuring a bulk sample. The ECCI is sometimes difficult to characterize the crystal structure and grain boundaries because it detects a mixture of BSEs originating from composition, channeling contrast and a diffraction pattern, while the EBSD has the limitation that a sample should be tilted significantly. Therefore, the lateral spatial resolution is about 100 nm in these methods and it would be difficult to analyze fine crystal structures and grain boundaries.
In order to improve the issues, we applied a multi-segmented BSE detector[3)]. The detector is segmented to 16 parts located above a sample and detects BSEs. The method is similar to the ECCI method. However, in practice it is possible to detect only the diffraction patterns by using the new segmented detector. As a result, it is much more clearly separate the grain boundaries than with the ECCI method. The principle is that the diffraction patterns detected by 16 segments in each element are integrated to calculate the signal intensity distribution and display it as a grain boundary image. Because similar intensities can be obtained from the same diffraction pattern, the grains with similar signal intensities are evaluated as the same crystal orientation with high approximation. The Euclidean distance[4)] was used to compare the signal intensities.
We also tried to apply the decelerating method which is a SEM column technique for improving the electron probe diameter. In the decelerating method, incident electrons keep high energy when passing through an objective lens. Finally, the electron energy is reduced down just before the electron is landed to a sample. The method reduces the spherical aberration coefficient (Cs) and the chromatic aberration coefficient (Cc) related to the electron probe diameter and the spatial resolution can be improved[5)].
In this study, we will report that we tried to quickly acquire the grain boundary image with high spatial resolution using the multi-segmented BSE detector combined with the SEM-deceleration method.

Thermal Expansion Coefficient of Silicon Nanoparticles with Nanometer Resolution Bibash Sapkota, Prakash Parajuli, Serdar Ogut and Robert Klie; University of Illinois at Chicago, United States

With the size of electronic devices getting smaller and smaller, it has become important to understand thermal expansion coefficients and thermal properties in sub-nanometer scale [1-3]. However, traditional techniques, such as scanning thermal microscopy or Raman thermometry are limited in spatial resolution due to mechanical constraints or optical diffraction limit [1-3]. In the present work, we will utilize a novel approach of non-contact thermometry based on the combination of low-loss electron energy-loss spectroscopy (EELS) with first principles density functional theory (DFT) modeling to measure the thermal expansion coefficient (TEC) of materials with nano-meter resolution. The approach has been well-tested on 2D materials such as transition metal dichalcogenides (TMDs), graphene and MoS2 by Hu et al [1]. In present work, we will extend the approach to Si nanoparticles to determine its TEC as a function of the temperature. In this contribution, we will also explore the effects of particle size, orientation and composition on the TEC, as well as the limits of measuring the local temperature using this approach.

Determination of Valence in Mn-Containing Oxides by Using Soft X-Ray Emission Spectroscopy (SXES) with Electron Microscopy Yohei Kojima, Shunsuke Asahina, Shogo Koshiya, Takanori Murano and Hiroshi Onodera; JEOL Ltd., Japan

Mn-containing oxides are important materials that have been widely used for industrial applications such as battery, magnetic and superconducting materials. Therefore, a novel material of Mn-containing oxides has been remarkably investigated to improve their capability and quality. They have various physical properties because Mn usually has divalent, trivalent or tetravalent and each valence has different d-electron numbers in Mn-containing oxides. Thus, the determination of valence in Mn-containing oxide is a very important factor to know the characteristics of the material. As an analytical method for Mn valence, X-ray Absorption Fine Structure (XAFS) method is frequently performed in synchrotron radiation facilities [e.g. 1]. X-ray analysis in the synchrotron radiation facilities is quite powerful as it allows in-situ observation. However, it is difficult to conduct an analysis with a finer structure because the X-ray beam size is on the order of microns. For the chemical state analysis in a micro or nano-ordered structure, the method combining with Transmission Electron Microscopy (TEM) and Electron Energy-Loss Spectroscopy (EELS) is popular. Although this method has a high spatial resolution and high energy resolution, EELS cannot directly obtain information of the valence band associated with chemical bonding of the material. Recently, SXES that can be installed in Scanning Electron Microscope (SEM) and Electron Probe Micro-Analyzer (EPMA), has been developed for the chemical state analysis of a bulk with fine structures [2]. Soft X-ray means the X-ray with energies from 10 eV to a few keV, and includes the X-ray generated by electron transition from valence bands to inner-shell levels. Therefore, we can obtain chemical bonding information by spectral analysis of this X-ray. So far, we reported a valence analysis of Fe oxides by using SEM-SXES system and “Flank” method [3] suggested by Höfer et al. [4]. Flank method proceeds as below:
1) Calculating a spectrum difference between Fe2+ endmember and Fe3+ endmember.
2) Setting Flank positions of Fe Lα and Lβ at the maximum or minimum value position in the difference spectrum.
3) Taking the Lβ/Lα intensity ratio at the Flank position.
This method has higher resolution for valence than the conventional method of peak-intensity and area-intensity ratios. In this study, we attempt to apply this method for Mn-containing oxides.
MnO, Mn2O3 and MnO2 purchased from Hori Mineralogy Ltd. were used for samples. There is no element detected by SXES other than Mn and O. The SXES measurement was performed by using FE-SEM (JEOL JSM-7900F) equipped with SXES (SS-94040SXSER). The soft X-ray spectra were acquired at accelerating voltages of 10 kV, 5 kV and 2 kV with a beam current of 50 nA and acquired for 5 minutes.
In this study, we compared the intensity ratio of Mn Lβ/Lα calculated by the Flank method, peak-intensity ratio method and area-intensity ratio method. As a result, it is found that the Flank method has a higher energy resolution for the valence of Mn than the conventional peak-intensity ratio method and area-intensity ratio method for all accelerating voltages used in this study at 2, 5 and 10 kV. It is expected that this method will be widely applied to the valence analysis of Mn-containing oxides used in various industrial applications.

Late News: Using Direct Electron Detector Technologies to Determine Local Structure and Chemistry of Nanostructures Alexandre Foucher and Eric Stach; University of Pennsylvania, United States

Direct electron detectors have revolutionized the field of structural biology and are beginning to find applications in materials science and nanoscience. Here, we show how these detectors can improve the ability of transmission electron microscopy to understand the physical and electronic structure of nanoparticles and thin films. These newly developed direct electron detection cameras reduce the signal-to-noise ratio compared to conventional CMOS / CCD cameras. In this study, electron

energy loss spectroscopy (EELS) spectra obtained from several materials systems - Ti2-xNbxC MXenes, Mo4VAlC4 MAX phase and CoPt nanoparticles - are quantified, and the improved signal quality with the direct detection system is demonstrated. We compared the effect of probe size, aperture size, camera length, and imaging filter aperture size on the signal-to-noise ratio. For nanoparticles and thin films, it was shown that probe size and camera length had the strongest influence on the signal intensity arising from inelastically scattered electrons. In contrast, imaging filter aperture size plays a minor role. The optimization of these parameters makes it possible to routinely perform valence-state analysis at an atomic level, with a resolution comparable to bulk approaches such as X-ray photoelectron spectroscopy or X-ray absorption spectroscopy (XAS). The increased Detected Quantum Efficiency (DQE) combined with a sub-pixel detection setting is also beneficial for recording diffraction patterns to perform electron pair-distribution function (ePDF) analysis from these same systems. The improvements in the quality of both spectral and scattering data can be expected to make transmission electron microscopy an even more powerful tool for characterizing nano materials.

Synthesis of Si Block-Containing Gradient Block Copolymer with Increased Assembly Kinetics via Systematic Homopolymer Control for the Fabrication of a Perpendicular Lamellar Pattern Yemin Park, Seung Won Song and Yeon Sik Jung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The advancement in modern electronics has led to miniaturization of device and increase in demand for ultra-small and highly integrated device technology. Extreme ultraviolet lithography (EUV) has been utilized to meet the demand for patterning nano-elements of 20nm or less, however has issues regarding stochastic effects causing defects in the system. To resolve this issues, directed self-assembly of block copolymers has been considered as a promising candidate to aid EUV to develop of sub-10 nm patterns. To achieve the sub-10 nm pattern, block copolymers with high Flory-Huggins parameter (χ) is generally required for high quality pattern resolution. However, a few issues arise when using high χ block copolymers. First, high χ values generally lead to a large surface energy difference between the individual polymer blocks preventing formation of perpendicularly oriented lamellar patterns and reduce horizontal alignment of polymer blocks. Neutral brush layer coating on the substrate is an option to reduce the energy difference, but does not fully resolve the issue as it not only requires additional processes and cost but also cannot be applied on substrates with prefabricated patterns. Secondly, high χ block copolymer has slower self-assembly kinetics, leading to increased defect occurrence and self-assembly time. Therefore, a deliberate design for block copolymers with moderately high χ values as well as rapid kinetics is required for facile DSA of perpendicular patterns.
Here, we suggest a newly designed block copolymer that can achieve high χ value while forming perpendicular lamellar pattern. The key to the block copolymer design is incorporating a gradient copolymer block with Si-containing block to promote universal perpendicular alignment of lamellar morphology without the need for additional surface treatment or neutral brush layer. The block copolymer was synthesized by reversible addition-fragmentation chain-transfer polymerization to form a styrene (S)/ 2,3,4,5,6-pentafluorostyrene (PFS) gradient with a Si-containing 4-(tert-butyldimethylsiloxy)-styrene (4BDSS) copolymer block (P(S-*g*-PFS)-*b*-P4BDSS). The styrene/ pentafluorostyrene gradient copolymer consists of gradual composition change from the block junction region to the tail, which creates surface energy difference enough to energetically drive perpendicular lamellae formation, well supported by a thermodynamic model. Furthermore, by mixing P4BDSS homopolymer block with the block copolymer, the kinetic factor can be increased to be greater than that of existing high χ block copolymers to accelerate the self-assembly time and reduce the number of defect occurrence.

Machine Learning Approach to Long Time Step Molecular Dynamics for Hard Sphere Systems Ka Chun Chan; Karlsruhe Institute of Technology, Germany

Atomistic simulation techniques such as molecular dynamics (MD) provide an accurate and precise description of atomic motion, molecular structure and permit the prediction of the physical and chemical properties of molecular system. However, MD requires expensive computation of energy and force which leads to significant computational effort. This severely limits MD applications to biological system and soft matter physics on long time scales.
The usual MD time step is approximately 1/10 of the fastest frequency of the molecular system. In order to accelerate the MD computation, we propose a machine learning approach to propagate the molecular system instead of the usual MD time step. As a first step we developed a machine learning (ML) propagator for hard-sphere systems that propagates the molecular system with each atomic collision as a new time step. The proposed algorithm learns the time evolution of the atomic motion and the collision between atoms, such that the neural network are able to predict the system trajectory, identify the collided atomic pairs and correct the trajectory of the collided pairs for each collision time step. We will discuss the perspective of this newly ML propagator for the acceleration of MD simulations and further application to the molecular system with long time scales.

Late News: High Throughput Prediction of Stress-Strain Curve of Thermoplastic Elastomer Model Block Copolymers by Combining Hierarchical Simulation and Deep Learning Takeshi Aoyagi; National Institute of Advanced Industrial Science and Technology, Japan

Thermoplastic elastomer (TPE) is a typical industrial product, in which the microphase separation of block copolymer is utilized. The products can be seen in daily life, elastic fiber, film and adhesive for examples. The dynamic properties such as non-linear stress-strain (S-S) behavior are key issue to design such industrial products. The phase separated structure as well as a polymer chain structure affects the S-S behaviors. However, it is often the case that complicate metastable structures are observed in industrial products, and it is not simple to find the relation between such phase separated structures and S-S behaviors. To tackle the problem, we applied hierarchical simulation and deep learning technique. We chose ABA type triblock copolymers, where A blocks and B blocks form glassy domain and rubbery domain respectively, as a TPE model. Stress-strain curve of wide variety of volume fraction and phase separated structures were investigated by hierarchical simulation of self-consistent field theory and coarse-grained molecular dynamics. Furthermore, we applied 3D-convolutional neural network (3D-CNN) to make regression between the phase separated structures and S-S curves obtained by the coarse-grained molecular dynamics simulation. The predicted S-S curve of untrained structures using trained 3D-CNN showed good agreement with simulation, and high-throughput prediction could be realized comparing to the computationally intensive simulation.

This work was supported by a JSPS Grant-in-Aid for Scientific Research on Innovative Areas: “Discrete Geometric Analysis for Materials Design” [Grant Number 17H06464].

Late News: AI-Guided Coarse-Graining for More Efficient Modeling of SARS-CoV-2 Spike Glycoprotein Ziji Zhang[1], David Zhang[2], Aditya Narayanan[3], Aditya Ramabadran[4], Marcia Simon[1], Miriam H. Rafailovich[1], Yuefan Deng[1] and Peng Zhang[1,1]; [1]Stony Brook University, The State University of New York, United States; [2]Fremont High School, United States; [3]College Station High School, United States; [4]Lynbrook High School, United States

Objectives: The SARS-CoV-2 spike glycoprotein (S-protein), the presumed key receptor for binding to various material substrates, promotes the entry to host cells, and thereby causes infection. The binding dynamics of the S-protein to various substrates including organic, inorganic materials, and living cells is of great interest in biological science and clinical medicine. The all-atomic molecular dynamics (MD) simulations that are known to generate reliable results while mitigating potential biological risks for laboratory research are prohibitively expensive in computing time and resources.
Methods: We develop a coarse-grained (CG) model of the S-protein by intelligently learning the parameters from the corroborated *in vitro* and *in silico* data using DNNs on IBM’s supercomputer. The CG parameters are optimized with the protein in water to provide a medium that offered fluidity *in vivo*. The MD data produced by GROMACS, are fed to the DNN to predict the force field among the CG particles to be simulated in LAMMPS. The loss function that measures the discrepancy between MD values, NN prediction, and CGMD functions, is minimized during the learning process. CG models speed up the all-atomic model by coalescing atoms to form macromolecules and thereby forgoing the unnecessary calculations of the internal degrees of freedom. The CG force field is electro-free and the solvent is modeled using DPD at the mesoscopic scales. The interactions between the proteins, their surrounding solvent, and the surface they bind to are described by formulating a hybrid of the Morse-repulsive and the dissipative terms. Besides, AI is also used to predict the associated temporal scale parameters.
Results: The VMD model builder is used to construct two different CG models, shape-based coarse-graining (SBCG) and residue-based coarse-graining (RBCG), to the S-protein atomic data (PDB: 6VXX) which has 45,246 atoms, and evaluated their robustness with comparison to atomic-scale simulation. The nonbonded Lennard-Jones and bonded interaction parameters in the SBCG model, consisting of 355 beads with approximately 150 atoms per bead, were learned from the all-atom simulations. The bonded interaction parameters were tuned until the stiffness constants deviated less than 25% from those derived from the atomic-scale simulations. The RBCG model consists of 6498 beads, with approximately 7 atoms per bead, built with the RBCG 2007 topology file inside the Martini force field. We then solvated the model with Martini water and ionized the model with Na^+ and Cl^- ions. After minimizing the CG system potentials, we successfully ran GPU-accelerated simulations with multiple runs to assess the impacts of the incrementally increasing timesteps to 14 fs. For verification and validation, the preliminary RMSD values were compared with the all-atomic simulations as the control, involving a single S-protein solvated in a water box with neutralizing ions at a temperature of 310K. The RMSD trends were converged which means our CG models have stable structures. Minimizing the differences of RMSD values by AI enables us

to obtain more accurate parameters for longer simulations.
Discussions and Future Work: Our CG model uses learned parameters from big data to accelerate the conventional all-atomic MD by 4~5 orders of magnitude, without significant loss of accuracy. As the first AI-guided multiscale CG model, it may help enable a thorough investigation of the binding dynamics of the S-protein at varied ambient conditions including temperature and pH values. The limitation of this work may be that depending on different research needs, this CG model could achieve protein chain level accuracy, but not the atomic level. Our AI-guided modeling methodology can be generalized conveniently to study a large collection of materials, *e.g.*, fibrinogen.
Acknowledgment: The project is supported by OVPR&IEDM COVID-19 Grant, SUNY-IBM Consortium Award and Garcia High School Program.

Late News: Mesoscale Modeling of Controlled Erosion of Tetra-Arm Polyethylene Glycol Based Nanogels Eric F. Miller, Vaibhav A. Palkar and Olga Kuksenok; Clemson University, United States

Controlled degradation of micro- and nanogels finds its use in several applications. For instance, in the healthcare field, drugs containing gel particles are utilized for drug delivery. Drug release from such gels can be controlled via degradation of the hydrogel network triggered by various external stimuli. A better understanding of the gel degradation process will aid in the development of such applications. Computational modeling of gel degradation allows one to capture the dynamics of the degradation process depending on the degradation rate constant, initial crosslink density, size of the nanogel particle, and polymer-solvent affinity. To this end, we have developed a Dissipative Particle Dynamic (DPD) approach to capture the degradation of tetra-arm polyethylene glycol based nanogels. These networks are of interest since they have near-ideal network structure thereby exhibiting superior mechanical strength prior to the controlled degradation. Within our simulation approach, we model bond breaking during degradation as a stochastic process. Our results allow us to identify two distinct stages of the nanogel degradation. During the first stage, the bonds breaking within the gel results in the decrease in the crosslink density within the bulk of the gel particle and small tetra-arm pieces breaking off the surface of the nanogel (surface erosion). During the second stage, bulk erosion and reverse gelation occurs. We characterize the transition between the two stages by focusing on the time evolution of the radius of gyration of the largest cluster and reduced degree of polymerization during the degradation process. We show that during the surface erosion, the radius of gyration of the largest cluster increases due to the effective decrease in the crosslink density being a major process, while during the second stage, this trend is reversed. We identify the effects of the gel size and an initial crosslink density on the crossover between the surface and bulk erosion. Our results represent a first mesoscale simulation study of a crossover between the surface and bulk erosion in gels.

An Atom-Probe Tomography Study of High-Nickel Steel Weld Deposits with a Hierarchical Microstructure Amir R. Farkoosh[1], Daniel H. Bechetti[2], Matthew F. Sinfield[2], Jeffrey D. Farren[2] and David N. Seidman[1,3]; [1]Northwestern University, United States; [2]Carderock Division, Naval Surface Warfare Center, United States; [3]Northwestern University Center for Atom-Probe Tomography (NUCAPT), United States

Fabrication of steel structures requires joining by fusion welding. As requirements for weight and cost savings drive increased demand for advanced high-strength, high-toughness structural steels, the ability to balance mechanical performance and microstructural robustness of steels for the spectrum of welding processes poses a significant challenge. One aspect of this challenge is material responses to reheating during multi-pass welding. Thermal transients induce extensive microstructural changes in prior weld passes, whose nature and magnitude are highly dependent on the specifics of the chosen welding processes and the steel's composition. Herein, we present a new high-nickel steel, developed at the Naval Surface Warfare Center Carderock Division, which exhibits a positive response to the intrinsic heat treatment imposed during multi-pass welding processes. Because of the non-equilibrium solidification conditions, the weldments exhibit a hierarchical microstructure with several unique features, including: (i) cellular/dendritic substructure due to constitutional super-cooling; (ii) micro-segregation; (iii) high oxygen and hydrogen concentrations; and (iv) different amounts of lath martensite, and retained austenite across the fusion zone. Here, site-specific atom-probe tomography has become an essential tool that enables us to study the different regions of this hierarchical microstructure in great detail. The atom-probe tomography experiments are complemented by differential interference contrast optical microscopy, TEM, X-ray diffraction, and EBSD to study the microstructural features over hierarchical length scales. We have demonstrated that it is possible to produce a fine martensitic microstructure, which is reinforced by a high number density of V(N,C) nanoprecipitates, without post-weld heat treatments, leading to both high-strength and toughness. The presence of the V(N,C) nanoprecipitates has a twofold benefit: (i) provides dispersion strengthening; and (ii) removes nitrogen and diffusible hydrogen from the microstructure, which improves the ductility of the weldments and increases resistance against hydrogen embrittlement. The fundamental knowledge acquired in this study is also utilized to optimize the alloy system for the fabrication of structural components

through additive manufacturing processes.

F.MT05.06.02
Dose Rate and Temperature Effect on the Alpha Prime Precipitation in Ion Irradiated Ultra-High Purity Fe-Cr Alloys Yajie Zhao[1], Arunodaya Bhattacharya[2], Caleb Massey[2], Pengcheng Zhu[1], Cristelle Pareige[3], Philip Edmondson[2], Jean Henry[4] and Steven Zinkle[1]; [1]the University of Tennessee, United States; [2]Oak Ridge National Laboratory, United States; [3]Université et INSA de Rouen, France; [4]CEA, France

Cr-rich alpha prime (α') precipitates are detrimental to the mechanical properties of FeCr based ferritic-martensitic steels. Understanding α' precipitation under irradiation conditions is essential for the application of this steel in nuclear reactor environments. To study the effect of dose rate (ballistic dissolution) and irradiation temperature (radiation-enhanced diffusion) on α' formation, ultra-high purity Fe-Cr alloys with 18 wt.% Cr (in either solid solution or thermally aged to form pre-existing α'precipitates) were irradiated with 8 MeV Fe ions to a midrange (~1 um) dose of 0.35-3.5 displacements per atom (dpa) between 300-450 °C at 10^{-3}, 10^{-4} and 10^{-5} dpa/s. Following irradiation, atom probe tomography (APT) was employed to characterize the number density, radius and Cr concentration of Cr-rich clusters. Homogeneously distributed α' precipitates were revealed when radiation-enhanced diffusion dominates over ballistic dissolution (>300°C). All clusters are identified and quantified through the maximum separation method. The cluster Cr concentrations decrease as irradiation temperature decreases or dose rate increases. This is consistent with the less solute enrichment revealed by the proxigram across the iso-concentration interface. However, despite the irradiation conditions, all of the measured values are well below the equilibrium Cr concentration for α' phase suggested by the phase diagram. The radius and number density of α' clusters are similar and within statistical errors for different specimens. The segregation of Cr, C and N atoms to dislocation loops was also observed.

This research was sponsored by the Office of Fusion Energy Sciences, U.S. Department of Energy under contract DE-AC05-00OR22725 with UT-Battelle, LLC and grant # DE-SC0006661 with the University of Tennessee. The fabrication of the Fe-Cr binary alloys has been carried out within the framework of the EUROfusion Consortium and has received funding from the Euratom research and training program 2019–2020 under Grant Agreement No. 633053.

F.MT05.06.03
High-Yield Cryo-APT Workflow Using a Low-Temperature Microgripper Lorenz G. Lechner[1], Andrew Smith[2] and Stephan Kleindiek[2]; [1]Kleindiek Inc., United States; [2]Kleindiek Nanotechnik, Germany

Focused-ion beam (FIB) target preparation is the gold standard for creating site-specific specimen for atom probe tomography (APT). However, FIB preparation can introduce artifacts, such as contamination, amorphization, and heating. One way to minimize sample damage is the usage of cryo-FIB. Cooling the specimen during FIB milling reduces heating related damage and limits the diffusion of Ga. Cryo-FIB sample preparation as part of a complete cryo-APT workflow enables the study of soft and unstable materials, e.g., organic solar cells or high-mobility hydrogen impurities.
However, FIB lift-out preparation requires modifications to succeed at low temperatures. Conventional techniques for in-situ lift-out use beam induced deposition to temporarily attach the specimen to a manipulator and permanently mount the specimen on a sample support structure. These "soldering" techniques use metal-organic precursor gases injected into the microscope chamber and locally decomposed using the electron or ion beam. Unfortunately, these gas-phase deposition processes do not work at low temperatures because the precursors form thick condensates on all cold surfaces. Alternative techniques, like beam cured adhesives, are also not feasible at cryogenic temperature.
Here, we demonstrate a gas-free cryo-liftout workflow using a low-temperature microgripper. The gripper assembly consists of a 3-axis micromanipulator equipped with an insulated gripper thermally anchored to the microscope's cold shield. Piezo motors position the system and actuate the gripper jaws with nanometer precision. The specimen is mounted inside the microscope on a cryo-stage. The region of interest is partially released from the bulk material using FIB cutting. The gripper grabs the specimen and — after a final release cut — maneuvers it onto a micro-post. After the specimen is attached to the post using redeposition welding, the gripper releases the specimen. In the last preparation step, annular FIB milling gives the sample its final shape.
In contrast to using conventional manipulation, there is no need to temporarily join the probe and specimen and subsequently cut them free. This simplification makes the process faster and more reliable, overall increasing its yield.

Atom Probe-Aided Design of Additively Manufactured High-Temperature Aluminum Alloys Richard A. Michi, Amit Shyam, Alex Plotkowski and Jonathan Poplawsky; Oak Ridge National Laboratory, United States

Conventional aluminum alloys cannot be utilized in the 250–450 °C temperature range due to a lack of microstructural stability, creating a technological gap currently filled by steels, titanium alloys, and Ni-base superalloys. Replacement of these materials with aluminum alloys has significant implications for the energy and transportation sectors (e.g., increased engine operating temperature and efficiency, lightweighting, cost reduction), but has yet to be achieved. In this talk, we will give examples of APT analysis aiding in the design of new generations of high-temperature, additively manufactured aluminum alloys specifically targeted for use in the 250–450 °C temperature range. In particular, we will show how APT analysis reveals Zr and Mn segregation to the coherent and semi-coherent interfaces of θ' precipitates in a novel additively manufactured Al-Cu-Zr-Mn alloy, leading to thermal stability up to 350 °C. We will also discuss how the accurate measurement of matrix solute supersaturations facilitated by APT aid in the design of heat treatments for precipitation-strengthened alloys with thermally stable phases and the observations of refined, nanoscale microstructural features formed during the additive manufacturing process. APT was conducted at ORNL's Center for Nanophase Materials Sciences (CNMS), which is a U.S. DOE Office of Science User Facility.

F.MT05.06.07
Tracking Coincident Pair Separation with Varying Concentration Reveals Insights on Nitride Field Evaporation Olivia G. Licata and Baishakhi Mazumder; University at Buffalo, SUNY, United States

The unique ability of Atom probe tomography (APT) to study three-dimensional atomic distribution relies on the field evaporation of ions onto a position-sensitive detector. Multiple ion events reaching the detector within the same pulse period can result in compositional and spatial inaccuracies. Ideally, in APT analysis, acquisition parameters and conditions are modified so that the occurrence of multi-hit events is limited. Some material systems have a higher tendency for multi-hit events during field evaporation in APT, such as those containing boron, carbon, oxygen, nitrogen, and compound semiconductor materials. Under these unavoidable circumstances, these unique events have shown the potential to provide insight on field evaporation and material structure [1, 2]. Here, we define a metric by tracking the distance between coincident detector events within a heterostructure to gain insight on the unique evaporation behavior and crystallographic origin of nitride species. The distributions of pair distances are investigated for each species and region, to understand the influence of elemental composition on evaporated ion separation.

$Al_{0.3}Ga_{0.7}N$/AlN/GaN heterostructures, grown via molecular beam epitaxy (MBE) and metal-organic chemical vapor deposition (MOCVD), were utilized as test structures. Trends in mean and median pair separation distances were consistent between the two preparation methods. Additionally, individual pair species showed agreement within 0.2 mm in detector space. This finding allows for the distinction of Al-x and Ga-x events based on their pair separation. Interestingly, Al-x events show higher separation values than Ga-x events. This is in disagreement with the known lattice constants of Al-N and GaN. This result suggests that crystallographic spacing is not the dominant influence on pair separation. A more likely mechanism is related to the unique field evaporation of the species as well as characteristics of the surface field during acquisition. The crystallographic orientation upon evaporation may also play a role in the resulting pair separation. Distributions of pair separation distance were utilized to investigate variability in the spread of multi-hit events across heterostructure layers. The most prominent feature was the consistent bimodality of Al^{2+}-N_2, suggesting two separate evaporation phenomena. This unique behavior may originate from a combination of dissociation events and correlated events occurring for the same species.

This in-depth analysis presents a statistical protocol for interpreting multi-hit events from APT data. The reported findings help define species-specific evaporation trends within a compound semiconductor heterostructure in an aim to expand the application of APT to complex systems. Defining the relation between multi-hit events and structural chemistry will extend the current capabilities of APT to gain insight on atomic spacing that was previously unattainable without the aid of additional characterization methods. Furthermore, this methodology can be applied to other material systems to qualify the likelihood of correlation, potential dissociation trends, and crystallographic nature.

Atom Probe Tomography and First Principal Calculation to Study N-Type Doping in $(Al_xGa_{1-x})_2O_3$ Jith Sarker, Ankit Sharma, Uttam Singisetti and Baishakhi Mazumder; University at Buffalo, The State University of New York, United States

Efficient n-type doping in ultra-wide bandgap $(Al_xGa_{1-x})_2O_3$ is a key for the realization of high frequency transistors with theoretical performance limit. Group IV elements (Si, Sn and Ge) are being considered as efficient donors in $(Al_xGa_{1-x})_2O_3$ as they are predicted to substitute in cation sites and contribute in conductivity [1]. First principal calculations by density functional theory (DFT) proposed that Si is the most promising candidate for achieving n-type conductivity in $(Al_xGa_{1-x})_2O_3$ as it remains a shallow donor at the highest range of Al composition while other donors are likely to transform into deep level defects at high Al-$(Al_xGa_{1-x})_2O_3$ [1]. Incorporation of Si in $(Al_xGa_{1-x})_2O_3$ has been reported experimentally. The dopant behavior in these films including dopant distribution, layer homogeneity, segregation/clustering with varying alloy composition is not reported so far. It has been reported for similar wide bandgap system, AlGaN that n-type doping introduces point defects such as cation vacancies (V_{Ga} and V_{Al}). These defect sites act as charge trapping centers by interacting with dopants and forms complex defects (V_{Ga}-Si_{Ga} or V_{Al}-Si_{Al}) [2]. This results in reduced carrier mobility at high doping regime and is termed as "compensating knee" [2]. Similar investigation on dopant behavior in $(Al_xGa_{1-x})_2O_3$ is not reported yet. It is crucial to have in depth understanding of dopant interaction down to atomic level structural chemistry of $(Al_xGa_{1-x})_2O_3$ films is pivotal to achieve excellent doping profile.

Atom probe tomography (APT) was employed to investigate the atomic level dopant behavior and dopant interaction in $(Al_xGa_{1-x})_2O_3$ with varying Al content (x = 0.10-1.0). APT reveals that at low Al content, Si distribution is homogeneous while some high Si density island-like regions appears at high Al content (x80%). The statistical radial distribution function (RDF) was used to understand the dopant interaction in by exploring the nearest neighbor chemistry in the bulk regions of each $(Al_xGa_{1-x})_2O_3$ layer. RDF in layers with low Al contents (x = 10-20%) showed high Ga concentration in regions surrounding the Si atoms with Al concentration being very low, indicating Si is substituting in Ga sites. Ga concentration drops at the position of Si atoms implying the presence of V_{Ga}. This result indicates the potential V_{Ga}-Si_{Ga} defect complex formation. At high Al (x = 60-100%), high Al concentration was observed around Si atoms with Al concentration dropping at the location where Si atoms reside, indicating Al site occupancy with possible V_{Al}-Si_{Al} complexes. The initial interpretation of APT results coincided with what was observed in case of GaN, AlGaN and Ga_2O_3 and would account for compensating effect in $(Al_xGa_{1-x})_2O_3$.

The information obtained from APT would provide a guide to the first principal DFT study of Si doped $(Al_xGa_{1-x})_2O_3$. DFT calculation will be performed to confirm the site specific substitution of dopants in $(Al_xGa_{1-x})_2O_3$ at low and high Al content. DFT will confirm the vacancy, interstitial or vacancy-interstitial complex defects by evaluating the formation enthalpy of these defects and defect complexes at different Al contents that would explain carrier compensation in wide bandgap semiconductors.

We acknowledge Dr. Hongping Zhao's group in Dept. of ECE at the Ohio State University for providing the samples.

APT Revels the Synergistic Role of Mn and Zr/Ti in Producing θ'/$L1_2$ Co-Precipitates in Al-Cu Alloys Jonathan Poplawsky[1], Brian Milligan[2,1], Lawrence Allard[1], Dongwon Shin[1], Patrick Shower[1], Matthew Chisholm[1] and Amit Shyam[1]; [1]Oak Ridge National Laboratory, United States; [2]Colorado School of Mines, United States

Typical AlCu-alloys used for automotive applications can only withstand temperatures up to 250 ºC. Increasing this temperature will improve fuel efficiency. The presence of the θ' (Al_2Cu) precipitate in these alloys is critical for the alloy hardness; however, θ' is a metastable precipitate that disappears (transforms) at higher temperatures, destroying the alloy properties. Recently, an affordable and castable Al-Cu alloy that retains θ' and maintains its strength after a lengthy exposure to 350 ºC was developed (> 200 Hrs). The addition of Mn in combination with Zr and their segregation to precipitate interfaces play a significant role in stabilizing the metastable θ' precipitates, while adding Zr and Mn separately only improves the stability to 200 °C and 300 °C, respectively. A series of atom probe tomography (APT) and scanning transmission electron microscopy (STEM) experiments on Al-Cu-Mn-Zr/Ti-containing alloys subjected to long-term annealing (up to 2,100 h) in the critical temperature range, 300 °C and 350 °C, were performed to reveal how Mn and Zr work synergistically to stabilize the strengthening phase (θ'). The experimentally observed solute segregation to θ' precipitate interfaces (APT) and atomic structure at the interfaces (STEM) were used to guide density functional theory (DFT) simulations to understand how Mn and Zr additions change the energetics of θ' in an Al-matrix. The APT and STEM results reveal that Mn additions reduce interfacial energy, and thus, stabilize θ' long enough for the slower diffusing Zr atoms to segregate to coherent θ' interfaces that eventually create a θ'/ $L1_2$-$Al_3(Zr_x,Ti_{1-x})$ co-precipitate structure. The co-precipitate is highly stable, is a key factor that governs microstructural stability beyond 300 °C. This study reveals how solute additions

with different stabilization mechanisms can work in concert to stabilize a desired microstructure, and the results provide insights that can be applied to other high-temperature alloy systems.

This research was supported by the DOE Office of Energy Efficiency and Renewable Energy, Vehicle Technologies Office, Propulsion Materials Program and the DOE Basic Energy Sciences, Materials Sciences and Engineering Division. APT was conducted at ORNL's Center for Nanophase Materials Sciences (CNMS), which is a US DOE Office of Science User Facility. The authors appreciate the support provided by the Oak Ridge Leadership Computing Facility at the ORNL. The authors thank Ray Unocic and Allen Haynes (ORNL) for reviewing the manuscript. The authors would also like to thank Dana McClurg for heat treatments and hardness measurements and James Burns for APT sample preparation and APT operation.

Late News: Specimen Preparation of Environmentally Sensitive Materials for Compositional and Structural Analysis at the Atomic Scale by Correlative APT and TEM Studies Cecile Bonifacio[1], Daniel Perea[2], Pawel Nowakowski[1] and Paul Fischione[1]; [1]E.A. Fischione Instruments, Inc., United States; [2]Pacific Northwest National Laboratory, United States

Atom probe tomography (APT) is a powerful characterization technique for obtaining three-dimensional structure and materials composition at the atomic scale and is complementary to transmission electron microscopy (TEM). In tandem, the two techniques provide detailed characterization of structure, composition, and chemistry. However, the full potential of both of these techniques is typically hindered by artifacts from specimen preparation (e.g., Ga implantation and amorphization) and environmental conditions that degrade the specimen's surface (e.g., surface oxidation). Dual beam FIB (DB-FIB), which is an efficient tool for removing a substantial amount of material and in situ electron beam imaging, allows more control when shaping the APT specimen tip and is typically used to prepare APT specimens. However, Ga-induced damage and amorphization from FIB milling can result in ambiguous results, especially for Al/Al alloys and Ga-containing materials. In fact, it was recently shown that amorphization due to the high energy Ga beam during FIB milling dramatically affected the shape of the mass spectrum due to tip heating during APT acquisitions in Si APT specimens. Studies such as this provoke this study of using low energy Ar ion milling post-FIB milling to obtain high-quality APT specimens. Low energy (< 1 keV) Ar ion milling has been shown to improve TEM specimen quality by removing amorphization and Ga implantation from FIB prepared specimens. We present a post-FIB specimen preparation of APT specimens under controlled environments using concentrated beam (< 1 µm), low energy Ar^+ milling for the removal of manufacturing damage, oxides and FIB-induced damage for TEM and APT analyses. This controlled environment is integrable to current APT environmentally controlled transfer system.

Al and Mg metals and their alloys were chosen as test specimens due to their highly oxidizing properties. The APT specimens were prepared in a FIB system using standard lift-out methods and annular milling. The APT specimen preparation workflow from FIB to an Ar^+ milling system using a FIB vacuum transfer system was interfaced with a glovebox in between transfers. For ease of specimen handling and transfer, the half-grid with the APT specimens was secured in the cartridge of a TEM vacuum transfer specimen holder that is compatible with the ion milling system. Ar^+ milling was performed by using a concentrated ion beam that is rastered longitudinally within a defined area on the APT specimen at decreasing milling energies. TEM, energy dispersive X-ray spectroscopy (EDS), and APT characterization were performed under controlled environments before and after ion milling to determine the removal of surface oxides and FIB-induced damage. Quantification of the removal of FIB-induced damage and the workflow's ability to prevent specimen oxidation and contamination will be presented.

F.MT05.06.11

Late News: Atom Probe Tomography and Model-Free Methods for Analysis of Kinetics of a Binary Co-Sn Alloy Muna S. Khushaim[1], Fatimah Alahmari[2], Delphine Chassaing[3] and Torben Boll[3]; [1]Taibahu University, Saudi Arabia; [2]Imam Abdulrahman bin Faisal University, Saudi Arabia; [3]Karlsruhe Institute of Technology, Germany

Recent studies of lithium-ion batteries suggest that the use of binary *CoSn* alloys as anodes should provide an improvement over currently used anode materials [1]. However, the implementation of *CoSn* alloys is challenging due to uncertainties regarding the phase transformations within this system. In order to understand these, we evaluate the compositions of different intermetallic compounds produced via the peritectic reactions, nucleate and grow within the microstructure of binary *Sn* -25 at.% *Co* by employing atom probe tomography (APT). Owing to its capability, APT with its exceptional capabilities of spatially resolution and quantitative chemical analyses is presented as a sophisticated analytical tool to elucidate the underlying process of the phase transition behaviour of different *Co-Sn* intermetallic compounds and the local structure of the solid solution. The APT results revealed the presence of *Co* clusters with (54.1 ± 0.1) at.% *Co* , (23.34 ± 0.3)

at.% *Co* and (0.6 ± 0.1) at.% *Co* in pure Sn phase [2], which is consistent with the equilibrium phase diagram that indicates there is limited solubility of *Co* in *Sn* (up to 0.6%) at a temperature of 1196 °C . This limited solubility of *Co* atoms induced the formation of different observed intermetallic phases that are *CoSn* and $CoSn_3$. This study demonstrates the unique capabilities of APT to characterize a series of peritectic reactions within the binary *Co-Sn* alloy. Moreover, crystallization kinetics of the crystallization reactions in *Co-Sn* alloy system were investigated under non-isothermal as well as isothermal conditions. These investigations were performed by using of model -free (isoconversion) methods. The results show decreasing on the activation energy for the crystallization kinetics for *CoSn* and $CoSn_3$ phases with increasing temperature, which reveals the involvement of two processes of nucleation and diffusion during the crystallization of these intermetallic phases.

Direct Correlation of Structure and Optical Properties of Defect Related Colour Centres in Hexagonal Boron Nitride Soumya Sarkar, Sinu Mathew, Manohar Lal, T. Venky Venkatesan and Silvija Gradecak; National University of Singapore, Singapore

Hexagonal boron nitride (h-BN) has recently emerged as a prominent nanophotonic material due to observation of several unique optoelectronic phenomena such as natural hyperbolicity, strong second order non-linearities and robust deep UV emission. Specifically, its ultra wide bandgap ~ 6eV can host midgap defects that often exhibit intense room temperature quantum emission. Understanding the origin of such defect related emission is crucial to harness their technological potential. Here, we report controlled tailoring of defect states in hBN by focussed helium ions using a helium ion microscope and present a direct correlation of their structural and optical properties using a combination of Raman, photoluminescence (PL), cathodoluminescence (CL) and high resolution electron microscopy. We observe that while end of range defects cause an evolution of sp^3 phase in the otherwise sp^2 hBN leading to bright and previously unreported near infrared emission, near surface defects contribute to strong visible emitters often attributed to single photons. Our results provide a comprehensive overview of defect related colour centres in hBN across a wide spectral range that would serve as a platform to realize next generation quantum optoelectronic devices.

Practical Deep Learning in Scanning Probe Microscopy Joshua Agar; Lehigh University, United States

Deep learning (DL) has transformed tasks of computer vision and natural language processing. There has been significant interest in emulating this success in scanning probe microscopy and spectroscopies more broadly. While there has been a boon in DL theory developed to address non-scientific problems, and these have been applied in science, their success has been underwhelming. For DL to make transformative breakthroughs in science, it must address practical scientific challenges. For example, in scientific problems, symmetry, order, periodicity, and scale require consideration in ways not needed in conventional DL and solutions. Moreover, scientific problems require that the models are interpretable and parsimonious, rather than through randomness and multiplicity.
In this presentation, we discuss progress on developing practical scientific theory and methodologies of deep learning to address challenges in scanning probe microscopy (SPM). We will discuss how computer vision models' scientific aptitude can be improved through the addition of symmetry awareness to enable the formation and search of latent spaces of image similarity. We will discuss how to build fully-unsupervised learning models capable of conducting spectral unmixing of noisy and complicated hyperspectral images commonly collected in multimodal SPM. We specifically highlight challenges and methodologies to control the structure, shape, and statistical distribution of the learned latent manifold, how to deal with long spectral sequences, and control sparsity. Furthermore, we will demonstrate how custom physics-informed regularizers can encourage parsimonious learning. Finally, we will conclude with how to deploy these models in practice. We will specifically highlight how to prune these models to fit on resource-constrained neural processing units for real-time deployment, where inference on the order of milliseconds is required.

Data Mining of Spatially Resolved Heterogeneous Electrical Conduction in Fuel Cells Yunseok Kim; Sungkyunkwan University, Korea (the Republic of)

The electrodes of a polymer electrolyte membrane fuel cell (PEMFC) primarily contain a Pt/C catalyst and Nafion binder. Because these components play crucial roles in the redox reaction and proton transport, respectively, their distributions can directly affect the electrochemical reactivity, and thus, the device performance. Even though analyzing the component distribution is important to understand its electrochemical reactivity and improve the device performance, it is challenging to determine it for the PEMFC electrode. In this presentation, I will summarize our recent effort for visualizing the spatial distribution of the electrode components and their heterogeneous electrical properties using multidimensional current–voltage (I–V) spectroscopy combined with data mining. The electrical properties of the electrode components, i.e., the Pt/C catalyst and Nafion binder, were explored by I–V spectroscopy, and their electrical heterogeneity was spatially classified based on the shapes of the measured I–V curves by cluster analysis. These results imply that it is possible to get more insight on the data analysis in AFM even using a simple machine learning technique. Furthermore, the proposed method is expected to be applicable for investigating in detail not only the spatial properties of PEMFC electrodes, but also the properties of various material systems.

Time Lapse Scanning Ion Conductance Microscopy (SICM) Combined with Super Resolution Optical Fluctuation Imaging (SOFI) Georg Fantner, Samuel Mendes Leitao, Vytautas Navikas, Barney Drake and Aleksandra Radenovic; Ecole Polytechnique Federale de Lausanne, Switzerland

One of the key advantages many SPM techniques have for cell biology studies is their ability to non-destructively image cells in physiological environments. Using time lapse microscopy, it is then possible to observe how the cells change over time either during growth, development or due to drug treatments. For bacterial cells, time lapse atomic force microscopy (AFM) has been very helpful in understanding how cells grow, divide and react to antibiotic stresses. For soft mammalian cells however, long term time lapse using AFM is more difficult due to the complex and time varying force interaction between

the tip and the cell surface. For these cells, scanning ion conductance microscopy (SICM) would be better suited for time lapse experiments. Unfortunately, standard SICM instruments require 10s of minutes for good quality images, which is often too slow to follow important cell dynamics. In this talk I will describe a microscope we have developed for time resolved SICM imaging of mammalian cells that enables imaging durations of up to 48h with image acquisition times as low as 3 seconds. We have combined this SICM instrument with super-resolution optical fluctuation imaging (SOFI) to complement the morphological SICM data with biochemical fluorescence information. With this instrument we study cell growth, motility, macropinoytosis and cell differentiation.

8:24 AM *F.MT02.02.04
Classification of Active Materials and Binder in a Composite Anode Using Multi-Modal Scanning Probe Microscopy Seungbum Hong; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Here, we present a multimodal scanning probe microscopy study of a composite anode with a dispersed lithium silicon titanium phosphate (LSTP) lithium ion conductor for all-solid-state batteries. We used electro-chemical strain microscopy (ESM) and lateral force microscopy (LFM) to analyze the electromechanical response and friction force dependence as a function of the measurement parameters such as the tip loading force and AC drive voltage. We found that the sensitivities of friction force and ESM amplitude could be valid markers to identify each component in the composite anode. In addition, we visualized the distribution of active ionic sites of lithium ions in the region of LSTP and binder materials based on Pearson's correlation analysis between nanoscale ESM and LFM results. With the suggested technique, various components of composite electrodes can be directly visualized and distinguished in ambient conditions, with their properties being measured simultaneously. These methods will provide insights into the optimal conditions of composite electrodes and allow for developing next-generation all-solid-state batteries.

Mapping Nanoscale Viscoelasticity and Relaxation Times Underlying Growth and Shape of Multicellular Organisms Using Multifrequency AFM Jacob Seifert, Casey Adam, Alba Piacenti and Sonia Contera; University of Oxford, United Kingdom

The dynamic shapes of biologial tissues emerge from a complex interplay of physics, chemistry and genetics, which determines--at each temporal and spatial scale--the mechanical properties that eventually form the structures of living organisms. Shape and mechanical stability of living organisms rely on precise control in time and space of growth, which is achieved by dynamically tuning the mechanical (viscous and elastic) properties of their hierarchically built structures from the nanometer up.
It is now well-established that cellular behaviour (including stem cell differentiation) crucially depends on the mechanical properties of the cells' environment. Much attention has been directed towards the importance of the *stiffness* of the natural (extracellular matrix, ECM) or artificial matrices where cells grow, with the purpose of either understanding mechanotransduction, or controlling the behaviour of cells in tissue engineering. While stiffness (i.e. the capacity of a material to elastically store mechanical energy) has been the focus of most experimental research, neither cells nor matrices are elastic. Biological systems dissipate energy (i.e. they are viscous) and hence they do not respond to mechanical deformations instantaneously (like an ideal Hookean spring), but present different time responses at different spatial scales that characterise their responses to external stimuli.
Measuring viscoelasticity (especially at the nanoscale) has remained experimentally challenging [1,2]. In my talk I will present atomic force microscopy (AFM)-based techniques to measure and map the viscoelasticity of living tissues, cells, membranes, collagen, ECMs, and tissue engineering matrices across the spatial and temporal (from Hz to 100s of kHz) scales, and chirp-based spectroscopic techniques to assess viscoelasticity from Hz to 100s kHz at the nano and micro scale developed in my lab. I will also present tests for assessing which viscoelasic model better fits the experimental AFM results. Our results have uncovered that extracellular matrices of both living plants and tumours present an almost perfect linear viscoelastic behaviour that is key to understand their growth and shape. I will present our work showing how the growth and shape of the roots, leaves and hypocotyl of living Arabidopsis thaliana living plants are related to the nanoscale viscoelasticity of plant cell walls at the time scales probed by multifrequency AFM.

Thermal Scanning Probe Lithography and Å-Indentation for Manipulating and Characterizing 2D Materials Elisa Riedo, Francesco Lavini, Filippo Cellini, Xiaorui Zheng, Annalisa Calò, Tengfei Cao, Edoardo Albisetti and Xiangyu Liu; New York University, United States

The ability to characterize and manipulate materials down to the atomic scale for tuning their mechanical and physical properties is the cornerstone of material science. Two-dimensional (2D) materials in particular are getting large attention because their extremely thin size gives rise to unique and groundbreaking properties.
Here we explore two different research topics. On one side we show how heat delivered by a scanning probe can be used for manipulating the electrical properties of 2D materials, and on the other side we present a recent scanning probe microscopy method to perform Å indentation experiments in supported 2D materials.
Among various novel materials, two-dimensional molybdenum disulfide (MoS_2) is of particular interest due to its large band gap, low dielectric constant, and heavy carrier effective mass. Currently, a key issue in creating high performing field-effect transistors (FETs) based on MoS_2 and other transition metal dichalcogenides (TMDC) films is the poor quality of the metal contacts fabricated on these atomic layers, and the difficulty to pattern dopants. Here, we report a strategy based on thermal scanning lithography (tSPL) to fabricate metal contacts on 2D materials with high reproducibility [1], and we demonstrate the integration of tSPL with a flow-through reactive gas cell to achieve nanoscale control of dopants in monolayer MoS_2 [2]. The tSPL produced defects can present either p- or n-type doping on demand, depending on the used gasses, allowing the realization of field effect transistors, and p-n junctions with precise sub-μm spatial control, and a rectification ratio of over 10^4. Doping and defects formation are elucidated by means of X-Ray photoelectron spectroscopy, scanning transmission electron microscopy, and density functional theory. We find that p-type doping in HCl/H_2O atmosphere is related to the rearrangement of sulfur atoms, and the formation of protruding covalent S-S bonds on the surface. Alternatively, local heating MoS_2 in N_2 produces n-character.
Moreover, we report on the elastic properties of supported 2D graphene and h-BN films by the use of modulated Å-Indentation, a novel scanning probe microscopy (SPM)-based technique capable of achieving sub-Å indentation depths during force-indentation measurements [3, 4]. By using extremely small amplitude oscillations (<<1 Å) at high frequency, we show how Å-Indentation enables non-destructive local accurate measurements of the contact stiffness and out-of-plane elastic moduli of ultra-thin ultra-stiff films, including CVD diamond films (thus even up to TPa range stiffness), as well as the transverse moduli of supported graphene and h-BN (<1 nm thickness) films. Å-Indentation thus obtains *in-situ* elasticity measurement combining superior resolution and indentation depths as small as 0.3 Å with AFM nanoscale topographical imaging. Thanks to this technique, we experimentally demonstrate that at room temperature and under localized indentation pressure, a single layer of graphene on top of a carbon interface layer (buffer layer), on SiC, exhibits a transverse stiffness superior to bulk diamond [3]. Extending the capabilities of the Å-indentation technique to the analysis of other 2D materials, these studies explore similar pressure-induced phase transition in hexagonal boron nitride (h-BN). We demonstrate that 2-layer h-BN flakes, on SiO_2, consistently exhibit a transverse elastic modulus almost two times larger than that of the bare substrate. This stiffening effect is observed only for flakes of thickness between 2 to 5 atomic layers, but not in single- nor multilayer (> 6-layer) h-BN, and is related to the conversion of h-BN to cubic BN (c-BN) induced by the pressure applied through the indenter.

Paddled Cantilever for AFM Beyond Topography Hanna Cho; The Ohio State University, United States

Atomic Force Microscopy (AFM) is one of the most powerful and versatile tools to image and characterize materials with nanometer scale resolution, leading to the development of nano-/bio- science and technology. While AFM technology has advanced significantly by expanding its functionality beyond a nanoscale imaging tool, the majority of AFM users still find it difficult to employ the advanced techniques and interpret the data correctly due to artifacts. Such difficulties mainly originate from the complex dynamics of the AFM probe system, used as a mechanical transducer to deliver the tip-sample interaction force.

We address this issue by altering the AFM cantilever design. The current state of the art AFM probe is a single-body system, in the shape of a rectangular or triangular beam, which is not ideal for carrying more than one type of information. In

contrast, the new AFM probe, so-called paddled cantilever, is reshaped to have a two-field microcantilever design with a considerable dimensional discrepancy in the component part. By doing so, this mechanical transducer provides two discrete transduction channels such that they respond independently to the variations in surface topography and material properties/functionality. Thus, AFM users can effortlessly implement the advanced AFM schemes with minimal ambiguity, complications, and artifacts, by simply employing this new AFM probe.

Since the prototype device of paddled cantilever was first introduced, our team has taken effort to develop a batch fabrication process and, thus, have this advanced technology widely available for AFM users. The detailed dynamics of fabricated paddled cantilevers have been investigated by using the interferometric displacement sensor (IDS) with AFM to directly measure their deflection. The measured deflection along the whole cantilever revealed that the frequency of inner-paddle is not affected by the tip stiffness while its amplitude is proportional to the displacement input delivered through the tip. This is the basis how the paddled cantilever can provide two discrete transduction channels for functional AFM. A theoretical model based on a 2 degree-of-freedom system is also presented to understand the dynamic characteristics of paddled cantilever under various operational conditions. Because the design of paddled cantilever is simple to feasibly integrate into, and compatible with, current AFM probes and systems, this technology will easily extend the AFM functionality to characterize multi-physical properties beyond topography by providing a dual-channel mechanical transducer.

8:56 AM *F.MT02.04.01
Conductive Colloidal Scanning Probe Microscopy Christine Kranz and Sven Daboss; Ulm University, Germany

Scanning electrochemical probe microscopy (SEPM) techniques such as scanning electrochemical microscopy (SECM) and in particular the hybrid techniques such as atomic force microscopy combined with scanning electrochemical microscopy (AFM-SECM) enable high resolution topographical imaging along with electrochemical information [1] but also electrochemical force spectroscopic measurements [2]. Recently, we introduced a new type of electrochemical scanning probe tip for combined AFM-SECM measurements providing instead of a conventional AFM tip, a conductive colloidal sphere attached to an otherwise insulated cantilever [3]. Such conductive spherical probes may consist of boron-doped diamond [4], a highly attractive electrode material, or may be electrochemically modified, e.g., functional polymers, suitable for force spectroscopic measurements such as adhesion measurements under potential control.
In this contribution, we present AFM-SECM measurements and electrochemical force spectroscopy using conductive colloidal AFM probes. Due to the spherical geometry and the low spring constant of the cantilever, these probes are highly suitable for mapping nanomechanical properties at soft samples, i.e. bacterial cells. Colloidal probes with BDD as spherical electrode can be used for various SPM experiments including conductive AFM given the physical and electrochemical inertness of BDD, for force spectroscopy under potential control providing information on electrified interfaces, and for AFM-SECM measurements. Notably, all these experiments can be performed with the same BDD-AFM-SECM probe. Colloidal probes can be modified with polymers i.e. polydopamine, which properties may be altered by applying potential to the spherical electrode. Single cell force spectroscopy on bacterial adhesion along with studies at electrified interfaces will be presented.

Nanoscale Ion Transport Dynamics—From Conjugated Polymers to Halide Perovskites Solar Cells David S. Ginger[1,2]; [1]University of Washington, United States; [2]Pacific Northwest National Laboratory, United States

Imaging ion transport in nanostructure materials has applications in systems from neuromorphic computing, to electrochemical energy storage, and solar cells. We utilize multimodal imaging to probe transport phenomena in these systems. For instance, by combining nanoscale vibrational spectroscopy with structural imaging we can correlated local anion diffusion with structural phase transitions in conjugated polymer films being explored for neuromorphic computing and bioelectronics applications. We also combine similar IR imaging with time-resolved electrostatic force microscopy (trEFM) to uncover the dynamics of ion transport in various 3D and 2D halide perovskites of interest for applications in optoelectronics, especially solar cells, where ion transport can be a primary contributor to device aging and failure. This work bridges advances in scanning probe microscopy with tools from data science to better understand materials design rules for new applications.

Tracking the Dynamics of Liquids and Solutes at Solid Nano-Interfaces Luca Piantanida[1,2], Amir F Payam[1,3], Clodomiro Cafolla[1] and Kislon Voitchovsky[1]; [1]Durham University, United Kingdom; [2]Boise State University, United States; [3]Ulster University, United Kingdom

The molecular organisation and dynamics of liquids near the surface of solids underpins processes such as molecular exchanges, electrochemistry, nanofluidics, biomolecular function and lubrication. Depending on the local topographical and chemical properties of the solid, the behaviour of the interfacing liquid can vary significantly at the nanoscale, with consequences for interfacial processes. Scanning probe microscopies can derive local insights into the equilibrium organisation of interfacial liquids, often with sub-nanometre resolution. However, deriving quantitative information about the local liquid *dynamics* remains a considerable challenge.
Here we review some of our recent results obtained by combining high-resolution atomic force microscopy with highly localised rheological measurements to deduce quantitative information about the motion of liquids and dissolved molecules along immersed solids. We show that the dynamics is highly system-dependant and can be dominated by either the local configurational entropy or the interface or enthalpic interactions. We also describe a novel approach to quantify the preferred flow direction naturally adopted by liquids near walls, locally and with nanometre precision. The approach, based on AFM, combines a vertically oscillating tip with high frequency lateral oscillations to derive directional information about the interfacial liquid at each point of the system. To illustrate the method's capabilities, we investigate the dynamics of aqueous solutions containing different metal ions along the surface of a graphene oxide flake. We identify ion-specific flow dynamics that can be related to the well-established sieving properties of graphene oxide membranes.

9:20 AM *F.MT02.06.02
Using High-Speed, Molecularly-Resolved AFM and Fast Force Mapping to Investigate Nucleation and Solution Structure at Surfaces James J. De Yoreo[1,2], Benjamin Legg[2,1], Elias Nakouzi[1], Andrew G. Stack[3], Sebastien Kerisit[1], Christopher A. Mundy[1,2], Gregory K. Schenter[1], Jaehun Chun[1] and Kislon Voitchovsky[4]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States; [3]Oak Ridge National Laboratory, United States; [4]Durham University, United Kingdom

Investigating nucleation from solutions is challenging, because it is a consequence of unstable density fluctuations, making the structures and events that must be probed both transient in nature and small in spatial extent. Moreover, when nucleation is heterogeneous, it is inherently linked to the structure and dynamics of the interfacial region between the bulk solution and the underlying substrate. Thus high-speed, molecularly resolved AFM combined with fast force mapping (FFM) provides a powerful and unrivalled combination to investigate nucleation from solution onto surfaces. Here I illustrate the deep level of fundamental insight into mechanisms of nucleation and the structure of the interfacial region made possible with these methods using results from investigations into nucleation of gibbsite ($Al(OH)_3$) on muscovite mica (001) and the structure of electrolyte solutions above mica and boemite (AlOOH) surfaces. In the case of gibbsite nucleation, we combine AFM observations of individual molecular adsorbates, transient clusters, and stable islands with Monte Carlo simulations to put together a coherent picture of surface speciation and nucleation. The results reveal a surface population of ions that is dominated by hydrolyzed species ($Al(OH)_2^+$ and $Al(OH)^{2+}$) even though Al^{3+} vastly dominates the bulk solution. These adsorbed ions evolve into subcritical clusters with increasing saturation state and temperature, constituting a population that decreases exponentially with size and exhibits dynamic fluctuations consistent with classical predictions. However, severe discrepancies with classical theory emerge when the values of key thermodynamic parameters are extracted from the AFM data. These discrepancies are resolved when the impact adsorbate charge on the capacitance of the mica-solution system is taken into account in calculating the work of cluster formation, but reveal a film formation process that occurs within a single phase region. Thus, the results imply that the gibbsite films constitutes a nanostructured 2D mesophase. To define the solution structure above boehmite and mica surfaces at lattice resolution, we developed a self-consistent scheme to decouple long-range tip-sample interactions from short-range solvation forces. In the case of boehmite, the results are benchmarked against molecular dynamics simulations that explicitly include the effects of the tip with different levels of approximation and systematically account for tip size, chemistry, and confinement effects. We find four laterally structured water layers within one nanometer of the surface, with the highest water densities at sites adjacent to hydroxyl groups. The findings reveal a complex relationship between site-specific chemistry, water density, and long-range particle interactions; and represent a major step forward towards quantitative data interpretation and widespread implementation of 3D FFM.

Machine Learning to Enhance Analysis of AFM Images Dalia G. Yablon[1] and Ishita Chakraborty[2]; [1]SurfaceChar LLC, United States; [2]Stress Engineering, United States

Machine learning (ML) is permeating many areas of research including drug design, modeling, and materials design. In the realm of characterization, ML is only beginning to be integrated into experimentation and processing to improve the workflow. Here, the potential of ML to play a role in analysis of atomic force microscopy images is explored in two distinct applications.
The first area involves a classic application in ML of image recognition. A convolutional neural net was trained on AFM phase images of different polymer blends and achieved 100% accuracy in differentiating test data, compared with 94% accuracy with a less powerful traditional neural network. This study takes advantage of classic data augmentation methods to increase the sample size since the quantity of AFM images is limited by long acquisition times. The second application

involves using ML to conduct particle analysis in challenging AFM images where the background is varied and many of the particles are linked in a matrix phase. This study serves as an example of the ultimate customizable image analysis where the training of the model takes place on the specific class of challenging images. The hope is that this study serves as a building block for future, more powerful applications of the powerful ML tool in more challenging problems that will also be discussed including establishing structure-property relationships and autonomous operation of AFM.

5:40 AM F.MT02.01.05
Elucidating Bimodal Angular Dynamics of Protein Nanorods at Solid-Liquid Interfaces by High-Speed AFM and Machine Learning Shuai Zhang[1,2], Robbie Sadre[3], Benjamin Legg[1,2], Harley Pyles[1], Talita P. Leite[3], E. Wes Bethel[3], David Baker[1], Oliver Ruebel[3] and James J. De Yoreo[2,1]; [1]University of Washington, United States; [2]Pacific Northwest National Laboratory, United States; [3]Lawrence Berkeley National Laboratory, United States

Bio-macromolecules, including peptides, proteins, DNA and peptoids, self-assemble into bio-hybrid materials with two dimensional (2D) hierarchical architectures at solid-liquid interfaces, exhibiting relative epitaxial matching. While the structural details have been elucidated experimentally and rationalized through molecular simulations, in-situ characterizations of dynamics defining orientational selection of bio-macromolecular arrays at single molecular level with temporal resolution in second, are still limited.
In this presentation, we will report the most recent study of angular dynamics of individual protein nanorods[1] on (001) plane of muscovite mica by high-speed atomic force microscopy (HS-AFM) and machine learning (ML) based analysis. We quantitatively analyzed their free energy landscapes and elucidated the transition possibilities between various orientational states for a range of nanorod lengths and electrolytes. After comparing ML based analysis with standard physical models for nanorod dynamics in 2D, we found that the transitions between minima go through bimodal mechanisms. Unlink the in-plane Brownian motion between adjacent minima in the energetic barrier heights, the motion between more distant minima is analogous to Levy-flights, indicating the existence of a second high-energy angular motion for the proteins. This work provides the workflow for in-situ understanding biomacromolecular dynamics at solid-liquid interfaces and the insights for further improving the general approach of managing bio-macromolecular hierarchical architectures with high accuracy and efficiency.

Time Lapse Scanning Ion Conductance Microscopy (SICM) Combined with Super Resolution Optical Fluctuation Imaging (SOFI) Georg Fantner, Samuel Mendes Leitao, Vytautas Navikas, Barney Drake and Aleksandra Radenovic; Ecole Polytechnique Federale de Lausanne, Switzerland

One of the key advantages many SPM techniques have for cell biology studies is their ability to non-destructively image cells in physiological environments. Using time lapse microscopy, it is then possible to observe how the cells change over time either during growth, development or due to drug treatments. For bacterial cells, time lapse atomic force microscopy (AFM) has been very helpful in understanding how cells grow, divide and react to antibiotic stresses. For soft mammalian cells however, long term time lapse using AFM is more difficult due to the complex and time varying force interaction between the tip and the cell surface. For these cells, scanning ion conductance microscopy (SICM) would be better suited for time lapse experiments. Unfortunately, standard SICM instruments require 10s of minutes for good quality images, which is often too slow to follow important cell dynamics. In this talk I will describe a microscope we have developed for time resolved SICM imaging of mammalian cells that enables imaging durations of up to 48h with image acquisition times as low as 3 seconds. We have combined this SICM instrument with super-resolution optical fluctuation imaging (SOFI) to complement the morphological SICM data with biochemical fluorescence information. With this instrument we study cell growth, motility, macropinoytosis and cell differentiation.

Classification of Active Materials and Binder in a Composite Anode Using Multi-Modal Scanning Probe Microscopy Seungbum Hong; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Here, we present a multimodal scanning probe microscopy study of a composite anode with a dispersed lithium silicon titanium phosphate (LSTP) lithium ion conductor for all-solid-state batteries. We used electro-chemical strain microscopy (ESM) and lateral force microscopy (LFM) to analyze the electromechanical response and friction force dependence as a function of the measurement parameters such as the tip loading force and AC drive voltage. We found that the sensitivities of friction force and ESM amplitude could be valid markers to identify each component in the composite anode. In addition, we visualized the distribution of active ionic sites of lithium ions in the region of LSTP and binder materials based on Pearson's correlation analysis between nanoscale ESM and LFM results. With the suggested technique, various components of composite electrodes can be directly visualized and distinguished in ambient conditions, with their properties being measured simultaneously. These methods will provide insights into the optimal conditions of composite electrodes and allow for developing next-generation all-solid-state batteries.

5:30 AM F.MT02.02.05
Hyperspectral Image Analysis of Graphene Derivatives Using Tip-Enhanced Raman Spectroscopy Chiung-Wei Huang[1], Xiao You[1,2], Kizhanipuram Vinodgopal[3] and Joanna M. Atkin[1]; [1]University of North Carolina, United States; [2]Texas A&M University, United States; [3]North Carolina Central University, United States

Interest in graphene has grown considerably in the last decade due to its unique optical and electrical properties. However, some potential applications of graphene, such as transistors, require a bandgap, which is challenging to generate in graphene. One strategy is to tune local electronic properties by chemical modification through oxidation and surface functionalization. Using transition metal complexes, a desirable energy gap can be opened up in graphene.
Understanding and thereby controlling the mechanism of functionalization is yet hampered by the high degree of structural and chemical disorder in graphene and graphene derivatives. Pure graphene contains inhomogeneous morphological defects such as grain boundaries, edges, and wrinkles. Engineering the electronic properties by surface modification can often lead to a larger degree of inhomogeneity in chemical composition, molecular structures, and the degree of sp^2 conjugation.
Since the number of molecules needed for chemical modification is low, macroscopic methods such as energy-dispersive X-ray spectroscopy or X-ray photoelectron spectroscopy lack the spatial and chemical sensitivity necessary to detect modifications in graphene.
In this work, we employ functional scanning probe microscopy (SPM) techniques that offer spatially resolved, chemically specific and quantitative information on chemically modified graphene derivatives.
Tip-enhanced Raman spectroscopy (TERS) is a powerful surface analysis technique that offers nanometer-resolved images with site-specific chemical fingerprints. We demonstrate nanoscale TERS mapping of structural and functional groups on graphene derivatives. We employ machine learning (ML) tools to extract information on chemical components and their spatial distribution from the hyperspectral TERS maps.
We validate the components resulted from ML-aided analysis by comparing the principal components with density functional theory (DFT) based calculation. The prediction of vibrational modes from DFT offers insights into understanding the site-specific derivative molecules and the bonding between molecules and graphene.
We further extend surface characterization by combining TERS with Kelvin probe force microscopy (KPFM) to locally examine the electrical properties. In conjunction with illumination, we employ KPFM to estimate the local conduction and valence band edge energies. This in situ measurement allows a direct correlation of local topography, chemical composition, and electronic properties.
These methods can be applied to correlated SPM data to obtain complex compositional information that is challenging to gain from any conventional method. By combining nanometer-resolved TERS and KPFM imaging, with computation-aided ML and analysis, we have offered a comprehensive view of chemical and spatial information and demonstrated a generally applicable approach for improving the accuracy of surface characterization. We expect this work to provide a more profound understanding of the molecular binding structures with guidance for optimizing graphene semiconductors and devices.

5:40 AM F.MT02.02.07
Volume Production of Optical Transformer-Based Campanile Scanning Near-Field Probes Integrated on an AFM Cantilever Keiko Munechika[1], Khai Le[1], Adam Legacy[1] and Stefano Cabrini[2]; [1]HighRI Optics, Inc, United States; [2]Lawrence Berkeley National Lab, United States

Near-field scanning optical microscopy (NSOM) has become one of the most crucial and powerful techniques to characterize

the chemical, physical, and biochemical properties of materials with nanometer-scale resolution in real-time. A key element for any NSOM systems that combine optical spectroscopy with scanning probe microscopy is the actual probe itself. An ideal NSOM probe provides a strong local electromagnetic field enhancement, efficient far-field to near- field coupling, nanoscale spatial resolution, background-free operation, and broadband photon-plasmon coupling to enable high spatial and temporal resolution. One of the most exciting optical probe architectures based on an optical transformer, "campanile," was recently developed and has been successfully used for multidimensional spectroscopic imaging of nanostructures with nanoscale resolution, providing insights into novel optoelectronic process[1]. However, making such probes requires both the expertise and the facility, and reproducibility is a significant issue. The economic production of reasonable volumes of such probes is not possible. There is a critical need for the development of optical tip technology to yield high-performance and reliable near-field probes and to become available to the broader user community. The realization of such probes would impact nanoscale research at the same level that atomic force microscopes did when paving the way to modern nanoscale science. We present a wafer-scale realization of Campanile near-field scanning optical probes fabricated on an AFM platform. Figure 1 illustrates a 2D sketch and a scanning electron micrograph (SEM) image of an optical transformer on a cantilever. The figure shows the Boron Nitride flake sample and its topographical image taken by the Campanile AFM probe. Optical measurement results show a promising sign of probes' functionality with a strong polarization dependence response, which is a tell-a-tale sing of a campanile. This work paves the way for low cost and volume manufacturing of near-field probes suitable for high-resolution hyperspectral imaging.

5:50 AM F.MT02.02.08
Probing Nanoscale Surface Phenomena by *In Situ* Near-Field Second Harmonic Generation Microscopy Yoonsoo Rho[1], Hee K. Park[2] and Costas Grigoropoulos[1]; [1]University of California, Berkeley, United States; [2]Laser Prismatics LLC, United States

Accurate monitoring and control of surface chemical reaction by adsorbates on metal oxide semiconductors are of key interest in many electrochemical systems. These nanoscale surface chemistries are often probed by X-ray photon spectroscopy (XPS), scanning tunneling microscopy (STM), and tunneling electron microscopy (TEM) at high vacuum. However, these methods are not suitable for in-operando experiment under various gas environments and the use of energetic particles can potentially disturb the surface chemistry. In contrast, optical second harmonic generation (SHG) is a simple, non-invasive, vacuum-free, and sensitive probing method for surface chemistry. The intrinsic broken inversion symmetry of surface can induce SHG signals, which can be altered by changes in charge distribution at the surface, depending on the presence of chemical adsorbates. Integrated with tip-based scanning near-field optical microscopy (SNOM), optical SHG can interrogate various nanoscale surface phenomena and their dependence on the gas environment without complicated sample preparation.

Here, we demonstrate *in-situ* tip-based near-field SHG microscopy of chemical reactions at the surface of metal oxide nanowires, including titanium oxide (TiO_2), zinc oxide (ZnO), and vanadium oxide (VO_2). The nanoscale SHG can be amplified by local electric field enhancement by the tip-apex and provide surface chemical state with nanoscale resolution. Based on this method, we *in-situ* probed the reactions of oxygen and water vapor at the surface of TiO_2 and ZnO, depending on the local vacancy density and the occurrence of catalytic reaction at elevated temperature. In addition, strain effect on the local phase transition in VO_2 nanowires was probed on a mechanical clamped structure at controlled temperature. The correlated TEM inspection of these nanowires showed surface defects and phase state consonant with the near-field SHG imaging. We believe that the presented *in-situ* near-field SHG microscopy can provide powerful means for in-operando probe of various physicochemical phenomena.

6:00 AM F.MT02.02.09
Latest Advances in Nanoscale Chemical Imaging and Spectroscopy Anirban Roy[1], Honghua Yang[1], Qichi Hu[1] and Curtis Marcott[2]; [1]Bruker Nano Surfaces, United States; [2]Light Light Solutions, United States

For the last few decades the rapid growth in the field of nanoscience and technology has led to the development of new characterization tools for nanoscale materials. Traditional IR and Raman spectroscopy and imaging offers excellent chemical insights; however, the spatial resolution is limited by the optical diffraction limit (~l/2). Although, recent Super-resolution microscopy techniques [1, 2] offer superior spatial resolution, they are primarily implemented in fluorescence imaging, hence needs external fluorophore tag for detection. Alternatively, high resolution multimodal imaging platforms offer unique combination of SPM and chemical spectroscopy/spectrometry, such as, IR, Raman and SIMS to probe nanoscale chemistry without external fluorophore. One of the above techniques, namely, nanoscale IR spectroscopy/imaging offers a "tag free" spectral detection by exploiting an AFM probe [3] to detect either photothermal expansion force (PTIR/AFM-IR) or near field scattered IR light (s-SNOM) with high spatial resolution beyond optical diffraction limit (2-5 mm).

Recent developments in PTIR/AFM-IR and s-SNOM technology have significantly augmented the speed and spatial resolution for chemical analysis. Exploiting different modalities in AFM, such as, contact, tapping and other heterodyne force detection modes (e.g., ultrasonic and/or acoustic force microscopy), we are able to acquire IR images at a specific absorption band simultaneously with sample topography and viscoelastic properties, providing a complete set of topographical, chemical and mechanical insights with ~10 nm spatial resolution. These high-resolution measurements are currently accompanied by high speed tunable lasers with broad spectral coverage ranging from 800-3600 cm^{-1}, encompassing full capability of FTIR characterization for dimensions orders of magnitudes smaller than the optical diffraction limit. For example, Figure 1c shows topography and chemical map of PS-*b*-LDPE block copolymer on a silicon substrate. IR images at 1466/2920 cm^{-1} and 1488/3032 cm^{-1} highlight the distribution of low-density polyethylene (LDPE) and polystyrene (PS), respectively with feature sizes ~50 nm or smaller.
Along with high spatial resolution, high speed spectral acquisition enables acquiring hyperspectral data cube with large set of data. These high-volume data set opens up new avenues for machine learning algorithm for data processing and analysis, e.g., high resolution spectral map reconstruction using pan-sharpening algorithm [4].

In this presentation, we will highlight the technical background and applications of these emerging technologies in different fields, e.g., nanomaterials, life sciences, polymers, microelectronics etc.

6:10 AM F.MT02.02.10
3D Ferroelectric Domain Wall Imaging by FIB and SPM Erik Roede[1], Aleksander B. Mosberg[1], Donald M. Evans[1], Theodor Secanell Holstad[1], Zewu Yan[2], Edith Bourret[3], Antonius T. van Helvoort[1] and Dennis Meier[1]; [1]Norwegian University of Science and Technology, Norway; [2]ETH Zürich, Switzerland; [3]Lawrence Berkeley National Laboratory, United States

Charged ferroelectric domain walls are naturally occurring quasi-2D objects with a range of functional properties and potential technological applications. The hexagonal manganites ($RMnO_3$, R= Sc, Y, In, Dy to Lu) are an important model system for the study of domain walls, as these improper ferroelectrics naturally develop all orientations of 180° domain walls, including neutral and charged configurations. The charge state and properties are determined by the orientation and geometry of the domain wall, giving rise to rich electronic behavior. At the surface, the "projected" domain wall properties can readily be characterized, for example using scanning probe microscopy (SPM) and photoemission electron microscopy (PEEM), whereas mapping of their characteristics in three dimensions remains challenging.

In this work, I will discuss the use of focused ion beam (FIB) techniques for extending the surface information from SPM studies into 3D. As a first example case, I will discuss the use of FIB to prepare ferroelectric lamella samples with well-defined domain wall configurations determined via correlated microscopy techniques. In order to access the complete 3D information, surface SPM is combined with FIB tomography to image ferroelectric domain walls with nanoscale resolution and correlate the local sub-surface geometry with the measured properties at the surface. Understanding how the 3D geometry of the domain walls influences their local electronic response is an important step toward unlocking their full intrinsic functionality and application in nanoelectronics devices.

6:20 AM F.MT02.02.11
The LaserFIB – Uniting High-Resolution Microscopy and Massive Material Ablation Sample Prep Tobias Volkenandt, Fabián Pérez-Willard, Benjamin Tordoff and Luyang Han; Carl Zeiss Microscopy GmbH, Germany

Modern materials research in combination with innovative fabrication and processing techniques enable development of increasingly complex materials and advanced components. Analyzing these new materials and understanding their microstructure requires sophisticated characterization tools. Focussed ion beam scanning electron microscopes (FIB-SEMs) are well established for sample analysis and preparation at the nano- to micro-scale in 2D, 3D or even 4D. However, when it came to sample modification and analysis at even larger scales up to millimeters FIB-SEMs were facing a challenge.

With the LaserFIB we present and introduce a new system to solve this challenge and bridge this gap. The LaserFIB features

a fs laser that has been integrated with a ZEISS Crossbeam. This combination enables high-resolution SEM imaging and FIB patterning as well as site-specific, large-scale sample structuring and preparation using the laser. All laser processing is done in a separate chamber extending the airlock to avoid damage and contamination of the components in the instrument's main chamber (Fig. 1). The massive material ablation by the laser is highly efficient in large volume bulk material removal and offers a way to gain access to deeply buried regions of interest (ROIs). Large cross-sections can be prepared in seconds and subsequently get analyzed by SEM leveraging all sorts of analytical techniques (e.g. EDS or EBSD). If needed the FIB allows to fine-polish the cross-section face for undisturbed imaging, however, it has been shown that details of the microstructure are already visible after laser polishing only and even suitable for e.g. EBSD analysis.

In this contribution we will introduce the new LaserFIB and explain the site-specific workflow in detail. Application examples covering different sample materials and applications will be shown. Among these are e.g. correlative sample preparation for X-ray nano-tomography, micro-mechanical testing and large-scale cross-sectioning.

6:30 AM F.MT02.02.12
Late News: Antiferromagnetic Spin Cycloidal Orders Imaged with a Commercial Scanning Nitrogen-Vacancy Magnetometer Hai Zhong, Alexander Stark, Felipe Favaro and Patrick Maletinsky; Qnami AG, Switzerland

Antiferromagnetic thin films attract significant interest for future low-power spintronic devices. They are largely insensitive to external magnetic fields, exhibit domains with negligible cross-talk and can be switched at THz frequencies [1]. Furthermore, in multiferroics where antiferromagnetism can coexist with ferroelectricity, it is possible to control the magnetic state electrically - a particularly appealing feature for future device applications.
In this talk, we show how the Qnami ProteusQ^{TM} -- a commercial room temperature scanning nitrogen-vacancy magnetometer (SNVM) -- can be used to quantitatively image antiferromagnetic spin textures with proven DC field sensitivity of ~ 2 μT/√Hz. We image the spin cycloid of a multiferroic bismuth ferrite ($BiFeO_3$) thin film and extract a period of about 103 nm, indicative of a type II spin cycloid. [2] In addition, we take advantage of the quantitative nature of SNVM to extract an average magnetic moment density of 0.08 ± 0.02 μ_B /Fe in the $BiFeO_3$ film. These findings agree well with reported vibrating sample magnetometer results (M_S = 0.06 μ_B /Fe) on similar, strained $BiFeO_3$ thin films. [3] Our results shed light on future design requirements for reconfigurable nanoscale spin textures in such multiferroic systems.

F-MT02

5:00 AM *F.MT02.03.01
Mapping Nanoscale Viscoelasticity and Relaxation Times Underlying Growth and Shape of Multicellular Organisms Using Multifrequency AFM Jacob Seifert, Casey Adam, Alba Piacenti and Sonia Contera; University of Oxford, United Kingdom

The dynamic shapes of biologial tissues emerge from a complex interplay of physics, chemistry and genetics, which determines--at each temporal and spatial scale--the mechanical properties that eventually form the structures of living organisms. Shape and mechanical stability of living organisms rely on precise control in time and space of growth, which is achieved by dynamically tuning the mechanical (viscous and elastic) properties of their hierarchically built structures from the nanometer up.
It is now well-established that cellular behaviour (including stem cell differentiation) crucially depends on the mechanical properties of the cells' environment. Much attention has been directed towards the importance of the *stiffness* of the natural (extracellular matrix, ECM) or artificial matrices where cells grow, with the purpose of either understanding mechanotransduction, or controlling the behaviour of cells in tissue engineering. While stiffness (i.e. the capacity of a material to elastically store mechanical energy) has been the focus of most experimental research, neither cells nor matrices are elastic. Biological systems dissipate energy (i.e. they are viscous) and hence they do not respond to mechanical

deformations instantaneously (like an ideal Hookean spring), but present different time responses at different spatial scales that characterise their responses to external stimuli.
Measuring viscoelasticity (especially at the nanoscale) has remained experimentally challenging [1,2]. In my talk I will present atomic force microscopy (AFM)-based techniques to measure and map the viscoelasticity of living tissues, cells, membranes, collagen, ECMs, and tissue engineering matrices across the spatial and temporal (from Hz to 100s of kHz) scales, and chirp-based spectroscopic techniques to assess viscoelasticity from Hz to 100s kHz at the nano and micro scale developed in my lab. I will also present tests for assessing which viscoelasic model better fits the experimental AFM results. Our results have uncovered that extracellular matrices of both living plants and tumours present an almost perfect linear viscoelastic behaviour that is key to understand their growth and shape. I will present our work showing how the growth and shape of the roots, leaves and hypocotyl of living Arabidopsis thaliana living plants are related to the nanoscale viscoelasticity of plant cell walls at the time scales probed by multifrequency AFM.

Thermal Scanning Probe Lithography and Å-Indentation for Manipulating and Characterizing 2D Materials Elisa Riedo, Francesco Lavini, Filippo Cellini, Xiaorui Zheng, Annalisa Calò, Tengfei Cao, Edoardo Albisetti and Xiangyu Liu; New York University, United States

The ability to characterize and manipulate materials down to the atomic scale for tuning their mechanical and physical properties is the cornerstone of material science. Two-dimensional (2D) materials in particular are getting large attention because their extremely thin size gives rise to unique and groundbreaking properties.
Here we explore two different research topics. On one side we show how heat delivered by a scanning probe can be used for manipulating the electrical properties of 2D materials, and on the other side we present a recent scanning probe microscopy method to perform Å indentation experiments in supported 2D materials.
Among various novel materials, two-dimensional molybdenum disulfide (MoS_2) is of particular interest due to its large band gap, low dielectric constant, and heavy carrier effective mass. Currently, a key issue in creating high performing field-effect transistors (FETs) based on MoS_2 and other transition metal dichalcogenides (TMDC) films is the poor quality of the metal contacts fabricated on these atomic layers, and the difficulty to pattern dopants. Here, we report a strategy based on thermal scanning lithography (tSPL) to fabricate metal contacts on 2D materials with high reproducibility [1], and we demonstrate the integration of tSPL with a flow-through reactive gas cell to achieve nanoscale control of dopants in monolayer MoS_2 [2]. The tSPL produced defects can present either p- or n-type doping on demand, depending on the used gasses, allowing the realization of field effect transistors, and p-n junctions with precise sub-μm spatial control, and a rectification ratio of over 10^4. Doping and defects formation are elucidated by means of X-Ray photoelectron spectroscopy, scanning transmission electron microscopy, and density functional theory. We find that p-type doping in HCl/H_2O atmosphere is related to the rearrangement of sulfur atoms, and the formation of protruding covalent S-S bonds on the surface. Alternatively, local heating MoS_2 in N_2 produces n-character.
Moreover, we report on the elastic properties of supported 2D graphene and h-BN films by the use of modulated Å-Indentation, a novel scanning probe microscopy (SPM)-based technique capable of achieving sub-Å indentation depths during force-indentation measurements [3, 4]. By using extremely small amplitude oscillations (<<1 Å) at high frequency, we show how Å-Indentation enables non-destructive local accurate measurements of the contact stiffness and out-of-plane elastic moduli of ultra-thin ultra-stiff films, including CVD diamond films (thus even up to TPa range stiffness), as well as the transverse moduli of supported graphene and h-BN (<1 nm thickness) films. Å-Indentation thus obtains *in-situ* elasticity measurement combining superior resolution and indentation depths as small as 0.3 Å with AFM nanoscale topographical imaging. Thanks to this technique, we experimentally demonstrate that at room temperature and under localized indentation pressure, a single layer of graphene on top of a carbon interface layer (buffer layer), on SiC, exhibits a transverse stiffness superior to bulk diamond [3]. Extending the capabilities of the Å-indentation technique to the analysis of other 2D materials, these studies explore similar pressure-induced phase transition in hexagonal boron nitride (h-BN). We demonstrate that 2-layer h-BN flakes, on SiO_2, consistently exhibit a transverse elastic modulus almost two times larger than that of the bare substrate. This stiffening effect is observed only for flakes of thickness between 2 to 5 atomic layers, but not in single- nor multilayer (> 6-layer) h-BN, and is related to the conversion of h-BN to cubic BN (c-BN) induced by the pressure applied through the indenter.

Paddled Cantilever for AFM Beyond Topography Hanna Cho; The Ohio State University, United States

Atomic Force Microscopy (AFM) is one of the most powerful and versatile tools to image and characterize materials with nanometer scale resolution, leading to the development of nano-/bio- science and technology. While AFM technology has advanced significantly by expanding its functionality beyond a nanoscale imaging tool, the majority of AFM users still find it difficult to employ the advanced techniques and interpret the data correctly due to artifacts. Such difficulties mainly originate from the complex dynamics of the AFM probe system, used as a mechanical transducer to deliver the tip-sample interaction force.

We address this issue by altering the AFM cantilever design. The current state of the art AFM probe is a single-body system, in the shape of a rectangular or triangular beam, which is not ideal for carrying more than one type of information. In contrast, the new AFM probe, so-called paddled cantilever, is reshaped to have a two-field microcantilever design with a considerable dimensional discrepancy in the component part. By doing so, this mechanical transducer provides two discrete transduction channels such that they respond independently to the variations in surface topography and material properties/functionality. Thus, AFM users can effortlessly implement the advanced AFM schemes with minimal ambiguity, complications, and artifacts, by simply employing this new AFM probe.

Since the prototype device of paddled cantilever was first introduced, our team has taken effort to develop a batch fabrication process and, thus, have this advanced technology widely available for AFM users. The detailed dynamics of fabricated paddled cantilevers have been investigated by using the interferometric displacement sensor (IDS) with AFM to directly measure their deflection. The measured deflection along the whole cantilever revealed that the frequency of inner-paddle is not affected by the tip stiffness while its amplitude is proportional to the displacement input delivered through the tip. This is the basis how the paddled cantilever can provide two discrete transduction channels for functional AFM. A theoretical model based on a 2 degree-of-freedom system is also presented to understand the dynamic characteristics of paddled cantilever under various operational conditions. Because the design of paddled cantilever is simple to feasibly integrate into, and compatible with, current AFM probes and systems, this technology will easily extend the AFM functionality to characterize multi-physical properties beyond topography by providing a dual-channel mechanical transducer.

5:45 AM F.MT02.03.04
Detection of Defects in the Molecular Coating on Nanoparticles Using AFM Ringing Mode Nadia Makarova[1], Maxim Dokukin[1,2,3] and Igor Sokolov[1,1,1]; [1]Tufts University, United States; [2]NanoScience solutions Inc, United States; [3]Sarov Physics and Technology Institute, Russian Federation

A novel mode of AFM, FT-NanoDMA (Fourier transform dynamical mechanical analyzer), can be used to obtain information on the viscoelastic properties of individual cells. Compared to the recently introduced AFM-NanoDMA, FT-NanoDMA allows obtaining storage and loss modulus of multiple frequencies simultaneously. Also, the FT-NanoDMA design allows measuring the mechanics of biological cells, both fixed and alive, directly in a culture dish. Although it was demonstrated on the example of plant cells, the thick wall of those cells did not allow to resolve any features of the cell structure.
Here we demonstrate the ability of FT-NanoDMA to obtain high-resolution information on the viscoelastic properties of individual eukaryotic cells, which express a highly diverse distribution of its mechanical properties. Zebrafish melanoma cells and human osteoblast cells were studied. The storage, loss modulus and loss angle (the phase difference between the sample oscillation and the response of AFM cantilever) were simultaneously recorded for 9 different frequencies of oscillation ranging between 15 to 300 Hz. The obtained maps can be compared with a fluorescent optical image of the same cells. The results are discussed and different ways of visualizing these multidimensional data presented.

5:55 AM F.MT02.03.05
Multidimensional Viscoelastic Tomography of Eukaryotic Cells with AFM FT-NanoDMA Mode Nadia Makarova[1], Maxim Dokukin[1,2,3] and Igor Sokolov[1]; [1]Tufts University, United States; [2]National Research Nuclear University MEPhI, Russian Federation; [3]NanoScience solutions Inc., United States

A novel mode of AFM, FT-NanoDMA (Fourier transform dynamical mechanical analyzer), can be used to obtain information on the viscoelastic properties of individual cells. Compared to the recently introduced AFM-NanoDMA, FT-NanoDMA allows obtaining storage and loss modulus of multiple frequencies simultaneously. Also, the FT-NanoDMA design allows measuring the mechanics of biological cells, both fixed and alive, directly in a culture dish. Although it was demonstrated on the example of plant cells, the thick wall of those cells didn't allow to resolve any features of the cell structure.
Here we demonstrate the ability of FT-NanoDMA to obtain high-resolution information on the viscoelastic properties of individual eukaryotic cells, which express a highly diverse distribution of its mechanical properties. Zebrafish melanoma cells and human osteoblast cells were studied. The storage, loss modulus and loss angle (the phase difference between the sample oscillation and the response of AFM cantilever) were simultaneously recorded for 9 different frequencies of oscillation ranging between 15 to 300 Hz. The obtained maps can be compared with a fluorescent optical image of the same cells. Using different load forces, we can probe mechanical properties at different indentation depth. This can bring a possibility to present a sort of tomography of cell mechanics. The excessive amount of data raises the problem of data visualization. The results are discussed and different ways of visualizing these multidimensional data are presented.

Mapping Nanomechanical Properties of Proteins and Polymers with Bimodal AFM Simone Benaglia and Ricardo Garcia; Instituto de Cienca de Materiales de Madrid, Spain

Fast, high-resolution mapping of the viscoelastic properties of soft matters, represents a major goal of atomic force microscopy (AFM) [1]. Bimodal AM-FM AFM is a suitable method for this purpose, since it allows the simultaneous acquisition of nanomechanical properties without losing in resolution and acquisition speed. This multifrequency configuration combines the robustness and simplicity of an amplitude modulation (AM) feedback in the first mode, with the sensitivity and a high signal-to-noise ratio of a frequency modulation (FM) feedback in the second mode. Finally, through the use of the appropriate contact mechanics model, it is possible to determine elastic and viscous properties of the analyzed sample [2].
Here we show how bimodal AM-FM is applied to extract the elastic properties of soft samples, such as proteins and polymers. Specifically, we characterize the elastic properties of a single protein in liquid, the 20S proteasome which in living organism plays a proteolytic role [3], and the elastic properties of a poly(styrene-block-methylmethacrylate) (PS-b-PMMA) copolymer sample [4].

Physiologically Relevant Mechanics of Biodegradable Polyester Nanoparticles Using AFM Nourin Alsharif, Behnaz Eshaghi, Bjoern Reinhard and Keith A. Brown; Boston University, United States

Despite the extensive use of biodegradable polyester nanoparticles for drug delivery, there is a lack of systematic studies that report the mechanics of these nanoparticles at physiologically relevant conditions. Given that nanoparticle mechanics have been reported to strongly influence nano-bio interactions, the accurate characterization of polymer nanoparticles is critical to understanding their behavior *in vivo*. Here, we use indentation experiments on poly(lactic acid) (PLA) and poly(lactide-co-glycolide) (PLGA) nanoparticles using atomic force microscopy (AFM) to identify their mechanical properties at different temperatures in both air and in water. While the particles are rigid at room temperature under dry conditions, their stiffness decreases by as much as 50 fold under physiological conditions (i.e. in water at 37 °C). Differential scanning calorimetry (DSC) confirms that this decrease in stiffness upon heating and immersion in water can be attributed to the phase transition of the nanoparticles from the glassy state to the rubbery state. This combination of AFM and DSC characterization allows us to determine the plasticizing effects of nanoscale size, polymer molecular weight, and immersion in water. Specifically, PLA and PLGA nanoparticles under 50 kDa molecular weight were found to exhibit glass transition temperatures below 37 °C in water, indicating that these biomedically-relevant nanoparticles will be rubbery in biological environments. Lastly, we investigate indentation experiments at elevated temperatures in air and find that insufficient AFM probe heating complicates the determination of nanoparticle temperature, thus preventing accurate recapitulation of the transition behavior for the nanoparticles. The artifacts observed while measuring particle mechanics in air further motivates nanoparticle mechanical characterization in water. Collectively, these experiments provide insight for experimentalists exploring the relationship between polymer nanoparticle mechanics and *in vivo* behavior, namely that thermoanalytical characterization can distinguish

whether the physiologically-relevant mechanical properties can be accurately estimated using bulk material characterization and help identify processes necessary for direct characterization of polymer nanoparticles.

6:25 AM F.MT02.03.10
Multiscale Characterization of Silk Nanofibrils—From Assembly Dynamics to Nanomechanics Hui Sun and Benedetto Marelli; Massachusetts Institute of Technology, United States

Naturally occurring biopolymers are promising building blocks for a new generation of multifunctional materials that can work at the biotic-abiotic interface and better interact with the environment. Particularly, silk fibroin – a structural protein extracted from *Bombyx mori* silkworm cocoons, has attracted a lot of attention in the recent decades due to the potential use as technical material in a broad range of applications, encompassing drug delivery, regenerative medicine, food coating, printable sensors and optoelectronics etc. As more manufacturing methodologies with silk fibroin are being developed, a key question yet to be answered is how to endow silk fibroin-based bulk materials with complex nanoscale features. Unlike most of the current nanofabrication strategies that mainly focused on manipulation of nanostructures from the top-down perspective, we choose to approach this question by designing specific folding and assembly pathways of silk fibroin that result in highly ordered β-sheeted nanofibrils. Atomic force microscopy (AFM) in combination with a set of correlative optical, spectroscopy and X-ray scattering techniques are employed to probe the detailed mechanism of nanofibrils formation, from the driving forces for disorder-to-order transition to sequence-structure-property relationships across scales. In particular, high resolution nanomechanical data of silk fibroin at single fibril level in both dried and hydrated states are acquired by using AFM-based bimodal force microscopy and fast force mapping. Factors including silk fibroin molecular weight and crystallinity are found to directly correlate with the nanomechanical properties.

Probing Elastic and Viscoelastic Properties at Solid-Solid Interfaces Across Time and Temperature Bede Pittenger, Sergey Osechinskiy, John Thornton, Sophie Loire and Thomas Mueller; Bruker, United States

The mechanical response of heterogeneous samples like polymer composites and thin films is controlled by the properties of the microstructure of the material. Since confinement effects and interphase formation can alter properties of the microphases, measurements on these samples must be localized at the nanometer scale to provide the needed property distribution. Mechanical properties of polymers are generally time dependent, so a full understanding requires measurements over a range of frequencies and temperatures as is provided (for bulk samples) by techniques such as dynamic mechanical analysis (DMA).
Atomic Force Microscopy (AFM) has the resolution and mechanical sensitivity to provide the needed local mechanical property information. However, previous AFM measurements of viscoelastic properties have suffered from some significant drawbacks. Contact resonance [1], for example, provides mechanical property maps at known frequencies, but the cantilever resonances are many orders of magnitude higher than DMA, making comparisons indirect at best. Intermittent contact methods like TappingMode [2], force volume, and PeakForce Tapping [3] face challenges in calculating intrinsic mechanical properties like storage and loss modulus (or tan delta) at well-defined frequencies due to the non-linear process of making and breaking contact.
A new mode called AFM-nDMA provides viscoelastic results which can be directly compared with bulk DMA. It provides spectra of storage and loss modulus across frequency and temperature allowing construction of master curves through Time Temperature Superposition [4]. These measurements are localized by the probe-sample contact, allowing observations to be co-located with high-resolution AFM imaging modes. This presentation will apply AFM-nDMA to investigate the mechanical properties of heterogeneous polymeric samples near interfaces between components and within microscopic domains. Time (and temperature) dependence of these properties will also be examined.

Topographic Lithography and Tomography with Atomic Force Microscopy Will Linthicum, Jingfeng Song, Thomas Moran and Bryan D. Huey; University of Connecticut, United States

Tomographic Atomic Force Microscopy (AFM) uniquely enables volumetric mapping of nanoscale materials properties such as ferroelectricity, conductivity or photoconductivity. Based on alternating imaging and milling with the AFM probe itself,

this approach is effective for surface planarization to diminish topographic artifacts. It can also be extended for more complex surface patterning, such as fabricating smooth or stepped gradients in the remaining material thickness. Accordingly, the milling efficiency and conditions are compared for epitaxial monolithic thin films, multilayers, and polycrystalline samples, with the results demonstrating a coupling to bulk mechanical properties and also grain boundary energies. Such insight is beneficial to optimizing future AFM-based shape-engineered surfaces, which are valuable for follow-on investigations of thickness dependencies, subsurface structures, and other volumetric inhomogeneities.

Conductive Colloidal Scanning Probe Microscopy Christine Kranz and Sven Daboss; Ulm University, Germany

Scanning electrochemical probe microscopy (SEPM) techniques such as scanning electrochemical microscopy (SECM) and in particular the hybrid techniques such as atomic force microscopy combined with scanning electrochemical microscopy (AFM-SECM) enable high resolution topographical imaging along with electrochemical information [1] but also electrochemical force spectroscopic measurements [2]. Recently, we introduced a new type of electrochemical scanning probe tip for combined AFM-SECM measurements providing instead of a conventional AFM tip, a conductive colloidal sphere attached to an otherwise insulated cantilever [3]. Such conductive spherical probes may consist of boron-doped diamond [4], a highly attractive electrode material, or may be electrochemically modified, e.g., functional polymers, suitable for force spectroscopic measurements such as adhesion measurements under potential control.
In this contribution, we present AFM-SECM measurements and electrochemical force spectroscopy using conductive colloidal AFM probes. Due to the spherical geometry and the low spring constant of the cantilever, these probes are highly suitable for mapping nanomechanical properties at soft samples, i.e. bacterial cells. Colloidal probes with BDD as spherical electrode can be used for various SPM experiments including conductive AFM given the physical and electrochemical inertness of BDD, for force spectroscopy under potential control providing information on electrified interfaces, and for AFM-SECM measurements. Notably, all these experiments can be performed with the same BDD-AFM-SECM probe. Colloidal probes can be modified with polymers i.e. polydopamine, which properties may be altered by applying potential to the spherical electrode. Single cell force spectroscopy on bacterial adhesion along with studies at electrified interfaces will be presented.

Controlled Manipulation of Benzene Radicals Across Different Energy Landscapes Omur E. Dagdeviren[1], Chao Zhou[1], Milica Todorovic[2], Eric Altman[1] and Udo Schwarz[1]; [1]Yale University, United States; [2]Aalto University, Finland

The manipulation of single molecules has become possible with the continued development of scanning probe microscopy techniques. Thereby, the manipulation path can be chosen at will, and energy barriers between potential minima on that pathway can be quantified, as can the energy landscape around the molecule before and after manipulation. To explore the practicality of this novel pathway to catalysis research, we selected iodobenzene molecules on a Cu (100) surface as a model system. To this end, we first break the iodine atom from the benzene ring by applying a controlled bias voltage. A specific manipulation path is chosen and then the tip is moved at constant but continuously reduced heights while recording the oscillation amplitude A and phase phi with the microscope operated in our recently developed tuned-oscillator (TO) detection scheme [1]. To preserve the accuracy of the recovered tip-sample interaction potentials and forces, we use oscillation amplitudes significantly larger than the decay length of the tip-sample interaction potential [2,3]. We then manipulated the benzene radical away from the iodine atom and measured the required energy barrier. With increasing distance from the iodine atom, the energy barrier required to move benzene radical decreases. Our experiments are disclosing the effect of local surface chemistry on controlled manipulation of molecules.For further insight, we also compared with computational results obtained using a Bayesian Optimization Structure Search (BOSS) protocol [4], a machine learning technique developed at

Aalto University that delivers the minimum energy pathways and entire energy landscapes with minimal computational effort.

5:25 AM F.MT02.04.03
Characteristics of Charged Ferroelectric Domain Walls Under Alternating Voltages Frequencies Jan Schultheiß[1], Erik Lysne[1], Jakob Schaab[2], Edith Bourret[3], Zewu Yan[2,3], Lukas Puntigam[4], Stephan Krohns[4], Donald M. Evans[1] and Dennis Meier[1]; [1]NTNU Norwegian University of Science and Technology, Norway; [2]ETH Zurich, Switzerland; [3]Lawrence Berkeley National Laboratory, United States; [4]University of Augsburg, Germany

Ferroelectric domain walls are naturally occurring interfaces, separating regions with different orientation of the spontaneous polarization. The domain walls can have fundamentally different electronic properties than the surrounding domains. It is now established that the walls exhibit unusual electronic conduction under direct voltages (d.c.) and distinct vibrational modes under alternating voltages (a.c.) in the microwave regime. In contrast, very little is known about their behavior at low a.c. frequencies, where the walls respond adiabatically.
Here, we map the response of charged ferroelectric domain walls in the adiabatic regime under a.c. voltages in the kilo- and megahertz range. In our model material, $ErMnO_3$, a.c.-cAFM conduction contrasts drop at significantly different frequencies for different types of domain walls. The characteristic frequencies at which the domain wall contrast vanishes is determined by the local polarization configuration of the adjacent domains. Extending the research on electronic transport mechanisms into the a.c. regime is an important step towards a better understand of the unusual conduction at ferroelectric domain walls and the future development of domain wall based nanoelectronic devices, such as filters, phase shifters, or tunable capacitors.

5:35 AM F.MT02.04.05
Tomographic Piezoresponse Force Microscopy for 3D Vizualization and Analysis of Superlattice Dielectrics and Multiferroics Thomas Moran[1], Jingfeng Song[1], Will Linthicum[1], Keigo Suzuki[2], Tadasu Hosokura[2], Koji Murayama[2], Erik Roede[3], Dennis Meier[3] and Bryan D. Huey[1]; [1]University of Connecticut, United States; [2]Murata Manufacturing Co., Ltd., Japan; [3]Norwegian University of Science and Technology, Norway

Tomographic AFM (TAFM) extends atomic force microscopy beyond the measurement of surface properties and into the realm of three-dimensional analysis. For certain materials, the AFM tip can be used as a both a probe and a milling tool, measuring properties such as current or piezoresponse while simultaneously removing material from the surface. Instead of thousands of 2-D pixels, this yields datasets with millions of 3-D voxels, but all still with nanoscale resolution. The resulting tomographic reconstructions enable unprecedented visualization and analysis of heterogeneous materials, particularly those with isolated or networked sub-surface features, surface coatings, or vertical property gradients. This is especially applicable for 3-D mapping of thickness-dependent properties in functional materials including ferroelectric domain structures and interconnected conduction pathways. Examples are highlighted for both BTO/STO superlattices with multilayer chip capacitor applications, and also ferroelectric domain wall-based nanoelectronic devices such as single crystal $ErMnO_3$.

5:45 AM F.MT02.04.06
Identifying Ferroelectric Polarization Switching in Ultra-Thin HZO Film with Scanning Capacitance Microscopy and Interferometric Piezo Force Microscopy Haigang Zhang[1], Keith Jones[1], Ryan Wagner[1], Suraj Cheema[2] and Roger Proksch[1]; [1]Asylum Research, Oxford Instruments, United States; [2]University of California, Berkeley, United States

Ferroelectric thin films epitaxially grown on silicon have attracted great interest for their potential application in energy-efficient electronics for their controllable ferroelectric polarization switching. As ferroelectric materials are made thinner, however, the ferroelectricity is usually suppressed, especially in the archetypal ferroelectric perovskite systems have so far proved unsuitable for thickness scaling and integration with modern semiconductor processes. Recently, Zr-doped HfO_2 grown by atomic layer deposition on silicon has been to be an exciting thin film ferroelectric material that is compatible with conventional Si processing[1, 2] However, such switching is not be easily demonstrated by conventional bulk-based characterization techniques due to the current leakage involved with such ultrathin films. Even though the conventional

scanning probe microscopy-based PFM has unique advantages in terms of nanoscale spatial resolution and ease of use, but is subject to crosstalk associated with long-range cantilever-sample electrostatic interactions which can be mistaken for localized piezoelectricity. We have developed and implemented an interferometric displacement sensor (IDS) that mitigates this problem.[3, 4] In addition, we have developed a new, high-sensitivity scanning capacitance microscopy (SCM) module. Recently, we have used these new approaches to study ferroelectricity in ultra-thin HZO films (1 nm).[2] We will discuss SCM and IDS butterfly loops that provide unambiguous evidence of localized ferroelectric behavior. Most importantly, both techniques eliminate the commonly observed artifacts thus provide conclusive evidence of polarization switching in this technologically relevant ultra-thin ferroelectric film grown on silicon.

Amplitude and Frequency Analysis for Open-Loop Sideband Frequency-Modulation Kelvin Probe Force Microscopy Gheorghe Stan; National Institute of Standards and Technology, United States

In the last years new open-loop (OL) Kelvin probe force microscopy (KPFM) modes [1] were introduced to facilitate a faster and more accurate surface potential characterization at the nanoscale. Based on high-speed data capture, the OL KPFM modes observe the tip-sample electrostatic interaction in the time domain, which potentially can increase the temporal resolution by few orders of magnitude in comparison to common closed-loop (CL) KPFM implementations that rely on frequency domain detection [1, 2]. In this work, the high-speed digitization for open-loop sideband frequency-modulation (FM) KPFM is presented in terms of amplitude and frequency responses of the cantilever. In both cases, the tip-sample contact potential difference (CPD) is extracted from the time series analysis of the signals. This interpretation is demonstrated to be superior to the more common used analysis of the parabolic bias dependence of the OL KPFM signals. The OL sideband FM-KPFM amplitude and frequency responses were compared side-by-side to their CL AM-KPFM and CL FM-KPFM counterparts on materials of different surface potentials and subjected to various bias voltages. Notably, the OL sideband FM-KPFM frequency retains the tip-confinement sensitivity that is characteristic to the FM-KPFM based modes while the OL sideband FM-KPFM amplitude suffers from cantilever stray capacitive couplings much in the same way as the common CL AM-KPFM mode [3].

6:05 AM F.MT02.04.08
Late News: Photo-Sensitive Kelvin Probe Force Microscopy for Embedded Silicon-Oxide Interface Characterization Valentin Aubriet[1,2,3], Benjamin Grevin[4], Kristell Courouble[2], Mickael Gros-Jean[2] and Lukasz Borowik[1]; [1]CEA-LETI, France; [2]STMicroelectronics, France; [3]LTM (CEA-LETI/Minatec), France; [4]Univ. Grenoble Alpes, CNRS, CEA, INAC, SYMNES, France

Interfaces characterization is crucial for several types of devices like light emitting diodes, solar cells, photodetectors or transistors. In the particular case of photodetectors it is important to characterize such interfaces to see the impact of passivation, where defects present at the interfaces impact the dark current of the device. Moreover, such parameters like surface photovoltage (SPV) or carrier lifetime can reflect the influence of defects, even when embedded [L Borowik et al, Nanotech. (2010)].
For this particular purpose, we use heterodyne Kelvin Probe Force Microscopy (h-KPFM) [Yasuhiro Sugawara et al, Appl. Phys. Lett. (2012)] under illumination to characterize the silicon interfaces embedded under different types of oxides, specifically Al_2O_3, Al_2O_3/Ta_2O_5, HfO_2, SiN, SiO_2. In addition, we adopt a pump probe approach [Murawski, J. et al, J. Appl. Phys. (2015)] in order to time-resolve the photovoltage (tr-SPV). Besides of the capability to measure SPV, tr-SPV and charge carrier dynamics, the particularity of this setup is the analysis of these parameters as function of different illumination wavelengths and the possibility to perform in-depth dependent measurements.
In this work, we will present the developed experimental method using h-KPFM under frequency modulated and wavelength

dependent illumination in order to probe interfacial physical processes (i.e. the charge carrier dynamics and the influence of interface on surface photovoltage). Furthermore, we will correlate the h-KPFM results with additional interfacial characterization procedures (Corona Oxide Characterization Of Semiconductor method) [Marshall Wilson et al, AIP Conference Proceedings (2001)]. Finally, we will demonstrate the interest of a time-resolved approach (i.e. pump probe h-KPFM) for the characterization of embedded interfaces.

6:15 AM F.MT02.04.09
Electrical Characterization of Phase Change Random Access Memory (GST) by C-AFM in Ultra-High Vacuum Mariem Ben Youssef[1,2], Serge Blonkowski[2], Olga Cueto[2], Chiara Sabbione[2] and Martin Kogelschatz[3,1,2]; [1]LTM-CNRS, France; [2]CEA-LETI, France; [3]Université Grenoble Alpes, France

Ge_2 Sb_2 Te_5 (GST-225) is one of the most promising materials for use in phase change memory devices, which presents good scalability and high endurance. The operation of the PCM devices consists in switching between a high conductive (On) state and a low conductive (Off) state, which correspond respectively to the crystalline and amorphous phase. The switching from the OFF to the ON state (Set) is obtained by applying voltage pulses that heat the GST-225 material by Joule effet, leading to its crystallization. The switching from the ON state to the OFF state (Reset) is obtained by applying shorter pulses with higher voltages in order to quench the GST-225 and obtain the amorphous phase. For resistive memory cells the current necessary to obtain the phase change is in the order of serveral hundred of microamperes.
Conductive AFM (C-AFM) is widely used for the characterization of the electrical properties of materials at the nanometer scale. It allows in principle to obtain electrical information at nanometric scale while avoiding expensive lithographic processes. At present, the cyclability of writing and erasing process with C-AFM is limited by various pratical factors, namely the high oxidation of the GST-225 in ambient conditions and the current limitation due to the tip degradation. For those reasons, successive Set and Reset steps were not observable, until now, on unpatterned samples by C-AFM. Those limitations can be overcome by using ultra-high vaccum in order to protect the GST-225 against oxidation and utilization of full diamond tips that resist to high current conditions.
In this work, we studied the electrical characteristics of phase change materials at nanometric scale by C-AFM under Ultra High Vaccum in pulse mode. We show that the used experimental configuration allows to cycle unpatterned GST-225 layers between the set and the reset state. We measured the resistive switching characteristics of GST-225 and reached 50 cycles. The experimental results will be compared to temperature and resulting crystalline fraction obtained by finite element simulation.

Nanoscale Ion Transport Dynamics—From Conjugated Polymers to Halide Perovskites Solar Cells David S. Ginger[1,2]; [1]University of Washington, United States; [2]Pacific Northwest National Laboratory, United States

Imaging ion transport in nanostructure materials has applications in systems from neuromorphic computing, to electrochemical energy storage, and solar cells. We utilize multimodal imaging to probe transport phenomena in these systems. For instance, by combining nanoscale vibrational spectroscopy with structural imaging we can correlated local anion diffusion with structural phase transitions in conjugated polymer films being explored for neuromorphic computing and bioelectronics applications. We also combine similar IR imaging with time-resolved electrostatic force microscopy (trEFM) to uncover the dynamics of ion transport in various 3D and 2D halide perovskites of interest for applications in optoelectronics, especially solar cells, where ion transport can be a primary contributor to device aging and failure. This work bridges advances in scanning probe microscopy with tools from data science to better understand materials design rules for new applications.

5:15 AM F.MT02.05.03
Correlative Imaging of the Local Optoelectronic Properties within Single and Multijunction Halide Perovskite Solar Cells Elizabeth Tennyson[1], Kyle Frohna[1], William Drake[1], Florent Sahli[2], Quentin Jeangros[2], Christophe Ballif[2] and Samuel D. Stranks[1,1]; [1]University of Cambridge, United Kingdom; [2]École Polytechnique Fédérale de Lausanne, Photovoltaics and Thin-Film Electronics Laboratory, Switzerland

The functional properties of halide perovskite semiconductors at the micro and nanoscales are heterogeneous,[1] and there is a pressing need to understand how these properties (electrical, chemical, etc.) influence one another and affect overall photovoltaic (PV) performance. In this presentation, we begin by showing a variety of correlative microscopy methods that have been applied to perovskite solar cells to investigate the local electrical, chemical, and optical properties of single-junction devices.[2–4] For this, Kelvin probe force microscopy, nano-IR imaging, time-of-flight secondary ion mass spectroscopy depth profiling among other characterization techniques were implemented. These results reveal that the perovskite's (i) nanoscale voltage response depends on its chemical composition (ii) charge carrier dynamics depend on the incident photon energy (i.e. wavelength), and (iii) altered chemical properties due to the inclusion of potassium additives impact the electrical response in three dimensions.

Beyond single-junction perovskite PV, and a promising real-world application for this material class, is the multi-junction perovskite/c-Si solar cell. Not only are perovskites complex on their own, but when embedded within a textured heterojunction, the interactions between device architecture and material performance introduces new challenges. Commercial c-Si solar cells are etched to form micro-scale, randomly distributed pyramids on their front side, complicating the growth of the perovskite top cell. It is not well understood how the local light-matter interactions of the perovskite material behave when incorporated into this type of multijunction architecture. Therefore, we present optoelectronic microscopy measurements correlated with optical simulations of perovskite on textured c-Si solar cells. Through wide-field, hyperspectral photoluminescence (PL) imaging, we measure the photon out-coupling of the perovskite material and find both a spectral and spatial dependence on the geometrical patterning which dominates any grain-to-grain variation that is typically found in perovskite PL measurements.[5] Such heterogeneity reveals the importance of the underlying c-Si texture design, suggesting that tuning the surface morphology could lead to a homogenization of the perovskite's PL emission, which may boost the multi-junction solar cell efficiency.

Scanning Probe Studies of Transition Metal Perovskite Chalcogenides Under Illumination Marudachalam Shanmugasundaram[1], Boyang Zhao[2], Fei Hou[3], Shanyuan Niu[4], Jan Seidel[3] and Jayakanth Ravichandran[2]; [1]HORIBA Instruments Inc, United States; [2]University of Southern California, United States; [3]University of New South Wales, Australia; [4]Stanford University, United States

The design, synthesis, and characterization of new semiconductor materials are important for the growth of electronics and energy solutions such as solar cells and fuel cells. Perovskite materials in particular are being investigated due to their compositional flexibility resulting from a wide range of stoichiometry in their design in contrast to conventional materials like silicon, thereby leading to a wide variety of optoelectronic properties. Some perovskites such as organic-inorganic lead halide perovskites and perovskite oxides are well-known for their power conversion efficiency and for their potential catalytic applications respectively. However, their respective toxicity / instability issues and the large energy gaps (>3 eV) pose serious challenges for their practical optoelectronic applications. Recently, transitional metal perovskite chalcogenides have emerged as a viable semiconductor that can address these issues (stability, abundance, toxicity, cost, and performance) as high performance photovoltaic materials, but a detailed understanding of their electronic and optical properties remains a key open question.
Here, we report the Scanning Probe Microscopy studies on the surfaces of single crystals of transition metal perovskite chalcogenides such as barium zirconium sulfide ($BaZrS_3$, $Ba_3Zr_2S_7$) using Kelvin Probe Force Microscopy (KPFM), and Raman and photoluminescence spectroscopy. Besides nominally undoped crystals, we also studied transitional metal doped

(Cr doping on Zr sites). While the nominally undoped $BaZrS_3$ has a bandgap of 1.8 eV, it shows strong photoluminescence at ~1.25 eV when a dopant such as chromium is introduced. KPFM was used to map the surface potential as well as electro-mechanical contrast proportional to capacitance. In addition, a precise optical coupling of the Raman microscope with the Scanning Probe Microscope allows surface potential changes to be mapped under dark and illuminated conditions. The surface potential of $Ba_3Zr_2S_7$ and Cr-doped $BaZrS_3$ changes dramatically in a reversible manner with laser illumination, highlighting the strong light-matter interaction and luminescent characteristics. It was found that this behavior is strongly dependent on the wavelength and laser power. The measured contact potential difference values provide indirect information on the evolution of work function during light illumination providing qualitative information on the quasi-Fermi level splitting induced by the photo-excitation. In summary, a unique combination of optical microscopy and scanning probe microscopy instrumentation were used to study optical, electronic, and photovoltaic properties of perovskite chalcogenides to evaluate their suitability for advanced photonic and energy applications.

5:35 AM F.MT02.05.05
Understanding the Chemico-Physical Interactions in Metal Halide Perovskites by Multimodal Imaging Techniques Yongtao Liu[1,2], Anton Ievlev[2], Nikolay Borodinov[2], Liam Collins[2], Stephen Jesse[2], Kai Xiao[2], Mahshid Ahmadi[1], Bin Hu[1], Sergei V. Kalinin[2] and Olga Ovchinnikova[2]; [1]The University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States

Metal halide perovskites (MHPs) have shown promising applications in optoelectronic devices. Further improvement of MHPs devices toward commercialization necessitates a clear understanding of the factors impacting the functionality of MHPs. To date, ionic migration, ferroic behavior, structural distortion are mostly debated mechanisms credited with the functionality of MHPs. Given the interconnected nature of ionic states, ferroic properties, and structural distortion due to the screening effect and the compensation effect, the interactions among these properties can no longer be ignored. Here, in the combination of scanning probe microscopy (SPM) with other chemical and functional imaging techniques, as well as the machine learning approach, we have systematically investigated the ion migration, ferroic behavior, lattice strain, crystallographic orientation, and charge transport in MHPs and discovered a number of interesting phenomena. We have discovered the hysteretic ion migration—including intrinsic compositional ions (e.g. $CH_3NH_3^+$, I^-) and decomposition chemical species (e.g. $CH_3NH_3^+$ decomposition products)—in MHPs based devices by directly detecting ion migration by a newly developed time-resolved time-of-flight secondary ion mass spectrometry (tr-ToF-SIMS). Using time-resolved Kelvin probe force microscopy (tr-KPFM), we revealed how this hysteretic ion migration affects the local charge distribution in MHPs. We for the first time specified the contribution of $CH_3NH_3^+$ and I^- migration to the current-voltage hysteresis in an MHP device. In addition, we found that the $CH_3NH_3^+$ migration is strongly coupled with a local lattice strain change and hence impacts the ferroic behavior of $CH_3NH_3PbI_3$. Confocal photoluminescence microscopy study combining with piezoresponse force microscopy, electron backscatter diffraction, etc. directly unveiled the impact of chemical, strain, and ferroic properties on the charge recombination and transfer in MHPs. Altogether, our work offers a picture describing the interconnection of ionic, structural, ferroic, and optoelectronic properties of MHPs, which is expected to help to enhance the performance and the stability of MHPs-based optoelectronic devices.

SESSION F.MT02.06: SPM in Liquid Environment

Tracking the Dynamics of Liquids and Solutes at Solid Nano-Interfaces Luca Piantanida[1,2], Amir F Payam[1,3], Clodomiro Cafolla[1] and Kislon Voitchovsky[1]; [1]Durham University, United Kingdom; [2]Boise State University, United States; [3]Ulster University, United Kingdom

The molecular organisation and dynamics of liquids near the surface of solids underpins processes such as molecular exchanges, electrochemistry, nanofluidics, biomolecular function and lubrication. Depending on the local topographical and chemical properties of the solid, the behaviour of the interfacing liquid can vary significantly at the nanoscale, with consequences for interfacial processes. Scanning probe microscopies can derive local insights into the equilibrium organisation of interfacial liquids, often with sub-nanometre resolution. However, deriving quantitative information about the local liquid *dynamics* remains a considerable challenge.
Here we review some of our recent results obtained by combining high-resolution atomic force microscopy with highly

localised rheological measurements to deduce quantitative information about the motion of liquids and dissolved molecules along immersed solids. We show that the dynamics is highly system-dependant and can be dominated by either the local configurational entropy or the interface or enthalpic interactions. We also describe a novel approach to quantify the preferred flow direction naturally adopted by liquids near walls, locally and with nanometre precision. The approach, based on AFM, combines a vertically oscillating tip with high frequency lateral oscillations to derive directional information about the interfacial liquid at each point of the system. To illustrate the method's capabilities, we investigate the dynamics of aqueous solutions containing different metal ions along the surface of a graphene oxide flake. We identify ion-specific flow dynamics that can be related to the well-established sieving properties of graphene oxide membranes.

5:15 AM *F.MT02.06.02
Using High-Speed, Molecularly-Resolved AFM and Fast Force Mapping to Investigate Nucleation and Solution Structure at Surfaces James J. De Yoreo[1,2], Benjamin Legg[2,1], Elias Nakouzi[1], Andrew G. Stack[3], Sebastien Kerisit[1], Christopher A. Mundy[1,2], Gregory K. Schenter[1], Jaehun Chun[1] and Kislon Voitchovsky[4]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States; [3]Oak Ridge National Laboratory, United States; [4]Durham University, United Kingdom

Investigating nucleation from solutions is challenging, because it is a consequence of unstable density fluctuations, making the structures and events that must be probed both transient in nature and small in spatial extent. Moreover, when nucleation is heterogeneous, it is inherently linked to the structure and dynamics of the interfacial region between the bulk solution and the underlying substrate. Thus high-speed, molecularly resolved AFM combined with fast force mapping (FFM) provides a powerful and unrivalled combination to investigate nucleation from solution onto surfaces. Here I illustrate the deep level of fundamental insight into mechanisms of nucleation and the structure of the interfacial region made possible with these methods using results from investigations into nucleation of gibbsite ($Al(OH)_3$) on muscovite mica (001) and the structure of electrolyte solutions above mica and boemite (AlOOH) surfaces. In the case of gibbsite nucleation, we combine AFM observations of individual molecular adsorbates, transient clusters, and stable islands with Monte Carlo simulations to put together a coherent picture of surface speciation and nucleation. The results reveal a surface population of ions that is dominated by hydrolyzed species ($Al(OH)_2^+$ and $Al(OH)^{2+}$) even though Al^{3+} vastly dominates the bulk solution. These adsorbed ions evolve into subcritical clusters with increasing saturation state and temperature, constituting a population that decreases exponentially with size and exhibits dynamic fluctuations consistent with classical predictions. However, severe discrepancies with classical theory emerge when the values of key thermodynamic parameters are extracted from the AFM data. These discrepancies are resolved when the impact adsorbate charge on the capacitance of the mica-solution system is taken into account in calculating the work of cluster formation, but reveal a film formation process that occurs within a single phase region. Thus, the results imply that the gibbsite films constitutes a nanostructured 2D mesophase. To define the solution structure above boehmite and mica surfaces at lattice resolution, we developed a self-consistent scheme to decouple long-range tip-sample interactions from short-range solvation forces. In the case of boehmite, the results are benchmarked against molecular dynamics simulations that explicitly include the effects of the tip with different levels of approximation and systematically account for tip size, chemistry, and confinement effects. We find four laterally structured water layers within one nanometer of the surface, with the highest water densities at sites adjacent to hydroxyl groups. The findings reveal a complex relationship between site-specific chemistry, water density, and long-range particle interactions; and represent a major step forward towards quantitative data interpretation and widespread implementation of 3D FFM.

5:30 AM F.MT02.06.03
High-Speed Bimodal AFM Nanomechanical Mapping of Collagen Self-Assembly Victor Gisbert[1], Simone Benaglia[1], Manuel Uhlig[1], Roger Proksch[2] and Ricardo Garcia[1]; [1]Instituto de Ciencia de Materiales de Madrid (ICMM-CSIC), Spain; [2]Oxford Instruments-Asylum Research, United States

Collagen is the most abundant structural protein of the extracellular matrix. The assembly of collagen fibrils play relevant roles in a variety biological processes. The formation fibrils during the self-assembly process of collagen I have been studied by AFM [1,2]. Those studies lacked the time and mechanical properties resolution to clarify the mechanism of the earlier stages of collagen assembly and fibril structure formation. We have developed a high-speed bimodal AFM that combines the *ms* time resolution of high-speed AFM [3] with the nanomechanical force sensitivity of bimodal AFM [4,5]. High-speed bimodal AFM characterizes the earliest stages of the self-assembly of the collagen fibrils by proving time-resolved and high-spatial resolution maps of the evolution of the elasticity of the fibrils during the growth.

Atomic-Scale Mapping of Hydrophobic Layers on MoS2, MoSe2, WS2, WSe2 and Graphene Immersed in Water Manuel R. Uhlig, Daniel Martin-Jimenez and Ricardo Garcia; ICMM CSIC, Spain

Solid-liquid interfaces are highly relevant for a number of phenomena in nature and technology. However, when it comes to hydrophobic surfaces, the structure of water in close proximity to the surface and its role in mediating interactions are not well understood. Two dimensional materials provide a variety of large and atomically flat surfaces that are mildly hydrophobic. We exploited the angstrom resolution capabilities of three-dimensional AFM [1,2] to image the interfacial water organization on MoS2, MoSe2, WS2, WSe2 and graphene.
We demonstrate that these interfaces are characterized by layers of oscillating density within 2 nm above the solid surface (Fig. 1a). The distances between adjacent layers for MoS2, MoSe2, WS2 and WSe2 and graphene are ≈ 0.50 nm (Fig. 1b). This value is larger than the one predicted and measured for water density oscillations (≈ 0.30 nm) [2,3]. The experiments indicate that on 2D material surfaces water molecules are expelled from the vicinity of the surface and replaced by several molecular-size hydrophobic solvation layers.

Closed-Loop Nanopatterning of Fluids with Scanning Probes Verda Saygin, Bowen Xu, Sean Andersson and Keith A. Brown; Boston University, United States

High-throughput screening technologies such as microtiter plates enable chemists and biologists to simultaneously perform thousands of experiments in an automated fashion. While transformatively smaller than the vials used by the prior generation, the typical working volume for microtiter plates is in the range of microliters and there are still far too many compounds to study even with this degree of miniaturization. Scanning probe lithography (SPL) could provide a path to continuing this miniaturization in fluid handling as it encompasses approaches to pattern fluids with volumes at least 10^9 times smaller than what is achievable in microtiter plates. While the patterning of such sub-fL volumes has been demonstrated with various different materials over the years, to achieve controlled and reliable experimentation with SPL, it is crucial to have precise control over the size of features and amount of fluid that is transferred in real time. Here, we enable closed-loop control over the fluid written using SPL by combining a novel process for quantifying the fluid on a cantilever, the utilization of a tipless cantilever architecture, and a control strategy for adjusting writing parameters *in situ*. Specifically, we employ a two harmonic mode inertial sensing algorithm to reliably quantify the amount and location of fluid on the cantilever. Critically, sensing the mass of liquid on the cantilever before and after a fluid transfer event allows us to monitor the deposited amount with precision approaching the fL scale. This capability allows us to investigate the fundamental mechanisms and characteristics of fluid transport at this scale. Taking inspiration from experiments of fluid transfer between macroscopic parallel plates, we find that the fraction of the liquid that is transferred from the cantilever to the substrate is only a function of speed of the cantilever and surface energies of the substrates. Based on this discovery, we show that the amount of fluid that will be transferred can be predicted based on the amount of ink on the cantilever, hence it is possible to control the transferred amount by selecting writing parameters. With this insight in hand, we develop a closed-loop process for writing patterns with designed feature sizes. Given the versatility of scanning probes to characterize fluids once they are written, this work lays the foundation for multifunctional research systems in which chemical experiments are set up, performed, and evaluated at the nanometer scale.

Tip-Scanning AFM with Photothermal Excitation for Stable Operation in Liquid Environments Christian Bippes, Jonathan Admas, Lukas Howald, Simon Fricker, Patrick Frederix and Dominik Ziegler; Nanosurf AG, Switzerland

AFM is a valuable tool for biologists and biophysicists to investigate structure, mechanics, and dynamics of biological

samples from single proteins or DNA molecules through lipid layers, protein matrices and hydrogels to whole cells or cellular assemblies. To preserve the physiological, hydrated state of these entities, most of these experiments are performed in an aqueous environment. Our newest instrument, the P6, is optimized to facilitate both high-resolution and large area measurements in any liquid environment. The fully motorized scan head includes a three-axis flexure-based tip scanner. Its proprietary design features an ultra-low-noise detection system with non-moving light sources. Moreover, the scan head is equipped with photothermal excitation (PTE). This is superior to the common piezo-acoustic excitation as it solely drives the cantilever without moving any other parts of the system, resulting in unparalleled excitation stability, especially in liquid operation. Textbook-like cantilever tuning results in high ease-of-use imaging and enables quantitative understanding of tip-sample interaction forces. The linear frequency response and high bandwidth of PTE enables multifrequency and high-speed applications. The instrument is compatible with any inverted optical microscope allowing for combined investigation of biological samples with AFM and various optical microscopy techniques, such as fluorescence imaging or super resolution imaging techniques. Apart from imaging, PTE also opens up new horizons for measurement modes and analysis techniques. PTE is, for instance, used to measure the mass of living cells at unprecedented time and mass resolution. [2] More advances in PTE-based techniques are to be expected soon.
Here, we show how we could overcome the engineering challenges posed by the different features of the scan head (full motorization, tip scanner and PTE) by employing a new opto-mechanic design. [1] This allowed building a stiff, large-range scanner that, in combination with sophisticated lowest noise-electronics and PTE, allows to routinely achieve high-resolution imaging in aqueous buffer solution, such as revealing the secondary structure of dsDNA.

6:10 AM F.MT02.06.07
Simulating Electrochemical Environments at Metal-Liquid Interface Yuhan Mei and Aaron Deskins; Worcester Polytechnic Institute, United States

Liquid-solid interfaces occur in many systems, such as batteries, catalysts, or in naturally occurring geochemical systems. Surface reactions may be strongly influenced by the presence of a liquid. In heterogenous catalysis, a solvation environment can be crucial in enabling surface certain reactions, such as oxidation reactions or electro catalysis reactions. The presence of the liquid-solid interface can speed up the reactions, increase the selectivity of products and open up new favorable reaction pathways. Therefore, it is important to understand the role of solvent in the liquid-solid interface surface reactions. For electrochemical systems, such as in batteries or electrocatalysts, the electrode potential can also have a significant impact on the chemisorption of molecules at metal surfaces as well as surface reactions. For instance, the electric field can affect the adsorption strength, the adsorption site and the intermolecular vibrational frequencies. Solvent and electrical field effects may both strongly influence surface reactivity. However, modeling efforts often ignore these two phenomena, or may not treat such phenomena appropriately. Methods to better describe electrochemical environments are still being developed and are an ongoing area of research. Herein, we modeled using density functional theory to simulate the ethanol oxidation reactions (EOR). We assessed how both the solvent and electrical fields influence important C-C and C-H bond scission reactions. Different solvation models exist for treating solvation. Implicit solvation models treat the solvent as a continuum and are generally “cheap” in terms of computational time. Explicit solvation models involve modeling the solvent molecules using density functional theory. Such calculations may be more computationally expensive, but in principle more accurate. Hybrid solvation models combine both the implicit and explicit approaches. We evaluated all three solvation models for describing surface chemistry on the Rh(111) surface, which is a typical catalyst for the EOR. Our results show that the reactions involving C-C and C-H scission are favorable in the presence of explicit water molecules due to intermolecular H bonding. However, the influence of hydrogen bond is negligible in the implicit solvation models. Thus, implicit models fail to properly describe solvent effects on ethanol oxidation. Our results do indicate that C-C and C-H bond scission becomes more favored when using a hybrid solvation model. The hybrid solvation model allows an efficient combination of both implicit and explicit solvation approaches. Field effects are also important in that they can have cause the adsorption energies of intermediates to fluctuate depending on the applied potential. The potential also can affect the energy barrier for bond breaking reactions. Our results assess the influence of the applied potential, and how modulating the potential may influence desired reactions. Overall, our work provides valuable insights on the effects of solvation and electric fields on surface chemistry in systems like batteries or electrocatalysts. We highlight a compelling approach to accurately and efficiently modeling electrochemical interfaces.

6:20 AM F.MT02.06.08
Nanoscale Electrochemistry Study Using SECCM Option of Park Systems Jiali Zhang, Byong Kim and Keibock Lee; Park Systems Inc., United States

Scanning electrochemical cell microscopy (SECCM) is a nanoelectrochemical scanning probe technique that creates a confined electrochemical cell (droplet) via meniscus contacting the surface by employing an electrolyte filled micropipette containing quasi-reference counter electrode(QRCE).[1] It is particularly useful to investigate the heterogeneity, or local electrochemical properties of the electrode surfaces by direct mapping the electroactivity with nanoscale resolution.
In this study, the electrochemically reversible $[Ru(NH_3)_6]^{3+/2+}$ electron transfer process at a highly ordered pyrolytic graphite (HOPG) surface was recorded using Park NX12 AFM system. A single barrel glass nanopipette with Ag/AgCl inserted as QRCE was utilized. Using previous successful experience in commercializing pipette-based electrochemical microscopy,[2] Park Systems' hardware and software enables localized nanoscopic cyclic voltammetry measurements conducted at each pixel each time the meniscus contacts the surface. Thus, a spatially resolved surface electroactivity mapping of HOPG at various scan rates were created with high-throughput at the micro-/nanoscale. The difference in electrochemical activity measured at the edge plane relative to the basal plane surface was shown.
This work demonstrates that Park Systems' commercial SECCM option is promising for quantitative electroanalysis at the nanoscale, with potential applications in energy storage (battery) studies and corrosion research.

Measuring Steady-State and Time-Resolved Photoluminescence from a Positionable, Micrometer-Sized Observation Volume Eugeny Ermilov, Volker Buschmann, Christian Oelsner, Frank Birke, Matthias Patting and Rainer Erdmann; PicoQuant GmBh, Germany

Over the years, luminescence spectroscopy has established itself as one of the fundamental methods for analyzing the photophysical properties of a variety of samples, ranging from simple organic molecules, complexes, luminescent proteins to semiconductors. The commonly used steady-state methods (i.e. excitation and emission spectroscopy) provide valuable insights into the photophysics of samples. However, such results give only a partial view of sample behaviors after photoexcitation. A further piece of the puzzle is often revealed by performing time-resolved luminescence spectroscopy. Studying luminescence lifetime data of materials is a very powerful analytical tool for spectroscopists and microscopists alike, as it provides insights into excited state dynamics of molecules, complexes, nanoparticles, or semiconductors. The fluorescence or phosphorescence lifetime is an intrinsic characteristic of luminescent species. It indicates how long species under consideration will remain in electronically excited states before returning to ground state. Each emitting species has a characteristic luminescence lifetime, that can be influenced by its environment.
A series of spectroscopic and microscopic methods based on luminescence lifetime have been developed and provide further information, which are not accessible by steady-state experiments. For example, with fluorescence lifetime imaging microscopy (FLIM), a very well established imaging method in life science, it is possible to gather lifetime information and spatial information as combination of a sample. This combined data can help to understand biochemical or physical processes by detecting changes in local environment such as pH, temperature, or ion concentration, and to identify molecular interactions or conformation changes via Förster Resonance Energy Transfer (FRET).
Time-resolved photoluminescence measurements are powerful tools in materials science also, e.g. for characterization of key parameters like charge carrier dynamics and mobility in semiconductors. Furthermore, combining spectral, spatial and lifetime information often provide a much better understanding of different dynamic processes occurring in luminescent samples.
Here we will demonstrate the performance of a spectrometer-microscope assembly for characterization and analysis of different materials in terms of lifetime, spectral and spatial resolution, as well as ability to measure long luminescence decays (in µs and ms time scales) using laser drivers with burst capabilities. The abilities of this multi-dimensional approach will be demonstrated with a series of examples reflecting a broad range of applications in materials science research.

F.MT02.07.03

Effect of Oxygen on the Electro-Thermal Properties of Gallium Doped ZnO Based Transparent Heater Jasmine Beckford, Makhes K. Behera, Sangram K. Pradhan and Messaoud Bahoura; Norfolk State University, United States

There is growing interest in thin-film transparent heaters (TFTH) for optoelectronics, and a plethora of domestic usages such as smart windows, defrosters in automobiles and other applications. In this work, we present the growth and characterization of TFTH made of gallium doped zinc oxide (GZO). GZO thin films are deposited by pulsed laser deposition (PLD) with a varying range of oxygen (0-10 mTorr) on glass. Ga doped (5 atomic weight percentage) ZnO target was made in the laboratory using $Ga_2O_3$and ZnO powder. GZO is deposited on glass. Atomic force microscopy images reveal that the films are very smooth with excellent surface roughness. The temperature-dependent resistivity was measured using a linear four-probe technique and the sample showed low sheet resistance values. Our TFTH's exhibited high optical transparency value if (>85%) from transmission data. GZO transparency heaters showed a stable and reproducible Joule heating effect and the temperature reached easily 60°C by the application of low input (~8 V) voltage. This research funding may be beneficial for the potential use of GZO as transparent conducting oxide materials for possible applications in the emerging areas of low-cost power electronics, and flexible and wearable optoelectronic devices.

F.MT02.07.04

Visualization of Polarization Fatigue in PZT-5H of Piezoelectric Energy Harvester with Piezoresponse Force Microscopy Seongmun Eom[1], Jeongjae Ryu[1], Jaegyu Kim[1], Seongwoo Cho[1], Jiwon Yeom[1], Eunnuri Cho[1] and Seungbum Hong[1,2]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]KAIST Institute for NanoCentury, Korea (the Republic of)

Energy harvester converts wasted energy into usable electrical energy. Recently, with the rise of Internet of Things (IoT) technology, various types of sensors have been embedded into systems such as mobile and wearable devices, and unmanned equipment. Since it is difficult to supply all the energy required by many sensors with wired power systems, many studies have been conducted to overcome the issue of wired power through energy harvesting technology. Piezoelectric energy harvesters can generate the electrical energy to convert directly the applied strain energy from mechanical energy such as vibration. However, the major challenges of piezoelectric energy harvesters are the relatively low power yield and the degradation of the energy harvesting device due to fatigue caused by tens of millions of vibrations. Here we conducted the accelerated stressed cycle test in the low frequency range of 30 Hz band for a commercially available piezoelectric energy harvester, which is composed of a PZT-5H piezoelectric layer and a flexible substrate. Subsequently, we visualized the piezoelectric fatigue in microscopic region, and evaluated the degradation characteristics using piezoresponse force microscopy (PFM) to correlate the macroscopic fatigue with micron scale ferroelectric domain behavior.

F.MT02.07.05

Nanomechanical and Local Electrical Properties of Conjugated Polymer Thin Films Prepared Through Antisolvent Dripping and Electrochemical Doping Krystal House, Hemanth Maddali and Deirdre O'Carroll; Rutgers, The State University of New Jersey, United States

Conjugated polymers have been extensively studied due to their tunable optical and electronic properties relevant to thin-film optoelectronic devices. Several techniques have been used to modify the electrical properties of these polymers, including solvent processing methods to enhance morphology, and molecular doping to enhance conductivity. Addition of a solvent in which the polymer has poor solubility (antisolvent) to the polymer solution prior to spin coating has been shown to improve the morphology of polymer thin films by promoting increased aggregation during solvent evaporation while spin coating. Here, we study the local physical and nanomechanical properties of several common conjugated polymer thin films prepared using an antisolvent dripping method in which the antisolvent is added during, rather than before, the spin coating process. This approach is expected to aid crystallization and produce uniform, stable, films.

Using atomic force microscopy (AFM), we establish a direct relation between the physical, mechanical, and electrical properties of conjugated polymer thin films prepared through antisolvent dripping and electrochemical doping. Phase imaging and fast force mapping (FFM) are used to visualize the nanoscale crystalline and amorphous domains. Additionally, in the case of doped conjugated polymer films, FFM and conductive AFM measurements (CAFM) have been combined for simultaneous measurement of topography, Young's modulus, and current. The combined FFM and CAFM technique splits the biased sample into a grid of points and records the deflection of the cantilever as a function of tip sample separation at each point, as well as the current measured through the sample by the tip, allowing for a direct comparison of mechanical and electrical properties at the nanoscale. The solvent used for the polymer precursor solution and antisolvent used during spin

coating were chosen based on Hansen solubility parameters (HSP). Using HSPs a list of good and poor solvents for the polymers were determined. Choosing a high-boiling-point, good solvent in the precursor solution ensures this solvent remains long enough during spin coating to allow for mixing with the poor solvent added during antisolvent dripping. This provides sufficient time for rearrangement of molecular chains to form a more ordered structure. In addition, for electrochemically doped conjugated polymer films, we find that higher dopant concentrations, and increased conductivity, occur in nanoscale crystalline domains compared to amorphous domains. Raman mapping and energy dispersive spectroscopy support the AFM findings at the micron scale. These results can be used to tune the morphology and resultant electrical properties of conjugated polymer films for use in electronic and optoelectronic devices.

F.MT02.07.06
Vanishing Calibration Error with Magic Ratio AFM—Improving the Accuracy of Modulus Measurement Through Error Propagation Analysis Richard J. Sheridan, David Collinson and L. Catherine Brinson; Duke University, United States

We present a new modality of force-curve-based AFM that eliminates systematic bias in the calculation of elastic modulus from cantilever spring constant calibration errors in force curve analysis. We show that the ratio between the probe deflection and substrate indentation has important implications for the uncertainty of modulus measurement when using generalized adhesive Hertzian indentation models. This error analysis codifies the widely understood rule-of-thumb tradeoff that must be made: if the cantilever deflection is much greater than the material indentation, bias due to error in cantilever calibration will be amplified, whereas if the cantilever deflection is much smaller than material indentation, photodetector noise will dominate. For example, attempts to measure the modulus of a stiff material with a very compliant probe result in a high indentation ratio and a large systematic error due to deflection sensitivity calibration. Our work reveals that, under the common calibration methods which involve the equipartition theorem, a special, “magic” indentation ratio appears between these limits with the ability to annihilate spring constant calibration error. In this presentation, the theory underlying the existence and error-nullifying properties of magic ratio indentation will be shown, followed by demonstrations on real data through custom analysis code and black-box commercial application routines. Caveats and limitations of magic ratio AFM will be discussed, as well as recommendations for users and manufacturers of AFM instruments. Additionally, opportunities for modulus measurement error mitigation with multi-modal and multi-functional methods will be surveyed.

One Light Source Does It All—A Versatile Broadband IR Laser Source for Nanoscale IR Imaging and Spectroscopy Honghua Yang, Qichi Hu and Anirban Roy; Bruker Nano Surfaces Division, United States

Nanoscale infrared spectroscopy and imaging techniques - AFM-IR and s-SNOM offer non-invasive material characterizations at the sub-diffraction limit. Recent development in AFM-IR and s-SNOM have significantly advanced the spatial resolution and detection sensitivity [1, 2]. However, the spectral range of the techniques are limited to 800-1900 cm^{-1} and 2700-3600 cm^{-1} which typically involves multiple laser sources. The demand for a versatile laser source that can provide wider tuning range and accommodates both AFM-IR and s-SNOM, therefore, motivates design and implementation of new light source and detection techniques.

In this presentation, we demonstrate a novel method of extending both AFM-IR and sSNOM to the full mid-IR range by coupling with a broadband laser source. Based on OPO/DFG tunable IR generation and seeded by a powerful fs pump laser, the novel broadband laser source delivers an ultra-broadband (6 octave) nano spectroscopy. For AFM-IR, a new modulation scheme is developed to modulate the broadband light at a repetition rate that matches one of the contact resonance frequencies of the AFM cantilever for resonance enhancement. The resulting spectrum is obtained by integration with an FTIR unit achieving 670 – 4000 cm^{-1} with a typical 4 cm^{-1} spectral resolution in a single laser shot. For s-SNOM measurements, the broadband laser operates in the quasi-cw mode, enabling both s-SNOM spectroscopy and imaging [3]. This versatile system sets a new standard in terms of flexibility and tuning range the for the two complementary nanoscale IR techniques.
In this context, we also highlight the laser performance and demonstrate its application on several representative samples which achieved promising new insights in the understanding of a multitude of different materials.

Frontiers in Imaging Functional Behavior in Nanoscale Heterostructures Using Lorentz Transmission Electron Microscopy Charudatta Phatak; Argonne National Laboratory, United States

Confinement of magnetic structures geometrically as well as energetically, leads to novel and unexpected domain behavior. Lorentz transmission electron microscopy (LTEM) is ideally suited for quantitative analysis of magnetic domains and microstructure in functional nanoscale heterostructures. The current state of art LTEM enabled using aberration correctors allows for imaging down to sub-nanometer scale in field-free conditions. In this talk, the study of magnetic domain behavior in strongly interacting magnetic nanostructures namely artificial spin ices, curved 3D magnetic nanostructures, and functional materials that host skyrmions will be presented.
Artificial spin ice lattices consist of lithographically patterned arrays of interacting magnetic islands that exhibit magnetic frustration. We will present the results on emergence of magnetic excitations in such lattices which are topologically non-trivial as well as control of magnetic frustration and emergent ordering such as antiferromagnetic to ferromagnetic phase transition using lattice geometry. Furthermore, we will present a novel approach to understand such frustration behavior based on network topology that can be extended to use of graph neural networks to analyze and predict the behavior of spin ice lattices.
Topologically non-trivial spin textures such as skyrmions present unique opportunities to explore exciting fundamental phenomena, such as the topological Hall effect, as well as novel applications, such as skyrmion-based spintronics. The application of LTEM to visualize and understand the magnetic spin textures in multilayer $[Pt/Co]_x$ thin films that can host skyrmions as well as controlled fabrication of skyrmions using Ga ion implantation will be discussed. In-situ magnetization reversal was used to understand the stability of the skyrmions.
Finally, we will also present a new approach based on machine learning for phase retrieval in LTEM that improves the achievable phase sensitivity and spatial resolution.

8:30 AM *F.MT03.03.03
Nanoscale Measurements of Vibrations, Dispersions and Emergent Phenomena Using Monochromated Electron Energy Loss Spectroscopy Jordan Hachtel; Oak Ridge National Laboratory, United States

Advances in electron monochromation have led to a sea change in electron energy loss spectroscopy (EELS) over the last 6 years. Modern monochromators scanning transmission electron microscopes (STEM) have improved EELS energy resolution by an order of magnitude (from ~50 meV down to < 5 meV). This new level of energy resolution enables direct access to a

host of new phenomena, such as phonons, vibrational modes, infrared optical excitations, and low-lying states in the electronic structure. Moreover, it also presents many new opportunities to probe difficult and complex systems by exploiting novel interactions between the electron beam and these ultra-low energy excitations. As a result, monochromated EELS is a highly versatile tool that can be applied to a wide range of different disciplines and materials systems and deliver exciting results.

In this talk, I will focus on three different materials systems where monochromated EELS presents a unique opportunity to provide new insights into important topics: biological, optical, and quantum materials. In terms of biological materials, I will demonstrate how we can the efficient long-range coupling of vibrational modes to the electron beam, to provide in depth spectroscopic analysis of ultra-beam sensitive biological materials. Furthermore, I will demonstrate how we can use the combine the natively high spatial and spectral resolution of monochromated EELS with various flavors of momentum-resolution to probe the dispersions of infrared quasiparticles directly at the nanoscale. Lastly, I will discuss how we can apply this technique to coupled networks of colloidal nanoparticles to examine emergent properties in quantum systems.

This work was performed at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility. This research was conducted, in part, using instrumentation within ORNL's Materials Characterization Core provided by UT-Battelle, LLC, under Contract No. DE-AC05- 00OR22725 with the DOE, and sponsored by the Laboratory Directed Research and Development Program of Oak Ridge National Laboratory, managed by UT-Battelle, LLC, for the U.S. Department of Energy.

Monochromated STEM EELS of Phononic and Photonic Excitations Kartik Venkatraman, Qianlang Liu, Barnaby D. Levin and Peter A. Crozier; Arizona State University, United States

The enhanced energy resolution of recently developed monochromators now make it possible to use electron energy-loss spectroscopy (EELS) in the scanning transmission electron microscope (STEM) to probe materials systems in new ways. This powerful spectroscopic capability combined with the small focused electron probe opens the door to explore photonic and phononic/vibrational excitations with high spatial resolution [1-3]. Here we describe recent advances leading to nanoscale and atomic resolution vibrational spectroscopy and novel approaches to probe guided photonic modes in dielectric particles. The fast electron in the electron microscope can excite vibrational modes in materials either through dipole interactions (similar to IR absorption spectroscopy) or impact scattering (similar to inelastic neutron scattering). The spatial localization of these two scattering mechanisms is very different. Impact scattering typically involves higher momentum transfers yielding a spatially localized spectral signal. In a crystal, high momentum transfer interactions are associated with exciting the short wavelength phonon modes at the Brillouin zone boundaries (BZB). Efficient excitation of these modes requires experimental conditions that favor Bragg scattering from the associated Miller planes. This can be easily accomplished in the conventional STEM EELS geometry by tilting the crystal into a suitable zone axis orientation and using a probe convergence angle that spans the Bragg angle associated with the BZB of interest. This convergence angle also permits a small probe to be formed which enables resolution of the associated Miller plane spacing. We have used this approach to demonstrate nanoscale and atomic resolution on a sample of Si, SiO_2 and BN [1]. EELS can also be employed to explore the characteristic photonic modes present in dielectric nanoparticles since the electron beam can provide a source of virtual photons to illuminate the object. We have explored the variation in photonic modes for high refractive index oxide particles such as TiO_2, Ta_2O_5 and CeO_2 [2]. The modes show up as peaks in the bandgap region of the spectrum. The energies of the modes are determined not only by the particle shape and size but also due to coupling between adjacent particles. Coupling between phonons and IR photons can give rise to phonon polaritons [3,4]. Polariton characteristics are also influenced by sample geometry, and so the polaritonic modes can be manipulated by changing the sample shape/size. Here we use STEM EELS to demonstrate variations in the polaritonic response on patterned SiO_2 thin films.

Friday Afternoon, December 4, 2020
F.MT03

1:45 PM *F.MT03.03.01
Materials Science Applications of Four Dimensional–Scanning Transmission Electron Microscopy (4D-STEM) Colin Ophus; Lawrence Berkeley National Laboratory, United States

Traditional scanning transmission electron microscopy (STEM) detectors are large, monolithic regions that integrate a subset of the transmitted electron beam signal scattered from each electron probe position. These STEM imaging experiments record only 1-5 values per probe position, throwing away most of the diffracted signal information. With the introduction of extremely high speed direct electron detectors, we can now record a full image (2D data) of the diffracted electron probe scanned over the sample (2D grid of positions), producing a four-dimensional dataset we refer to as a 4D-STEM experiment. These diffraction images of the electron probe are extremely rich in atomic-scale information, such as the sample structure, orientation, composition, phonon spectra, defect structure and more. The spacing between adjacent STEM probes can be varied from below one Angstrom to hundreds of micrometers, allowing us to probe the functional length scale of materials and devices.

In this talk, I will discuss how 4D-STEM can be used to measure various properties important to materials science. I will show several examples of nanobeam electron diffraction used to measure sample structure, orientation and strain, for samples ranging from metallurgical alloys to conductive polymers. I will also show how 4D-STEM can enable phase contrast imaging methods. Finally, I will also show how the scattering matrix (S-matrix) formalism can be used both to numerically invert sample structure under conditions of multiple scattering of the electron beam, and also for very fast simulation of large 4D-STEM datasets. I will show an updated version of Prismatic, our open source simulation code that includes GUIs for easy application.

2:15 PM *F.MT03.02.02
Imaging Chemical Reactions in Solution Using Distributed Electron Microcopy Joseph P. Patterson; University of California, Irvine, United States

Imaging chemical reactions in solution is essential for the understanding complex mechanisms involved in nanomaterial synthesis. Liquid phase electron microscopy (LP-EM) is an emerging technique capable of directly monitoring morphological changes of materials in solution with a unique combination of temporal and spatial resolution. LP-EM has been used to study the reaction mechanisms such as metal nanoparticle formation, polymer self-assembly, wet etching of semiconducting materials, growth of metal−organic frameworks, nucleation of calcium carbonate and Li electrodeposition. These studies provided an unprecedented insight into nanoscale reaction mechanisms that have significantly improved our understanding of nanomaterial synthesis. The primary challenge for the field of LP-EM is understanding the role that the electron beam plays in the observed mechanism. It is common to perform control experiments to establish a critical dose limit with which a process can be observed. A consequence of having to work below a critical dose limit is that LP-EM has mostly been used to monitor reactions over a period of seconds to minutes, despite the fact that many reactions take place over hours to days. Furthermore, even after a critical dose has been established, it is impossible to completely rule out the role of the electron beam using LP-EM experiments alone. Consequently, it is essential to study reaction mechanisms using multiple imaging modalities. Cryo-EM can also provide direct high-resolution information on reaction mechanisms in solution. The advantage of cryo-EM is that electron beam effects are well understood and, using appropriately low doses, are insignificant. The disadvantage of cryo-EM is that it is impossible to know the history or future of any individual particle being imaged. Consequently, the data on reaction mechanisms has to be presented by selecting images that the user determines to be representative of the process occurring in solution. For simple processes that evolve homogenously, it is possible to determine a mechanism with high confidence using cryo-EM alone. However, for complex processes that evolve heterogeneously, the confidence with which mechanisms can be determined by cryo-EM alone is low. Here, a simple process is defined as a process with a single step or single pathway and a complex process is defined as a process with multiple steps or multiple pathways. A homogenous evolution is characterized by a process where only one particle state is observed at each

sampled time point, while a heterogeneous evolution is characterized by a process where multiple states are observed at each sampled time point. Consequently, cryo-EM is limited in its ability to resolve complex heterogeneous processes. Despite the obvious benefits of combining LP-EM and cryo-EM, most studies using these techniques have been only conducted with a single EM modality. Here we discuss the application of distributed electron microcopy for studying reaction mechanisms in solution. The term distributed is used because the data required to understand the mechanism is shared between multiple imaging modalities and sample preparation methods. The strength of this approach is that our proposed hypothesis is consistent with data taken from experiments with complementary benefits and limitations.

2:45 PM *F.MT03.02.01
Crystal Growth via Oriented Attachment—5-Fold Twin Formation Dongsheng Li[1], Miao song[1], Gang Zhou[2] and Ning Lu[3]; [1]Pacific Northwest National Laboratory, United States; [2]Institute of Metal Research, Chinese Academy of Sciences, China; [3]University of Michigan, United States

Oriented attachments are recognized as a common pathway for crystal growth in both natural and synthetic systems, leading interface free or twin related structures. The occurrence of 5-fold twinned nanoparticles leads to unique properties. However, nearly 200 years after their discovery, the formation mechanism is still ambiguous. Using in situ high-resolution transmission electron microscopy combined with molecular dynamics simulations, we demonstrate that 5-fold twinning occurs via repeated oriented attachment of ~3 nm Au nanoparticles. These oriented attachment events create high-energy grain boundaries, which accumulate strain during atomic rearrangements and consequently decompose via nucleation and growth of a special class of twins whose net strain is zero, inducing the 5-fold twin structures. The results provide a quantitative understanding of the 5-fold twinning process; this knowledge provides guidance for interpreting and controlling twin structures and morphologies of a wide range of materials.

Mapping Structure and Composition of Intact Li-Metal Anodes after Cycling Katherine L. Jungjohann[1], Katharine Harrison[1], Daniel Long[1], Renae Gannon[2], Laura Merrill[1], Subrahmanyam Goriparti[1] and Steven Randolph[3]; [1]Sandia National Laboratories, United States; [2]University of Oregon, United States; [3]Thermo Fisher Scientific, United States

The electrolyte 2.8 M lithium bis(fluorosulfonyl)imide (LiFSI) in dimethoxyethane (DME) has demonstrated good cycling behavior and stable Li morphology upon plating and stripping for high-capacity Li batteries, which is thought to be due to the formation of a stable solid-electrolyte interphase (SEI) layer for good ionic transport. Characterization of this SEI layer on lithium metal has been limited, due to the air-sensitivity and beam sensitivity of these materials, as well as the incompatibility of the electrolyte with the high vacuum environment necessary for nanoscale characterization with electron microscopy techniques. New cryogenic stages and transfer tools have enabled the characterization of frozen solid-liquid interfaces for lithium metal structures. Here, we used cryogenic focused ion beam (FIB) and ultrashort pulse laser ablation to create a cross-section of the lithium metal anode in contact with the electrolyte at various plating/stripping cycles to understand the morphological evolution of the lithium and SEI. Additionally, with cryo-FIB we utilized lift-out procedures under cryogenic temperatures for extraction of a lamella sample for investigation using scanning/transmission electron microscopy with energy dispersive x-ray spectroscopy and electron energy loss spectroscopy. The nanoscale chemical maps have allowed for a greater understanding of the SEI components and how they redistribute with reaction to the lithium metal over the course of many cycles. These results present a step towards visualization of the intact battery stack. We have determined a failure mechanism beyond short circuiting of the lithium metal anodes, due to reaction of the lithium with this LiFSI in DME chemistry.

5:15 AM *F.MT03.01.02
Maximizing the Information Provided by High-Resolution EELS and Zero-Loss Filtered 4D-STEM Using a Hybrid Pixel Direct Detector with High Dynamic Range Christoph T. Koch[1], Benedikt Haas[1], Alberto Eljarrat[1], Wouter Van den Broek[1], Marcel Schloz[1], Johannes Müller[1], Holm Kirmse[1], Thomas C. Pekin[1], Tracy Lovejoy[2] and Ondrej Krivanek[2,1]; [1]Humboldt University of Berlin, Germany; [2]Nion Company, United States

Recent progress in aberration correction and monochromation in the scanning transmission electron microscope (STEM) has enabled a wide range of new experiments that greatly enhance the depth of information becoming accessible in materials characterization. Direct detection of electron diffraction patterns and spectra became available just at the right time to push the limits of detectability and resolution of these electron optically advanced instruments even further and make experimental data fully quantifiable, to the point, where the match of simulations and experiment is ultimately only limited by counting statistics.

We will report on the recent development of advanced data reconstruction algorithms for recovering the dielectric function from relativistic EELS spectra [1], a versatile ptychography reconstruction algorithm that includes various regularization options [2], and other ways to process 4D-STEM data [3]. We will present results obtained by applying these algorithms to data having been recorded using a monochromated STEM (Nion HERMES microscope operating between 30 … 200 kV, EELS-resolution < 6 meV, spatial resolution < 0.07 nm) [4] equipped with a Dectris ELA hybrid pixel detector [5] that combines true single electron sensitivity, high speed (> 5000 fps for 514 x 1030 pixels at reduced bit depth, and 2250 full fps at 16 bit) and nearly perfect point spread function (1.3 pixels in integration mode) with the capacity for a high dynamic range (> 10^7). Being able to detect spectra and (zero-loss filtered) diffraction patterns without read-out noise greatly increases the level at which these reconstruction algorithms can extract the underlying dielectric function, local crystal structure or maps of the electrostatic potential.

Example applications that will be presented include the extraction of IR-dispersion information from high-resolution EELS of plasmonic nanostructures and a comparison of various data processing algorithms (ptychography, center-of-mass, etc.) applied to (zero-loss filtered) 4D-STEM data.

Exploiting Dynamical Scattering in 4D-STEM to Reveal Challenging Material Structures Joanne Etheridge[1], Wei Chao[1], Espen Drath Bøjesen[2], Bryan Esser[1], Matus Kranak[3], Weilun Li[1], Timothy Petersen[1] and Changlin Zheng[4]; [1]Monash University, Australia; [2]Aarhus University, Denmark; [3]Quantum Detectors Ltd, United Kingdom; [4]Fudan University, China

Convergent beam electron diffraction (CBED) provides a two-dimensional map of the intensity of scattered beams as a function of angle of incidence. Imprinted on the CBED pattern is a historical record of the multiple interactions of the electron wavefield as it is scattered within the specimen, making the pattern acutely sensitive to the specimen structure.

For more than half a century, this sensitivity has been exploited to determine crystal symmetries, refine crystal structures and measure bonding charge density distributions, to name just a few examples [1,2].

Today, with the advent of new, high speed, high dynamic range detectors, it is possible to read out the whole CBED pattern at each position of an electron beam as it is raster scanned across a specimen (often called "4D-STEM") [3]. This delivers an unprecedented wealth of specimen information buried in terabytes of data! How can we decode this data to extract the specimen information we want? Various schemes, including ptychography and differential phase contrast, have been demonstrated successfully with fast detectors. These various approaches have enabled enhanced image resolution, mapping of electric and magnetic fields, strain, polarisation domains and octahedral tilts (for a review, see [3]).

In this paper, we will discuss some approaches that exploit the power and sensitivity of dynamical electron scattering that underpins 4D-STEM, to provide alternative imaging contrast mechanisms and interpretative schemes that can reveal targeted specimen information. We illustrate these with applications to metallic nanoparticles, beam-sensitive functional perovskites and semiconducting nanostructures.

The application of LTEM to visualize and understand the magnetic spin textures in multilayer $[Pt/Co]_x$ thin films that can host skyrmions as well as controlled fabrication of skyrmions using Ga ion implantation will be discussed. In-situ magnetization reversal was used to understand the stability of the skyrmions.
Finally, we will also present a new approach based on machine learning for phase retrieval in LTEM that improves the achievable phase sensitivity and spatial resolution.

6:00 AM F.MT03.01.05
Tracking the Layered-to-Rock Salt Phase Transition in $LiNiO_2$ by 4D STEM Anuj Pokle[1], Shamail Ahmed[1], Matteo Bianchini[2], Manveer Singh Munde[1], Pascal Hartmann[2], Torsten Brezesinski[2], Andreas Beyer[1], Jürgen Janek[2] and Kerstin Volz[1]; [1]Philipps-Universität Marburg, Germany; [2]Karlsruhe Institute of Technology (KIT), Germany

The layered oxide cathode materials are promising candidates for high energy density lithium-ion batteries (LIB). However, the Ni-rich layered compounds, especially the end member $LiNiO_2$ (LNO), suffer from stoichiometric challenges (Li/Ni ratios) and instability issues leading to structural degradation [1,2]. It is challenging to synthesize LNO without defects, which further results in severe capacity loss during electrochemical cycling. The phase transition structure/ mechanism is widely under debate, and obtaining a thorough insight is crucial for enhancing the cathode material performance. Directly visualizing the structure at the atomic scale can give us further insight, nonetheless detecting the light elements in energy materials is not trivial.

All the major studies over imaging lithium are carried out on free-standing single-crystalline nanoparticles [3]. However, the real cathode active materials (CAMs) are polycrystalline particles composed of densely packed primary particles/nanocrystals. This poses challenges in sample preparation to achieve the optimum thickness parameters to visualize lithium. In this report, we have investigated the phase transformed region using aberration-corrected scanning transmission electron microscopy (AC-STEM) combined with the pixelated detector (pnCCD). Selecting specific regions in the convergent beam electron diffraction (CBED) patterns and calculating the so-called virtual enhanced ABF (eABF) images is shown to enhance the contrast of the lighter elements even in the thicker sample of ~ 95 nm [4-6]. Moreover, to verify the dependency of this technique at various thicknesses, final gradational thinning of the focused ion beam (FIB) prepared lamellae is carried out by focused low energy Ar-ion NanoMill. Ultimately, we apply the HAADF (high angle annular dark field), ABF, and eABF imaging techniques simultaneously to image the entire layered-to-rock salt phase transition region.

Interestingly, we have been able to access the phase transformed region in between the layered and the rock-salt structure by collecting four-dimensional datasets (4D STEM). This has enabled us to atomically track Ni as well as the light elements, especially lithium and oxygen. The analysis of the layered-to-rock salt phase transition region suggests that there is no sharp interface, as previously assumed. Instead, the transformation appears to take place gradually [1]. The current findings warrant a re-examination of commonly assumed models on this important class of energy materials. Moreover, our results shine a light on the phase transformation mechanism at high spatial resolution and can influence the future design for stabilizing LNO against structural transitions.

Expanding the Dimensions of a Small, Two-Dimensional Diffraction Detector Xi Chen[1], Matthew Hauwiller[1], Abinash Kumar[1], Aubrey Penn[2] and James M. LeBeau[1]; [1]Massachusetts Institute of Technology, United States; [2]North Carolina State University, United States

4D STEM has gained popularity in recent years and is now widely applied to the quantitative phase and orientation mapping[1], strain mapping[2], electromagnetic field measurements[3], and ptychographic reconstructions[4]. The realization of routine 4D STEM is closely related to the development of new detectors. Direct electron detectors, for example, have

overcome the limitations faced by CCD and indirect CMOS sensors, providing much higher dynamic range and frame rate, while maintaining single-electron sensitivity. In some cases, e.g. the hybrid pixel array detectors, these detectors are limited in size. (Medipix3 has 256x256 pixels [5], the EMPAD has 128x128 pixels [6]). Therefore, it is of great value to be able to expand the effective size of a small detector.

In this presentation, we demonstrate a method to increase the effective size of a small detector by capturing and combining sub-regions of reciprocal space. We will highlight how to script the microscope to shift the diffraction pattern across the detector. Taking control of the diffraction shift also allows more flexibility in practical application. For example, this technique can be used to capture only certain segments of reciprocal space to save time and storage. It is possible to acquire along an annulus of the diffracted intensity to avoid the central beam and capture only high angle diffuse scattering. In this case, the diffraction pattern can be shifted in a ring pattern instead of a normal grid pattern. Furthermore, we will show how this technique expands a small detector's application space. Electrons all the way out to the objective lens bore can be captured with a high sampling rate. Limitations and challenges of acquiring such data will also be discussed.

As for reconstruction, we will highlight our automated routine to accurately and precisely align the data post-acquisition. We will also examine the challenges associated with reconstructing the datasets, including rotating the pattern shift axes and lens hysteresis. Consistency of the alignment will also be discussed. We also explore the accuracy of the reconstruction as a function of pattern exposure time and sub-pattern overlap to help guide experimental parameters. Finally, we will also show that being able to capture the Bragg peak intensities at the same time as diffuse scattering provides opportunities for quantitative diffraction analysis.

Correlation Between Structural Heterogeneity with Ductility and Glass Forming Ability in Metallic Glasses Using 4D Scanning Transmission Electron Microscopy Soohyun Im[1], Pengyang Zhao[2], Geun Hee Yoo[3], Gabriel Calderon[1], Mehrdad Abbasi Gharacheh[1], Olivia G. Licata[4], Baishakhi Mazumder[4], Eun Soo Park[3], Yunzhi Wang[1] and Jinwoo Hwang[1]; [1]The Ohio State University, United States; [2]Shanghai Jiao Tong University, China; [3]Seoul National University, Korea (the Republic of); [4]University of Buffalo-SUNY, United States

We determine the correlation between the structural heterogeneity and unprecedented detailed parameters of medium range ordering (MRO) using 4-dimensional scanning transmission electron microscopy (4-D STEM). The details of MRO constitute nano-scaled structural heterogeneity, such as the type, size, and fraction of MRO structures, which are directly correlated with the important properties, including the ductility and glass forming ability of Zr-Cu-Co-Al metallic glasses. In this study, the quantitative analyses of the data are enabled by our 4-D STEM using the new-generation Electron Microscopy Pixel Array Detector (EMPAD). This new detector can not only support high dynamic range, which is necessary for the quantification, but also take nanodiffraction patterns continuously throughout a large sample area with oversampling. Thus, it allows us to obtain the statistically reliable information on the structural heterogeneity at the nanoscale. We confirm the fact that the important properties of Zr-Cu-Co-Al MGs and Ti-Zr-Ni-Be MGs are directly related to the determined MRO parameters. In the Zr-based MG system, the smaller and more diverse MRO types result in high ductility, and more structurally frustrated MRO type relates to the higher glass forming ability. In the case of Ti-based MGs, the addition of Be in Ti-Zr-Ni can break down icosahedral-MRO structure, which is our hypothesis based on the angular correlation analysis.

Crystal Growth via Oriented Attachment—5-Fold Twin Formation Dongsheng Li[1], Miao song[1], Gang Zhou[2] and Ning Lu[3]; [1]Pacific Northwest National Laboratory, United States; [2]Institute of Metal Research, Chinese Academy of Sciences, China; [3]University of Michigan, United States

Oriented attachments are recognized as a common pathway for crystal growth in both natural and synthetic systems, leading interface free or twin related structures. The occurrence of 5-fold twinned nanoparticles leads to unique properties. However, nearly 200 years after their discovery, the formation mechanism is still ambiguous. Using in situ high-resolution transmission electron microscopy combined with molecular dynamics simulations, we demonstrate that 5-fold twinning occurs via repeated oriented attachment of ~3 nm Au nanoparticles. These oriented attachment events create high-energy grain boundaries, which accumulate strain during atomic rearrangements and consequently decompose via nucleation and growth of a special class of twins whose net strain is zero, inducing the 5-fold twin structures. The results provide a quantitative understanding of the 5-fold twinning process; this knowledge provides guidance for interpreting and controlling twin structures and morphologies of a wide range of materials.

5:15 AM *F.MT03.02.02
Imaging Chemical Reactions in Solution Using Distributed Electron Microcopy Joseph P. Patterson; University of California, Irvine, United States

Imaging chemical reactions in solution is essential for the understanding complex mechanisms involved in nanomaterial synthesis. Liquid phase electron microscopy (LP-EM) is an emerging technique capable of directly monitoring morphological changes of materials in solution with a unique combination of temporal and spatial resolution. LP-EM has been used to study the reaction mechanisms such as metal nanoparticle formation, polymer self-assembly, wet etching of semiconducting materials, growth of metal−organic frameworks, nucleation of calcium carbonate and Li electrodeposition. These studies provided an unprecedented insight into nanoscale reaction mechanisms that have significantly improved our understanding of nanomaterial synthesis. The primary challenge for the field of LP-EM is understanding the role that the electron beam plays in the observed mechanism. It is common to perform control experiments to establish a critical dose limit with which a process can be observed. A consequence of having to work below a critical dose limit is that LP-EM has mostly been used to monitor reactions over a period of seconds to minutes, despite the fact that many reactions take place over hours to days. Furthermore, even after a critical dose has been established, it is impossible to completely rule out the role of the electron beam using LP-EM experiments alone. Consequently, it is essential to study reaction mechanisms using multiple imaging modalities. Cryo-EM can also provide direct high-resolution information on reaction mechanisms in solution. The advantage of cryo-EM is that electron beam effects are well understood and, using appropriately low doses, are insignificant. The disadvantage of cryo-EM is that it is impossible to know the history or future of any individual particle being imaged. Consequently, the data on reaction mechanisms has to be presented by selecting images that the user determines to be representative of the process occurring in solution. For simple processes that evolve homogenously, it is possible to determine a mechanism with high confidence using cryo-EM alone. However, for complex processes that evolve heterogeneously, the confidence with which mechanisms can be determined by cryo-EM alone is low. Here, a simple process is defined as a process with a single step or single pathway and a complex process is defined as a process with multiple steps or multiple pathways. A homogenous evolution is characterized by a process where only one particle state is observed at each sampled time point, while a heterogeneous evolution is characterized by a process where multiple states are observed at each sampled time point. Consequently, cryo-EM is limited in its ability to resolve complex heterogeneous processes. Despite the obvious benefits of combining LP-EM and cryo-EM, most studies using these techniques have been only conducted with a single EM modality. Here we discuss the application of distributed electron microcopy for studying reaction mechanisms in solution. The term distributed is used because the data required to understand the mechanism is shared between multiple imaging modalities and sample preparation methods. The strength of this approach is that our proposed hypothesis is consistent with data taken from experiments with complementary benefits and limitations.

"Live" Visualization of Catalysts at Atomic-Resolution Stig Helveg; Center for Visualizing Catalytic Processes (VISION), Department of Physics, Technical University of Denmark, Denmark

Electron microscopy has progressed extraordinarily to become a powerful tool for studying nanostructured catalysts at the atomic-scale. Advances in electron optics and detection have made atomic-resolution electron microscopy capable of resolving the three-dimensional surface structure of the complex catalytic nanomaterials. In parallel, the introduction of differentially pumped electron microscopes and micro-electro-mechanical-system devices has enabled *in situ* observations of catalysts during the exposure to gasses at pressures of up to atmospheric levels and temperatures of up to several hundred centigrade as well as *operando* studies by concurrent measurements of catalytic functionality. While these developments build a foundation for time-resolved observations of catalysts at the atomic-scale, such observations are challenged by electron-beam-induced alterations of the catalysts and mass-transport phenomena in the fluid phase. In this contribution, I will outline electron microscopy advances addressing the chemical relevance of atomic-scale visualizations. Moreover, I will showcase these *"live"* visualizations for exploring the dynamical and functional behavior of complex catalytic nanomaterials.

5:45 AM F.MT03.02.04
Investigating the Effect of *In Situ* Heating on the Morphology and Composition of Temperature-Responsive Polymers by Using Energy-Filtered Transmission Electron Microscopy Dalaver H. Anjum[1], Rahul Shevate[2,3] and Klaus-Viktor Peinemann[2]; [1]Khalifa University, United Arab Emirates; [2]King Abdullah University of Science & Technology (KAUST), Saudi Arabia; [3]University of Houston, United States

Transmission electron microscopy (TEM) is a powerful materials' characterization technique for investigating their structure and properties at nanoscale dimensions. It has become an indispensable tool in the present era of nanoscience and nanotechnology. In this study, we employed the energy-filtered TEM (EFTEM) mode to investigate the effect of in-situ heating on the thin-layers of a stimuli-responsive (temperature) poly(N-isopropylacrylamide) (pNIPAm) which has been covalently attached to hollow titania (TiO_2) nanowires. The temperature-responsive behavior was characterized by observing the morphology and composition of samples as a result of heating. The pNIPAm has the swelling to shrinking transition temperature defined as lower critical solution temperature (LCST) of ~32 °C at standard conditions. We characterized the morphology and composition of the samples below and above the phase transition temperature of the pNIPAm by applying in-situ heating inside TEM. The EFTEM imaging and elemental mapping were applied at room temperature to determine the conformity of the pNIPAm layer and the elemental distributions of all elements present in samples. In the analysis, the elemental distribution of the element carbon (C) was attributed to the presence of the pNIPAm layer in the samples. The TiO_2 nanowires regions in the samples were identified by the overlapping of generated titanium (Ti) and oxygen (O) elemental maps. The EFTEM analysis was then repeated at the same sample regions by applying incremental in-situ heating, during which the temperature of samples was increased from ambient (23 °C) to high (100 °C) temperature with an interval of 10 °C. The acquired results revealed that the phase transition temperature of the pNIPAm came out to be 95 °C inside the TEM, which was higher than the expected value. Similarly, during the cooling of samples inside the TEM, the pNIPAm did not revert to the original morphology once the samples reached room temperature. However, the pNIPAm was found to recover the morphology by cooling the samples in standard atmospheric conditions. In conclusion, our findings show that the pNIPAm may exhibit a different swelling to shrinking behavior inside the TEM than under standard atmospheric conditions. The discrepancy is believed to be due to the rate of heat transfer between the surrounding environment and the samples and the relative humidity at ambient conditions, which evidently play a critical role for the pNIPAm transition from swelling to shrinking as well as from shrinking to swelling phase.

5:55 AM F.MT03.02.05
Insights into the Real-Time Structural Dynamics of Liquid-Vapor Interface at Nanometer Resolution by *In Situ* TEM Amy Ren[1,2], David Lu[1,3] and Gang Ren[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California Santa Babra, United States; [3]Brown University, United States

Visualization of the dynamic structure of the liquid, essential for studying the virus and cell activity, has remained elusive for decades due to lack of an effective tool for direct visualization beyond micrometer resolution. Here, we designed a simple liquid-cell for encapsulating the liquid state of sodium for transmission electron microscopic (TEM) observation. The real-time dynamic structure of the liquid-vapor interface was imaged and videoed by TEM on the sample of electron irradiated sodium chloride (NaCl) crystals, a well-studied sample with low melting temperature and quantum super-shells of clusters. The nanometer resolution images exhibit the fine structures of the capillary waves, composed of three zones of structures and features, i.e. flexible nanoscale fibers, nanoparticles/clusters, and a low-pressure area that sucks the nanoparticles from the liquid to the interface. Although the phenomenon was observed based on irradiated NaCl crystals, the similarity of the phenomenon to predictions suggest our first-time videos of the dynamic structure might be useful in validating long-debated theoretical models of the liquid-vapor interface. By implemented the technique to biology, we imaged virus and cell in wet for insights into the 3D structure of the intermediates of viral infection cell.

6:05 AM F.MT03.02.06
Electron Microscopy Study of Nanoparticles During Electrocatalytic Reactions Jinglong Guo[1], Xue Rui[1], Dongyoung Chung[2], Pietro Papa Lopes[2] and Robert Klie[1]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States

The oxygen evolution reaction (OER) plays an important role in energy conversion and storage applications, such as metal–air electrochemical cells and the production of hydrogen from water electrolysis. Metal oxide nanoparticles acting as high-quality electro-catalysts allows for anionic redox of oxygen at the particle surface. [1] However, this reaction may lead to considerable dissolution and degradation of the nanoparticle catalyst. Perovskite oxides have been previously demonstrated that, by enhancing the hybridization between the O 2p and transition metal 3d orbitals, the OER activity can be enhanced significantly. [2] KOH electrolyte with Fe impurities have been found to significantly increase the activity of Ni-based perovskite oxides electrocatalysts. [3] In this contribution, we evaluate the role of Fe impurities together with Sr-doping on $LaCoO_3$ based materials on the activity and stability for OER in alkaline electrolyte using combination of scanning transmission electron microscopy (STEM) imaging, electron energy loss spectrum (EELS) and energy dispersive x-ray spectroscopy (EDXS). Our analysis is conducted on the same particles on pristine and after cycling (Identical-Location TEM; ILTEM), which enables us to track the effect of electrochemical cycling on the particles. In addition to the $La_{1-x}Sr_xCoO_3$ catalysts, we also studied MnWO particles decorated with Ir catalyst nanoparticles using the ILTEM approach. From the comparison of the same particles on pristine and after cycling, the dissolution of the Ir nanoparticle on the surface of MnWO particles was observed. The results will be combined with first principal calculation to show the effect of surface composition and structural evolution during activity of OER.

5:00 AM *F.MT03.03.01
Monochromated STEM EELS of Phononic and Photonic Excitations Kartik Venkatraman, Qianlang Liu, Barnaby D. Levin and Peter A. Crozier; Arizona State University, United States

The enhanced energy resolution of recently developed monochromators now make it possible to use electron energy-loss spectroscopy (EELS) in the scanning transmission electron microscope (STEM) to probe materials systems in new ways. This powerful spectroscopic capability combined with the small focused electron probe opens the door to explore photonic and phononic/vibrational excitations with high spatial resolution [1-3]. Here we describe recent advances leading to nanoscale and atomic resolution vibrational spectroscopy and novel approaches to probe guided photonic modes in dielectric particles. The fast electron in the electron microscope can excite vibrational modes in materials either through dipole interactions (similar to IR absorption spectroscopy) or impact scattering (similar to inelastic neutron scattering). The spatial localization of these two scattering mechanisms is very different. Impact scattering typically involves higher momentum transfers yielding a spatially localized spectral signal. In a crystal, high momentum transfer interactions are associated with exciting the short wavelength phonon modes at the Brillouin zone boundaries (BZB). Efficient excitation of these modes requires experimental conditions that favor Bragg scattering from the associated Miller planes. This can be easily accomplished in the conventional STEM EELS geometry by tilting the crystal into a suitable zone axis orientation and using a probe convergence angle that spans the Bragg angle associated with the BZB of interest. This convergence angle also permits a small probe to be formed which enables resolution of the associated Miller plane spacing. We have used this approach to demonstrate nanoscale and atomic resolution on a sample of Si, SiO_2 and BN [1]. EELS can also be employed to explore the characteristic photonic modes present in dielectric nanoparticles since the electron beam can provide a source of virtual photons to illuminate the object. We have explored the variation in photonic modes for high refractive index oxide particles such as TiO_2, Ta_2O_5 and CeO_2 [2]. The modes show up as peaks in the bandgap region of the spectrum. The energies of the modes are determined not only by the particle shape and size but also due to coupling between adjacent particles.

Coupling between phonons and IR photons can give rise to phonon polaritons [3,4]. Polariton characteristics are also influenced by sample geometry, and so the polaritonic modes can be manipulated by changing the sample shape/size. Here we use STEM EELS to demonstrate variations in the polaritonic response on patterned SiO_2 thin films.

Nanoscale Measurements of Vibrations, Dispersions and Emergent Phenomena Using Monochromated Electron Energy Loss Spectroscopy Jordan Hachtel; Oak Ridge National Laboratory, United States

Advances in electron monochromation have led to a sea change in electron energy loss spectroscopy (EELS) over the last 6 years. Modern monochromators scanning transmission electron microscopes (STEM) have improved EELS energy resolution by an order of magnitude (from ~50 meV down to < 5 meV). This new level of energy resolution enables direct access to a host of new phenomena, such as phonons, vibrational modes, infrared optical excitations, and low-lying states in the electronic structure. Moreover, it also presents many new opportunities to probe difficult and complex systems by exploiting novel interactions between the electron beam and these ultra-low energy excitations. As a result, monochromated EELS is a highly versatile tool that can be applied to a wide range of different disciplines and materials systems and deliver exciting results.

In this talk, I will focus on three different materials systems where monochromated EELS presents a unique opportunity to provide new insights into important topics: biological, optical, and quantum materials. In terms of biological materials, I will demonstrate how we can the efficient long-range coupling of vibrational modes to the electron beam, to provide in depth spectroscopic analysis of ultra-beam sensitive biological materials. Furthermore, I will demonstrate how we can use the combine the natively high spatial and spectral resolution of monochromated EELS with various flavors of momentum-resolution to probe the dispersions of infrared quasiparticles directly at the nanoscale. Lastly, I will discuss how we can apply this technique to coupled networks of colloidal nanoparticles to examine emergent properties in quantum systems.

This work was performed at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility. This research was conducted, in part, using instrumentation within ORNL's Materials Characterization Core provided by UT-Battelle, LLC, under Contract No. DE-AC05- 00OR22725 with the DOE, and sponsored by the Laboratory Directed Research and Development Program of Oak Ridge National Laboratory, managed by UT-Battelle, LLC, for the U.S. Department of Energy.

5:30 AM *F.MT03.03.04
Vibrational EELS in the STEM at Single Atom Sensitivity Fredrik S. Hage[1,2], G. Radtke[3], Demie Kepaptsoglou[1,4], M. Lazzeri[3], L.J. Allen[4,5] and Quentin Ramasse[1,6]; [1]SuperSTEM Laboratory, SciTech Daresbury Campus, United Kingdom; [2]University of Oxford, United Kingdom; [3]Sorbonne Université, MuséumNational d'Histoire Naturelle, UMR CNRS 7590, Institut de Minéralogie, de Physique des Matériaux et de Cosmochimie, France; [4]The University of Melbourne, Australia; [5]Ernst Ruska-Centre for Microscopy and Spectroscopy with Electrons, Forschungszentrum Jülich, Germany; [6]University of Leeds, United Kingdom

Vibrational electron energy loss spectroscopy (EELS) in the scanning transmission electron microscope (STEM) has over the recent years emerged as a versatile tool for characterizing molecular to bulk or surface vibrational modes in a wide range of materials systems, at the nanoscale [1]. The possibility of going beyond the nanoscale, reaching atomic resolution, has been discussed extensively in the community. We recently demonstrated such a capability using a so-called dark-field (DF) experimental geometry, suppressing the relative spectral contribution of elastic and delocalized inelastic *dipole* scattering by phonons, favoring instead beam electrons having undergone localized *impact* phonon scattering [2]. This approach allows for acquiring phonon structure images using the acoustic and/ or optical phonon EEL peaks [2] and, is equally applicable to polar [2] and non-polar materials [3]. Moreover, these results verify experimentally that annular dark field (ADF) Z-contrast imaging is based on beam electrons being scattered inelastically by phonons, in agreement with the quantum excitation of phonons model [2]. As a next step, we applied this methodology to probe the vibrational response of a single tri-valent

substitutional Si atom in a single layer of suspended graphene. Spatially resolved EEL spectra show a characteristic vibrational signature associated with the Si impurity, localized to the defect atom itself. This is rationalized by means of density functional theory (DFT) calculations, attributing the measured response to the Si atom inducing pseudo-localized phonon modes: i.e. defect modes hybridizing with the graphene bulk continuum, setting up resonant states [3]. Possible applications of the demonstrated atomic resolution and single atom sensitivity, as well as practical aspects of the experimental approach, will be discussed.

5:45 AM *F.MT03.03.05
Tailored Nanoscale Plasmon-Enhanced Vibrational Electron Spectroscopy Luiz H. Galvao Tizei; CNRS, France

Atomic vibrations and phonons are an excellent source of information on nanomaterials that we can access through a variety of methods including Raman scattering, infrared spectroscopy, and electron energy-loss spectroscopy (EELS). In the presence of a plasmon local field, vibrations are strongly modified and, in particular, their dipolar strengths are highly enhanced, thus rendering Raman scattering and infrared spectroscopy extremely sensitive techniques.
In this contribution [1], we experimentally demonstrate that the interaction between a relativistic electron and vibrational modes in nanostructures is fundamentally modified in the presence of plasmons. This could be observed due to the current developments in electron optics, making possible the generation of sub-nanometer wide sub-10 meV electron beams with 60 keV primary energy. We finely tune the energy of surface plasmons in metallic micrometer-long Ag nanowires in the vicinity of hexagonal boron nitride flakes, making it possible to monitor and disentangle both strong phonon–plasmon coupling and plasmon-driven phonon enhacement at the nanometer scale. Because of the near-field character of the electron beam–phonon interaction, optically inactive phonon modes are also observed. Besides increasing our understanding of phonon physics, our results hold great potential for investigating sensing mechanisms and chemistry in complex nanomaterials down to the molecular level.
The strong coupling limit is reached between surface plasmons and phonon modes as the largest coupling constant, *g*, reached was 52 meV and the full width at half maximum of the two coupled excitations were 23 and 19 meV. The signature of strong coupling is observed along the whole nanowires, including for nanowire regions far away from any h-BN (point to the coherence of the coupled modes along the nanowire). The spatial dependence at nanometer scale of these modes will be described.
More interestingly, the presence of plasmons modify the way fast electrons couple to bulk modes of h-BN, leading to enhancement of their signal and the observation of usually “dark modes”. As an example, the ZO-phonon mode of hBN, usually not observed for electron beams perpendicularly incident on an h-BN flake, can be observed when close to metallic nanowires. We will describe how this enhanced signature changes as a function of the distance of the electron probe to the nanowire surface, varying in the tens-of-nanometers scale. Experiments have been performed with the ChromaTEM microscope (TEMPOS project, ANR-10-EQPX-50), a modified Nion HERMES200 operated at 60 kV. The electron beam was set to have an energy spread in the 6-10 meV range and a nanometer size. Experiments are under way to achieve similar enhancement in molecular systems.
If time allows, recent nano-optics experiments using ChromaTEM will be discussed.

6:00 AM *F.MT03.03.06
Nanoscale Optical and Vibrational Spectroscopy of Low-Dimensional Materials in Electron Microscope Ryosuke Senga; AIST, Japan

The excitations of quasiparticles govern the physical properties of low-dimensional materials. Furthermore, assessing the irregular stacking sequences and behaviours at imperfect sections (such as boundaries and edges) is undoubtedly important to understand the performance of nanodevices. However, such local information has usually been averaged in conventional inelastic scattering techniques using x-ray, neutron, and light sources because of their diffraction limit. We demonstrate the nanoscale optical and vibrational spectroscopy of 1D or 2D materials by using a monochromatic electron source mounted in a transmission electron microscope (TEM).
All experiments were performed using a TEM (JEOL TripleC#2 at 30–60 kV) equipped with a Schottky field emission gun, a double Wien filter monochromator, and delta correctors. The energy resolution was set to a value less than 50 meV and allowed to access the quasiparticle excitations (i.e. phonon, exciton, and plasmon) of low-dimensional materials by electron energy-loss spectroscopy (EELS). The EEL spectra were collected using a GATAN GIF quantum spectrometer designed for

low-voltage operations.
The spatial and momentum resolutions in electron microscopes balance each other and can be finely tuned with magnetic/electrostatic lenses. For instance, an atomically thin probe can be formed with an integration of a large momentum space. This allows us to extract local information from single defects. We have successfully measured the optical gap transitions from a defect of an individual semiconducting carbon nanotube [1,2]. Recently, atomically localized vibrational spectroscopic techniques have also been developed [3,4].
In contrast, an electron probe consisting of a parallel beam has a higher momentum resolution and provides dispersions of quasiparticle excitations. The EEL spectra are collected from each momentum transfer (q) by a pinhole aperture or a q-slit in a diffraction plane. Using this method, we have obtained phonon dispersions of graphene and h-BN from a single layer. Interestingly, the inelastically scattered electrons by phonon excitations provide sufficient signals at a large q even in the second and third Brillouin zone. Such signal enhancement due to a charge modulation at a large q helps draw a phonon dispersion curve of graphene even from a single layer. In addition, the spatial resolution of this method (a few to a few tens of nanometres, depending on its momentum resolution) is more advantageous than other dispersion measurement techniques such as inelastic x-ray spectroscopy. By maintaining the momentum resolution better than ±0.2 $Å^{-1}$, each vibrational mode can be assigned at a region of a few tens of nanometres. Therefore, the propagation of each phonon mode at defects such as edges in graphene has been unambiguously visualized [5]. Such local spectroscopy with a large flexibility could help unravel the defect physics of quantum matters.

6:15 AM F.MT03.03.07
Improving the Resolution of Polymer EELS by Exploiting the Beam-Induced Chemistry Robert Colby, Yu Fan and Donald Carpenter; ExxonMobil Research and Engineering Company, United States

Electron energy loss spectroscopy (EELS) can be used to identify polymers and similar organics, but is limited by the rate at which materials damage when probed with ~100 kV electrons. Any modern scanning transmission electron microscope (STEM) is routinely capable of producing a sub-nanometer probe, but the fluence rate (electrons/nm^2 s) needed to achieve enough signal at this level of resolution cannot be tolerated by most organics, even at low temperatures. Many polymers show signs of damage well below 10 electrons/$Å^2$, a threshold frequently identified for studying organic material. Even with ongoing detector improvements, “damage-free” EELS fine structure mapping of polymers with nanometer-sized pixels does not seem conventionally attainable. However, the ways in which an electron beam modifies a given polymer—and the resulting changes that can be observed with EELS—are arguably even more unique than the initial EELS fine structure.

The type and extent of beam-induced chemistry for a given polymer depends on at least dose, dose-rate, sample temperature, and vacuum conditions. These dependencies provide opportunities to exploit beam damage as a means for polymer chemistry identification. Beam-induced chemistry significantly precedes substantial mass loss and/or sample distortion in many polymers, particularly at cryogenic temperatures. The simplest option is to probe the fluence dependence by recording a series of STEM-EELS maps with a fixed current and temperature. These 4D fluence-dependent EELS maps can be collected with total fluences normally considered too high for accurate polymer identification, while at lower fluence rates, enabling spatial higher resolution mapping. This will be demonstrated for model polymer blends for <20 nm pixels, using a spectrometer with a CCD-based EELS detector.

Many studies have unintentionally mapped damaged polymers, and/or specifically measured damage evolution with EELS, but resolving and using the beam-induced evolution of sample chemistry to improve mapping is novel. Ultimately, spatial resolution is still limited by beam-induced changes: e.g., the rate of mass loss and the diffusion of generated radicals and gases. While application to polymer EELS will be shown, the approach is quite generic to materials with a measurable chemical evolution preceding significant sample morphology change.

6:25 AM F.MT03.03.08
Isotope Effect in the Vibrational Modes of hBN Flakes Fadil Iyikanat[1], Andrea Konecna[1] and F. Javier Garcia de Abajo[1,2]; [1]ICFO-Institut de Ciencies Fotoniques, Spain; [2]ICREA-Institució Catalana de Recerca i Estudis Avançats, Spain

In this study, we perform first-principles calculations to investigate the effect of isotopic substitutions in the vibrational modes of hBN flakes. Using density functional theory calculations the ground state atomic configuration and the dynamical matrix of hBN flake are obtained. The eigenmodes and eigenfrequencies are calculated by diagonalization of the dynamical matrix. Using semiclassical formalism, the interaction between a focused electron beam and vibrations is described. We employ this approach to predict the effect of isotopes on the spatially-resolved electron energy-loss spectra (EELS) of hBN flakes.

Spontaneous and Stimulated Electron-Photon Interactions in Nanoscale Plasmonic Near Fields Matthias Liebtrau[1], Murat Sivis[2], Armin Feist[2], Hugo Lourenco-Martins[2], Nicolas Pazos-Perez[3], Ramon A. Alvarez-Puebla[3,4], Javier Garcia de Abajo[5], Albert Polman[1] and Claus Ropers[2]; [1]AMOLF, Netherlands; [2]University of Goettingen, Germany; [3]Universitat Rovira i Virgili, Spain; [4]Catalan Institution for Research and Advanced Studies, Spain; [5]ICFO–The Institute of Photonic Sciences, Spain

We study spontaneous and stimulated interactions between high-energy electrons and photons in nanoscale plasmonic near fields using Electron Energy Loss Spectroscopy (EELS), Cathodoluminescence (CL) spectroscopy and Photon-Induced Near-field Electron Microscopy (PINEM) in a Scanning (Transmission) Electron Microscope (S(T)EM). In recent years, EELS, CL and PINEM have enabled tremendous advances in probing (resonant) optical materials excitations with extreme spatial, temporal and energy resolution [1,2]. In EELS and CL, the time-varying evanescent electric field of the swift electrons serves as an ultra-broadband excitation source that can couple to a wide range of optical modes in a material [3]. The energy transfer during this interaction is a *spontaneous* process, resulting in a characteristic electron energy loss (EELS) and the subsequent emission of light (CL). Conversely, in PINEM, the electrons interact with an intense laser-driven near-field, giving rise to both electron energy-gain and -loss transitions by *stimulated* absorption and emission of photons at an energy determined by the laser frequency [4,5].

We demonstrate spatially-resolved EELS, CL and PINEM measurements of highly-localized dipolar optical fields at the sharp tip apexes of a chemically-synthesized Au nanostar [6]. We highlight similarities and differences between the measured EELS, CL and PINEM distributions, and discuss the role of the underlying excitation mechanisms driven either by the electron itself (EELS and CL) or the external laser (PINEM). Supported by electromagnetic boundary element method calculations for a simplified model geometry, we show that in the limit of a single isolated tip mode, spatial variations in the spontaneous and stimulated electron-photon interactions are purely determined by the modal electric near field profile, irrespective of the excitation source.

The interaction strength between free electrons and localized optical fields scales with the Fourier amplitude of the electric near field component along the electron trajectory at a single spatial frequency that is determined by the electron velocity [3,7,8]. As a consequence, the measured EELS, CL and PINEM distributions depend on the initial electron energy, with the maximum interaction strength shifting towards smaller electron energies for increasing field confinement. In general, the full three-dimensional (3D) reconstruction of an electric near-field distribution is therefore only possible by extensive tomographic measurements at multiple electron energies. Yet, using PINEM we show that for an axially-symmetric tip, we can determine the laser-induced surface charge density profile along the tip contour and thus obtain the desired 3D near-field distribution from a single measurement at a fixed electron energy and incident angle.

Strategies for Quantifying the 3D Atomic Structure and the Dynamics of Nanomaterials Using Model-Based STEM Sandra Van Aert[1], Annick De Backer[1], Annelies De wael[1], Jarmo Fatermans[1], Ece Arslan Irmak[1], Thomas Friedrich[1], Ivan Lobato[1], Lewys Jones[2], Arjan den Dekker[3], Peter Nellist[4] and Sara Bals[1]; [1]EMAT, NANOLab Center of Excellence, University of Antwerp, Belgium; [2]CRANN & School of Physics, Trinity College Dublin, University of Dublin, Ireland; [3]imec-Vision Lab, University of Antwerp, Belgium; [4]Department of Materials, University of Oxford, United Kingdom

Quantitative 3D characterization at high resolution is often required in order to fully exploit structure–property relations of nanomaterials. In recent years, the resolution of electron tomography has reached the atomic scale. However, for a successful 3D reconstruction using electron tomography multiple exposures are required, which is not always feasible when studying, e.g., radiation-sensitive nanostructures. In order to overcome these limitations, an alternative method can be used where the 3D atomic structure is reconstructed from atom counts obtained from a single ADF STEM projection image. These atom counts can be used to create an initial atomic model which serves as an input for an energy minimization to obtain a relaxed 3D reconstruction of a nanostructure [1].

To count atoms with single-atom sensitivity, a minimally required electron dose is necessary, while on the other hand the risk of knock-on damage, induced by the high energy electrons, puts an upper limit on the tolerable dose. An important challenge is therefore to develop experimental strategies to optimize the electron dose by balancing atom-counting fidelity versus the risk of knock-on damage. To achieve this goal, a statistical framework combined with physics-based modelling of the dose-dependent processes is proposed and experimentally verified. This model enables an investigator to theoretically predict, in advance of an experimental measurement, the electron dose resulting in an unambiguous quantification of nanostructures in their native state with the highest attainable precision [2].

For beam-sensitive materials, where the optimal electron dose can be low, the images will exhibit a limited signal-to-noise ratio and additionally, they will show a very weak contrast in the presence of light elements. In order to reliably detect the presence or absence of atomic columns and even single atoms, the maximum *a posteriori* (MAP) probability rule is proposed as a model-order selection method in which a Bayesian framework is used [3]. By using MAP selection, the probabilities for an increasing number of atomic columns present in an experimental image can be calculated. This method therefore allows us to predict the most probable atomic structure. In addition, in recent work we investigated the use and potential benefit of deep convolutional neural networks to restore low dose, scan noise distorted ADF STEM images.

Our method for atom-counting opens up new opportunities to measure variations of the 3D atomic structure of nanoparticles under the flow of a selected gas [4]. *In situ* experiments clearly demonstrate that many questions in materials science require a quantification of the material's dynamics from a series of sequentially recorded images. However, the standard approach for atom-counting, where each frame is analyzed individually, does not take advantage of the time aspect available in a series of ADF STEM images. We therefore extended the atom-counting method using the so-called factorial hidden Markov model. This new method is very promising for revealing atomic scale dynamics [5]. In conclusion, new developments in the field of quantitative STEM will be presented enabling one to reliably quantify dynamic structural changes resulting from adatom dynamics, surface diffusion, beam effects or during *in situ* experiments.

Three-Dimensional Charge Density, Electric Field and Electrostatic Potential Mapping of an Electrically-Biased Needle Using Off-Axis Electron Holography Fengshan Zheng[1], Vadim Migunov[1,2], Jan Caron[1], Hongchu Du[1,2], Giulio Pozzi[1,3] and Rafal E. Dunin-Borkowski[1]; [1]Forschungszentrum Juelich, Germany; [2]RWTH Aachen University,

Germany; [3]University of Bologna, Italy

The electrical properties of nanoscale electronic devices, such as *p-n* junctions, transistors and light-emitting diodes, are affected strongly by the presence of defects, dopants, interfaces and surfaces [1]. Just as the performance of field emitters is influenced by geometrical factors such as their shape, curvature and crystallographic orientation [2], in atom probe tomography the shape, chemistry and defects in a needle-shaped specimen can affect the trajectories of field-evaporated ions and the fidelity of the reconstruction of the three-dimensional (3D) atomic positions [3], while tip-enhanced catalytic efficiency is influenced by the shape and species of the tip [4]. A knowledge of the 3D charge density, electric field and electrostatic potential inside and around such nanostructures is therefore required.

Off-axis electron holography provides direct access to the projected electrostatic potential within and around a specimen in the transmission electron microscope (TEM) [5]. Here, we combine off-axis electron holography with electron tomography and a model-based iterative reconstruction algorithm [6] to determine the 3D charge density, electric field and electrostatic potential within and around an electrically-biased C fibre needle. The needle was prepared using a standard focused ion beam preparation procedure. A Nanofactory holder was used for electrical biasing. A µm-sized Au tip was used as a counter-electrode at a distance of 4.5 µm from the needle. The diameter of the apex of the needle was ~60 nm and its length was ~2.5 µm. Two tomographic tilt series of off-axis electron holographic phase images were acquired between -52° and +48° with a tilt increment of 4°. One series was acquired without an electrical bias applied to the needle. This dataset includes only the mean inner potential contribution to the phase. It was used to reconstruct the 3D morphology of the needle and to subtract the mean inner potential contribution to the phase from a second dataset recorded with an electrical bias of 40 V applied to the needle.

The reconstructed 3D charge density in the needle reveals that the charge density is greatest at the apex and has a maximum value of 2.94×10^{18} cm^{-3}. 2D slices extracted from the 3D reconstruction show that the charge density distribution is asymmetrical. The majority of the charge is found to be located close to the surface of the needle. A region with a locally increased charge density may be associated with damage by Ga bombardment during sample preparation. The 3D electric field and 3D electrostatic potential are calculated from the reconstructed 3D charge density on the assumption that image charges are defined by the counter-electrode. The strength of the electric field is greatest close to the apex of the needle and has a maximum value of ~0.25 GV/m [7].

3D Characterization of Supported Catalysts Using Dual Axis Electron Tomography Jessi van der Hoeven, Stephan Kraemer, Tanya Shirman, David Bell, Cynthia Friend and Joanna Aizenberg; Harvard University, United States

Supported metal catalysts, consisting of finely dispersed metal nanoparticles on high-surface-area supports, are key players in chemical industry. The interplay between the metal and supporting oxide is an important parameter in modulating the properties of heterogeneous catalysts. To gain fundamental understanding, and therefore increase our control over these metal-support interactions, 3D visualization with nano-scale precision is crucial.

Here, we achieve a quantitative 3D characterization of the local environment of metal nanoparticles embedded in a metal oxide support using dual axis electron tomography. Specifically, we studied raspberry colloid templated (RCT) catalysts – a porous silica support with partially embedded $Au_{97}Pd_3$ and Au nanoparticles in the pore walls [1] – which are active hydrogenation and oxidation catalysts [2][3]. By performing the tomography analysis over two perpendicular tilt axes, we minimized the missing wedge artifacts around the metal particles, allowing the assessment of the particle shape and geometrical confinement of 400 individual nanoparticles. We complemented the electron tomography analysis with a wet-chemical approach relying on metal overgrowth, to visualize the chemical accessibility of nanoparticles within the support. A combination of silver overgrowth on embedded Au nanoparticles and aberration-corrected high-angle annular dark-field

scanning transmission electron microscopy (HAADF-STEM) imaging, and Energy Dispersive X-ray spectroscopy (EDX) mapping unveiled that although the particles were substantially embedded in the silica support they were exposed to the pore network and are readily accessible through the interconnected micropores of the silica matrix in the RCT catalyst. Altogether our work provides a general approach to probe the geometrical confinement and chemical accessibility of a statistically relevant number of metal nanoparticles in supported catalysts in three dimensions and with nano-scale precision.

Nanoscale Photogrammetry—Correlation of 3D Representations with SIMS in a Single Instrument Alexander D. Ost, Jean-Nicolas Audinot and Tom Wirtz; Luxembourg Institute of Science and Technology (LIST), Luxembourg

The trend in miniaturisation of devices is increasing the need for characterisation techniques that are capable of investigating objects in 3D at nanoscale with both structural and chemical information. Microscopy and spectroscopy are correlated together to overcome the boundaries of each technique and to go beyond the limitations of microscopy in data treatment. In this context, we have coupled a Zeiss Orion NanoFab Helium Ion Microscope (HIM) with a specifically designed Secondary Ion Mass Spectrometry (SIMS) system in order to add analytical capabilities to the microscope [1]. In the standard HIM mode, the instrument provides secondary electron (SE) images with a sub-nm lateral resolution. These ultra-high resolution SE images can be correlated in 2D with sub-20 nm resolution SIMS images to combine the nanoscale structure and composition information for a deeper understanding of the investigated samples [2].

This two-dimensional correlative microscopy approach has been extended to three dimensions by creating 3D SE–SIMS representations of nanomaterials to give a more extensive view on the analysed objects [3]. Therefore, photogrammetry is used i.e. the sample stage is tilted and SE images are taken at a specific pattern of rotation angles with a He^+ primary beam around the region of interest (ROI). The 2D SE images are implemented into a photogrammetry software to obtain a 3D SE model observable at all possible angles and magnifications. The SIMS images of the ROI are acquired in-situ at normal incidence with a Ne^+ primary beam and projected then onto the 3D photogrammetry representation using correspondence points and by overlaying both image textures. The result displays SE and SIMS information together throughout the 4D reconstruction enhancing specimen visualisation and data interpretation.

In this presentation, we will show step-by-step the workflow of 4D reconstruction for real case studies in nanomaterials applications to illustrate the potential of this method for a variety of many other fields.

abTEM—*Ab Initio* Transmission Electron Microscopy Image Simulations Toma Susi and Jacob Madsen; University of Vienna, Austria

Transmission electron microscopy (TEM) is a powerful tool for studying the properties of materials down to the atomic level. In many cases, the quantitative interpretation of images requires simulations based on atomistic structure models. Image simulation for TEM has typically relied on the independent atom model (IAM) that neglects bonding effects, which are measurable and important for understanding many systems. The rearrangement of charge due to bonding is directly detectable in HRTEM images and can be crucial for the interpretation of small differences in the atomic contrast [1]. Moreover, the recent rise in popularity of the four-dimensional (4D) scanning TEM has been partially due to promises of unprecedented sensitivity to electromagnetic fields [2]; however, such data call for rigorous theoretical interpretation through simulations.

Since all electrons and the nuclear cores contribute to the scattering potential, simulations that go beyond the IAM have relied on computationally highly demanding all-electron calculations. We have developed a method to generate ab initio electrostatic potentials when describing the core electrons by projector functions. Combined with an interface to quantitative image simulations, this implementation enables an easy and fast means to model electron scattering. By comparing simulated transmission electron microscopy images and diffraction patterns to experimental data, we can show an accuracy equivalent to earlier all-electron calculations at a much lower computational cost [3].

We have now implemented this method in a freely available open-source program based on Python, dubbed “abTEM” for ab initio Transmission Electron Microscopy. abTEM integrates directly with two popular open-source Python codes: the Atomic Simulation Environment (ASE) [4] for setting up atomistic models, and GPAW for calculating electrostatic potentials based on the real-space projector-augmented wave implementation of density functional theory [5]. A highly efficient first-principles description of van der Waals interactions can be included via the libvdwxc library [6].

abTEM is designed for accuracy and includes up to the second-order expansion of the multislice solution of the high-energy Schrödinger equation and uses the correct integration of the sub-slicing of the three-dimensional potential [7]. Due to integration with ASE, it is straightforward to model temperature in the frozen phonon approximation using realistic configurations from molecular dynamics simulations. abTEM works as a standard full-featured multislice simulation program, and we have additionally implemented features for speeding up simulations at some cost to accuracy.

We demonstrate the capabilities of our method by modeling twisted bilayer graphene, which has recently received considerable attention due to its extraordinary and highly tunable properties [8]. This system requires on the order of a thousand atoms to represent in simulations, which, to our knowledge, is the largest system ever to be used in a quantitative electron microscopy image simulation that includes an accurate representation of bonding effects. The differences are subtle due to the large contribution of the cores; hence a great deal of care needs to be taken when extracting charge rearrangements solely based on (S)TEM measurements.

More information about abTEM is available online [9].

Development of Magnetic-Field-Free Atomic Resolution STEM Naoya Shibata[1,2]; [1]The University of Tokyo,

Japan; [2]JFCC-NSRL, Japan

Aberration-corrected scanning transmission electron microscopy (STEM) is a powerful technique to directly observe atomic-scale structures and chemistry inside materials and devices. In the state-of-the-art STEM, a probe size of less than 0.5Å in diameter has been experimentally realized. By combining with new elaborate STEM detectors, we can not only image single atoms, but can also image electric field distribution of atoms through differential phase contrast (DPC) imaging techniques. It then becomes tempting to observe magnetic fields at very high resolution, which should strongly correlate with the properties of magnetic materials and devices. However, high spatial resolution observation of magnetic materials is essentially very difficult, because high magnetic fields (~2T) are always exerted on samples inside the magnetic objective lens. In recent years, we have developed a new magnetic objective lens system that realizes a magnetic field free environment at the sample position. Using this new objective lens system combined with the state-of-the-art higher order aberration corrector, atom-resolved imaging in a magnetic field free environment has been achieved. The details of this magnetic-field-free STEM and the material application results will be presented in the talk.

5:30 AM *F.MT03.05.03
Ultra-Fast Nano-Optic with a High Brightness Transmission Electron Microscope Sophie Meuret[1], Yves Auad[2], Luiz Tizei[2], Huan-Cheng Chang[3], Florent Houdellier[1], Mathieu Kociak[2] and Arnaud Arbouet[1]; [1]CEMES/CNRS, Netherlands; [2]Laboratoire de Physique des Solides, France; [3]Institute of Atomic and Molecular Sciences, Taiwan

Nanoscale properties rule the emission and absorption of light by nano-structures, for example the shape of metallic nanoparticles or the atomic design of semiconductor heterostructures. To overcome the diffraction limit of light (≈400 nm) one of the best techniques is electron microscopy. Indeed, the electron beam probes nano-object with sub-nanometer resolution. Both Cathodoluminescence (CL) and electron energy loss spectroscopy (EELS) study the optical properties of nanostructures. They probe, for example, the luminescence properties for CL [1] and the local density of state for EELS [2]. Time-resolved electron microscopy is emerging since a decade, expanding the possibilities of these two techniques. In this presentation, we will use a unique time-resolved transmission electron microscope based on a cold-FEG electron gun [3]. This technology allows, among other things, to reach a spatial resolution of 1 nanometer in pulsed mode. We will discuss the latest results of electron energy gain spectroscopy and the acquisition of the first cathodoluminescence decay traces in a transmission electron microscope.
Electron energy gain spectroscopy is the study of the coupling of a fast-electron with the near field created by the interaction of light with the nanostructure [4]. The group of Zewail in Caltech did the first experimental study in 2009 [5] followed by a few groups [6]. In this presentation, we will discuss electron gain spectroscopy using the first cold-FEG transmission electron gun [7]. **This unique TEM allows the highest spatial resolution and highest brightness, leading to a spatial resolution of 1 nm and a strong interaction between the electron beam and the near field.**
The development of time-resolved Cathodoluminescence (TR-CL) enabled the measurement of the lifetime of excited states in semiconductors with a sub-wavelength spatial resolution. It was used for example to measure the influence of stacking faults on the GaN exciton [12]. Recently, the first pump-probe cathodoluminescence experiment using diamond revealed the effect of electron excitation on the nitrogen vacancy color center [15]. These results demonstrate that TR-CL is essential to study the correlation between semiconductor optical and structural properties (composition, defects, strain…). **While all these pioneering studies were done using a scanning electron microscope, the improvement of the spatial resolution and the combination with other electron-based spectroscopies offered by transmission electron microscopes will be a step forward for TR-CL**. In this presentation, we will discuss the first time-resolved cathodoluminescence experiments within a transmission electron microscope.

Quantum Effects in the Interaction of Optical Excitations and Fast Electrons Valerio Di Giulio[1], Mathieu Kociak[2] and Javier Garcia de Abajo[1,3]; [1]ICFO, Spain; [2]Université Paris Sud XI, France; [3]ICREA, Spain

Electrons, used as probes in electron microscopes, are of primal importance to measure material properties with unequalled combined spatial and energy resolution. For instance, inelastically scattered electrons can be collected and energetically separated in order to obtain spectra as a function of their energy loss or, with the same purpose, the radiated light can be collected in the far field and filtered in polarization and frequency. In particular, electron energy loss spectroscopy (EELS) can be considered the richest source of information as it carries the influence from the surface-sustained modes as well as from the bulk response of the system. Additionally, the synchronization of ft laser illumination with electron pulses at the sample opens the routes to study the ultrafast dynamics of nanostructured materials and their influence on optical near-fields. The evanescent components, produced by the excitations in the material, efficiently overcomes the unavoidable energy-momentum mismatch between free photons and free electrons yielding appreciable light-electron couplings. This strong interaction leads to multiple exchanges of quanta between the electron and the optical field, accompanied by a complex sub-fs dynamics. Based on this principle, photon-induced near-field electron microscopy (PINEM) is performed by analysing the resulting multiple gain and loss features in the electron spectra. PINEM experiments have so far relied on coherent light sources (i.e., lasers), for which the measured spectra are well reproduced by assuming sample bosonic excitations that are coherently populated with a large number of quanta. The probability of each electron spectral peaks associated with a net exchange of l quanta is then simply given by squared Bessel function. Additionally, this technique, performed with coherent light, has been combined with an electron free propagation of few millimeters to yield a temporal compression of the electron density of the order of attoseconds. Despite the numerous results obtained in this context, different aspects of the interaction between free electrons and confined light remain unexplored. For instance, the effects induced by the replacement of the coherent laser pulses with a quantum light source on electron spectra, are expected to show interesting physics significantly departing from the one previously studied.

In this work, we use quantum-optics methods in order to describe the quantum nature of the optical field and to understand how the resulting electron spectra strongly depend on the statistics of the sample excitations and their population, whose autocorrelation functions are directly retrieved from the ratios of electron gain intensities. In particular, in the limit of highly populated mode, we recover the usual results of classical PINEM for Fock and coherent states but we find a significant difference in the distribution of the gain and loss peaks of electron spectra in the case of thermal state. Furthermore, we study the role of quantum states of light, e.g. squeezed states, in shaping the longitudinal part of the electron wave function after a macroscopic propagation distance observing a faster compression of the electron density for light states with low phase uncertainty.

In conclusion, we consider this work of fundamental importance in the understanding of quantum many bodies excitations and their statistics as well as in the ability of tailoring the electron wave function via the use of light.

5:55 AM F.MT03.05.05
Electron Beam Aberration Correction Using Optical Near Fields Andrea Konecna and Javier Garcia de Abajo; ICFO, Spain

Over last decades, electron microscopy has become very powerful and versatile technique for nano- or atomic-scale imaging and spectroscopy [1]. Major advancements and outstanding capabilities have been made possible thanks better spatial and temporal control over the amplitude and phase of the wave function that characterizes the fast electrons used as sample probes. Control over the beam shape is commonly achieved by means of complex arrangements of magneto- and electrostatic electron lenses that enable sub-Ångstrom focusing and beam scanning, as well as correcting aberrations of electron optics. The phase of the electron wave function can be additionally modified by introducing static phase plates.

We envision an alternative to traditional electron-optics elements emerging by using optically-driven phase plates and enabling dynamical shaping of electron-beam wave functions both in space and time. This approach capitalizes recent experimental demonstrations of wave function control through optical near fields [2-4]. The electron-light interaction can in principle allow us to generate arbitrary electron beam shapes; as an application with high potential for improving the resolution of electron microscopes, we employ it here to correct for aberrations of standard electro- or magneto-static lenses

used in current setups.

We demonstrate aberration correction via the interaction of the electron wave function with suitably profiled optical fields. We illustrate this concept by focusing on primary spherical aberration, which due to rotational invariance typically requires complex and expensive aberration correctors. Our work suggests that an optical corrector can help to significantly improve the focal spot and beam profile over the aberrated configuration, and that it can be in principle used to eliminate any undesired beam distortions in both standard and ultrafast (scanning) transmission electron microscopy. Optical aberration correctors could offer better versatility and compactness with respect to traditional corrector designs, and we foresee that they could open a new era of electron microscopy both in aberration correction and in the generation of on-demand electron beams.

6:05 AM F.MT03.05.06
Photon Emission Dynamics in Cathodoluminescence Induced by Picosecond Electron Pulses Magda Sola-Garcia[1], Marnix Vreugdenhil[1], Kelly W. Mauser[1], Sophie Meuret[2] and Albert Polman[1]; [1]AMOLF, Netherlands; [2]CEMES-CNRS, France

Ultrafast electron microscopy allows for the study of nanoscale material dynamics at picosecond time resolution. Electron pulses are typically generated using pulsed-laser induced photoemission from the electron cathode, and often multiple electrons are emitted within a single picosecond pulse. Here we study the dynamics of photon emission after excitation by dense collision cascades generated with controlled electron pulse densities. We use an ultrafast SEM cathodoluminescence (CL) microscope equipped with a pump-probe configuration, which enables a direct comparison between electron and light excitation.
Our pump-probe SEM-CL microscope is based on a 1-30 keV SEM equipped with a Schottky field-emission electron cathode. We use 250-femtosecond laser pulses at a wavelength of 258 nm to excite the W/ZrO electron cathode at a repetition rate from 200 kHz up to 25 MHz and create picosecond electron pulses by photoemission. By tuning the laser power we vary the average number of electrons per pulse from less than 1 up to 500. We record $g^{(2)}(\tau)$ autocorrelation statistics of the CL emission at a wavelength of 450 nm from InGaN/GaN quantum wells using a Hanbury-Brown and Twiss interferometer with 70 ps temporal resolution.
Previous work using continuous and ns-pulsed electron beams has shown that strong bunching ($g^{(2)}(0)$ up to150) of CL photons can occur when exciting a sample with high-energy electrons, due to the fact that a single collision cascade can generate multiple CL photons [1,2]. Here, we extend this method to study bunching after excitation with ps electron pulses created using photoemission. We find that $g^{(2)}(0)$-1 decreases inversely proportional to the number of electrons per pulse, similar to the trend with electron current found in previous work. We introduce an analytical and a statistical model to describe the bunching process and reproduce the measured dependence of $g^{(2)}(\tau)$ on electron density in the ps pulses. Further analysis shows how the number of excitations/photons generated in each collision cascade can be derived from the data. The results suggest that despite the very high density of collision cascades, non-linear effects do not play a role in the plasmon generation, carrier diffusion and carrier recombination effects that follow electron impact on the InGaN/GaN quantum wells.
Next, we use the SEM-CL microscope in pump-probe configuration, by sending part of the femtosecond laser into the SEM chamber. We use this to further study the dynamics of carrier generation and recombination in electron and laser-excited semiconductors [3]. We probe the decay dynamics of bandgap emission in GaAs and CZTS (Cu_2ZnSnS_4) upon ps electron excitation (at 5-30 keV) and 250 fs laser excitation (λ=345 and 517 nm). We study the variations in carrier decay dynamics as a function of laser power and electron pulse density, to deduce the contribution of the different radiative and non-radiative decay mechanisms in each case. These results allow us to compare carrier densities in dense collision cascades and optically excited volumes in these semiconductors.
Finally, we combine CL and PL measurements to perform pump-probe spectroscopy, in which we use a delay stage to control the time between arrival of electron and laser pulses on the sample. We use the electron as a pump and the laser as a probe, and vice versa, aiming to probe non-linear effects in the evolution of dense electron cascades generated by picosecond electron pulses.

Mapping Structure and Composition of Intact Li-Metal Anodes after Cycling Katherine L. Jungjohann[1], Katharine Harrison[1], Daniel Long[1], Renae Gannon[2], Laura Merrill[1], Subrahmanyam Goriparti[1] and Steven Randolph[3]; [1]Sandia National Laboratories, United States; [2]University of Oregon, United States; [3]Thermo Fisher Scientific, United States

The electrolyte 2.8 M lithium bis(fluorosulfonyl)imide (LiFSI) in dimethoxyethane (DME) has demonstrated good cycling behavior and stable Li morphology upon plating and stripping for high-capacity Li batteries, which is thought to be due to the formation of a stable solid-electrolyte interphase (SEI) layer for good ionic transport. Characterization of this SEI layer on lithium metal has been limited, due to the air-sensitivity and beam sensitivity of these materials, as well as the incompatibility of the electrolyte with the high vacuum environment necessary for nanoscale characterization with electron microscopy techniques. New cryogenic stages and transfer tools have enabled the characterization of frozen solid-liquid interfaces for lithium metal structures. Here, we used cryogenic focused ion beam (FIB) and ultrashort pulse laser ablation to create a cross-section of the lithium metal anode in contact with the electrolyte at various plating/stripping cycles to understand the morphological evolution of the lithium and SEI. Additionally, with cryo-FIB we utilized lift-out procedures under cryogenic temperatures for extraction of a lamella sample for investigation using scanning/transmission electron microscopy with energy dispersive x-ray spectroscopy and electron energy loss spectroscopy. The nanoscale chemical maps have allowed for a greater understanding of the SEI components and how they redistribute with reaction to the lithium metal over the course of many cycles. These results present a step towards visualization of the intact battery stack. We have determined a failure mechanism beyond short circuiting of the lithium metal anodes, due to reaction of the lithium with this LiFSI in DME chemistry.

Identifying High-Temperature Superconductivity at Complex Oxide Interfaces Y. Eren Suyolcu[1,2], Gennady Logvenov[1] and Peter A. van Aken[1]; [1]Max Planck Institute for Solid State Research, Germany; [2]Cornell University, United States

Transition metal oxide heterostructures host many novel functionalities and have stimulated large interest due to the possibilities of tailoring the functionalities at the atomic layer scale. It is the complex interactions at the interfaces of epitaxial oxide systems that contribute to intriguing physical effects induced by the local variation of electronic and ionic species. In this work, we focus on high-temperature superconductivity (HTSC)[1] of La_2CuO_4-based iso-structural and non–iso-structural systems. In particular, we fabricate (i) $La_{1.6}A_{0.4}CuO_4$–La_2CuO_4 (A = Ca, Sr, Ba) metallic–insulating (M–I) bilayers [2] and (ii) $(La,Sr)_2CuO_4$–$SrMnO_3$–$LaMnO_3$–La_2CuO_4 multilayers [3] using atomic-layer-by layer oxide molecular beam epitaxy (ALL-Oxide MBE) [4].
In order to correlate local structure and superconducting properties, we extensively probe the interfaces using aberration-corrected analytical scanning transmission electron microscopy (STEM) techniques including high-angle annular dark-field (HAADF) and annular bright-field (ABF) imaging, electron energy-loss spectroscopy (EELS), and energy-dispersive X-ray spectroscopy (EDXS). For the atomic-resolution analyses, a JEOL JEM-ARM200F STEM equipped with a cold field-emission electron source, a probe C_s-corrector (DCOR, CEOS GmbH), a Gatan GIF Quantum ERS spectrometer and a large solid-angle JEOL Centurio SDD-type EDXS detector was used. STEM imaging and EELS were performed at probe semi-convergence angles of 20 mrad and 28 mrad, respectively. The collection angles for HAADF and ABF images were 75-310 mrad and 11-23 mrad, respectively. O-O picker tool [5] software has been utilized for STEM image quantification.

The choice of the dopant substantially influences the superconducting mechanisms as a consequence of the dopant distribution near the nominal M–I bilayers interfaces. In the case of Sr- and Ca-doping, sharp interfaces induce striking interface effects, *i.e.* electronic redistribution. Differently, for Ba-doped bilayer, HTSC is attributed to "classical" homogeneous doping determined by cationic intermixing.[6] Moreover, we demonstrate that sharper Sr-doped La_2CuO_4 interfaces can be achieved by the heteroepitaxial contacts with manganite layers. The dopant distribution in La_2CuO_4 is affected by the elemental intermixing at the first atomic monolayer of the interfacial $LaMnO_3$ contact. Different superconducting behavior (interface vs filamentary) at the two different interface systems are correlated with the interface sharpness and will be discussed in detail.

5:25 AM F.MT03.06.03
Imaging and Quantification of Topological Charges in $BiFeO_3$ Domain Walls Marco Campanini[1], Elzbieta Gradauskaite[2], Morgan Trassin[2], Di YI[3], Pu Yu[3], Ramamoorthy Ramesh[4], Rolf Erni[1] and Marta D. Rossell[1]; [1]Empa, Switzerland; [2]ETHZ, Switzerland; [3]Tsinghua University, China; [4]University of California, United States

Domain walls (DWs) in ferroelectrics constitute the two-dimensional (2D) boundary region between domains characterized by different values of the order parameter, i.e. the ferroelectric polarization. One of the most striking properties of DWs is their ability to carry a bound charge, due to the screening by the free carriers of the material. In ferroelectric oxides, such charged DWs behave as 2D conductive pathways embedded in an insulating matrix. This special feature has raised a vast interest in conductive DWs for their potential use in future nanoelectronics. In particular, as the DWs in ferroelectric oxides are often movable under an external electric field, [1,2] they represent a very promising element for novel rewritable circuitry.
Deepening our knowledge about the charge screening processes is of fundamental relevance to achieve a complete understanding of their conduction properties. However, the lack of experimental techniques that are directly sensitive to the localized charges with sub-nanometer resolution makes the identification and the quantification of the screening charges a challenging problem.
In this study, we perform an atomic-scale study of the origin of the enhanced conductivity in charged 109° tail-to-tail (T-T) domain walls in the archetype multiferroic $BiFeO_3$ (BFO), by combining state-of-the-art scanning probe techniques – such as piezo-response force microscopy (PFM) and conductive atomic force microscopy (cAFM) – with differential phase-contrast (DPC) scanning transmission electron microscopy (STEM). [3]
Our study was conducted on the heterostructure $BiFeO_3$ (120 nm)/$La_{0.7}Sr_{0.3}MnO_3$ (5 nm)/$SrRuO_3$ (1 nm)/$SrTiO_3$ grown by pulsed laser deposition. The ferroelectric domain pattern observed by PFM displays the typical contrast of 71° DWs with head-to-tail DWs, which are oriented along the main directions of the cubic substrate. Interestingly, strongly charged T-T DWs are generated at the merging points of 71° stripes with different orientations. Thanks to their topologically charged state, these charged DWs display enhanced conductivity.
The analysis of the atomic displacements from high-resolution high-angle annular dark-field (HAADF) STEM demonstrates that the charged T-T domain wall presents a mixed Ising-Néel structure and is composed of a strained core with a lateral thickness of 6-8 unit cells. The charged-state of the DW was initially assessed by computing the density of bound charge (ρ_B) starting from the polarization maps. In particular, we image a distribution of positive charges mostly localized at the DW, with localized maxima separated a few nanometers from each other. The ρ_B reaches a maximum value of 1 oxygen vacancy (O_v) every 4 unit cells.
In order to directly image the topological charges at the DW, we employ the differential-DPC (dDPC) imaging technique. The differential form of DPC – thanks to its enhanced sensitivity to low Z species – has been recently been proven to be effective for imaging light elements, such as N, [4] Li, [5] and O. [6] By using dDPC, we successfully image the O columns in the BFO layer and thus map the O_v distribution along the DW core.
Our results elucidate the nature of the conductive DWs in BFO, providing new insights about their structure and charge

screening phenomena. In particular, combining atomic displacement mapping and dDPC-STEM imaging we can image and quantify the local charges that are responsible for their high conductivity. This work paves the way for future studies about the structure-properties relationship in such charged DWs.

5:35 AM F.MT03.06.04
Competition Between Doping and the Polar Instability in a Ferroelectric Superconductor Salva Salmani-Rezaie[1], Kaveh Ahadi[2,1] and Susanne Stemmer[1]; [1]University of California, Santa Barbara, United States; [2]North Carolina State University, United States

The competition between polar distortions and the mobile charge carriers is a problem of longstanding interest to the development of a quantum theory of ferroelectricity. It is also a key issue for polar superconductors, which are a promising route to unconventional Cooper pairing.
$SrTiO_3$ is an incipient ferroelectric in unstrained, stoichiometric form, but easily becomes ferroelectric when subjected to small perturbations, including chemical substitution or applied stress. Ferroelectricity precedes superconductivity in doped, strained $SrTiO_3$, suggesting a complex relationship between two instabilities. Using an atomic-resolution scanning transmission electron microscope, we show atomic-scale evidence of the interplay between itinerant electrons and the correlated polar distortions above Curie temperature.
The undoped, strained $SrTiO_3$ films show correlated polar nanodomains above Curie temperature, suggesting an order-disorder type ferroelectric phase transition. We observe a systematic suppression of the correlated polar distortions, i.e. nanodomains, and ferroelectricity with introducing Sm dopants. The itinerant electrons screen polar distortions and disrupt nanodomains above Curie temperature. Increasing the dopant density, strain field of the dopants overlap and randomize the polar distortions. The results provide direct evidence that the long-range Coulomb interactions, already present in the paraelectric phase, are driving the ferroelectric transition and are becoming increasingly short-ranged with doping. Moreover, we show that the disorder caused by the dopant atoms themselves presents a second contribution to the destabilization of the ferroelectric state. This disorder completely destroys the nanodomains at high dopant concentrations, thereby. The results thus provide evidence for two distinct mechanisms that suppress the polar transition with doping and the presence of both competing and collaborative microscopic interactions in a ferroelectric superconductor. We also observe an inverse relationship between the critical temperature of superconductivity and the magnitude of polar distortions. Understanding the nature of ferroelectric transition and its interplay with itinerant electrons is of interest for testing the different proposed theoretical models for superconductivity in $SrTiO_3$.

5:45 AM F.MT03.06.06
Toward Precision Manupulation of Materials in the Transmission Electron Microscope Cassandra Pate[1], Joshua Agar[2] and Mitra L. Taheri[1]; [1]Johns Hopkins University, United States; [2]Lehigh University, United States

Realization of precision, close-loop processes requires an integrated suite of integrated hardware [1], software [2] and modeling [3], and materials synthesis/optimization. With spatio-temporal control, deterministic synthesis can be achieved in quantum devices, patterned assemblies, and tailored additive manufacturing of materials. Real time processing multidimensional (hyperspectral) data signals benefit from machine learning approaches presenting an opportunity for implementation of a feedback loop for manufacturing of critical technologies, from quantum computers to 3D printed turbine blades. In order to probe specific phenomena, stimulus and detection must be linked; without real time “learning,” key events are left undetected due to temporal resolution limits or failed temporal triggering alignments. Novel detector designs enable manufacturing processes to be viewed “in operando” at high acquisition speeds (upwards of 4000 fps).The combination of machine learning with these detectors makes automation for atomic-scale manipulation a realistic goal. Here we present the application of machine learning techniques to hyperspectral data to demonstrate a framework for understanding rapidly evolving phenomena using convolutional neural networks trained on >10,000 spectra collected at 400 frames per second during an electron beam manipulation of complex oxide structures. We extend these studies to despite very noisy data collected at 400 fps. unsupervised learning via feature extraction instead of comparing to known labels, which enables the analysis of situations when otherwise inaccessible transformations or metastable states occur. These techniques provide the ability to precisely and predictively tune complex materials toward. To that end, we will highlight extension of these

techniiques to surface termination manipulation in 2D materials.

Excited State Pathways for Electron Beam Induced Point Defect Manipulation in Graphene
Nanomaterials Panchapakesan Ganesh[1], David B. Lingerfelt[1], Tao Yu[2], Jacek Jakowski[1] and Bobby Sumpter[1]; [1]Oak Ridge National Laboratory, United States; [2]University of North Dakota, United States

The use of scanning transmission electron microscopes to manipulate substitutional defects in graphene has recently been demonstrated and modeled using ground state molecular dynamics, but the role of electronic excitations induced through inelastic electron scattering in promoting these transformations has so-far remained unexplored. In this work[1,2,3] we probe the effects of electronic excitations on the structural dynamics of localized-defects induced by an electron-beam (a point-charge perturbation), such as substitutional Si/P in graphene quantum-dots as well as the recently observed mobile Si-C_3 defects in graphene nanoflakes. Particularly, the ground and excited state potential energy barriers for the structural transformations are evaluated using time-dependent density functional theory and reveal that the barriers for such localized structural transformations can be effectively lowered upon excitation to the defect-centered excited state through an electronically nonadiabatic pathway. Optically bright excited states in which the barrier is decreased are identified in the low energy region of the electronic spectrum, suggesting that photoexcitation can modulate the reactivity of defects in graphene under electron beam irradiation. Implications of this discovery on directing localized nanoscale transformations using electron-beams will be further discussed, especially in quantum-materials.

5:00 AM F.MT03.07.01
Imaging Polymer Crystallinity with STEM Hui Luo, Hazel Assender and Peter Nellist; University of Oxford, United Kingdom

The spatial atomic structure of PEN is accessible for the first time with ptychographic reconstruction under low dosage illumination.

Introduction
Organic crystalline structures have been determined by diffraction methods that only generate average structural information from the characterization region. However, crystal structure and orientation in polymers, which depends on e.g. temperature, interfacial interactions and strain, will vary locally. To resolve the detailed microstructure, high resolution imaging is required.
In a case study of annealed thin films of polyethylene naphthalate (PEN) [1], crystalline domains were found to vary with the depth from a surface. We use PEN as a model system to demonstrate high resolution imaging of polymer crystals. High resolution imaging of polymers is limited by the low contrast generated by light elements and beam damage from the high-intensity illumination that is used to get sufficient resolution. Low dose imaging techniques applied here have proved very helpful to acquire data from the pristine structure before it is significantly altered by radiolysis.

Ptychography
A thin polymer specimen can be treated as a weak phase object. When the electron probe scans through a thin specimen consisting of light elements, the amplitude is not expected to change significantly, while the phase contrast will offer more useful information.
Ptychography [2] is a dose efficient imaging technique with phase retrieval capacity by making use of a 4D STEM dataset. It has these advantages: i) Phase can be retrieved by Wigner-Distribution Deconvolution, and lens aberration can be corrected

in post-acquisition computation. ii) Depth information can be obtained with optical sectioning, from the 4D dataset recorded in only one scan. This is very useful for beam sensitive materials. iii) Equipped with a fast-pixelated detector, the dataset recorded in low dose illumination can be adjusted to give sufficient signal for reconstruction.

High resolution image of PEN with discrepancy from XRD

Figure. 1 shows a ptychographic image of a grain in PEN. Many of the spatial frequencies present in the image, such as the (200) spacing, agree with previous models derived from X-ray diffraction studies. Noticeable in Figure. 1, however, there are some details between the (200) planes that are not predicted from the previous model. This information can only be uncovered by direct imaging.

This technique will enable the study of crystallography and defects of soft matter, hence assist us understand the property-structure relation of synthetic polymers at atomic level, and potentially the structure of natural macromolecules, e.g. protein, DNA, RNA.

Graphene Encapsulation Sample Platform for Imaging and Analysis of Biological Cells Christopher Arble[1], Hongxuan Guo[2], Alessia Matruglio[3], Lisa Vaccari[4] and Andrei A. Kolmakov[1]; [1]NIST, United States; [2]Southeast University, China; [3]University College London, United Kingdom; [4]Elettra Sincrotrone Trieste, Italy

Label-free spectroscopy and microscopy of live cells offers the capability to examine in-vivo conditions of cellular functions and structure providing valuable insight into biomolecular components of cells [1]. The physicochemical insulation of a samples' biologically relevant environment and instrumentation is critical for the proper understanding of underlying processes and reactions for label-free investigations. The recent development of two dimensional (2D) materials, i.e. graphene, makes it possible to isolate the sample environment from UHV conditions using these materials as molecularly impermeable, electron transparent membranes [2]. The latter opens the application of vacuum-based analytical techniques such as soft x-rays and electrons for in vivo cellular studies. Herein we report the design and fabrication of graphene encapsulated liquid cell platform designed to be suitable for in-situ studies of hydrated biological samples. The encapsulation with graphene allows the sample to be intimately confined and have its interstitial fluid environment preserved while becoming suitable to be studied with multiple analytical techniques [3]. This approach reduces the parasitic adsorption and scattering of the surrounding matrix while still providing nourishment to the cells for an enhanced lifetime [4]. The platform consists of an array of Si3N4 windows on which the samples are deposited allowing for combinatorial batch analysis. The platform has a small cross-section with photon and electrons making it compatible with a wide range of spectroscopies and microscopies. Implementation of sample immobilization with a biocompatible patternable hydrogel media allows for an extended lifetime of realistic conditions and potentially extended cellular lifetimes under measurement. Preliminary results into the viability of graphene encapsulation for biological samples were conducted with fluorescence optical, SEM, and FTIR microscopies.

Investigating Solution-Processed Optoelectronic Materials with Cryo-EM Nikita Dutta, Nakita K. Noel and Craig Arnold; Princeton University, United States

Solution processing is a common first step in optoelectronic device fabrication, as it is a low-cost method with considerable flexibility. While it has been observed in several systems that solution chemistry affects both the morphology and properties of the deposited material, the manner in which these effects arise is rarely well understood; this is due in large part to the experimental difficulty of characterizing materials in solution. Here we demonstrate how cryo-electron microscopy (cryo-EM) can be used to overcome this challenge, sharing results from two technologically relevant systems: chalcogenide glasses and lead-halide perovskites. We show multiple cryo-EM methods, including single particle analysis, and discuss how an informed choice of method can reveal unique information about each material. Our results shine a light into the black box of solution processing, ultimately enabling better control over film morphology and optoelectronic performance.

5:30 AM F.MT03.07.05
Characterizing the Mesoscale Organization of Beam-Sensitive Organic Semiconductors Using Low-Dose Transmission Electron Microscopy Camila Cendra[1], Christopher J Takacs[2] and Alberto Salleo[1]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

Electronic and ionic transport in semiconducting polymers depends strongly on both molecular structure and mesoscale morphology. Transmission electron microscopy (TEM) studies of semiconducting polymers have proven to be challenging due to their inherent beam sensitivity and the interconnectedness of the physical processes occurring at various length scales. The complex, often hierarchical, internal structure of these molecular systems requires characterization tools that allow us to correlate structure from the nanoscale through the mesoscale all the way to their macroscopic properties. We leverage advances in high-resolution TEM (HRTEM) hardware, such as ultra-sensitive detectors and the use of cryogenic temperatures, and parallel computing data analytics tools to characterize the mesoscale organization of semiconducting polymers across areas similar in size to electronic devices (~ 10 μm^2). The vast amount of data acquired from HRTEM imaging enables a statistical approach, which is necessary given the inherently disordered nature of semicrystalline materials.

We directly image the structure of a series of semicrystalline conjugated polymers using a fast read-out direct detector to record dose-fractionated exposure series (i.e., “movies”). The dose-fractionated exposure series are then analyzed using Fourier space image processing techniques and computer-based corrections for beam-induced specimen motion. The structure is spatially resolved through mapping of the alkyl (100) or backbone (001) spacing reflections, revealing the rich, peculiar nature of the nanoscale organization of semiconducting polymers. Through analysis of the local orientational correlations, we provide insights into the mesoscale organization of these materials. In addition, constructed orientation maps and director field lines with nanoscale resolution (~3 – 5 nm) allow us to visualize the alignment of molecular chains and understand electronic connectivity. The results show how beam-sensitive organic materials can be visualized and characterized at the nanoscale level using low-dose HRTEM to uncover their long and short-range organization, which is essential for understanding their macroscopic functional properties.

5:40 AM F.MT03.07.06
Understanding Order in Disordered Organic Semiconductors Christopher J. Takacs; SLAC National Laboratory, United States

Organic semiconductors are of interest for a variety of applications such as biocompatible electronic devices, transistors, batteries, and solar cells. The morphology and self-assembly of these materials strongly influence charge and ion transport. While our fundamental understanding of structure-function relationships has improved greatly in recent years, significant questions remain about the nature of order at the nanoscale, the role of mesoscale organization, and its connection to the device transport properties. Here I discuss recent work examining the structure of a high-mobility semiconducting polymer previously thought to be amorphous. Thin-film synchrotron scattering, x-ray free-electron laser nano-diffraction, cryo-EM, and 4D-STEM are combined to demonstrate a rich, hierarchal organization with significant local fluctuations in molecular packing and signs of homoepitaxial order. These results combined with molecular modeling suggest a range of intra- and inter-molecular defects that break translational order but allow good long-range electronic coupling necessary for high mobility. This case highlights the need to develop and apply new high-resolution structural probes in heterogenous systems to self-consistently understand structure in disordered materials.

Continuously Variable Temperature Cryo-STEM: Atomic-Resolution from 100 K to Room Temperature and Beyond Elisabeth Bianco, Berit Goodge, Ismail El Baggari, Noah Schnitzer and Lena Kourkoutis; Cornell University, United States

Sub-Ångström-resolution STEM has become a routine tool to study radiation-hard inorganic crystals, but only recently has it been achieved at cryogenic temperatures. This advancement has provided the capability to capture exotic electronic states, such as charge ordering [1-3]. However, precisely tracking the emergence of low-temperature states requires high-resolution and precision STEM across a broad range of temperatures, cryogenic and intermediate, which remains a serious challenge. Here, we demonstrate a new side-entry, dual-tilt cryogenic holder (HennyZ) that combines liquid nitrogen cooling with fast, local heating *via* a 6-pin MEMS device. This enables intermediate temperature studies at atomic resolution and the flexibility for more complex experiments, such as coupling with *in situ* biasing [4]. Sub-Å resolution is enabled by consistently low drift rates of 0.3-0.4 Å/s in the full temperature range from ~100-1000 K. Furthermore, the local heating in this continuously variable temperature (CVT) cryo-STEM approach allows the temperature to be cycled repeatedly and rapidly within a single experiment, affording novel dynamic studies. Understanding structural changes in materials at the atomic scale and at temperatures where they occur is critical for manipulating quantum states. We demonstrate CVT cryo-STEM as an effective local probe for revealing unexpected structural phenomena, such as metastable intermediate phases, in Nb_3Br_8—a 2D magnetic material [5,6].

3D Morphology of Double Gyroid and Double Diamond BCP Tubular Networks Edwin Thomas and Xueyan Feng; Texas A&M University, United States

Block copolymers (BCPs) self assemble into a wide variety of periodic structures and elucidating their nano- and micro-structures has typically been accomplished by a combination of transmission electron microscopy and small angle xray scattering. Two of the more complex microdomain structures in BCPs are the double gyroid (DG) and double diamond (DD). We have developed a 3D reconstruction tool, slice and view scanning electron microscopy to create large volume tomograms of the DG and DD structures enabling detailed investigation of a host of supra- and sub- unit cell morphological characteristics. These include the nature of the curvature of the Intermaterial dividing surface (IMDS), the length and angle distribution of the network struts as well as distortions of the cubic unit cells into triclinic variants. In addition to the periodic structure, we have discovered and classified various point, line and surface defects. Because the minority component in the DG and DD phases are 3D continuous networks, defects lead to changes in topology. We find loop and bridging defects in the networks, as well as dislocation defects and sharp, coherent twin grain boundaries and wide non-crystalline grain boundaries. Such defects generally occur during nucleation and growth of the phase and are important for order-order phase transformations as well as for mechanical and transport properties.

Multiscale Strain Mapping and Mechanical Properties Determinations of 2024 Aluminum Alloys Using Transmission Electron Microscopy Techniques Florent Ravaux, Humaira Zafar, Cyril Aubry and Dalaver H. Anjum; Khalifa University of Science and Technology, United Arab Emirates

Lightweight aluminum (Al) alloys reinforced with a second phase are widely used in aerospace industry. Nanometer scale precipitates distributed in an aluminum matrix considerably change the mechanical properties of these alloys. The degree of coherency of those precipitates, their density, and material properties (such as Young's modulus) considerably change the bulk mechanical behavior of the alloys. Therefore, investigation of their properties is of great interest for improving alloy

characteristics.
The structure-property relationships between the precipitates and Al matrix are complex and often require advanced characterization techniques for their analysis. The formation of the precipitates results in the outbreak of internal stress fields due to the lattice mismatch between precipitates and Al matrix. Strain mapping techniques using Transmission Electron Microscope (TEM) are proven to be a powerful technique for investigating the mechanisms leading to the formation of stress fields. Commensurately, the technique of Electron Energy Loss Spectroscopy (EELS) provides a complementary information on the Young's modulus (Y_m) through the analysis of the energies of bulk plasmons.
In this study, different TEM techniques are applied to characterize the influence of the Cu precipitates in an Al alloy. We focused on the characterization of a specific material namely 2024 Al alloy composed of Al-4.35 Cu-1.5 Mg-0.64 Mn-0.5 Si-0.5 Fe (wt.%). The samples are treated at 495°C followed by water quenching. Different aging processes are carried out to control and accelerate the formation of particular precipitates known as θ". Strain mapping techniques capable of generating results at different field of views are applied to get insights on the properties of θ" precipitates. Specimens are prepared with a standard lamella process using Focused Ion Beam (FIB) scanning electron microscope and TEM experiments are performed using aberration corrected microscope of model Titan 80-300 ST from Thermo-Fisher Scientific.
Geometric Phase Analysis (GPA) is applied to high resolution STEM images in order to determine the strain in Al matrix around the θ" precipitates. This technique allows to determine at a very high spatial resolution the strain at the vicinity of the precipitates and their coherency. However, the field of view is limited to a 20 nm x 20 nm area. Nano beam diffraction (NBD) is used to determine strain at the microscale due to its higher field of view which allows to map mechanical deformation at the grain size scales. Due to the larger field of view (500 nm x 500 nm), this technique, combined with GPA, make the analysis of the strain inside grains possible and show the influence of the dislocations identified and localized with GPA.
Additionally, the determination of plasmon energies was carried out to evaluate the Y_m of the alloy at nanoscale. Moreover, the bulk modulus (B_m), and shear modulus (G_m) are established. Furthermore, the nano-indentation experiments and electron backscatter diffraction (EBSD) mappings are performed to correlate the bulk material properties to the nano and micro scale observations. In this way, a true structure property relationship of 2024 alloys has been investigated at bulk scales as well as at nanoscales.
In conclusion, the presented study shows that the employed techniques of TEM and EELS complement the results obtained by using the techniques of EBSD and nano indentation. Hence their combination enables to gather a deeper understanding of the strain relaxation mechanisms occurring in the alloy. This methodology resulted in the determination of a relation among (i) heat treatment, (ii) precipitates distribution and (iii) mechanical properties. In the end, the obtained results are used as inputs to propose a model for better prediction of mechanical properties of 2024 Al alloy.

Furthering the Resolution Limit of EBSD Jakub Holzer[1,2,3], Andrew Marshall[4,3], Pavel Stejskal[3], Chris Stephens[3] and Tomáš Vystavěl[3]; [1]Institute of Physics of Materials of CAS, Czechia; [2]Central European Institute of Technology of BUT, Czechia; [3]Thermo Fisher Scientific, Czechia; [4]The University of Surrey, United Kingdom

Electron Backscatter Diffraction (EBSD) has become an established crystallographic and microstructural characterization technique, particularly for metallurgical applications. The resolution of the technique is ultimately limited by the practical SEM probe size combined with the overlap of sampling interaction volumes. This spatial resolution is constrained further by the requirement to use high sample tilts to increase the diffraction contrast. As a result, certain applications often require the use of transmission Kikuchi diffraction, or other transmission electron microscopy (TEM) based techniques, which typically demand lengthy foil or lamellae preparation by focused ion beam. By utilizing an array of sensors capable of direct electron detection, mounted on a retractable arm around the microscope's objective pole piece, we are able gain several advantages compared to EBSD in a standard geometry. This tilt-free sample-to-detector geometry permits the collection of distortion free patterns from a well-defined area and the high sensitivity of the detector allows for pattern collection at lower incident electron energies. This enables a reduction of the sampling volume and has the potential for improved precision and physical spatial resolution with usable signal intensity. Here, we present an adapted methodology to determine the resolution of this tilt-free geometry together with the first experimental results on a molybdenum bi-crystal with a well-defined Σ3 boundary. By sampling perpendicular to the Σ3 boundary with 5nm step and evaluating the variation in the quality of the collected diffraction patterns, the physical resolution can be measured based on the full width at half maximum of the Gaussian curve fit of the pattern quality. Even with 5 nm step, the measured boundary on the indexed map is sharp. The EBSD results are further compared and validated by TEM measurements on lamellae prepared from the same specimen.

Multimodal Characterization of Hybrid Nanocomposite Materials—The Case Study of the Oleophilic Hydrophobic Magnetic (OHM) Sponge for Oil Spill Remediation Stephanie Ribet[1], Vikas Nandwana[1], Roberto dos Reis[1], Tirzah Abbott[2], Eric Roth[2] and Vinayak Dravid[1,2]; [1]Northwestern University, United States; [2]NUANCE Center, United States

There are significant intrinsic challenges to characterizing hybrid (hard-soft) materials due to the difference in properties between components of these structures. Nonetheless, establishing the structure-property relationships of these systems is an essential step in material design. Here we study the recently reported Oleophilic Hydrophobic Magnetic (OHM) sponge, a nanocomposite system that offers the ability to repeatedly adsorb 20-35 times its weight in oil. [1,2] The OHM sponge is synthesized by coating a polyurethane membrane with a nanocomposite, made of nanoparticles, such as Fe_3O_4, and graphite. In addition to the aforementioned challenge of distinguishing both the hard (nanocomposite) and soft (PU sponge) features, this hierarchical material necessitates exploration at multiple length scales. Given the physically and chemically complex characteristics of this membrane, a correlative multimodal approach is needed to study the fundamental underpinnings contributing to the performance of this material. We apply a combination of SEM, S/TEM and Raman spectroscopy to probe the structure, morphology and chemistry of the OHM sponge including with *operando* techniques.

Preparing thin samples for electron microscopy of hybrid materials can be difficult due to the nonuniform mechanical properties of the system. Here, we embed the OHM sponge in resin at the sub-micron scale and use an ultramicrotome cross section approach to directly assess the nature of the coating. Scanning electron microscopy and spectroscopy techniques provide rich atomic and electronic information about the sponge both on the micro (SEM/Raman) and nano (S/TEM) scale. Using a combination of backscatter electron imaging (compositional contrast) and EDS, the spatial distribution of iron oxide nanoparticles can be explored. Additionally, by exploiting the distinct graphite sp^2 (π bond) EELS edge and Raman spectral signature, we map the graphite distribution of the sponge, distinguishing it from the other carbon-based materials in the sample. This correlative approach is used to provide a complete assessment of the nature of this material and can be more broadly be applied to other hybrid systems. Further, dynamic electron microscopy is a powerful tool to observe reactions as the progress in real time, and ESEM experiments, in particular, provide a pathway to characterize the solid-fluid interactions that contribute to the OHM sponge's performance.

The presentation will emphasize the holistic understanding of OHM sponge and other hierarchical, hybrid materials that can be attained through correlative and multimodal characterization methods.

Nanoscale Nonlinear Optical Spectroscopy with Electron Beams Andrea Konecna[1], Valerio Di Giulio[1], Vahagn Mkhitaryan[1], Claus Ropers[2] and Javier Garcia de Abajo[1]; [1]ICFO - The Institute of Photonic Sciences, Spain; [2]4th Physical Institute-Solids and Nanostructures, University of Gottingen, Germany

Electron energy loss spectroscopy (EELS) nowadays allows us to acquire information on excitations in nanostructures with high spatial and spectral resolution over a broad energy range covering vibrational, optical (valence-electron) and core-electron excitations [1, 2]. The possibility of nanoscale mapping of optical response beyond the diffraction limit has made EELS one of the leading techniques in characterization of nanophotonic structures. However, EEL spectra are typically dominated by linear optical response, as the nonlinear contributions are negligible due to weak interaction between electrons and sample, which prevents the use of EELS in studying the nanoscale behavior of nonlinear optical fields.

The interaction between electrons and optical excitations in a sample can be substantially increased if the sample is excited by external optical pumping. Such a scenario is possible in photon-induced near field electron microscopy (PINEM), where we can reach scattering probabilities of order unity, and obtain multiple energy quanta exchanges between the electron probe and the optical field [3, 4]. Additionally, high light intensities can also trigger substantial nonlinearities in the sample response, which should be reflected in measured PINEM spectra.

In our work [5], we suggest PINEM as a suitable technique for nanoscale mapping of nonlinear optical response. In particular, we show that the interaction of electrons with nonlinear optical fields introduces asymmetries in otherwise symmetric PINEM spectra, which we demonstrate on several realistic examples. First we focus on studying second-harmonic (SH) response of spherical gold nanoparticles. We show that the evanescent SH field, which cannot be probed by

conventional nonlinear optical spectroscopies, gives rise to substantially asymmetric electron spectra under achievable illumination intensities. We further calculate SH field in gold nanorods and show that significant asymmetries in the PINEM spectra can be achieved for particular beam positions when the linear-field coupling is reduced. We envision that PINEM performed with variable illumination frequency and intensity could become a powerful technique for characterization of nonlinear optical response with unsurpassed combination of spatial and spectral resolution.

Observation of Crystal Grain Images by Using Multi-Segmented Back Scattered Electron Detector in Scanning Electron Microscope Yusuke Sakuda, Takeshi Otsuka, Mayu Ishino and Hiroshi Onodera; JEOL Ltd., Japan

The characters of a material depend on the crystal grain size and grain boundaries. Therefore, evaluation of crystals from a viewpoint of crystallography is extremely important. Various methods by using Scanning Electron Microscope (SEM) have been extensively developed for the evaluation of crystals because samples can be handled in a bulk state and observed in the region of μm to nm order. One common method is the Electron Channeling Contrast (ECCI) method[1)], which allows to obtain an image contrast corresponding to crystal grain boundaries by using the intensity difference of Back Scattered Electrons (BSEs) emitted from a bulk sample. The other common method is the Electron Backscatter Diffraction (EBSD) pattern method[2)]. The EBSD is possible to analyze crystal orientation distributions using diffraction patterns from a sample detected by a fluorescence screen. Those methods are quite useful for knowing grain distribution in the crystal as well. On the other hand, there are some issues in these methods of measuring a bulk sample. The ECCI is sometimes difficult to characterize the crystal structure and grain boundaries because it detects a mixture of BSEs originating from composition, channeling contrast and a diffraction pattern, while the EBSD has the limitation that a sample should be tilted significantly. Therefore, the lateral spatial resolution is about 100 nm in these methods and it would be difficult to analyze fine crystal structures and grain boundaries.
In order to improve the issues, we applied a multi-segmented BSE detector[3)]. The detector is segmented to 16 parts located above a sample and detects BSEs. The method is similar to the ECCI method. However, in practice it is possible to detect only the diffraction patterns by using the new segmented detector. As a result, it is much more clearly separate the grain boundaries than with the ECCI method. The principle is that the diffraction patterns detected by 16 segments in each element are integrated to calculate the signal intensity distribution and display it as a grain boundary image. Because similar intensities can be obtained from the same diffraction pattern, the grains with similar signal intensities are evaluated as the same crystal orientation with high approximation. The Euclidean distance[4)] was used to compare the signal intensities.
We also tried to apply the decelerating method which is a SEM column technique for improving the electron probe diameter. In the decelerating method, incident electrons keep high energy when passing through an objective lens. Finally, the electron energy is reduced down just before the electron is landed to a sample. The method reduces the spherical aberration coefficient (Cs) and the chromatic aberration coefficient (Cc) related to the electron probe diameter and the spatial resolution can be improved[5)].
In this study, we will report that we tried to quickly acquire the grain boundary image with high spatial resolution using the multi-segmented BSE detector combined with the SEM-deceleration method.

Thermal Expansion Coefficient of Silicon Nanoparticles with Nanometer Resolution Bibash Sapkota, Prakash Parajuli, Serdar Ogut and Robert Klie; University of Illinois at Chicago, United States

With the size of electronic devices getting smaller and smaller, it has become important to understand thermal expansion coefficients and thermal properties in sub-nanometer scale [1-3]. However, traditional techniques, such as scanning thermal microscopy or Raman thermometry are limited in spatial resolution due to mechanical constraints or optical diffraction limit [1-3]. In the present work, we will utilize a novel approach of non-contact thermometry based on the combination of low-loss electron energy-loss spectroscopy (EELS) with first principles density functional theory (DFT) modeling to measure the thermal expansion coefficient (TEC) of materials with nano-meter resolution. The approach has been well-tested on 2D materials such as transition metal dichalcogenides (TMDs), graphene and MoS2 by Hu et al [1]. In present work, we will extend the approach to Si nanoparticles to determine its TEC as a function of the temperature. In this contribution, we will also explore the effects of particle size, orientation and composition on the TEC, as well as the limits of measuring the local temperature using this approach.

F.MT03.08.11
Determination of Valence in Mn-Containing Oxides by Using Soft X-Ray Emission Spectroscopy (SXES) with Electron Microscopy Yohei Kojima, Shunsuke Asahina, Shogo Koshiya, Takanori Murano and Hiroshi Onodera; JEOL Ltd., Japan

Mn-containing oxides are important materials that have been widely used for industrial applications such as battery, magnetic and superconducting materials. Therefore, a novel material of Mn-containing oxides has been remarkably investigated to improve their capability and quality. They have various physical properties because Mn usually has divalent, trivalent or tetravalent and each valence has different d-electron numbers in Mn-containing oxides. Thus, the determination of valence in Mn-containing oxide is a very important factor to know the characteristics of the material. As an analytical method for Mn valence, X-ray Absorption Fine Structure (XAFS) method is frequently performed in synchrotron radiation facilities [e.g. 1]. X-ray analysis in the synchrotron radiation facilities is quite powerful as it allows in-situ observation. However, it is difficult to conduct an analysis with a finer structure because the X-ray beam size is on the order of microns. For the chemical state analysis in a micro or nano-ordered structure, the method combining with Transmission Electron Microscopy (TEM) and Electron Energy-Loss Spectroscopy (EELS) is popular. Although this method has a high spatial resolution and high energy resolution, EELS cannot directly obtain information of the valence band associated with chemical bonding of the material. Recently, SXES that can be installed in Scanning Electron Microscope (SEM) and Electron Probe Micro-Analyzer (EPMA), has been developed for the chemical state analysis of a bulk with fine structures [2]. Soft X-ray means the X-ray with energies from 10 eV to a few keV, and includes the X-ray generated by electron transition from valence bands to inner-shell levels. Therefore, we can obtain chemical bonding information by spectral analysis of this X-ray. So far, we reported a valence analysis of Fe oxides by using SEM-SXES system and “Flank” method [3] suggested by Höfer et al. [4]. Flank method proceeds as below:
1) Calculating a spectrum difference between Fe2+ endmember and Fe3+ endmember.
2) Setting Flank positions of Fe Lα and Lβ at the maximum or minimum value position in the difference spectrum.
3) Taking the Lβ/Lα intensity ratio at the Flank position.
This method has higher resolution for valence than the conventional method of peak-intensity and area-intensity ratios. In this study, we attempt to apply this method for Mn-containing oxides.
MnO, Mn2O3 and MnO2 purchased from Hori Mineralogy Ltd. were used for samples. There is no element detected by SXES other than Mn and O. The SXES measurement was performed by using FE-SEM (JEOL JSM-7900F) equipped with SXES (SS-94040SXSER). The soft X-ray spectra were acquired at accelerating voltages of 10 kV, 5 kV and 2 kV with a beam current of 50 nA and acquired for 5 minutes.
In this study, we compared the intensity ratio of Mn Lβ/Lα calculated by the Flank method, peak-intensity ratio method and area-intensity ratio method. As a result, it is found that the Flank method has a higher energy resolution for the valence of Mn than the conventional peak-intensity ratio method and area-intensity ratio method for all accelerating voltages used in this study at 2, 5 and 10 kV. It is expected that this method will be widely applied to the valence analysis of Mn-containing oxides used in various industrial applications.

Late News: Using Direct Electron Detector Technologies to Determine Local Structure and Chemistry of Nanostructures Alexandre Foucher and Eric Stach; University of Pennsylvania, United States

Direct electron detectors have revolutionized the field of structural biology and are beginning to find applications in materials science and nanoscience. Here, we show how these detectors can improve the ability of transmission electron microscopy to understand the physical and electronic structure of nanoparticles and thin films. These newly developed direct electron detection cameras reduce the signal-to-noise ratio compared to conventional CMOS / CCD cameras. In this study, electron energy loss spectroscopy (EELS) spectra obtained from several materials systems - Ti2-xNbxC MXenes, Mo4VAlC4 MAX phase and CoPt nanoparticles - are quantified, and the improved signal quality with the direct detection system is demonstrated. We compared the effect of probe size, aperture size, camera length, and imaging filter aperture size on the signal-to-noise ratio. For nanoparticles and thin films, it was shown that probe size and camera length had the strongest influence on the signal intensity arising from inelastically scattered electrons. In contrast, imaging filter aperture size plays a minor role. The optimization of these parameters makes it possible to routinely perform valence-state analysis at an atomic level, with a resolution comparable to bulk approaches such as X-ray photoelectron spectroscopy or X-ray absorption spectroscopy (XAS). The increased Detected Quantum Efficiency (DQE) combined with a sub-pixel detection setting is also beneficial for recording diffraction patterns to perform electron pair-distribution function (ePDF) analysis from these same systems. The improvements in the quality of both spectral and scattering data can be expected to make transmission electron microscopy an even more powerful tool for characterizing nano materials.

Coarse-Grained Modeling of Solid Polymer Electrolytes and Ion Conduction Lisa M. Hall; The Ohio State University, United States

Using solvent-free solid polymer electrolytes in batteries would reduce concerns about flammability and potentially decrease weight and cost, especially if their ion conductivity can be improved. Strategies to improve ion conduction in ion containing polymer materials include using bulky anions or using a high dielectric constant polymer. These both effectively decrease the strength of Coulomb interactions between ions at contact and can reduce ion agglomeration, which can improve conductivity. However, strong ion-polymer interactions can slow ion motion, and size asymmetry between ions may increase preferential solvation of cations versus the larger anions, lowering the transference number t_+ (fraction of conductivity contributed by the cation). We study these effects using coarse-grained molecular dynamics (MD) simulations which include a $1/r^4$ potential to capture size-dependent ion-monomer and ion-ion solvation effects. This is the same form as the interaction between an ion and an induced dipole. For block copolymer systems, we have also been guided by theoretical calculations to show the effects of macroscopic phase behavior. From MD, we calculate conductivity from ion mobilities in an external electric field, which improves accuracy versus the typical use of fluctuation dissipation relationships. We assess the impacts of ion size and polymer dielectric strength, including polymer dielectric strength contrast for block copolymer systems, on ion correlations, diffusion, and conductivity.

Molecular Modeling Discloses a Protein-Like Dynamical Transition in Non-Biological Macromolecules Letizia Tavagnacco; Sapienza University of Rome, Italy

Proteins are known to undergo a dynamical transition at low temperature, typically between 220 and 240 K. This transition consists in a steep enhancement of the protein atomic mobility which is related to the onset of anharmonic motions. At the same temperature proteins start to be biologically active and thus a full understanding of the molecular origin of this phenomenon is of particular relevance. While the protein dynamical transition always occurs in aqueous environment, with the protein confinement preventing the onset of ice crystallization, the role of water is still a controversial issue.
Here we focus on the low temperature behavior of a non-biological macromolecule, i.e. poly(N-isopropylacrylamide), commonly known as PNIPAM. This polymer is mostly exploited for its thermo-responsive nature, but it is also of interest because of its affinity with proteins in terms of energy landscape and amphiphilic chemical composition. Depending on the specific synthesis protocol, different PNIPAM based molecular architecture can be originated, such as linear chains or microgels, i.e. polymer network particles with a colloidal size. In this talk I will discuss two studies on the low temperature behavior of this synthetic soft material where atomistic molecular dynamics simulations are combined to elastic incoherent neutron scattering experiments.
In the first part I will provide a description of the evidences of the occurrence of a low temperature dynamical transition in PNIPAM microgels, akin to that observed in proteins [1,2]. This study is based on a nanoscale model of a microgel network in water, which quantitatively reproduces neutron scattering experiments. By correlating the information extracted from the analysis of the polymer relaxations times, water self-diffusion coefficients and hydrogen bonding interactions I will show that water-polymer coupling plays a driving role in the phenomenon.
In the second part, I will report the observation of a low temperature dynamical transition also in PNIPAM linear chains, which suggest a wide generality of the phenomenon, independently on the macromolecular architecture [3]. I will also show that simulations allow to identify the specific motions underlying the onset of the transition.

Ginzburg[1], Huikuan Chao[1], Irfan Khan[1], Steven Arturo[1], Jerome Claracq[2], Asjad Shafi[1], Weijun Zhou[1], Mirella Coroneo[3], Kshitish Patankar[1], Michael Desanker[1], Quan Yuan[1], Chi-Wei Tsang[1] and Paul Gillis[1]; [1]Dow Chemical Co, United States; [2]Dow Benelux B.V., Netherlands; [3]DOW ITALIA S.R.L., Italy

Rigid polyurethane (PU) foams play crucial role in improving energy efficiency of our homes, offices, and appliances. The preparation of an insulating rigid PU panel is a complex physico-chemical process that includes several concurrent reactions (blowing and gelling), polymer molecular weight build-up, gelation and vitrification, bubble nucleation and growth, Ostwald ripening and coalescence; these phenomena take place as the reacting fluid is pushed into a mold and must occupy the space there without leaving any voids or other imperfections. Designing this process – from selecting the right formulation components (surfactants, catalysts, polyols, isocyanates, etc.) to optimizing the mold geometry – is a complex task requiring multiple and expensive trials. We describe a new multiscale modeling framework aiming to predict the foam flow into the mold and the final foam properties as a function of the formulation. The modeling tool has been validated in several experimental tests and is being utilized to help design new rigid PU foam formulations to better satisfy customer needs.

Molecular Latent Space Simulators Hythem Sidky[1], Wei Chen[2] and Andrew Ferguson[1]; [1]The University of Chicago, United States; [2]University of Illinois at Urbana-Champaign, United States

Molecular dynamics (MD) is a powerful approach to probe molecular-level mechanisms, thermodynamics, and kinetics, but is limited to millisecond time scales even on the world's fastest supercomputers. We have developed molecular latent space simulators (LSS) to break this time scale barrier by learning highly efficient and accurate surrogate dynamical models of the long-time molecular dynamics. The LSS comprises three back-to-back deep learning networks with specialized architectures that are trained over modest MD training data to (i) learn an encoding of a molecular system into a slow latent space, (ii) construct a low-dimensional dynamic propagator in this space, and (iii) generatively decode molecular configurations to produce a synthetic molecular trajectory. The trained LSS is then deployed to generate novel ultra-long molecular trajectories at six orders of magnitude lower cost than MD. The low-cost of these synthetic trajectories enable resolution of rare thermodynamic states and kinetic transitions with arbitrarily low statistical uncertainties. In an application to Trp-cage mini-protein, we generate millisecond trajectories in just minutes of wall clock time, demonstrate excellent agreement with the structure, thermodynamics, and kinetics of the MD calculations, and resolve stabilities and rates with 10-fold higher accuracy.

Soft and Biological Materials Design via Cyber-Enabled Computational Methods Meenakshi Dutt; Rutgers, The State University of New Jersey, United States

There has been a recent surge in interest in soft and biological materials due to their potential applications in diverse areas including biomedicine, energy and nanoelectronics. The chemical diversity in the building blocks/sequences of the molecules constituting these materials yield an enormous molecular parameter space. A fundamental understanding of the impact of chemical block/sequence on the structure-activity relation of these soft and biological materials will accelerate their development and use, thereby accelerating the advancement of diverse disciplines.
Cyber-enabled computational methods, which integrate molecular simulations with analytical techniques, advanced computing and sampling tools, are used to study and develop new soft and biological materials with desired sequence/block-structure-activity properties in a more time- and cost-efficient way. The extended spatiotemporal scales connecting molecules to materials is addressed via the use of coarse-grained representations of the molecular species. The dynamics underlying the formation of the materials is resolved via the classical Molecular Dynamics simulation technique.

Curvature and De-Mixing in Asymmetric Bilayers—Effect of Protein Inclusions Shikha Prakash and Durba Sengupta;

National Chemical Laboratory, India

Topology and curvature changes in cellular membranes, especially in response to protein inclusions is important for a variety of cellular functions. Continuum elastic models such as the Helfrich model is able to describe several membrane elastic properties, but specific lipid-protein interactions (and feedback effects) are usually missing from these models. Here, we use coarse-grain molecular dynamics simulations to analyse the molecular-level mechanistic properties of a series of bilayers together with caveolin-1 as a protein inclusion . We show that in asymmetric, multi-component bilayers, differential stress between the two leaflets exists and may lead to non-additive curvature effects. The differential bilayer stress and the area mismatch cannot always be compensated directly in these systems. Binding of caveolin-1 can lead to a lipid clustering and de-mixing of multi-component bilayers. We show that the de-mixing is dependent both on specific protein-lipid interactions, as well as curvature-dependent lipid sorting. Our work is an important step in understanding mechanical properties of complex asymmetric bilayers and the role of protein inclusions.

Tuning the LCST-Like Transition of Elastin-Like-Peptide (ELP) and Conjugates of ELP to Collagen-Like-Peptide (CLP) Using ELP Sequence and Composition Arthi Jayaraman and Phillip Taylor; University of Delaware, United States

Peptide based biomaterials have garnered significant attention due to their ability to respond to external stimuli such as heat, light, and pH, thus allowing for controllable release of therapeutics for drug delivery applications and tunable mechanical and chemical properties for tissue engineering and *in vitro* cell culture applications. In this talk, I will present our recent work involving atomistic and coarse-grained molecular dynamics (MD) simulation studies of thermoresponsive polypeptides, specifically elastin-like peptides (ELP) and elastin-like peptide – collagen-like peptide (ELP-CLP) bioconjugates. ELPs are polypeptides that mimic the extracellular matrix protein, elastin, and are composed of repeat units of (VPGXG), where V, P, and G, are valine, proline, and glycine, respectively. The fourth residue, X, is termed the guest residue and can be any amino acid besides proline. Aqueous solutions of ELPs undergo a lower critical solution temperature (LCST)-like phase transition, wherein ELPs remain soluble below the transition temperature, T_t, and insoluble above T_t. We have focused our recent computational work on understanding the impact of substitution of F with Tyrosine (Y) and Tryptophan (W) guest residues and the sequence of these substitutions on the T_t of short ELPs in free state and when ELPs are conjugated to CLPs. Through a combination of atomistic and coarse-grained MD simulations we have described the molecular interactions that drive the observed shifts in the transition temperatures in our experimental collaborator's lab.

Interpretable Machine Learning for Structure/Property Relationships of Graphene Oxide Nanomaterials Amanda Barnard[1], Benyamin Motevalli[2] and Bronwyn L. Fox[3]; [1]The Australian National University, Australia; [2]CSIRO, Australia; [3]Swinburne University of Technology, Australia

Materials informatics, and the associated field of nanoinformatics, offer a plethora of new approaches to solving existing challenges in (nano)materials design. These enabling technologies leverage over 50 years of innovation in theoretical computer science on machine learning algorithms, and an even longer history of research in statistics to underpin the essential preliminary data science. Provided sufficient appropriate data is available to describe the material or system, new insights can be gained that would be otherwise obscured using conventional experimental or computational methods. Hidden structure/property relationships we can use to inform further research and materials development. Extracting useful insights (such as structure/property relationships) from data analytics and machine learning is however more complicated than simply gathering data and training models, since not all methods are interpretable, and interpretability is essential for decision making. Correlation is also different to causation, and so the importance relationships identified using many machine learning methods are not always actionable. In this presentation we will discuss the importance of accuracy, generalizability and interpretability, and demonstrate the advantages of combining a series of different machine learning methods to uncover

useful relationships between the properties, structure and processing conditions of graphene oxide nanoflakes.

AI Guided Materials Discovery and Design Subramanian Sankaranarayanan[1,2]; [1]Argonne National Laboratory, United States; [2]University of Illinois at Chicago, United States

The ever-increasing power of modern supercomputers, along with the availability of highly scalable atomistic simulation codes, has begun to revolutionize predictive modeling of materials. Molecular dynamics (MD), in particular, has led to breakthrough advances in diverse fields, including tribology, energy storage, catalysis, sensing. Furthermore, recent integration of MD simulations with X-ray characterization has demonstrated promise in real-time 3-D atomistic characterization of materials. The popularity of MD is driven by its applicability at disparate length/time-scales, ranging from *ab initio* MD (hundreds of atoms and tens of picoseconds) to all-atom classical MD (millions of atoms and tens of nanoseconds), and coarse-grained (CG) models (microns and tens of micro-seconds). Nevertheless, a substantial gap persists between AIMD, which is highly accurate but restricted to extremely small sizes, and those based on classical force fields (atomistic and CG) with limited accuracy but access to larger length/time scales. The accuracy and predictive power of classical MD is dictated by the empirical force fields, and their capability to capture the relevant physics. In this talk, we will present some of our recent work on the use of machine learning (ML) to seamlessly bridge the electronic, atomistic and mesoscopic scales for materials modeling. Our automated ML framework aims to bridge the significant gulf that exists between the handful of research groups that develop new interatomic potential models (often requiring several years of effort) and the increasingly large user community from academia and industry that applies these models. Our ML approach has showed marked success in developing force fields for a wide range of materials from metals, oxides, nitrides, hetero-interfaces to two-dimensional (2-D) materials and even water (arguably the most difficult system to capture from a molecular perspective). This talk will also briefly discuss our ongoing efforts to integrate such cheap yet accurate atomistic models with (a) AI techniques to perform inverse design and construct metastable phase diagrams of materials (b) Deep learning to improve spatiotemporal resolutions of ultrafast X-ray imaging.

Hiding in a Fluid—Autonomously Revealing Hidden Local Structures in Colloidal Systems Laura Filion; University of Utrecht, Netherlands

Developments in machine learning have opened the door to a new generation of methods for studying phase transitions, due to their ability to efficiently and autonomously identify complex patterns in many-body systems. Applications of machine learning techniques in statistical physics vary from locating phase transitions in spin systems to pinpointing weak spots in colloidal glasses. The rapid emergence of machine learning applications in both statistical mechanics and materials science demonstrates that these techniques are destined to become an important tool for soft matter physics.

One problem this tool seems ideally suited to solve, both experimentally and in simulations, is the identification of different (crystalline) phases – even on the level of a single particle. For example, when we use either experiments or simulations to look at crystallization at the microscopic level, it is always a challenge to determine which particles are part of the fluid, and which ones have already crystallized. In this talk I will describe how machine learning techniques can automatically figure this out for us, even if we do not know in advance what crystal structure to look for. We will also examine how such methods might reveal new structural insights in “purely” disordered systems like glasses.

Self-Directed Self-Assembly Alfredo Alexander-Katz and Hejin Huang; Massachusetts Institute of Technology, United States

Block copolymer (BCP) self-assembly, and in particular directed self-assembly (DSA), has provided a powerful route to fabricate complex thin film structures at small length scales. Despite DSAs success in fabricating various 2D patterns, fabrication of complex 3D nanostructures remains a challenge. Here, we will introduce a novel method, which we call Self-

Directed Self-Assembly, and demonstrate how it can be leveraged to assemble 3D designer nanostructures using block copolymers. In particular we will demonstrate that uniform and non-uniform multilayer nanostructures can be obtained through stacking two or more "orthogonal" block copolymers. Finally, by introducing a patterned substrate to the first layer and performing multilayer stacking, we will demonstrate how to propagate information upwards in the film. Different complex multilayer structures will be shown, and at the end we will present an outlook on exciting new computational and artificial intelligence avenues of research in this field.

Coarse-Grained Modeling of Solid Polymer Electrolytes and Ion Conduction Lisa M. Hall; The Ohio State University, United States

Using solvent-free solid polymer electrolytes in batteries would reduce concerns about flammability and potentially decrease weight and cost, especially if their ion conductivity can be improved. Strategies to improve ion conduction in ion containing polymer materials include using bulky anions or using a high dielectric constant polymer. These both effectively decrease the strength of Coulomb interactions between ions at contact and can reduce ion agglomeration, which can improve conductivity. However, strong ion-polymer interactions can slow ion motion, and size asymmetry between ions may increase preferential solvation of cations versus the larger anions, lowering the transference number t_+ (fraction of conductivity contributed by the cation). We study these effects using coarse-grained molecular dynamics (MD) simulations which include a $1/r^4$ potential to capture size-dependent ion-monomer and ion-ion solvation effects. This is the same form as the interaction between an ion and an induced dipole. For block copolymer systems, we have also been guided by theoretical calculations to show the effects of macroscopic phase behavior. From MD, we calculate conductivity from ion mobilities in an external electric field, which improves accuracy versus the typical use of fluctuation dissipation relationships. We assess the impacts of ion size and polymer dielectric strength, including polymer dielectric strength contrast for block copolymer systems, on ion correlations, diffusion, and conductivity.

5:15 AM *F.MT04.01.02
Molecular Modeling Discloses a Protein-Like Dynamical Transition in Non-Biological Macromolecules Letizia Tavagnacco; Sapienza University of Rome, Italy

Proteins are known to undergo a dynamical transition at low temperature, typically between 220 and 240 K. This transition consists in a steep enhancement of the protein atomic mobility which is related to the onset of anharmonic motions. At the same temperature proteins start to be biologically active and thus a full understanding of the molecular origin of this phenomenon is of particular relevance. While the protein dynamical transition always occurs in aqueous environment, with the protein confinement preventing the onset of ice crystallization, the role of water is still a controversial issue.
Here we focus on the low temperature behavior of a non-biological macromolecule, i.e. poly(N-isopropylacrylamide), commonly known as PNIPAM. This polymer is mostly exploited for its thermo-responsive nature, but it is also of interest because of its affinity with proteins in terms of energy landscape and amphiphilic chemical composition. Depending on the specific synthesis protocol, different PNIPAM based molecular architecture can be originated, such as linear chains or microgels, i.e. polymer network particles with a colloidal size. In this talk I will discuss two studies on the low temperature behavior of this synthetic soft material where atomistic molecular dynamics simulations are combined to elastic incoherent neutron scattering experiments.
In the first part I will provide a description of the evidences of the occurrence of a low temperature dynamical transition in PNIPAM microgels, akin to that observed in proteins [1,2]. This study is based on a nanoscale model of a microgel network in water, which quantitatively reproduces neutron scattering experiments. By correlating the information extracted from the analysis of the polymer relaxations times, water self-diffusion coefficients and hydrogen bonding interactions I will show that water-polymer coupling plays a driving role in the phenomenon.
In the second part, I will report the observation of a low temperature dynamical transition also in PNIPAM linear chains, which suggest a wide generality of the phenomenon, independently on the macromolecular architecture [3]. I will also show

that simulations allow to identify the specific motions underlying the onset of the transition.

Simulating Hydrodynamic Interactions in Topologically Complex Polymers Phillip Rauscher, Stuart Rowan and Juan de Pablo; The University of Chicago, United States

Over the last few decades, a great deal of attention has been given to topologically linked ring polymers by both the physics and chemistry communities. However, the dynamics of such systems remain largely unstudied. Indeed, these systems represent a major theoretical challenge as they are typically subject to both topological and hydrodynamic interactions, which make the equations of motion intractable. We circumvent this difficulty by considering the dynamics of linked rings with pre-averaged hydrodynamic interactions in the spirit of the Zimm model and demonstrate that the symmetries of the rings lead to a hydrodynamic decoupling of the internal ring relaxations. In other words, the hydrodynamic interactions occur only at the ring center-of-mass level. This decoupling dramatically simplifies the problem and actually holds for any averaging procedure, even for non-Gaussian polymers and non-equilibrium conditions. We use this result to design efficient algorithms for Brownian dynamics simulations which offer enormous computational speed-ups and use these methods to study the dynamics of catenated polymers.

5:55 AM F.MT04.01.06
Atomistic Resolution of the Effects of Charge Density on Polyelectrolyte Brush Microstructure via Molecular Dynamics Simulations Harnoor S. Sachar, Turash H. Pial, Bhargav S. Chava and Siddhartha Das; University of Maryland, United States

Polyelectrolyte (PE) brushes are formed when charge-bearing polymer molecules are grafted to a substrate in close vicinity of each other. PE brushes have been at the forefront of soft materials research for quite some time due to a plethora of applications ranging from ion sensing, emulsion stabilization, nanofluidic energy conversion to drug delivery and oil recovery. The most intriguing properties of PE brushes stem from their responsiveness to external stimuli such as the solvent quality, pH and bulk salt concentration. We use an all-atom Molecular Dynamics (MD) framework to study the effects of varying charge density on the microstructure of densely grafted planar polyacrylic acid (PAA) brushes. Such a variation in the PE charge density due to changes in the degree of ionization of the weakly acidic/basic PE functional groups is typically bought by a variation in the pH of the surrounding medium. We investigate the properties of the PE molecules such as brush height and chain mobility along with the local structure and distribution of the counterions and water molecules within the brushes. Our results uncover several non-intuitive phenomena such as a grafting density dependent non-monotonic variation in the static dielectric constant of water molecules within the brushes with the degree of ionization. Moreover, we observe a remarkable increase in the species storage capacity of the brushes with the degree of ionization as characterized by an enhancement in the number density of both counterions and water molecules trapped within the PE layer. Our results shall help answer fundamental questions regarding the behaviour of weak PE brushes which is vital to improve the efficiency of several PE brush-based devices such as nanomechanical gates, nanofluidic diodes, current rectifiers, etc.

6:05 AM F.MT04.01.07
Atomistically Resolved Electroosmotic Transport in Polyelectrolyte Brush Grafted Nanochannels Turash H. Pial, Harnoor S. Sachar, Parth Desai and Siddhartha Das; University of Maryland, United States

Polyelectrolyte (PE) brush grafted systems have been used in a plethora of applications for their responsiveness to different stimuli. Here, we have used all-atom molecular dynamics (MD) calculations to study PE brush grafted nanochannels with added salt and their response to external electric fields generating electroosmotic (EOS) transport. We have discovered that nanoconfinement creates an overscreening effect inside PE brush layer, which implies a presence of excessive counterions (Na^+) inside negatively PE brush layer. As a result, in low electric fields the overall EOS flow of the solvent water is dictated by the motion of the excess coions present in the brush-free bulk. Along with a higher concentration of coions in the bulk, higher velocity of coions than counterions in these applied electric fields also helps the solvent to move with coions.

Therefore, we find a fascinating scenario where the EOS flow is coion-dictated, while EOS flow has always been known to be counterion-dictated. On the other hand, for a larger electric field, the PE brush height reduces significantly and excludes some overscreening-inducing counterions into the brush-free bulk, which ensures parity in the number of coions and counterions in the bulk. Similar concentration and velocity of coions and counterions in the bulk in this electric field are overwhelmed by the larger residence time of water molecules inside the first solvation shell of counterions which ultimately results in a counterion dominated solvent flow in the direction of the applied electric field. Therefore, we encounter another highly surprising situation where the direction of the nanochannel EOS transport could be switche by merely changing the magnitude of the applied electric field.

Multiscale Modeling of Polymer Nanocomposite Interphase Boran Ma, Yilong Zhou, Gaurav Arya and L. Catherine Brinson; Duke University, United States

Multiphase polymer systems, including polymer nanocomposites (PNC), have a wide range of current and potential uses due to extraordinary tailorability of a variety of physical properties with small composition or processing changes. However, the details of the polymer physics controlling these changes is poorly understood. Modeling the interphase region in PNCs is crucial for achieving both better understanding of underlying physics and rational design of functional PNCs. Properties of the interphase region depend on that of the polymer matrix, nanoscale reinforcements, and surface chemistry in addition to microstructural characteristics of the distribution of nanoparticles in the PNCs. However, identifying the local property profile and the length scale of the interphase remains challenging. In this work, we establish a multiscale modeling framework to study the role that microstructure plays in determining bulk mechanical and viscoelastic properties of PNCs, bridging simulations at molecular and continuum level. Sensitivity of the structure--property relationship is also discussed.

6:25 AM F.MT04.01.09
High-Throughput Screening for Separation of H_2 and CH_4 in Functionalized IRMOF-1 Type Metal-Organic Frameworks Membranes Fangxi Wang, Abhishek T. Sose, Samrendra Singh and Sanket A. Deshmukh; Virginia Tech, United States

The microporous material Metal-Organic Frameworks (MOFs) show great potential in gas separation. Among them, Zinc-based isoreticular metal-organic frameworks (IRMOFs) share similar primitive cubic (pcu) topology with different linkers. Consequently, gas adsorption properties are different which is promising for gas separation. By decorating linkers with appropriate functional groups, its interaction with a particular gas molecule can be tuned to improve its selectivity and/or permeability. In this study, we have generated hypothetical MOFs by using different linkers and functionalizing them with urea, acetamides, CH_3, and CF_3. Several thousand structures were then used to perform the separation of H_2/CH_4 gas mixtures using non-equilibrium molecular dynamics (NEMD) simulations. Results show that the permeability of both H_2 and CH_4 decreases in the presence of functional groups compared to bare MOFs. The permeabilities of both gases are close to zero when the linkers which are perpendicular to the external force are fully saturated with the urea and acetamide groups. When the functional groups are located at the linkers which are parallel to the external force, the selectivity increases.

6:35 AM F.MT04.01.10
Thermal Gradient Driven Transport in Brush Functionalized Nanochannels Vishal Sankar Sivasankar, Harnoor S. Sachar, Sai Ankit Etha and Siddhartha Das; University of Maryland, United States

Liquid and ion transport in nanofluidic systems have wide applications in ionic sensing, energy generation, bio-medicine, and the development of biomimetic systems. In this study, we analyze liquid transport by applying thermal gradient in a nanochannel functionalized with backbone charged pH-responsive polyelectrolytes (PE) brushes which is modeled using recently developed Augmented Strong Stretching theory (SST). We find that grafting nanochannels with charged polyelectrolyte brushes leads to enhanced thermoosmotic (TOS) fluid flow when compared to the bare nanochannels, as opposed to the general understanding that the polymer/PE brushes retard the flow owing to increase in drag due to the brushes. This is due to the fact that the PE brush induced localization of the Electric Double Layer (EDL) charge density away from the nanochannel walls results in a larger background flow for the migration of these ions. We quantify the electric field induced due to TOS flow and analyze its three components: ionic, osmotic, and thermal components. For various chosen parameters, we witness that the TOS velocity is greater in magnitude for the nanochannels grafted with backbone charged PE

brushes when compared to the bare nanochannels or the nanochannels grafted with PE brushes with charge only at the end away from the wall.

6:45 AM F.MT04.01.11
Three-Dimensional Constitutive Model for Shear Thickening Gel and Its Applications Jinsu Kim, Yeonsong Kim and Woong-Ryeol Yu; Seoul National University, United States

There are few researches for constitutive modeling of shear thickening materials, though it is essential to predict their shear stiffening behavior, understand the mechanism of rate-dependent stiffness, and design new absorption devices. In this study, the constitutive model of shear thickening gels (STG) was developed by assuming STG consisting of soft and hard segments, the volume fraction of which are dependent on the shear rates. As such, two different rheological models were used for the soft and hard segments. The parameters of each rheological model were determined by carrying out the lap shear and pulling-out tests of STG. Finally, the developed constitutive model was validated by simulating the impact behavior of multi-layered sandwich composites including STG and polymer films and comparing the results with experiments.

6:55 AM F.MT04.01.12
Molecular Mechanism of Gas Separation Through Polymer-Metal Organic Framework (MOF) MMMs Abhishek T. Sose, Fangxi Wang and Sanket A. Deshmukh; Virginia Tech, United States

The need to develop environmentally friendly and energy efficient technology for gas separations can be fulfilled by polymer Mixed Matrix Membranes (MMMs) with Metal organic frameworks (MOFs). Gas separations via selective transport in MMMs have shown to enhance selectivity and permeability. In these MMMs, polymers, MOFs and the polymer-MOF interface are known to play an important role in determining the gas separation mechanism. However, fundamental understanding of the parameters determining the compatibility of the polymer-MOF interface and its effect on the separation mechanism is yet to be developed due to limitations of experimental characterization methods. In this study, we have performed all-atom molecular dynamics (MD) simulation of a model polymer-MOF MMMs of polystyrene (PS) and polyacrylic acids (PAA) polymers with IRMOF-1 and HKUST as fillers. We have also studied separation of complex gas mixtures such as CH_4/H_2 and N_2/CO_2 through these polymer-MOF MMMs performed using microsecond long all-atom nonequilibrium molecular dynamics (NEMD) simulations. Their simulation trajectories were analyzed in order to determine the effect of polymer rigidity and hydrophilicity, polymer chain length, and MOF geometry on their selectivity and permeability.

7:05 AM F.MT04.01.14
Late News: Meso Scale Modelling of Crystallizing Polymer Films—From Processing to Imaging Balaji Sesha Sarath Pokuri[1], Kiran Vaddi[2], Saurabh Kumar[1], Guoyan Zhang[3], Enrique Gomez[3], Olga Wodo[2] and Baskar Ganapathysubramanian[1]; [1]Iowa State University, United States; [2]State University of New York at Buffalo, United States; [3]The Pennsylvania State University, United States

Active layer morphology plays a critical role in the performance of organic electronics. For most high performing material systems, the process of morphology formation involves simultaneous phase separation and crystallization of the acceptor layer materials. In order to fully understand the influence of processing conditions on the device performance, it becomes important to understand the formation of morphology under state-of-the-art device manufacturing techniques like solvents, co-solvents, additives and substrate induced phase separation. In this work, we first propose a meso-scale modeling framework to account for the effects of crystallization in solvent evaporation induced phase separation processes. This proposed framework has the capability to (a) be extensible to multiple crystallizing components, and (b) use experimentally measurable parameters like heat of crystallization and energy barrier of crystallization. We then demonstrate this multi-phase, multi-physics finite element framework for modeling crystallization and phase separation to a current high performing material system like PM6-Y6. PM6-Y6 system has been shown by several recent studies to have interesting crystallization-phase separation behavior, as well as a very high power conversion efficiency. Using this material system, we investigate the effect of evaporating conditions on the active layer morphology. Furthermore, we integrate this framework with virtual instruments to create an end-to-end platform for in-silico in-situ morphology characterization - quantification tool.

5:00 AM F.MT04.02.02
Exploring Behavior of Compressed Microgel Suspensions Using Mesoscale Simulations Svetoslav Nikolov[1], Alberto Fernandez-Nieves[1,2,3] and Alexander Alexeev[1,2]; [1]Georgia Institute of Technology, United States; [2]University of Barcelona, Spain; [3]ICREA-Institucio Catalana de Recerca i Estudis Avancats, Spain

Microgels are highly compressible colloids that can swell and deswell by absorbing or expelling solvent from their interior. As such, suspensions of microgel particles can be concentrated far more than a suspension comprised of hard colloids. This leads to unusual mechanical properties of microgel suspensions including a drastic difference between the bulk and shear moduli. Microgels in compressed suspension can respond to compression in a variety of ways such as interpenetration, deformation, and shrinking. Previous experiments have offered insightful, but somewhat conflicting accounts of the behavior of individual microgels in compressed suspensions. We employ a mesoscale computational model to probe the mechanics and behavior of compressed microgel suspensions. We consider monodisperse microgels a viscous solvent and investigate the effects microgel architecture, the packing fractions, and solvent conditions on the suspension bulk modulus and the behavior of individual microgels. We use two methods to change the suspension packing fraction. In the first method, the suspension is volumetrically compressed, whereas in the second method the solvent quality is changed to induce microgel swelling and deswelling. We find that above random close packing microgels predominantly change the shape and mildly shrink. Microgel interpenetration remains relatively small and comparable to the mean distance between crosslinks. At higher packing fractions, microgels solely shrink. We find that the mechanics of suspension is defined by the bulk modulus of a single microgel. This result holds for microgels with different architectures, and insensitive to the method used to alter the suspension packing fraction even as the suspension undergoes colloidal gelation. Thus, the single-microgel bulk modulus established the correct mechanical measure for compressed microgel suspensions.

5:10 AM F.MT04.02.04
Development of Non-Bonded Interaction Parameters Between Molybdenum Disulfide and Water Abhishek T. Sose, Samrendra Singh, Preeya Achari and Sanket A. Deshmukh; Virginia Tech, United States

Molybdenum disulfide (MoS_2) is becoming increasingly popular as a substrate due to its more suitable electronic properties, higher signal-to-noise ratio, and increased biological compatibility as compared to graphene. Moreover, water is ubiquitous and most materials will inevitably come into contact with it. Consequently, understanding the structure of water at the MoS_2-water interface is imperative in determining the level of performance of MoS_2 devices in industrial and nanofluidic applications. Using experimental techniques, however, to understand interactions at the molecular level is too difficult using modern technologies. We have developed non-bonded FF parameters between an MoS_2 sheet and water molecules, which are represented by 12-6 Lennard-Jones (LJ) potential. The FF parameters were optimized to reproduce the macroscopic contact angle of water of ~69° on the MoS_2 sheet, which falls within the experimentally reported range of 65° to 75°. The MoS_2 sheet was represented by Stillinger-Weber (SW) potential. Three widely used water models, namely, SPC, SPC/E, and SPC/Fw, were used to model water. In order to validate the accuracy of the optimized FF parameters, the interaction energy of a single water molecule in its preferential orientation placed above a sheet of MoS_2 was calculated and compared to values reported in the existing literature. The structure of water at the MoS_2-water interface was also analyzed to validate the resulting parameters; specifically, the Z-density profile, average hydrogen bonds per molecule, and the angle made by the O-H vector with the normal to the MoS_2 sheet were calculated and studied.

5:20 AM F.MT04.02.05
Computational Modeling of MDI Additives in SBS-Modified Asphalt Jocelyn Ting, Eesha Khare, Kai Jin and Markus Buehler; Massachusetts Institute of Technology, United States

Asphalt, used for roads and pavements, is an important building material that must endure a wide range of temperatures for many years. Asphalt originates from crude oil and contains millions of distinct organic molecules whose interactions contribute to the mechanical properties of the mixture. The study of this ubiquitous and complex material in essential in order to make its components more sustainable as well as improve durability to reduce the frequency of replacement. The effects of additives on asphalt have been extensively studied empirically, and several molecular models have arisen for the purpose of predicting interactions computationally. However, due to the chemical complexity of the system, there is still a large effort to improve current molecular models to understand interactions between different organic components within asphalt. In this study we firstly validate and refine the SARA (saturates, aromatics, resins, and asphaltenes) model [1] of asphalt in conjunction with experimental results. Secondly, we will use the improved model to describe the impact of additives on asphalt performance. Here we show a multistep process in which we utilize xTB, a semi-empirical tight binding program [2]

to optimize molecular geometry, DFT for chemical property calculation, and molecular dynamics for large scale mechanical properties. We discuss how this approach of modeling complex molecular systems such as asphalt enables the rapid evaluation of several theoretical model compounds. We then use these results to propose potential additives for the improved sustainability and performance of asphalt.

Temperature and Humidity Triggered Framework Heterogeneity and Disorder and Its Impact on Catalytic Activity of 2D Metal-Organic Frameworks Mohammad Reza Momeni Taheri, Zeyu Zhang and Farnaz A. Shakib; New Jersey Institute of Technology, United States

Effects of framework deformation due to temperature and solvent (water) effects on the redox-active Co transition metal sites present in layered 2D conductive Co3(HTTP)2 metal-organic framework is studied in details. By combining classical molecular dynamics simulations with accurate and flexible ab initio parameterized force fields and ab initio periodic and cluster electronic structure calculations we show that including framework flexibility and solvent effects lead to higher reactivity for the oxidative dehydrogenation of propane to propene and hydrogen compared to the case that these effects are ignored in the conventional static electronic structure calculations.

Multiscale, Multiphysics Modeling of Rigid Polyurethane Foams Valeriy V. Ginzburg[1], Huikuan Chao[1], Irfan Khan[1], Steven Arturo[1], Jerome Claracq[2], Asjad Shafi[1], Weijun Zhou[1], Mirella Coroneo[3], Kshitish Patankar[1], Michael Desanker[1], Quan Yuan[1], Chi-Wei Tsang[1] and Paul Gillis[1]; [1]Dow Chemical Co, United States; [2]Dow Benelux B.V., Netherlands; [3]DOW ITALIA S.R.L., Italy

Rigid polyurethane (PU) foams play crucial role in improving energy efficiency of our homes, offices, and appliances. The preparation of an insulating rigid PU panel is a complex physico-chemical process that includes several concurrent reactions (blowing and gelling), polymer molecular weight build-up, gelation and vitrification, bubble nucleation and growth, Ostwald ripening and coalescence; these phenomena take place as the reacting fluid is pushed into a mold and must occupy the space there without leaving any voids or other imperfections. Designing this process – from selecting the right formulation components (surfactants, catalysts, polyols, isocyanates, etc.) to optimizing the mold geometry – is a complex task requiring multiple and expensive trials. We describe a new multiscale modeling framework aiming to predict the foam flow into the mold and the final foam properties as a function of the formulation. The modeling tool has been validated in several experimental tests and is being utilized to help design new rigid PU foam formulations to better satisfy customer needs.

Molecular Latent Space Simulators Hythem Sidky[1], Wei Chen[2] and Andrew Ferguson[1]; [1]The University of Chicago, United States; [2]University of Illinois at Urbana-Champaign, United States

Molecular dynamics (MD) is a powerful approach to probe molecular-level mechanisms, thermodynamics, and kinetics, but is limited to millisecond time scales even on the world's fastest supercomputers. We have developed molecular latent space simulators (LSS) to break this time scale barrier by learning highly efficient and accurate surrogate dynamical models of the long-time molecular dynamics. The LSS comprises three back-to-back deep learning networks with specialized architectures that are trained over modest MD training data to (i) learn an encoding of a molecular system into a slow latent space, (ii) construct a low-dimensional dynamic propagator in this space, and (iii) generatively decode molecular configurations to produce a synthetic molecular trajectory. The trained LSS is then deployed to generate novel ultra-long molecular trajectories at six orders of magnitude lower cost than MD. The low-cost of these synthetic trajectories enable resolution of rare thermodynamic states and kinetic transitions with arbitrarily low statistical uncertainties. In an application to Trp-cage mini-protein, we generate millisecond trajectories in just minutes of wall clock time, demonstrate excellent agreement with the

structure, thermodynamics, and kinetics of the MD calculations, and resolve stabilities and rates with 10-fold higher accuracy.

5:30 AM F.MT04.03.03
Accuracy of Classical Potentials for Polyethylene Structures Away from Equilibrium Keara Frawley, Lihua Chen, Huan Tran, Naresh Thadhani and Rampi Ramprasad; Georgia Institute of Technology, United States

Realistic simulations of polymers require a large number of atoms due to the anisotropic nature of their morphology. Although density functional theory (DFT) is considered highly accurate, it is too computationally expensive to handle large systems. Classical potentials used for molecular dynamics studies are trained on experimental or quantum mechanical equilibrium structures, and their accuracy away from equilibrium is not well known. This work is a comparative study of two widely used classical potentials—Optimized Potentials for Liquid Simulations (OPLS) and the reactive force-field (ReaxFF)—with respect to DFT. Their performance for polyethylene (PE), a simple model polymer, is benchmarked by comparing the classical energies, forces, and stresses against DFT.
The equilibrium crystal structure of PE is orthorhombic. In situations away from equilibrium, PE undergoes a phase transition to monoclinic. This work focuses on variations of these two crystal structures, along with some amorphous structures, to model realistic PE morphology. The energy resulting from the classical potentials is highly accurate when compared to DFT results. Force, an atomistic property, is not as easily captured, but stress, a bulk property, can also be accurately captured by classical potentials.
Additionally, a pressure-temperature phase diagram for PE is computed using OPLS and ReaxFF. ReaxFF performs better at high temperatures than OPLS when compared to experimental results. Although the classical potentials do not perfectly capture the DFT and experimental behavior, the results are close enough to justify their use when large system sizes are required. Consequently, these results will be used for shock simulations involving far from equilibrium structures.

5:40 AM F.MT04.03.04
Photocycloreversions within Confined Environments of Single Polymer Chains Modan Liu[1], Wolfgang Wenzel[1] and Hendrik Frisch[2]; [1]Karlsruhe Institute of Technology, Germany; [2]Queensland University of Technology, Australia

Folding single polymer chains into nanoparticles mimics the natural process of folding peptides into proteins, whilst for single chain nanoparticles (SCNP), the combinatorial possibilities in polymeric components, precise control over intramolecular crosslinks, and tailored functionalization of the synthetic nanoparticle expand potentials beyond natural mechanism. Light-gated reversible photocycloaddition reactions allow bonds to form and break within the SCNP for controlled folding via gauging irradiation wavelengths.
Here we developed a holistic coarse-grained molecular dynamics model of photocycloaddition reactions within the confined environment of single polymer chains, which grants real-time monitoring capabilities in the degree of intramolecular crosslinking and morphology of the polymer coil. It is revealed that in the confined environment, cycloaddition and cycloreversion reactions lost orthogonal addressibiliy, when both shorter and longer wavelength irradiations induce SCNP folding. Separated in timescales between bond recombination and diffusion, their collective effect results in wavelength-gated photostationary states where degree of crosslinking and polymer chain compaction converge both from simulation and experiment.
The developed model of single-chain polymer folding serves as a blueprint in understanding the quantitative structure-property relationship and control of photostationary states within polymer networks.

Multi-Scale Modelling and Decision Making in Industrial Applications of Soft Materials Using FORCE Frank Longford, Sean Parsons and Petr Kungurtsev; Enthought, United Kingdom

Industrial applications of soft materials need to consider a whole range of additional factors in combination to scientific knowledge provided by modelling techniques alone. A proposed technical solution may fail if it turns out not to be economically viable. Therefore, it is vital to factor business logic into an organization’s decision making process when designing and producing new products.

The Formulations and Computational Engineering (FORCE) project, implemented within the EU Horizon 2020 program (https://www.the-force-project.eu), aims to bring materials modelling to the heart of business decision making via creation of Business Decision Support Systems (BDSS). By doing so, industries will be able to make more knowledgeable decisions based not only on existing legacy data, but also on new data generated by state of the art multi-scale and multi-physics materials modelling. Development of the FORCE BDSS and Workflow Manager has been closely aligned to activities of the

European Materials Modelling Council (EMMC) and also builds on the SimPhoNy framework (https://www.simphony-project.eu) for multi-scale modelling in materials science.

The FORCE BDSS provides three key features:

- A **library** containing wrappers for state-of-the-art MCO algorithms
- A **platform** for designing and running MCO calculations on arbitrary systems
- A **framework** for integrating existing modelling and experimental pipelines together via a common universal data typing system

The interoperability of data between both modelling software and physical domains is placed at the core of our FORCE BDSS, which we demonstrate as the FORCE Workflow Manager GUI, available at https://github.com/force-h2020. This software provides an integrated framework that connects simulation models of varying complexity, experimental data sets and commercially relevant information together as a 'Workflow' pipeline construct. Consequently, users are able to select from a wide variety of parameters and key performance indicators (KPI) that can be used to identify the optimal trade off when making a business decision. For example, a set of KPIs may include material properties such as tensile strength or viscosity, but also component cost and availability. An integrated set of multi-criteria optimization (MCO) algorithms will then identify optimal outcomes to consider, typically by mapping out a Pareto frontier.

We report on an example use case targeting the industrial application of micelles that has been investigated using the software. By doing so, we demonstrate how the BDSS may be used to design simple pipelines that optimize chemical formulations by performing and processing molecular dynamics simulations. Our example MCO includes conflicting KPI goals that aim to yield the highest quality product under typical business constraints. Therefore we do not expect to be able to identify an optimal solution, but by exploring the Pareto frontier we attempt to locate the best set of trade offs that could be made for any given scenario.

Finally, we describe how the FORCE BDSS is not restricted as a modelling framework, but rather can be integrated into both data science and experimental laboratory pipelines. Future use cases aim to include Workflow constructs working with legacy datasets and containing a combination of simulation, machine learning and wet lab operations. By doing so, we open up the potential for machine learning and multi-scale modelling to be truly incorporated within an organization's R&D.

6:00 AM F.MT04.03.06
En-to-End Differentiable Molecular Simulations for Control and Learning Wujie Wang[1], Simon Axelrod[1,2] and Rafael Gomez-Bombarelli[1]; [1]Massachusetts Institute of Technology, United States; [2]Harvard University, United States

Molecular dynamics simulations use statistical mechanics at the atomistic scale to enable both the elucidation of fundamental mechanisms and the engineering of matter for desired tasks. The behavior of molecular systems at the microscale is typically simulated with differential equations parameterized by a Hamiltonian, or energy function. The Hamiltonian describes the state of the system and its interactions with the environment. In order to derive predictive microscopic models, one wishes to infer a molecular Hamiltonian that agrees with observed macroscopic quantities. Recent advances in automatic differentiation provide possibilities for the optimization and control of complex Hamiltonians with analytical gradients. From the perspective of engineering, one wishes to control the Hamiltonian to achieve desired simulation outcomes and structures, as in self-assembly and optical control, to then realize systems with the desired Hamiltonian in the lab. In both cases, the goal is to modify the Hamiltonian such that emergent properties of the simulated system match a given target. We demonstrate how this can be achieved using differentiable simulations where bulk target observables and simulation outcomes can be analytically differentiated with respect to Hamiltonians, opening up new routes for parameterizing Hamiltonians to infer macroscopic models and develop control protocols.

6:10 AM F.MT04.03.07
REACTER—A Heuristic Method for Reactive Molecular Dynamics Jacob Gissinger, Benjamin D. Jensen and Kristopher E. Wise; NASA Langley Research Center, United States

REACTER (www.reacter.org) is a heuristic protocol that enables the simulation of complex reactions using atomistic molecular dynamics (MD) with a fixed-valence force field. Incorporating reactions into classical MD with this approach allows modeling of reactive systems over greatly-increased time scales, enabling systems to be modeled with MD that would not otherwise be feasible. One or more competing multi-step reactions or series of reactions can be invoked simultaneously. Special treatment can be applied to neighboring atoms to relax high energy configurations while the simulation progresses.

The original version of REACTER, which was implemented in the open-source LAMMPS simulation package as *fix bond/react*, was only available for serial simulations. This work describes the expansion of *fix bond/react* for use in parallel simulations, as well as the addition of various new options, including deletion of reaction by-products, reversible reactions, and custom reaction constraints. These new capabilities are demonstrated through large-scale simulations (200,000+ atoms) of the polymerization of polystyrene and nylon 6,6. The morphologies of both polymers are analyzed after reaching >99% extent of polymerization. Finally, the newly-added reversible reactions feature is demonstrated by rupturing these highly-entangled systems under uniaxial strain by defining a chain scission reaction.

6:20 AM F.MT04.03.08
A High-Throughput Multi-Scale Infrastructure for Automating Materials Science Computations Rasha Atwi, Matthew Bliss and Nav Nidhi Rajput; Tufts University, United States

In this talk, I will present our group's effort to build a high-throughput infrastructure for the automated execution of materials science computations and analysis. This work is an extension of open-source Python packages that have been developed in Materials Project [1]: (1) *pymatgen* [2] for structure representation and input/output files generation and handling, (2) *FireWorks* [3] for managing workflows over computing resources, and (3) *Custodian* [4] for monitoring inevitable errors during the simulations and applying on-the-fly fixes. In our work, we benefit from these three libraries to build well-tested workflows for speeding up the prediction and screening of materials properties relevant to various applications with a focus on battery systems. At the backend, the infrastructure interfaces with the Gaussian [5] software which enables electronic structure calculations of chemical systems, and LAMMPS [6] open-source code for molecular dynamics (MD) simulations. In addition to its ability to handle the generation of input/data files and parsing of output files from the mentioned computational software, the infrastructure allows management of the collected data and storing it in MongoDB [7], a NoSQL database program using JSON-like documents with flexible schema. Examples of implemented Gaussian-based workflows include the calculation of electrostatic partial charges, NMR chemical shift, binding energy, ionization potential, electron affinity, and bond dissociation energy. Each derived property is saved in its own collection with auxiliary information like molecular metadata (smiles representation, chemical formula, …), which makes it easy to query and data-mine structure-property relationships. The user can tune the calculations by overriding default workflow parameters, for example, the functional and basis set, by-passing selected steps, or packing many jobs over multiple nodes for supercomputing resources. LAMMPS workflows allow the execution of MD simulations in different ensembles and analysis of the dumped trajectories for various dynamical and structural properties. The infrastructure enables coupling first-principles calculations with classical MD simulations to address chemical and physical phenomena occurring in a given system at different length and time scales. This approach aids in the development of databases required for training machine-learning models to accelerate the design and screening of materials with optimized properties for various materials science applications.

Chemcial Potential Differences in Small Systems Vilde Bråten[1], Øivind Wilhelmsen[1,2] and Sondre Kvalvåg Schnell[1]; [1]Norwegian University of Science and Technology, Norway; [2]Sintef, Norway

Free energy and other related properties are not averages of functions of the phase space coordinates of the system, which means that they can not be calculated directly from the simulation trajectory. Under this category we find the chemical potential, which can be calculated with the Widom [4] particle insertion method. One drawback of this method is that it becomes very inefficient and often fails at higher densities. We propose a new method which utilizes the size and shape dependency of small systems to extract chemical potential differences from molecular dynamics simulation trajectories. The method is based on the difference in behavior of small and large systems, which can be summarized by the surface area to volume ratio. Since this ratio is much larger for small systems, the surface effects become much more significant, and the

properties can no longer be directly compared to thermodynamic properties of macroscopic systems [1]. The Small System Method (SSM) [2], exploits the size dependency of these properties, and uses properties calculated for small systems to obtain the value of the same property for a macroscopic system. The small systems are created by placing small non-periodic subsystems at random positions inside a larger periodic reservoir. From statistical mechanics, the fluctuations in number of particles is coupled to different properties of the systems, like compressibility, heat capacity, partial molar volume and enthalpy. By combining SSM with the Overlapping Distribution Method originally developed by Bennett [3] we can also obtain values for chemical potential, pressure and free energy in the small systems. As with the previously mentioned properties, these can be extrapolated to the thermodynamic limit in order to obtain the macroscopic value of the properties. The method works well for a range of different densities, which makes it a promising alternative to the Widom [4] particle insertion method.

Soft and Biological Materials Design via Cyber-Enabled Computational Methods Meenakshi Dutt; Rutgers, The State University of New Jersey, United States

There has been a recent surge in interest in soft and biological materials due to their potential applications in diverse areas including biomedicine, energy and nanoelectronics. The chemical diversity in the building blocks/sequences of the molecules constituting these materials yield an enormous molecular parameter space. A fundamental understanding of the impact of chemical block/sequence on the structure-activity relation of these soft and biological materials will accelerate their development and use, thereby accelerating the advancement of diverse disciplines.
Cyber-enabled computational methods, which integrate molecular simulations with analytical techniques, advanced computing and sampling tools, are used to study and develop new soft and biological materials with desired sequence/block-structure-activity properties in a more time- and cost-efficient way. The extended spatiotemporal scales connecting molecules to materials is addressed via the use of coarse-grained representations of the molecular species. The dynamics underlying the formation of the materials is resolved via the classical Molecular Dynamics simulation technique.

5:15 AM *F.MT04.04.02
Curvature and De-Mixing in Asymmetric Bilayers—Effect of Protein Inclusions Shikha Prakash and Durba Sengupta; National Chemical Laboratory, India

Topology and curvature changes in cellular membranes, especially in response to protein inclusions is important for a variety of cellular functions. Continuum elastic models such as the Helfrich model is able to describe several membrane elastic properties, but specific lipid-protein interactions (and feedback effects) are usually missing from these models. Here, we use coarse-grain molecular dynamics simulations to analyse the molecular-level mechanistic properties of a series of bilayers together with caveolin-1 as a protein inclusion . We show that in asymmetric, multi-component bilayers, differential stress between the two leaflets exists and may lead to non-additive curvature effects. The differential bilayer stress and the area mismatch cannot always be compensated directly in these systems. Binding of caveolin-1 can lead to a lipid clustering and de-mixing of multi-component bilayers. We show that the de-mixing is dependent both on specific protein-lipid interactions, as well as curvature-dependent lipid sorting. Our work is an important step in understanding mechanical properties of complex asymmetric bilayers and the role of protein inclusions.

Tuning the LCST-Like Transition of Elastin-Like-Peptide (ELP) and Conjugates of ELP to Collagen-Like-Peptide (CLP) Using ELP Sequence and Composition Arthi Jayaraman and Phillip Taylor; University of Delaware, United States

Peptide based biomaterials have garnered significant attention due to their ability to respond to external stimuli such as heat, light, and pH, thus allowing for controllable release of therapeutics for drug delivery applications and tunable mechanical and chemical properties for tissue engineering and *in vitro* cell culture applications. In this talk, I will present our recent work involving atomistic and coarse-grained molecular dynamics (MD) simulation studies of thermoresponsive polypeptides, specifically elastin-like peptides (ELP) and elastin-like peptide – collagen-like peptide (ELP-CLP) bioconjugates. ELPs are polypeptides that mimic the extracellular matrix protein, elastin, and are composed of repeat units of (VPGXG), where V, P, and G, are valine, proline, and glycine, respectively. The fourth residue, X, is termed the guest residue and can be any amino acid besides proline. Aqueous solutions of ELPs undergo a lower critical solution temperature (LCST)-like phase transition, wherein ELPs remain soluble below the transition temperature, T_t, and insoluble above T_t. We have focused our recent computational work on understanding the impact of substitution of F with Tyrosine (Y) and Tryptophan (W) guest residues and the sequence of these substitutions on the T_t of short ELPs in free state and when ELPs are conjugated to CLPs. Through a combination of atomistic and coarse-grained MD simulations we have described the molecular interactions that drive the observed shifts in the transition temperatures in our experimental collaborator's lab.

5:45 AM F.MT04.04.04
Melanin-Based Materials as Biocompatible Mixed Conductors Micaela Matta and Alessandro Troisi; University of Liverpool, United Kingdom

Eumelanin is an amorphous insoluble pigment present in both mammals and invertebrates. This natural material consists of amorphous aggregates of DHI (5,6-dihydroxyindole) and DHICA (5,6-dihydroxyindole-2-carboxylic acid) oligomers, interacting via π-π stacking and hydrogen bonding.[1] Synthetic melanins are usually obtained using either DHICA or DHI and present a lower degree of structural disorder. Due to their dual protonic and electronic conductivity[2,3] and intrinsic biocompatibility, melanins are being investigated for energy storage/production[4] and as composite materials for biomedical applications.[5]
We present a systematic study of the electronic structure and conformational space of DHICA oligomers, characterized by a linear polymeric structure and strong antioxidant properties. Our computational insight not only fits well within existing experimental evidence, but can also predict the charge transport landscape in the bulk polymer.[6] We then use molecular dynamics simulations to study the fiber-like structures formed by this material, and investigate its morphology dependent properties.
Finally, we describe our approach towards the simulation of realistic DHI melanin aggregates using a combination of experimental evidence, chemical kinetics and molecular dynamics.

Structure-Mechanical Behavior Relation for the Facet Capsule Ligament via Multiscale Modeling Jacob Merson and Catalin Picu; Rensselaer Polytechnic Institute, United States

Hierarchical multiscale modeling is used in this work to model collagen based biotissues, with direct application to the

mechanics of the facet capsule ligament (FCL) of the spine. The biomaterial is modeled in the continuum sense using finite elements, whose constitutive description is provided by representative volume elements (RVEs) containing discrete representation of the underlying network. This technique offers a mechanism to predict the macroscopic properties of biological structures from the properties of the constituent fibers. A requirement of the hierarchical multiscale scheme is that RVEs at each material point must be much smaller than the corresponding continuum scale element. In fibrous materials, this can be problematic due to large size effects in three dimensions. Generalized boundary conditions are developed to mitigate the size effect and reduce the required size of the RVEs, therefore enabling larger multiscale models with increased macroscale geometry resolution. Predictions of the mechanical behavior of the FCL which account for the fiber-scale, microscale and ligament-scale collagen architecture are presented.

6:05 AM F.MT04.04.06
Quantum Multifractality in Thermal Conduction Across Random Interfaces Taishan Zhu[1,1], Giuseppe Romano[1], Martin Ostoja-Starzewski[2] and Jeffrey C. Grossman[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Illinois at Urbana-Champaign, United States

Self-affine morphology of random interfaces governs material functionalities across tribological, geological, (opto-)electrical and biological applications. However, the knowledge of how energy carriers or generally classical/quantum waves interact with structural irregularity is still incomplete. In this work, we study vibrational energy transport through random interfaces exhibiting different correlation functionals on the two-dimensional hexagonal lattice. We show that random interfaces are Cantor-composites populated on geometrical fractals, thus multifractals, and calculate their quantized conductance using atomistic approaches. The interfacial conductance increases when disorder enhances, and we obtain a universal scaling law. This scaling law contains self-similarity for mass perturbation, and exponential scaling of structural irregularity quantified by Hausdorf dimension. We resolve the modal characteristics by atomic Green's function, wavepacket simulation, and molecular dynamics, and ascribe the disorder-induced enhancement of conductance to the increased harmonic transmission of transverse and flexural modes, augmented by anharmonic interactions near interfaces. The multifractal nature and Cantor-composite picture may be extendable to charge and photon transport across random interfaces.

Interpretable Machine Learning for Structure/Property Relationships of Graphene Oxide Nanomaterials Amanda Barnard[1], Benyamin Motevalli[2] and Bronwyn L. Fox[3]; [1]The Australian National University, Australia; [2]CSIRO, Australia; [3]Swinburne University of Technology, Australia

Materials informatics, and the associated field of nanoinformatics, offer a plethora of new approaches to solving existing challenges in (nano)materials design. These enabling technologies leverage over 50 years of innovation in theoretical computer science on machine learning algorithms, and an even longer history of research in statistics to underpin the essential preliminary data science. Provided sufficient appropriate data is available to describe the material or system, new insights can be gained that would be otherwise obscured using conventional experimental or computational methods. Hidden structure/property relationships we can use to inform further research and materials development. Extracting useful insights (such as structure/property relationships) from data analytics and machine learning is however more complicated than simply gathering data and training models, since not all methods are interpretable, and interpretability is essential for decision making. Correlation is also different to causation, and so the importance relationships identified using many machine learning methods are not always actionable. In this presentation we will discuss the importance of accuracy, generalizability and interpretability, and demonstrate the advantages of combining a series of different machine learning methods to uncover useful relationships between the properties, structure and processing conditions of graphene oxide nanoflakes.

5:15 AM *F.MT04.05.03
AI Guided Materials Discovery and Design Subramanian Sankaranarayanan[1,2]; [1]Argonne National Laboratory, United States; [2]University of Illinois at Chicago, United States

The ever-increasing power of modern supercomputers, along with the availability of highly scalable atomistic simulation

codes, has begun to revolutionize predictive modeling of materials. Molecular dynamics (MD), in particular, has led to breakthrough advances in diverse fields, including tribology, energy storage, catalysis, sensing. Furthermore, recent integration of MD simulations with X-ray characterization has demonstrated promise in real-time 3-D atomistic characterization of materials. The popularity of MD is driven by its applicability at disparate length/time-scales, ranging from *ab initio* MD (hundreds of atoms and tens of picoseconds) to all-atom classical MD (millions of atoms and tens of nanoseconds), and coarse-grained (CG) models (microns and tens of micro-seconds). Nevertheless, a substantial gap persists between AIMD, which is highly accurate but restricted to extremely small sizes, and those based on classical force fields (atomistic and CG) with limited accuracy but access to larger length/time scales. The accuracy and predictive power of classical MD is dictated by the empirical force fields, and their capability to capture the relevant physics. In this talk, we will present some of our recent work on the use of machine learning (ML) to seamlessly bridge the electronic, atomistic and mesoscopic scales for materials modeling. Our automated ML framework aims to bridge the significant gulf that exists between the handful of research groups that develop new interatomic potential models (often requiring several years of effort) and the increasingly large user community from academia and industry that applies these models. Our ML approach has showed marked success in developing force fields for a wide range of materials from metals, oxides, nitrides, hetero-interfaces to two-dimensional (2-D) materials and even water (arguably the most difficult system to capture from a molecular perspective). This talk will also briefly discuss our ongoing efforts to integrate such cheap yet accurate atomistic models with (a) AI techniques to perform inverse design and construct metastable phase diagrams of materials (b) Deep learning to improve spatiotemporal resolutions of ultrafast X-ray imaging.

Hiding in a Fluid—Autonomously Revealing Hidden Local Structures in Colloidal Systems Laura Filion; University of Utrecht, Netherlands

Developments in machine learning have opened the door to a new generation of methods for studying phase transitions, due to their ability to efficiently and autonomously identify complex patterns in many-body systems. Applications of machine learning techniques in statistical physics vary from locating phase transitions in spin systems to pinpointing weak spots in colloidal glasses. The rapid emergence of machine learning applications in both statistical mechanics and materials science demonstrates that these techniques are destined to become an important tool for soft matter physics.

One problem this tool seems ideally suited to solve, both experimentally and in simulations, is the identification of different (crystalline) phases – even on the level of a single particle. For example, when we use either experiments or simulations to look at crystallization at the microscopic level, it is always a challenge to determine which particles are part of the fluid, and which ones have already crystallized. In this talk I will describe how machine learning techniques can automatically figure this out for us, even if we do not know in advance what crystal structure to look for. We will also examine how such methods might reveal new structural insights in “purely” disordered systems like glasses.

Multi-Resolution Convolutional Neural Networks for Inverse Problems Feng Wang[1,2], Alberto Eljarrat[2], Johannes Müller[2], Trond R. Henninen[1], Rolf Erni[1] and Christoph T. Koch[2]; [1]EMPA, Switzerland; [2]Institut für Physik,, Germany

Inverse problems in image processing, phase imaging, and computer vision often share the same structure of mapping input image(s) to output image(s) but are usually solved by different application-specific algorithms. Deep convolutional neural networks have shown great potential for highly variable tasks across many image-based domains, but sometimes can be challenging to train due to their internal non-linearity. We propose a novel, fast-converging neural network architecture capable of solving generic image(s)-to-image(s) inverse problems relevant to a diverse set of domains. We show this approach is useful in recovering wavefronts from direct intensity measurements, imaging objects from diffusely reflected images, and denoising scanning transmission electron microscopy images, just by using different training datasets. These successful applications demonstrate the proposed network to be an ideal candidate solving general inverse problems falling into the category of image(s)-to-image(s) translation.

Understanding Nanoscale Adhesion via Machine Learning on Topology-Adhesion Correlated Data Yijie Jiang[1], Nava Raj Khatri[1] and Xin Ji[2]; [1]University of North Texas, United States; [2]Thomas Jefferson University Hospital, United States

Adhesion is a ubiquitous phenomenon that exists between every pair of surfaces. As an interfacial force, adhesion becomes dominant at nanoscale compared with body forces. Nanoscale adhesion is critical for applications such as the design of

nanoscale devices, MEMS, and nanofabrication. Local roughness at the nano- and atomic-scales significantly influence the adhesion and can reduce the adhesion by more than one order of magnitude than that predicted by classic ideallized models. Statistical parameters, such as root mean square (rms) roughness, are proposed to develop new adhesion models and characterize nanoscale adhesion properties. Although the roughness is simplified into a statistical parameter in this way, it is inevitable to lose a lot of useful details of topological data. Here, we use machine learning to characterize interfacial adhesion properties based on nanoscale topology-adhesion correlated data. We perform high frequency quantitative nanoscale mechanical mapping (QNM) by AFM to simultaneously acquire topology at sub-nm resolution and adhesion at nanoscale at the interface between an AFM tip and a nominally flat surface. The adhesion varies over 20 folds (7.57 nN to 166.4 nN) due to nanoscale roughness. Local adhesion data is used as target and topological data at this and nearby locations (in-plane radius of 0.5 to 8 nm) is used as features. We use several machine learning methods to analyze the data, among which support vector regression (SVR) with radial basis function (RBF) kernel has the optimal performance. The prediction of the testing set (40% training and 60% testing data set) reaches r^2 more than 0.97. Based on the results of machine learning, we develop an interfacial mechanics model that establishes the relationship between detailed local topology and adhesion. This model can be generalized for different materials and interfaces to understand nanoscale adhesion and the effect of roughness.

Frequency-Dependent Dielectric Constant Prediction of Polymers Using Machine Learning Lihua Chen and Rampi Ramprasad; Georgia Institute of Technology, United States

The dielectric constant (ε) is a critical parameter utilized in the design of polymeric dielectrics for energy storage capacitors, microelectronic devices, and high-voltage insulations. However, agile discovery of polymer dielectrics with desirable ε remains a challenge, especially for high-energy, high-temperature applications. To aid accelerated polymer dielectrics discovery, we have developed a machine-learning (ML)-based model to instantly and accurately predict the frequency-dependent ε of polymers with the frequency range spanning 15 orders of magnitude. Our model is trained using a dataset of 1210 experimentally measured ε values at different frequencies, an advanced polymer fingerprinting scheme and the Gaussian process regression algorithm. The developed ML model is utilized to predict the ε of synthesizable 11,000 candidate polymers across the frequency range 60–10^{15} Hz, with the correct inverse ε vs. frequency trend recovered throughout. Furthermore, using ε and another previously studied key design property (glass transition temperature, Tg) as screening criteria, we propose five representative polymers with desired ε and Tg for capacitors and microelectronic applications. This work demonstrates the use of surrogate ML models to successfully and rapidly discover polymers satisfying single or multiple property requirements for specific applications.

Phase Separation of Binary Mixture from a Data-Driven Approach Joydeep Munshi and Ganesh Balasubramanian; Lehigh University, United States

Phase segregation of binary mixture has many applications including their popular application to investigate the evolution bulk heterojunction morphology (BHJ) from solvent evaporation of ternary mixture consisting of donor, acceptor and solvent molecules. Typically, macroscopic time evolution of phase separation is modeled computationally using system of coupled partial differential equations (PDE). Spontaneous separation of initially dispersed binary mixture is predominantly approximated by Cahn-Hillard equations. However, the numerical simulations using physics-driven PDE equations are iterated through a computationally expensive scheme until the final steady-state decomposition is achieved. On the other hand, deep learning techniques enabled great progress in the area of computer vision applied to microstructure evolution. We employ convolutional neural network (CNN) to predict phase segregation by sampling final decomposition of binary mixture purely based on observations from coarse-grained molecular dynamics simulations. Our deep learning approach can learn and predict non-linear physical phenomenon such as phase separation without any knowledge of the underlying atomic interactions between the constituent materials. The ability to infer phase segregation phenomena is potentially appealing for the rational microstructure design given several solution processing conditions, the initially dispersed microstructure consisting of the constituent materials and their interaction parameters.

6:25 AM F.MT04.05.12
Prediction of Defect Locations in Graphene Using Machine Learning Bowen Zheng and Grace Gu; UC Berkeley, United States

The presence of defects in two-dimensional (2D) materials, such as graphene, can deteriorate the properties, performances, and functionalities of graphene-based devices. The prior knowledge of defect information in graphene such as the defect type, size, and density allows us to make predictions of properties of graphene. Nevertheless, the detection of unknown defects

with an atomic-resolution probe such as transmission electron microscope is technically demanding and involves complex sample preparations. An alternative perspective arises when the thermal vibration of graphene sheets is examined. Because the absence or the substitution of an atom alters the boundary condition of adjacent oscillators, defective regions exhibit different vibrational properties compared to the pristine counterpart. However, the relation between defects and thermal vibration properties cannot be modeled explicitly. Here, we develop a machine learning-based approach to predict the unknown defect locations by thermal vibration topographies of graphene sheets, which overcomes the implicit relation between defect contents and vibration properties. Based on a kernel ridge regression model, two prediction strategies are developed, an atom-based method constructing data by atom indices, and a domain-based method constructing data by domain discretization. Trained by hundreds of thousands of vibrational energy distributions computed by molecular dynamics simulation, both methods can detect unknown graphene defects with a high accuracy. While the atom-based method is capable to predict a single-atom vacancy, the domain-based method can predict an unknown number of defects with an arbitrary distribution. The proposed data-driven strategy may also shed light on the defect detection in 2D materials of a broad variety.

6:35 AM F.MT04.05.13
Polymer Property Prediction and Design Through Multi-Task Learning Christopher B. Kuenneth, Lihua Chen, Huan Tran, Chiho Kim, Arunkumar Rajan and Rampi Ramprasad; Georgia Institute of Technology, United States

Polymers are an important and diverse class of materials that span a huge chemical and property space. Machine learning methods have been recently successfully deployed to explore this space, revealing previously unidentified and novel polymers. The training of machine learning models requires a numerical representation of polymers, commonly termed fingerprints, as inputs which are “mapped” to the polymer properties as outputs. Single-task machine learning models learn the mapping between fingerprints and individual properties, one at a time. In contrast, multi-task algorithms learn the mapping of the chemical structure to multiple properties simultaneously. The effectiveness of this multi-task approach is because cross-property correlations, when present, are exploited implicitly. In this work, we benchmark two neural network based multi-task models against two single-task models for 27 different polymer properties. All models are trained on a polymer database containing ~8,000 polymers encompassing ~16,000 property points. The multi-task models demonstrate superiority over the single-task models, specifically for correlated polymer properties. An interpretability analysis of the multi-task model has also been performed that allow for the extraction of structure-property design rules.

Probing the Complexity of Coarse Grained Potentials with Gaussian Process Regression Blake Duschatko, Jonathan Vandermause, Nicola Molinari and Boris Kozinsky; Harvard University, United States

Recent advances in machine learning have inspired the development of novel coarse grained molecular dynamics techniques wherein large length and time scale systems can be made more computationally tractable. Such regimes are essential for studying the dynamics soft materials, protein folding, and other complex processes that, in most cases, cannot be treated with current fully atomistic methods. In these schemes, where degrees of freedom in the all-atom picture are integrated out, one of the primary challenges lies in the construction of a free energy surface.

While the learned effective potential can be constructed on a variety of different physical bases, we consider those potentials that preserve the statistical mechanical properties of the atomistic system [1]. It is well known that the coarse graining process can induce complexity in the coarse grained potential that is not present in the all-atom case. In this work, we demonstrate the applicability of Gaussian processes for determining the optimal complexity of the free energy surface. This knowledge is crucial in designing models that are both computationally efficient and capture the essential physics of the problem.

In addition, we show the utility of active learning in the context of coarse graining. Recent efforts have shown that force field construction for ab initio molecular dynamics with Gaussian process regression [2] is amenable to active learning frameworks, and we demonstrate how this idea is transferable to coarse grained potentials. In this setting, we address the issue of “fine graining,” wherein an atomic representation of a given latent space despite the dramatic loss of information may be desirable.

Accelerated Discovery of Dielectric Polymer Materials Using Graph Attention Neural Networks Pankaj Rajak[1], Ankit Mishra[2], Ekin Dogus Cubuk[3], Ajinkya Deshmukh[4], Yang Cao[4], Greg Sotzing[4], Rajiv Kalia[2], Aiichiro Nakano[2], Rampi Ramprasad[5] and Priya Vashishta[2]; [1]Argonne National Laboratory, United States; [2]University of Southern California, United States; [3]Google Inc, United States; [4]University of Connecticut, United States; [5]Georgia Institute of Technology, United States

Polynorbornene (PNB) is an important amorphous polymer system, which has potential applications as a high energy density polymer due to its high breakdown strength with low dielectric loss and high thermal stability. Moreover, electrical properties of PNB can be significantly enhanced by incorporation of defects or synthesis with controlled crystallinity by hydrogenation reaction. However, this process is challenging, since it involves experimental synthesis and characterization of combinatorially large number of polymer systems to identify potential candidates. Here, we propose a deep learning-based graph neural network (GNN) model with attention mechanism that can identify polymer systems capable of exhibiting increased energy and power density. The GNN model is trained to predict dielectric constant for a polymer, where the training data for the high-frequency dielectric constant of PNB polymers are computed via ab-initio molecular dynamics simulation. The attention mechanism in our GNN model provides key insight about the functional groups and their spatial location inside the polymer chain that contributes the most in its dielectric properties. Our model can significantly aid experimental synthesis of potentially new dielectric polymer materials, which is otherwise difficult using simplistic statistical procedures.

Tensor-Field Molecular Dynamics—An Uncertainty-Aware, Scalable and Accurate Deep Learning Model of Interatomic Force-Fields for Reactive Dynamics Simulations Simon L. Batzner[1,2], Lixin Sun[1], Tess Smidt[3] and Boris Kozinsky[1]; [1]Harvard University, United States; [2]Massachusetts Institute of Technology, United States; [3]Lawrence Berkeley National Laboratory, United States

Deep Learning has great promise for accelerating Molecular-Dynamics simulations by learning complex representations of atomistic data. We present Tensor-Field Molecular Dynamics, an SE(3)-equivariant Graph-Neural Network that leverages rotationally equivariant graph convolutions to operate on geometric tensors (rather than only scalar values) to learn energies and forces of atomic systems. We demonstrate state-of-the art performance on a diverse series of systems, including molecules, complex surface reactions, solvated polymers, extended systems, and water. In addition, we show that our proposed methods generalizes well from very small training data sets, which challenges the common belief that deep neural networks require massive training sets for accurate predictions. We then analyze a series of resulting Molecular Dynamics Simulations and compare thermodynamic and kinetic properties to the original ab-initio simulations. Finally, quantifying uncertainty of model prediction is critical for reliable long dynamics simulations. We outline a scalable method to obtain predictive uncertainty estimates of energies and forces from Tensor-Field models and present results on several different systems.

7:15 AM F.MT04.05.17
Machine Learning and Multiscale Modeling Based Prediction of Electronic Properties of PEDOT:PSS Salvador Léon[1], Patrick Reiser[2], Loïc M. Roch[3], Alán Aspuru-Guzik[4] and Pascal Friederich[2,2]; [1]Universidad Politécnica de Madrid, Spain; [2]Karlsruhe Institute of Technology, Germany; [3]ChemOS, Switzerland; [4]University of Toronto, Canada

Many organic electronics applications such as organic solar cells or thermoelectric generators rely on PEDOT:PSS as a conductive polymer that is printable and transparent. It was found that doping PEDOT:PSS with sorbitol enhances the conductivity through morphological changes. However, the microscopic mechanism is not well understood. We combine multiscale modeling techniques with machine learning to investigate changes in morphological and electronic properties of PEDOT:PSS when doped with sorbitol. We find that sorbitol improves the alignment of PEDOT oligomers, leading to a reduction of energy disorder and an increase in electronic couplings between PEDOT chains. The high accuracy ($r^2 > 0.9$) and speedup of energy level predictions of neural networks compared to density functional theory enables us to analyze HOMO energies of PEDOT oligomers as a function of time which was computationally infeasible without machine learning. We find a surprisingly low degree of static energy disorder compared to other organic semiconductors. This finding might help to better understand the microscopic origin of the high charge carrier mobility of PEDOT:PSS in general and potentially

help to design new conductive polymers.[1]
We will furthermore show how the same machine learning approach can be applied to other organic semiconductors to evaluate static and dynamic energy disorder on an level of detail that was previously impossible due to the large computational cost of quantum mechanical calculations.

Predicting the Long-Time Creep Dynamics of Colloidal Gels from Their Static Structure by Machine Learning Han Liu and Mathieu Bauchy; University of California, Los Angeles, United States

the relationship, if any, between the structure and creep dynamics of gels remains elusive. Here, based on accelerated molecular dynamics simulations and classification-based machine learning, we show that the propensity of a gel to exhibit long-time creep is encoded in its static, unloaded structure. We extract a local, non-intuitive structural descriptor ("softness") that is strongly correlated with the dynamics of the gel particles—wherein the macroscopic creep rate exhibits an exponential dependence on the average softness. We find that creep results in a decrease in softness in the gel structure, which, in turn, explains the gradual decay of the creep rate over time.

7:35 AM F.MT04.05.19
Physics-Guided Machine Learning Model of Lithium-Ion Battery Systems Involving Multiple Physics, Scales and Phases Juner Zhu, Wei Li, Tomasz Wierzbicki and Martin Bazant; Massachusetts Institute of Technology, United States

Energy storage systems such as lithium-ion batteries (LIB) are ubiquitous in modern society with particular applications from consumer electronics to electric vehicles. One of the most fundamental challenges of studying and modeling the energy storage systems stems from the high dimensionality of the system, known as the *curse of dimensionality* (a great number of variables or degrees of freedom). For a commercial liquid-electrolyte battery cell, a comprehensive theoretical characterization of the LIB system should incorporate all the governing equations of the mechanics of the solid phases (electrodes, separator, and current collectors) and the liquid phase (electrolyte), the electrochemistry that involves mass transfer process of lithium ions, kinetics (rate of the reactions), and thermodynamics of materials, as well as the heat transfer processes over the electrodes and the whole battery cell. The complexity of the system increases exponentially considering that each of the governing equations has its own initial and boundary conditions that depend on the external loads and charge-discharge battery cycling behavior. Analytically solving such a system is almost impossible, and the real-world applicability of the existing so-called multi-physics numerical models based on the finite element method is usually hurt by the harsh conditions for convergence. Here, we use physics-guided machine learning algorithms to solve the coupled partial differential equations (PDE) of energy storage systems, and in this study, we demonstrate the applicability of the developed tool by using it to solve the poro-plasticity behavior of the battery, which involves Drucker-Prager/cap plasticity of the solid phase, Darcy's law of the liquid phase, as well as the continuity equations. A neural network taking the spatial coordinates as the input and the displacement and stress of the solid phase and the velocity and pressure of the liquid phase as the output is constructed to approximate the exact solution. The prediction of the overall mechanical response is compared with the experimental data as validation. At last, a simplified battery electrochemistry model based on the multiphase porous electrode theory (MPET) is incorporated into the poro-plasticity framework, and the overall model is implemented by designing neural networks to reflect the multiple physics.

Late News: High-Throughput Exploration of Materials-Phase Diagram Maps in Multi-Component Organic Blends Kiran Vaddi[1], Balaji Sesha Sarath Pokuri[2], Baskar Ganapathysubramanian[2] and Olga Wodo[1]; [1]University at Buffalo, United States; [2]Iowa State University of Science and Technology, United States

Organic thin films made of conjugated polymers and/or small molecules have captured the interest of the organic electronics industry due to their wide range of alterable properties (e.g., the color of light emission and solubility in organic solvents). High-performing devices have recently been designed with a multicomponent material system (as opposed to initial studies that focused on binary blends). This reaffirmed the need for a holistic approach to materials design beyond binary blends used to understand the mixing behavior and morphology formation during the fabrication of multicomponent organic thin films.

In this talk, we present a thermodynamics-based framework to identify the suitable solvents for a given electron-donor and accepting material with good performance as organic solar cells (OSC). We present high throughput exploration and construction of a material-phase diagram map that captures thermodynamics characteristics and facilitates understanding of the multicomponent solution's mixing behavior. Our analysis pipeline consists of (i) a physics based model to determine phase diagrams of multicomponent mixtures using the convex hull method; and (ii) high throughput analysis of a large set of phase diagrams using dimensionality reduction coupled with the clustering. To illustrate our pipeline, we derive the design rules for a few material systems typically used in OSC and compare it to the solubility sphere design rules.

SESSION F.MT04.06: Self-Assembly in Soft Materials

5:00 AM *F.MT04.06.02
Self-Directed Self-Assembly Alfredo Alexander-Katz and Hejin Huang; Massachusetts Institute of Technology, United States

Block copolymer (BCP) self-assembly, and in particular directed self-assembly (DSA), has provided a powerful route to fabricate complex thin film structures at small length scales. Despite DSAs success in fabricating various 2D patterns, fabrication of complex 3D nanostructures remains a challenge. Here, we will introduce a novel method, which we call Self-Directed Self-Assembly, and demonstrate how it can be leveraged to assemble 3D designer nanostructures using block copolymers. In particular we will demonstrate that uniform and non-uniform multilayer nanostructures can be obtained through stacking two or more "orthogonal" block copolymers. Finally, by introducing a patterned substrate to the first layer and performing multilayer stacking, we will demonstrate how to propagate information upwards in the film. Different complex multilayer structures will be shown, and at the end we will present an outlook on exciting new computational and artificial intelligence avenues of research in this field.

5:15 AM F.MT04.06.03
Multifarious Assemblies Designed Through Linker-Mediated Interaction of Colloidal Particles James Stahley and Mehdi Zanjani; Miami University, United States

DNA-mediated assembly of colloidal particles can be utilized to produce a variety of structures which may have desirable phononic, photonic, or electronic transport properties. Recent developments in linker-mediated assembly processes allow for interactions to be coordinated between many different types of colloidal particles more easily and with fewer unique sequences than direct hybridization. However, the dynamics of programmed self-assembly become increasingly more complex when coordinating interactions between three or more distinct interacting elements. In such cases particle pairs with similar binding energies are allowed to interact unpredictably, and enthalpically degenerate binding sites will be noticeably more present while numerous secondary phases may also result from the self-assembly process. Therefore, it is necessary to develop procedures for predicting feasible superstructure geometries for these systems before they can be implemented in material design.

Here we investigate the formation of multi-component ordered structures through self-assembly of spherically symmetrical colloidal particles of different sizes with a variety of interaction matrices. We utilize Molecular Dynamics (MD) and Brownian Dynamics (BD) simulations to study the growth behavior of systems with different types of interacting elements and predict the formation and stability of target structures. Our results provide direct guidelines for designing multifarious colloidal structures with three or more types of building blocks. We also study phononic spectrum of various ternary structures in order to identify the influence of key structural parameters on phonon bandgap frequencies and ranges. Overall, this study provides new directions for future experimental work to target formation of multi-component colloidal superstructures beyond the well-established binary symmetries studied in the past.

5:25 AM F.MT04.06.04
Advances in DPD Simulations for Block Copolymer Self-Assembly Hejin Huang and Alfredo Alexander-Katz; Massachusetts Institute of Technology, United States

Dissipative particle dynamics (DPD) has demonstrated excellent capabilities in describing the assembly and dynamics of

soft-matter systems in the past. Its intuitive representation and ease of use has been important to many areas, and in particular to self-assembly of block copolymers (BCPs). However, DPD in its original implementation to block copolymers is unable to capture accurately the different entropies for block copolymers at interfaces, which leads to erroneous qualitative results for BCP thin films. We have recently re-parameterized the DPD force field to yield accurate results in a multitude of thin film conditions. Here we present some of the unanticipated consequences of such new parametrization that appears to predict much better experimental results for phase transitions in BCPs than the traditional field theoretic methods. In particular we will introduce results from different densities to show how the order-disorder transition converges to a universal value similar to the experimental value, how the order-disorder transition is affected by polymer length, and finally how one can combine directly evolutionary algorithms to predict grapho and chemo epitaxial templates for desired thin film morphologies. Our results indicate that for typical copolymers with molecular weights below ~10^5 g/mol, the order disorder transition occurs at a universal value of χN. Furthermore, our results clarify the role of entropic elasticity in the order-disorder transition. Simple scaling arguments demonstrate that SCFT and its corrections will fail to capture the correct order disorder temperature in the short to medium length copolymers. Our work should be useful to understand how experimentally relevant BCPs self assemble in different conditions as well as introduce the audience to new advances in the DPD technique that allow it to rival any field theoretic method, especially considering that DPD is a much more intuitive platform which is easier to implement and that it has a smaller computational footprint.

5:35 AM F.MT04.06.05
Design of Porous Materials by Self-Assembly of Isotropically DNA-Functionalized Particles Runfang Mao and Jeetain Mittal; lehigh university, United States

The formation of porous structures such as diamond by bottom-up assembly remains one of the significant open challenges in colloidal systems. The interest in these materials with functional architectures stems from their broad potential applicability in diverse fields such as catalysis, separations, and photonics. The recently proposed approaches based on “DNA-functionalized particles” (DFPs) show promising results in the synthesis of low-coordination open structures such as diamond lattices in nanoparticle assemblies [1,2]. However, the underlying design approach in most of these cases is usually too complex to be scalable. In this work, for the first time, we demonstrate using muti-scale molecular simulations that low-coordination lattices (e.g., honeycomb in two-dimensional (2D) and diamond in three-dimensional (3D) systems) can be formed using simple isotropic functionalization of nanoparticles with DNA. The strength of our approach lies in its simplicity and potential ease with which the proposed design scheme can be implemented in the laboratory experiments.

Synthesis of Si Block-Containing Gradient Block Copolymer with Increased Assembly Kinetics via Systematic Homopolymer Control for the Fabrication of a Perpendicular Lamellar Pattern Yemin Park, Seung Won Song and Yeon Sik Jung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The advancement in modern electronics has led to miniaturization of device and increase in demand for ultra-small and highly integrated device technology. Extreme ultraviolet lithography (EUV) has been utilized to meet the demand for patterning nano-elements of 20nm or less, however has issues regarding stochastic effects causing defects in the system. To resolve this issues, directed self-assembly of block copolymers has been considered as a promising candidate to aid EUV to develop of sub-10 nm patterns. To achieve the sub-10 nm pattern, block copolymers with high Flory-Huggins parameter (χ) is generally required for high quality pattern resolution. However, a few issues arise when using high χ block copolymers. First, high χ values generally lead to a large surface energy difference between the individual polymer blocks preventing formation of perpendicularly oriented lamellar patterns and reduce horizontal alignment of polymer blocks. Neutral brush

layer coating on the substrate is an option to reduce the energy difference, but does not fully resolve the issue as it not only requires additional processes and cost but also cannot be applied on substrates with prefabricated patterns. Secondly, high χ block copolymer has slower self-assembly kinetics, leading to increased defect occurrence and self-assembly time. Therefore, a deliberate design for block copolymers with moderately high χ values as well as rapid kinetics is required for facile DSA of perpendicular patterns.
Here, we suggest a newly designed block copolymer that can achieve high χ value while forming perpendicular lamellar pattern. The key to the block copolymer design is incorporating a gradient copolymer block with Si-containing block to promote universal perpendicular alignment of lamellar morphology without the need for additional surface treatment or neutral brush layer. The block copolymer was synthesized by reversible addition-fragmentation chain-transfer polymerization to form a styrene (S)/ 2,3,4,5,6-pentafluorostyrene (PFS) gradient with a Si-containing 4-(tert-butyldimethylsiloxy)-styrene (4BDSS) copolymer block (P(S-*g*-PFS)-*b*-P4BDSS). The styrene/ pentafluorostyrene gradient copolymer consists of gradual composition change from the block junction region to the tail, which creates surface energy difference enough to energetically drive perpendicular lamellae formation, well supported by a thermodynamic model. Furthermore, by mixing P4BDSS homopolymer block with the block copolymer, the kinetic factor can be increased to be greater than that of existing high χ block copolymers to accelerate the self-assembly time and reduce the number of defect occurrence.

Machine Learning Approach to Long Time Step Molecular Dynamics for Hard Sphere Systems Ka Chun Chan; Karlsruhe Institute of Technology, Germany

Atomistic simulation techniques such as molecular dynamics (MD) provide an accurate and precise description of atomic motion, molecular structure and permit the prediction of the physical and chemical properties of molecular system. However, MD requires expensive computation of energy and force which leads to significant computational effort. This severely limits MD applications to biological system and soft matter physics on long time scales.
The usual MD time step is approximately 1/10 of the fastest frequency of the molecular system. In order to accelerate the MD computation, we propose a machine learning approach to propagate the molecular system instead of the usual MD time step. As a first step we developed a machine learning (ML) propagator for hard-sphere systems that propagates the molecular system with each atomic collision as a new time step. The proposed algorithm learns the time evolution of the atomic motion and the collision between atoms, such that the neural network are able to predict the system trajectory, identify the collided atomic pairs and correct the trajectory of the collided pairs for each collision time step. We will discuss the perspective of this newly ML propagator for the acceleration of MD simulations and further application to the molecular system with long time scales.

F.MT04.07.06
Late News: High Throughput Prediction of Stress-Strain Curve of Thermoplastic Elastomer Model Block Copolymers by Combining Hierarchical Simulation and Deep Learning Takeshi Aoyagi; National Institute of Advanced Industrial Science and Technology, Japan

Thermoplastic elastomer (TPE) is a typical industrial product, in which the microphase separation of block copolymer is utilized. The products can be seen in daily life, elastic fiber, film and adhesive for examples. The dynamic properties such as non-linear stress-strain (S-S) behavior are key issue to design such industrial products. The phase separated structure as well as a polymer chain structure affects the S-S behaviors. However, it is often the case that complicate metastable structures are observed in industrial products, and it is not simple to find the relation between such phase separated structures and S-S behaviors. To tackle the problem, we applied hierarchical simulation and deep learning technique. We chose ABA type triblock copolymers, where A blocks and B blocks form glassy domain and rubbery domain respectively, as a TPE model. Stress-strain curve of wide variety of volume fraction and phase separated structures were investigated by hierarchical simulation of self-consistent field theory and coarse-grained molecular dynamics. Furthermore, we applied 3D-convolutional neural network (3D-CNN) to make regression between the phase separated structures and S-S curves obtained by the coarse-grained molecular dynamics simulation. The predicted S-S curve of untrained structures using trained 3D-CNN showed good agreement with simulation, and high-throughput prediction could be realized comparing to the computationally intensive simulation.

This work was supported by a JSPS Grant-in-Aid for Scientific Research on Innovative Areas: “Discrete Geometric Analysis for Materials Design” [Grant Number 17H06464].

Late News: AI-Guided Coarse-Graining for More Efficient Modeling of SARS-CoV-2 Spike Glycoprotein Ziji Zhang[1], David Zhang[2], Aditya Narayanan[3], Aditya Ramabadran[4], Marcia Simon[1], Miriam H. Rafailovich[1], Yuefan Deng[1] and Peng Zhang[1,1]; [1]Stony Brook University, The State University of New York, United States; [2]Fremont High School, United States; [3]College Station High School, United States; [4]Lynbrook High School, United States

Objectives: The SARS-CoV-2 spike glycoprotein (S-protein), the presumed key receptor for binding to various material substrates, promotes the entry to host cells, and thereby causes infection. The binding dynamics of the S-protein to various substrates including organic, inorganic materials, and living cells is of great interest in biological science and clinical medicine. The all-atomic molecular dynamics (MD) simulations that are known to generate reliable results while mitigating potential biological risks for laboratory research are prohibitively expensive in computing time and resources.
Methods: We develop a coarse-grained (CG) model of the S-protein by intelligently learning the parameters from the corroborated *in vitro* and *in silico* data using DNNs on IBM's supercomputer. The CG parameters are optimized with the protein in water to provide a medium that offered fluidity *in vivo*. The MD data produced by GROMACS, are fed to the DNN to predict the force field among the CG particles to be simulated in LAMMPS. The loss function that measures the discrepancy between MD values, NN prediction, and CGMD functions, is minimized during the learning process. CG models speed up the all-atomic model by coalescing atoms to form macromolecules and thereby forgoing the unnecessary calculations of the internal degrees of freedom. The CG force field is electro-free and the solvent is modeled using DPD at the mesoscopic scales. The interactions between the proteins, their surrounding solvent, and the surface they bind to are described by formulating a hybrid of the Morse-repulsive and the dissipative terms. Besides, AI is also used to predict the associated temporal scale parameters.
Results: The VMD model builder is used to construct two different CG models, shape-based coarse-graining (SBCG) and residue-based coarse-graining (RBCG), to the S-protein atomic data (PDB: 6VXX) which has 45,246 atoms, and evaluated their robustness with comparison to atomic-scale simulation. The nonbonded Lennard-Jones and bonded interaction parameters in the SBCG model, consisting of 355 beads with approximately 150 atoms per bead, were learned from the all-atom simulations. The bonded interaction parameters were tuned until the stiffness constants deviated less than 25% from those derived from the atomic-scale simulations. The RBCG model consists of 6498 beads, with approximately 7 atoms per bead, built with the RBCG 2007 topology file inside the Martini force field. We then solvated the model with Martini water and ionized the model with Na^+ and Cl^- ions. After minimizing the CG system potentials, we successfully ran GPU-accelerated simulations with multiple runs to assess the impacts of the incrementally increasing timesteps to 14 fs. For verification and validation, the preliminary RMSD values were compared with the all-atomic simulations as the control, involving a single S-protein solvated in a water box with neutralizing ions at a temperature of 310K. The RMSD trends were converged which means our CG models have stable structures. Minimizing the differences of RMSD values by AI enables us to obtain more accurate parameters for longer simulations.
Discussions and Future Work: Our CG model uses learned parameters from big data to accelerate the conventional all-atomic MD by 4~5 orders of magnitude, without significant loss of accuracy. As the first AI-guided multiscale CG model, it may help enable a thorough investigation of the binding dynamics of the S-protein at varied ambient conditions including temperature and pH values. The limitation of this work may be that depending on different research needs, this CG model could achieve protein chain level accuracy, but not the atomic level. Our AI-guided modeling methodology can be generalized conveniently to study a large collection of materials, *e.g.*, fibrinogen.

Late News: Mesoscale Modeling of Controlled Erosion of Tetra-Arm Polyethylene Glycol Based Nanogels Eric F. Miller, Vaibhav A. Palkar and Olga Kuksenok; Clemson University, United States

Controlled degradation of micro- and nanogels finds its use in several applications. For instance, in the healthcare field, drugs containing gel particles are utilized for drug delivery. Drug release from such gels can be controlled via degradation of the hydrogel network triggered by various external stimuli. A better understanding of the gel degradation process will aid in the development of such applications. Computational modeling of gel degradation allows one to capture the dynamics of the degradation process depending on the degradation rate constant, initial crosslink density, size of the nanogel particle, and polymer-solvent affinity. To this end, we have developed a Dissipative Particle Dynamic (DPD) approach to capture the degradation of tetra-arm polyethylene glycol based nanogels. These networks are of interest since they have near-ideal network structure thereby exhibiting superior mechanical strength prior to the controlled degradation. Within our simulation approach, we model bond breaking during degradation as a stochastic process. Our results allow us to identify two distinct stages of the nanogel degradation. During the first stage, the bonds breaking within the gel results in the decrease in the crosslink density within the bulk of the gel particle and small tetra-arm pieces breaking off the surface of the nanogel (surface

erosion). During the second stage, bulk erosion and reverse gelation occurs. We characterize the transition between the two stages by focusing on the time evolution of the radius of gyration of the largest cluster and reduced degree of polymerization during the degradation process. We show that during the surface erosion, the radius of gyration of the largest cluster increases due to the effective decrease in the crosslink density being a major process, while during the second stage, this trend is reversed. We identify the effects of the gel size and an initial crosslink density on the crossover between the surface and bulk erosion. Our results represent a first mesoscale simulation study of a crossover between the surface and bulk erosion in gels.

Automation Advancements in Atom Probe Tomography Katherine Rice, Brian Geiser, Timothy Payne, Gard Groth, Edward Oltman and Daniel Lenz; CAMECA Instruments, Inc., United States

CAMECA's recent innovations in the areas of automated acqusition, reconstruction, and data analyis have greatly increased the throughput and utilizaton of the Local Electrode Atom Probe™ [1]. These advances position the commercial atom probe as a process monitoring tool for nanoscale devices, providing routine characterization for suitable applications for the microelectronics industry.
CAMECA's Chain Acquisition module enables atom probe data to be acquired from multiple samples, without user intervention, using a recipe-based architecture [2]. Image processing technology is used to do automatic alignment of specimens on a microtip coupon, enabling the user to build a list of specimens that can be analyzed according to individal experimental plans. Live calibration and automated ranging can be perfomed as the instrument is acquiring data, enabling both accurate charge state ratios and reduced user input to mass spectrum assignments. Automated local electrode testing can be performed between analyses, preventing a compromised electrode from affecting the quality of planned experiments, keeping a record of the electrode condtion over time, and notifying a user when an electrode may have decreased in quality. The experimenal conditions can also be dynamically changed with CAMECA's Scripted Acqusition module. Triggers can be defined to modify acqusition conditions in response to composition, background level, number of ions, or a variety of other experimental outputs. Scripted Acqusition can be used in conjunction with Chain Acqusition to further increase throughput; for example, the acqusition can be stopped after the region of interest is collected and automatically begin acquisition from the next specimen in the chain. This decreases acquisition overall time and increases the value of the dataset by only

collecting the necessary volumes. Project management allows scripts to easily be shared between users so that repeatable experiments can be conducted in laboratories around the world.
In addition to automated acqusitions, CAMECA's Atom Probe (AP) Suite enables recipe-based reconstructions and analysis. Reconstructions are completed automatically via user-entered parameters, so that the data is ready for review shortly after collection. Automated reconstruction parmeters can also be selected from a pre-existing list of experiment recipes. Further automated analysis can be queued with application of standard or custom analysis recipes applied to the finished reconstructions. This allows the analyst to repeatably extract the most important information from a dataset without manually applying the analysis steps. Together, these advances have made it faster and easier to collect data and reduce the experience requirements for new users to successfully collect and analyze data with atom probe tomography and reduce time-to-knowledge in the experimental process.

Navigating the Forest Through the Trees via Machine Learning—Detecting Morphology from Atom Probe Images Krishna Rajan; University at Buffalo, The State University of New York, United States

A paradox in APT is that while on the one hand, it provides an unprecedented level of imaging resolution in three dimensions, it is very difficult to obtain an accurate perspective of morphology or shape outlined by atoms of similar chemistry and microstructure. Hence, unlike scattering techniques such as electron microscopy, interfaces appear diffuse, not sharp. This, in turn, makes it challenging to visualize and quantitatively interpret the microstructure at the "meso" scale, where one is interested in the shape and form of the interfaces and their associated chemical gradients. In this presentation we provide an overview of the computational and machine learning approaches to characterize interface chemistry and morphology directly from atom probe images.

7:50 PM F.MT05.01.04
Cluster Analysis Using Machine Learning and Spatial Statistics Galen B. Vincent, Andrew P. Proudian and Jeramy D. Zimmerman; Colorado School of Mines, United States

Clustering of atoms and molecules significantly impacts material properties and is therefore important to characterize accurately. In this work, we use machine learning and spatial statistics to quantify clustering behavior in simulated and experimental APT data. We base our technique on Ripley's K-function analysis, *K(r)*, which is a sensitive measure of spatial correlation (*e.g.* clustering). We use features from the *K(r)* analysis to train a Bayesian regularized neural network (BRNN) to extract radius metrics, intra-cluster density, and background density.

For our test case, training data was simulated for a fixed solute density with clusters of various mean radius, radius variance, intra-particle density, background density, and number of particles. The system was verified on a set of similarly generated data sets, with over 90% of the BRNN-based estimates falling within 10% of the true radius values. Comparing the accuracy of our model against values obtained from the maximum separation algorithm (MSA) in our simulated APT data, we find that the MSA algorithm exhibits large variations based on user-defined inputs while the BRNN model quantifies morphologies accurately. We also apply this analysis to an experimental APT reconstruction with MgZn clusters in a 7000 series aluminum alloy, easily extracting cluster parameters from real APT data.

8:00 PM *F.MT05.02.03
Using a Laser-Pulsed Atom Probe Instrument for Thermal Processing David R. Diercks, Akansha Singh, Rajesh Jha, cristian ciobanu and Aaron Stebner; Colorado School of Mines, United States

Heat treatment of materials to improve performance has been employed for thousands of years. Control of the final size, composition, and distribution of the material's phases is of paramount importance and can be influenced by small changes in initial compositions, temperature, and annealing time. Therefore, knowing what occurs at the earliest stages of the

transformation process would shed insight into how to modify the materials for better control of their properties. It has been only within the last one hundred years that the characterization technologies for probing the nanometer-scale mechanisms behind the improved material performance resulting from heat treatments have been developed. While these tools have immensely expanded our understanding of materials and the mechanisms acting on them during thermal processing, there are still aspects that remain challenging to evaluate. In particular, sensitive quantitative compositional measurement with the combination of nano-scale spatial resolution and fractions of a second temporal resolution would provide needed insights into the earliest steps in diffusional processes.
Presented here is a demonstration of how the laser in a laser-pulsed atom probe instrument has been used to thermally induce crystallization and subsequently probe the resulting material structure for a Fe-Si-Nb-Cu-B alloy. Methods of estimating the laser induced temperature profile, determining the cumulative annealing time, and evaluating the resultant three-dimensional nanoscale crystallization are explored. Correlated transmission electron microscopy imaging and diffraction are used to supplement the atom probe results. The distribution of copper-rich cluster sizes and cluster densities measured by atom probe tomography are compared with Thermo-Calc modeling results. Through this example, advantages and limitations of using the atom probe as a processing tool are evaluated.

8:10 PM *F.MT05.02.01
Measuring Nanosized Void Chemistry at High Accuracy Using Atom Probe Tomography Xing Wang[1,2], Constantinos Hatzoglou[3,4], Yanwen Zhang[2,5], Baptiste Gault[6,7], Karren More[2], Francois Vurpillot[3] and Jonathan Poplawsky[2]; [1]The Pennsylvania State University, United States; [2]Oak Ridge National Laboratory, United States; [3]Normandie Université, France; [4]Norwegian University of Science and Technology, Norway; [5]The University of Tennessee, Knoxville, United States; [6]Max-Planck-Institut für Eisenforschung, Germany; [7]Imperial College London, United Kingdom

Nanosized voids, including pores and bubbles, are a common type of defects that can either improve or degrade the material properties. Voids are essentially empty cavities. Accurate measurement of the material chemistry around voids is important for understanding the void-material interactions. Atom probe tomography (APT) is a promising technique for this task because of its capability to reconstruct 3D positions of elements in materials with a high spatial resolution and chemical sensitivity. However, there has been a knowledge gap regarding how voids are imaged using APT. By performing a correlative scanning transmission electron microscopy (STEM) and APT analysis on void-containing materials, we demonstrated that voids could lead to obvious aberrations in APT reconstructions. Specifically, the local atomic density near voids in an APT dataset can either increase or decrease compared to the matrix. Field evaporation simulations combined with experiments revealed the physical mechanisms for these aberrations and identified the key factors that determined the nature of the aberrations. Based on this study, a general approach for quantifying elemental concentrations near voids using APT has been proposed that has higher accuracy than traditional STEM-based techniques. This approach has been applied to characterize elemental segregations near bubbles in medium and high-entropy alloys (HEAs). The accurate APT measurement shows that in Ni-based HEAs, both Cr and Fe become depleted near bubbles, but Cr depletes more, indicating higher vacancy mobility via Cr. This finding is consistent with the defect energies calculated based on density functional theory and explains the faster bubble growth rate in Ni-based HEAs containing Cr.

Atom Probe Tomography Using a Wavelength-Tunable Femtosecond-Pulsed Coherent Extreme Ultraviolet Light Ann Chiaramonti-Debay[1], Luis Miaja[1], Benjamin W. Caplins[1], David R. Diercks[2], Brian P. Gorman[2] and Norman A. Sanford[1]; [1]National Institute of Standards and Technology, United States; [2]Colorado School of Mines, United States

Atom probe tomography (APT) is a powerful tool for 3D materials characterization due to its desirable combination of high spatial resolution and high analytical sensitivity. In state-of the-art laser-pulsed APT, a near ultraviolet (NUV) laser ($E \approx 3.5$ eV to 3.6 eV; $\lambda \approx 355$ nm to 343 nm) incident on the specimen provides the thermal energy to overcome the activation barrier

for field ion evaporation. NUV laser-pulsed APT has been used to successfully analyze a wide range of materials including metals, semiconductors, insulators, biological materials, and even liquids. However, the data quality is often degraded due to artifacts from the thermal pulsing mechanism. These various artifacts manifest in the form of increased uncertainty in the quantification of specimen composition from the time-of-flight mass spectrometry measurement.

Photon energies in the extreme ultraviolet region of the electromagnetic spectrum (E ≈ 10 eV to 100 eV; $\lambda \approx$ 124 nm to 12 nm) are significantly higher than those in the near ultraviolet and as such, have the potential to trigger entirely new ionization and desorption mechanisms that are not possible with the much lower photon energies in the NUV band. These include various athermal ionization pathways and/or highly local heating that is entirely unlike that achieved using NUV sources.

Initial results from the world's first EUV (41.85 eV; λ = 29.6 nm) radiation-pulsed atom probe microscope will be presented. This instrument uses wavelength-tunable femtosecond-pulsed coherent EUV radiation from phase-matched high harmonic generation in a hollow-core capillary waveguide. EUV radiation-pulsed field ion emission in a variety of materials types will be discussed with respect to the quality of the mass spectrometry data and compared to results obtained using NUV sources. Specifically, the measured composition, time-independent background, time-delayed evaporation, charge state ratios, and multiple hit counts will be compared and related.

This project was made possible with material support from CAMECA Instruments through a Cooperative Research and Development Agreement.

8:34 PM F.MT05.02.04

Surface Dynamics Studies at the Nanoscale by Atom Probe Microscopy—Oxygen Atoms Tracking on Rh, Pt and PtRh Surfaces During H_2+O_2 Reaction Sten V. Lambeets[1], Thierry Visart de Bocarmé[2], Sylwia Owczarek[3], Norbert Kruse[4,1] and Daniel Perea[1]; [1]Pacific Northwest National Laboratory, United States; [2]Univsersité Libre de Bruxelles, Belgium; [3]University of Wroclaw, Poland; [4]Washington State University, United States

Metallic surfaces undergo a series of surface and subsurface structural and chemical transformations that drastically change their surface and mechanical properties. Understanding such dynamics from a fundamental science standpoint is particularly important in the case of heterogeneous catalysis, as such fundamental understanding is needed to build rational links between chemical/structural surface properties and the desired catalytic performance. This work addresses the dynamics of O_2 hydrogenation over rhodium (Rh), platinum (Pt) and PtRh alloy (10% wt Rh) revealed with Field Emission/Ion Microscopy (FIM/FEM). A comparative study is conducted with the use of other oxygen carrier gases: N_2O, CO and CO_2. Finally, Atom Probe Tomography (APT) is used to map the path of the oxygen atoms on and through the Rh surface.
FIM and FEM are capable to image the apex of sharp needles with nanometric lateral resolution. At the nanoscale, this apex is in the form of a hemisphere with a variety of exposed atomic planes and facets that can be simultaneously probed. Moorphology of such sample mimicks a single metal nanoparticle by its size and shape. FEM exhibits image contrast which is mainly determined by crystallographic plane-dependent variations of the work function. Local brightness variations on video-FEM is used to probe dynamic surface reactions[1]. The APT in turn provides a 3D atom-by-atom map of the entire apex volume with near atomic scale spatial resolution and part per million chemical sensitivity. By mapping the 3D distribution of Rh oxide and the morphology of the oxide/metal interface within the bulk after a controlled O_2(g) exposure, APT is used to explore the nature of oxygen atom penetration in the bulk.
Crystallographically-dependent chemical and structural dynamics of Rh and Pt surface oxidation during an ongoing oxygen exposure is directly observed with FIM/FEM. Focusing on Rh, we observe a mechanism of inter-facet cooperation between Rh{012} and Rh{113} crystallographic surface facets. Clean Rh surface (i.e. no oxide) exhibits bright contrast over {012} facets while {113} facets remain dark. However, upon exposure to oxygen originating from O_2, N_2, or CO_2, we observe simultaneously, an increase brightness over the {113} facets and a decrease in brightness over the {012} facets. This tells us that dissociative adsorption of O_{ads} occurs on the {012} and is followed by oxygen penetration into the subsurface through the {113}. Similar dynamics are observed on Pt and PtRh with exposure to other oxygen carrier gases of N_2O and CO_2. Additionally, the addition of H_2 recovers the original FEM pattern reflecting the reaction between H_{ads} and O_{ads}. This mechanism of inter-facet cooperation leads to a unique distribution of oxygen atoms within the bulk, which can be directly observed by APT. Following a 600s exposure of O_2 (2.0×10^{-2}Pa) at 700K of a pristine Rh needle (i.e. no native surface oxide), APT analysis reveals an anisotropic distribution of Rh oxides (RhO_x) and the complex morphology of the oxide/metal interface reflecting a specific crystallographic dependence[2]. An enhanced density of RhO_X^{n+} (x = 1 or 2 and n = 1 or 2) species are found both under the (111) central plane and along only one of the two three-fold symmetric crystal zones comprising the {113} facets. An iso-density surface of the APT reconstruction reveals a central accumulation of RhO_X species along the [111] direction, connected to the {113} vicinal facets. In summary, we conclude O_{ads} occurs on the

{012} and is followed by oxygen penetration into the subsurface through the {113} towards the [111].
The combination of FEM and APT analysis delivers new insight into the Rh oxide formation and offers exciting perspectives leading a better and more fundamental understanding of the heterogenous catalysis as well as corrosion dynamics.

Atom Probe-Aided Design of Additively Manufactured High-Temperature Aluminum Alloys Richard A. Michi, Amit Shyam, Alex Plotkowski and Jonathan Poplawsky; Oak Ridge National Laboratory, United States

Conventional aluminum alloys cannot be utilized in the 250–450 °C temperature range due to a lack of microstructural stability, creating a technological gap currently filled by steels, titanium alloys, and Ni-base superalloys. Replacement of these materials with aluminum alloys has significant implications for the energy and transportation sectors (e.g., increased engine operating temperature and efficiency, lightweighting, cost reduction), but has yet to be achieved. In this talk, we will give examples of APT analysis aiding in the design of new generations of high-temperature, additively manufactured aluminum alloys specifically targeted for use in the 250–450 °C temperature range. In particular, we will show how APT analysis reveals Zr and Mn segregation to the coherent and semi-coherent interfaces of θ’ precipitates in a novel additively manufactured Al-Cu-Zr-Mn alloy, leading to thermal stability up to 350 °C. We will also discuss how the accurate measurement of matrix solute supersaturations facilitated by APT aid in the design of heat treatments for precipitation-strengthened alloys with thermally stable phases and the observations of refined, nanoscale microstructural features formed during the additive manufacturing process. APT was conducted at ORNL's Center for Nanophase Materials Sciences (CNMS), which is a U.S. DOE Office of Science User Facility.

8:54 PM F.MT05.03.05
Atomic-Level Investigation of Preferential Impurity Segregation to Grain Boundaries in Y-TZP Through a Graph-Based Structure Olivia G. Licata[1], Parth Desai[1], Olga Wodo[1], Jonathan Poplawsky[2] and Baishakhi Mazumder[1]; [1]University at Buffalo, SUNY, United States; [2]Oak Ridge National Laboratory, United States

Yttria-stabilized tetragonal zirconia polycrystal (Y-TZP) is of great interest due to its superior corrosion, wear-resistance, and high flexural strength. Y-TZP exhibits a unique toughening mechanism when a stimulus is applied, in which it transforms from tetragonal (t) to monoclinic (m) phase. Over time, this transformation can lead to an aging phenomenon known as low-temperature degradation (LTD)[1]. The aging process is influenced by microstructural features, such as porosity, impurities, grain size, and stabilizer content. These features are also interlinked with one another, making the route for process optimization less clear. Grain boundaries (GBs) are thought to serve as the nucleation site for t-m transformation as well as the path for transformation propagation [2,3]. In an attempt to strengthen the GBs and limit LTD, commercial processing methods have introduced dopants and varying stabilizers to the zirconia microstructure. For every pair of yttria ions in Y-TZP, one oxygen vacancy is introduced (to neutralize the excess charge of Y^{3+})[4]. The annihilation of oxygen vacancies is widely accepted as the root cause of hydrothermal aging in Y-TZP; however, the underlying mechanism and its connection to the destabilization of the tetragonal phase is not fully understood. In this work, we will combine atomic-level insights on chemical distribution from atom probe tomography (APT) with graph-based materials representation to quantify the extent of elemental heterogeneity influence on microstructural features linked with the t-m transformation.

APT analysis was performed on a set of commercial 3Y-TZP ceramics (3 mol.% Y_2O_3), revealing trace levels of Aluminum (Al), Hafnium (Hf), and Silicon (Si), which were introduced in the raw material and during processing steps. The three-dimensional atom maps from APT demonstrated Y-rich GBs, with a limited number of GBs exhibiting preferential segregation of Al impurities, as well. Concentration profiles taken perpendicularly across the GBs indicated 5 at.% Y and 2 at.% Al within the GB and ~1.5 at.% Y throughout the matrix. APT analysis provides the three-dimensional positions and chemical identity for each atom. The positional data from regions of interest were converted to a graph representation, allowing for the definition and extraction of descriptors to understand the underlying physical phenomena. For example, the nearest neighbor distance between ions of the same species was used to define a descriptor that helps identify the number and distribution of phases present within the sample. Another descriptor was based on the shortest path consisting of Al to help assess the propensity of diffusion. These methods were further extended to understand the likelihood of an O vacancy in a particular region.

Our combined approach utilizes rigorous materials characterization techniques and informatics to quantify critical variations in microstructure related to the t-m transformation. Through graph-based representation, we define new metrics to correlate the microstructure with potential routes for degradation. These understandings will aid in the improved design and processing of zirconia-based ceramics to limit the susceptibility to LTD aging while maintaining their valuable mechanical properties. Our method enhances the capabilities of APT data to quantify the underlying phenomena of material degradation.

Exploring New Science Domains with Atom Probe Tomography Enabled by an Environmental Transfer Hub Daniel Perea; Pacific Northwest National Laboratory, United States

It is well known that environmental exposure of materials can lead to alteration, such as for example, the formation of an unintended surface oxide layer, that in some cases can affect the intended analysis. To prevent unwanted morphological or chemical alteration of specimens prior to analysis, control of the specimen environment during transfer between instruments is required for specimens sensitive to air or thermal exposure. At PNNL, we have developed a suite of hardware and experimental protocols for the preparation and handling of environmentally sensitive materials centered around the combination of a unique environmental transfer hub chamber, modified specimen suitcase device, and modified cryo FIB/SEM capabilities. The hub chamber design also allows the connection of ancillary tools, such as a gas phase reactor chamber for controlled surface reaction studies and UHV specimen transfer. The ability to prepare, manipulate, and transfer specimens under either cryogenic or vacuum conditions provides a means to uniquely apply APT analysis to address new science domains in biological, nuclear, and catalytic materials. Here I will describe in detail the design of our system and our developed workflows focusing on specific examples of APT analysis applied to *temperature sensitive* material systems requiring cryo specimen preparation and transfer, as well as *air sensitive* materials systems requiring vacuum or inert vacuum transfer.

9:14 PM F.MT05.05.03
Cryogenic Atom Probe Tomography for Hydrogen Characterisation in Steel Microstructures Eason Chen and Julie Cairney; The University of Sydney, Australia

The presence of hydrogen in steels can lead to catastrophic embrittlement/early-fracture. This is a serious issue for hydrogen transportation and storage. However, consensus has not been reached on the exact mechanism of hydrogen embrittlement, mainly due to the difficulty to provide direct evidence of the hydrogen-materials interactions that underpins the hypotheses [1]. In addition, a proposed solution to hydrogen embrittlement by using steels that contain hydrogen traps such as carbide precipitates [2], is limited in its effectiveness, due to the inability to directly observe the proposed hydrogen trapping at microstructural features.
As such, we used atom probe to study the hydrogen distribution at key features, including dislocations [3], grain boundaries [3], and both incoherent [3] and coherent [4] carbide precipitates in BCC/BCT iron matrix. To enable these studies, we charged the sample with deuterium (a hydrogen isotope) to avoid ambiguity from background hydrogen, and utilised a cryogenic sample transfer protocol to allow sufficient signal to be retained for observations. These efforts lead to the confirmations of: i) hydrogen enrichment at dislocations, providing a concrete validation of the hydrogen-enhanced dislocation mobility theory of embrittlement; ii) hydrogen enrichment at grain boundaries, underpinning the hydrogen-enhanced grain boundary decohesion theory; iii) the hydrogen at the interface between large, incoherent precipitates and the surrounding steel matrix, settling a long-standing debate around whether hydrogen trapping is an interfacial effect; and iv) the hydrogen at the interior of small, coherent carbides, suggesting hydrogen can internalise into carbides under certain conditions.

11:30 AM *F.MT05.01.01
The Quest for Nanometric Clouds and Clusters in Modern Engineered Materials Stephan Gerstl[1,2], Robin Schäublin[1,2], Lijuan Cui[3], Yong Dai[3], Severin Küchler[2], Vladimir Vojtech[2], Leonardo Pierobon[2] and Jörg F. Löffler[2]; [1]ETH Zurich, Switzerland; [2]ETH Zürich, Switzerland; [3]Paul Scherrer Institut, Switzerland

In this contribution, we review and demonstrate various methods by which we push our characterization limits to better understand nanometric features in the smallest – possibly the most influential – features in nanostructurally engineered materials. Oxide dispersion strengthening of steels for example and, more generally, materials relying on multi-phase strengthening, precipitation hardening, and cluster-strengthening all require an initial catalytic core for the formation of the desired precipitates or mesoscale phases. There is thus a thrust in looking for these pre-precipitation clusters and nano-clouds, which occur in a wide variety of materials research projects. For their analysis we take advantage of correlative techniques between Atom Probe Tomography (APT), Transmission Electron Microscopy, and electron backscatter diffraction, some in combination with modeling & simulation and others utilizing our original cryo-transfer enabling developments.
We will first focus on FeCr alloys, which model ferritic steels relevant for the fusion community. Here we find intriguing details in the cluster and interfacial chemistry in its α/α' decomposed high-purity binary system [1]. We applied multiple analysis methods to determine their precipitate core compositions, as their structurally coherent boundaries have often shown to be relatively broad compared to other matrix/precipitate systems.
In the field of ferritic steels for advanced nuclear facilities, the nascent irradiation induced clustering and precipitation of nuclear transmutation byproducts is generally investigated to better understand the alloys' evolution of mechanical properties over extended lifetimes and thus irradiation doses. In our near-atomic-scale study we are able to identify the isotopic specificity and thus the particular ions of interest that influence the steel's mechanical properties.
Focusing on SmCo high-temperature supermagnets, we are able to determine the geometry, packing density and local chemistry between Zr-rich nano-platelets and Cu-rich cells, which prove to strongly influence the magnetic properties, such as coercivity [2]. Among these phases, even the finest clustering features may have a strong impact on the macroscopic magnetic properties. With respect to light metals, we show results of room-temperature ('natural') aging of Al alloys, where we have also investigated further alloy classes in Al and Mg that require specimens to remain at cryogenic temperatures from after their creation – to focused ion beam sharpening of the APT tips – to transferring them to the atom probe and enable interrogating their arrested nanostructures [3,4,5].
These examples demonstrate the impact of near-atomic to nano-scale analyses not only to better understand the initial 'gatherings' of atoms (nano-clouds) within a structure, but to stress the continued need for pushing boundaries of highest-resolution characterization methods, the correlation amongst each other, and deploying cryo-vacuum transfer methods.

Local Uncertainty and Confidence Envelopes in Atom Probe Tomographic Reconstructions Andrew P. Proudian and Jeramy D. Zimmerman; Colorado School of Mines, United States

A unique advantage of APT is its ability to provide precise mass information (*i.e.* < 1 Da) over volumes of thousands of cubic nanometers with a three-dimensional spatial resolution of < 1 nm. This resolution completely depends on the reconstruction process used to convert the raw data into its final form for analysis: the method must be accurate yet fast enough to work on a typical APT dataset containing millions of ions. Any assessment of spatial signal (*e.g.* clustering) in APT relies on the fidelity of the reconstruction.

Currently, the vast majority of reconstructions fundamentally rely on point-projection. This method is fast but suffers from spatial resolution inaccuracies—such as ions being placed unphysically close or unphysical voids or variations in the sample shape—because of its assumptions about both the sample geometry and ion trajectories. Furthermore, current reconstruction techniques and analyses derived from them do not have an associated uncertainty because they usually generate only a single, user-directed reconstruction. This makes it laborious to compare different sets of inputs even though it is known that these parameters can cause the reconstructions to vary substantially even when constrained by other knowledge of the sample (*e.g.* TEM). As a result, APT experiments generally base conclusions off of a single reconstruction without stating a statistical confidence.

We have developed a reconstruction method that provides a solution envelope, increasing confidence in the conclusions drawn from the data regardless of the exact solution. This method does so without needing measurements of the sample other than APT. We explicitly account for the lower x-y resolution of APT by shifting points in x & y, which incorporates this uncertainty into subsequent analyses. This adjustment is determined by solving the well-studied Assignment and Exact Cover Problems for slices of data in detector space; this process can also constrain the reconstruction to maintain density and minimum particle spacing. We may then use the resultant solution sets to determine the robustness of the morphological signal as compared to a null hypothesis of random labeling using the tools of spatial statistics.

We evaluate this method using simulated APT data containing small (0.7 nm diameter) clusters of boron in a random close packed (RCP) matrix of silicon, a system in which there is an approximately 2:1 evaporation field difference that leads to chromatic aberrations. A conventional reconstruction completely loses the clustering signal ($p = 0.224$), even when optimized to minimize the positioning error with the known input pattern. In comparison, our method still recovers a clear clustering signature across the ensemble of reconstruction solutions ($p < 0.001$). These results demonstrate that this reconstruction method can significantly improve the accuracy of reconstructions and increase confidence in any morphological conclusions.

Nanoscale Visualization of Carbon Deposits and Magnesium Clusters in Zeolites Active in the Methanol-to-Olefins Process Sophie H. van Vreeswijk[1], Jonathan Poplawsky[2], Irina Yarulina[3] and Bert M. Weckhuysen[1]; [1]Utrecht University, Netherlands; [2]Center for Nanophase Materials Sciences, United States; [3]BASF Corporation, Netherlands

In the methanol-to-hydrocarbons (MTH) process, methanol is converted to more valuable products, such as olefins and aromatics, using zeolite or zeotype catalysts. Methanol can be obtained from conventional as well as from more renewable sources, such as biomass, carbon containing waste and CO_2, which explains the great commercial interest of this catalytic process. [1][2] The exact end-product of the process is determined by the zeolite pore structure and the number and nature of the acidic active sites. A key step in this MTH mechanism is the formation of a so-called hydrocarbon pool in which olefins and aromatic compounds function as activating and deactivating reaction intermediates. [3] Most of the unmodified proton form zeolites are extensively studied for their performance and deactivation in the MTH process. However, protons can be exchanged by other cations, which can drastically influence catalytic performance. [3] These influences on the catalytic behaviour are nonetheless not well understood.

In this work, magnesium was introduced in the chabazite structure SSZ-13 to (partially) replace the protons in the zeolite framework. This resulted in differences in both catalytic performance as well as catalyst deactivation. Using *operando* UV-Vis spectroscopy and *operando* X-ray diffraction, differences between reaction intermediates and catalyst characteristics can be linked to the catalytic performance.

Zeolites are notoriously difficult to study at the nano-scale, because of their instability under e.g. electron beams. [4] Atom probe tomography (APT) is uniquely positioned among all tomographic techniques; it can provide 3D chemical information

with sub-nm resolution, making it the only technique capable of finding nanometre scale relationships in these materials, and especially for studying elements that offer no significant z-contrast differences (e.g. Al and Si). With this technique we were able to visualize magnesium clusters, obtain information about the distribution of the magnesium with respect to the aluminium, as well as the correlation between magnesium and coke molecules after the MTH process.

To conclude, in this work both *operando* as well as APT studies on (un)-modified zeolites are described to be able to contribute to the unravelling of the MTH mechanism in the presence of e.g. Mg.

Stacking Order Dependent Elemental Diffusion Between STO/LMO/LASO Layers Revealed by Atom Probe Tomography Jith Sarker[1,2], Wei Guo[2], Manual Roldan[3], Hans Christen[2], Baishakhi Mazumder[1] and Jonathan Poplawsky[2]; [1]University at Buffalo-SUNY, United States; [2]Oak Ridge National Laboratory, United States; [3]Arizona State University, United States

Perovskite metal oxides (ABO_3) are highly promising for artificial superlattice fabrications due to their exceptional physical properties and chemical stabilities. Among perovskite metal oxide superlattice, $SrTiO_3$ (STO) and $LaMnO_3$ (LMO) based heterostructures has gained significant attention due to enhanced magnetic properties compared to bulk LMO, which is desirable for spintronic devices. Previous scanning transmission electron microscopy (STEM) results demonstrated that the oxygen octahedral rotation (the angle between Mn-O-Mn bonding) at the STO/LMO interface plays a vital role in tuning the magnetic moments in the LMO/STO superlattice. Diffusion of elements across these interfaces can also play a role in the magnetic properties; however, diffusion across these interfaces has not been well documented. STEM has been heavily used to study these materials because it is ideal for observing interfacial structure, but a small amount of interfacial elemental diffusion is difficult to quantify using analytical STEM techniques, such as electron energy loss spectroscopy (EELS). Atom probe tomography (APT) is a good candidate for quantifying the chemistry through these interfaces because it is a sub-nm resolution technique with a maximum sensitivity of ~10 ppm. To this end, APT was employed to map the interfacial chemistry of the STO/LMO superlattice structure. Two different superlattice structures were tested to isolate the top and bottom STO/LMO interfaces. STO/LMO/LASO (5x) and LASO/LMO/STO (5x) superstructures were grown by atomic layer deposition (ALD) on STO supstrates to isolate LMO grown on top of STO (LMO→STO) and STO grown on top of LMO (STO→LMO). The saturation magnetic moment per Mn ion was significantly higher for LMO→STO (M_S~1.67 μ_B per Mn ion) compared to STO→LMO (M_S~1.23 μ_B per Mn ion). Other samples grown in the same manner showed the same behavior. The APT results reveal differences in interfacial elemental diffusion that can explain the observed differences in magnetic behavior. In this presentation, the impact of growth order on elemental diffusion using ALD and how elemental diffusion influences magnetic properties will be discussed. This study provides a direct insight on how changes in interfacial structure and chemistry of LMO/STO superlattice can modify the subsequent magnetic functionalities when the growth sequence is reversed. This information is crucial for understand the ALD growth technique of complex oxides and how to optimize ferromagnetism in future spintronic devices. APT was conducted at ORNL's Center for Nanophase Materials Sciences (CNMS), which is a U.S. DOE Office of Science User Facility.

Alloying for Corrosion Resistance—The Effect of Manganese and Silicon on a Polycrystalline Nickel-Based Superalloy Stella Pedrazzini; Imperial College London, United Kingdom

Nickel superalloys are employed in the hottest part of jet engines and industrial gas turbines for power generation. In these harsh environments, sulphur contamination can occur in-service, causing reductions in the predicted component lifetime. Our work uses environmental exposures and state of the art characterisation to explore the effect of low-level silicon (0.5 wt%) and manganese (1 wt%) additions on the sulphidation and type-2 hot corrosion response of a polycrystalline nickel superalloy.

Silicon was added promote formation of a compact dual-layer chromia-alumina scale that reduced oxidation rate in long-term experiments. The silicon-containing alloy was more resistant to hot corrosion from coupled NaCl + SOx exposure.

Manganese improved oxidation resistance by creating MnCr2O4, which reduced the oxidation rate but did not change the oxide scale morphology. The presence of Mn (a known sulphur scavenger) proved less effective than silicon, reducing the sulphidation and corrosion damage extent but not the overall depth.

ODS Steels—The Ideal Case to Study Biases Occurring During APT Analysis of Nanoparticles Constantinos Hatzoglou[1,2], Bertrand Radiguet[1], Gerald Da Costa[1], philippe Pareige[1] and Francois Vurpillot[1]; [1]Groupe de Physique des Materiaux (GPM), France; [2]Norwegian University of Science and Technology (NTNU), Norway

Oxide Dispersion Strengthened (ODS) steels are promising candidates for future nuclear reactors, partly due to the fine and dense dispersion of the nanoparticles they contain. Until now, there was no consensus as to the nature of the nanoparticles, because their analysis pushed the techniques to their limits and in consequence, introduced some artefacts.
Atom probe tomography (APT) analysis of an ODS steel reveal a dense dispersion (10^{23}–10^{24} m^{-3}) of small (≈ 2 nm) nanoparticles enriched in Y, Ti and O. There are also numerous evidences of APT artefacts: high amount of matrix atoms in the particles (*i.e.* Fe and Cr), reconstructed morphology variations and so atomic density fluctuations, all depending of particles size. It appears that the current understanding of APT artefacts cannot explain all these observations. According to field evaporation simulations, composition and morphological biases result from a cross-over of ions trajectories. It then appears that the particles are pures in Y, Ti and O and therefore all the Fe and Cr atoms, observed in the particles (> 80 at.%), are coming for trajectories aberrations. This conclusion is supported by an analytical model (CCC), that can be applied to other materials, and by complementary experimental analysis (TEM measurements on extractive replica). Moreover, the proportion of Fe and Cr, artificially introduced in the particles, provides the composition of the Cr rich shell around the particles.
From this observation, a literature review shows a significant dispersion of the APT measurement in Y, Ti and O in the particles (considering only those elements), which makes precise characterization difficult. Several factors may be at the origin of this dispersion: the ODS steel (14YWT, MA957, 12YWT, MKCR…), the particles size, the data treatment protocol (and so the user), the APT used (ECOWATAP, LAWATAP, LEAP…) and its analysis conditions (pulse type, pulse fraction, temperature…). One of the objectives is to understand this measurement dispersion by limiting itself to the influence of the APT used. To do this, selected ODS steels was analyzed on different APT, available to the Material Physics Group and to the Norwegian University of Science and Technology and the data was processed by a single user with a quasi-automatic data treatment protocol.

Atom Probe Tomography for Steel Product Development Rosalia Rementeria; ArcelorMittal Global R&D, Spain

When it comes to structures, steel has an ability like no other material to provide outstanding and versatile combinations of strength and toughness, but also to boast with durability and cost efficiency. The properties of steel, as in most structural materials, are attainable by selection of the composition and adjustment of thermomechanical sequence and heat treatment. The migration and final distribution of solute atoms into the iron lattice and its inherent defects determines the performance of the end product. Atom probe tomography (APT) allows to image and quantify nano-scale phenomena relevant to steel metallurgy that have been known to exist for long but could not be directly observed, such as the first stages of tempering in carbon steels or solute decoration of dislocations, the so-known as Cottrell atmospheres. From the viewpoint of the properties, APT helps to understand in deep detail the mechanisms leading to precipitation strengthening, improved ductility, grain boundary pinning, toughness maximization or deterioration and grain boundary embrittlement, among others.
Steel is fun to play with due to its infinite combinations of interstitial and substitutional alloying elements, the various equilibrium and non-equilibrium reactions of the matrix and its complex and sometimes abundant lattice defect substructure. We will review here application cases of APT in steel product development carried out by ArcelorMittal in collaboration with leading institutions.

Correlative Microscopy of Stress Corrosion Cracking Using Atom Probe Tomography and High Speed Atomic Force Microscopy Tomas Martin[1], Stacy Moore[1], Robert Burrows[2], Loren Picco[3,1] and Oliver Payton[1]; [1]University of Bristol, United Kingdom; [2]National Nuclear Laboratory, United Kingdom; [3]Virginia Commonwealth University, United States

Stress corrosion cracking (SCC) is an important degradation mechanism in a number of key engineering applications, including water-cooled nuclear reactors. The mechanism behind SCC requires a susceptible material, a local stress and a corrosive environment, but the local behaviour and chemistry at the crack tip is complex and still not fully understood. For improved understanding of the SCC mechanism, it is necessary to better characterise the mechanical behaviour of the material during the formation of cracks, as well as the local chemistry at the crack tip. Atom probe tomography (APT) has been used previously to image the chemical composition of the grain boundary ahead of a crack tip in SUS316 stainless steel, showing that segregation of Ni plays an important role in sensitising the grain boundary to corrosive attack [1]. The high-speed atomic force microscope (HS-AFM) is a contact mode form of atomic force microscopy that can image the topography of surfaces at frames-per-second acquisition rates, enabling live images of chemical processes. Recent work with HS-AFM has observed real-time formation of cracks in 20Cr-25Ni-Nb stabilised stainless steel [2] and AISI Type 304 stainless steel [3] in a corrosive solution known to accelerate SCC. The ability to watch a grain boundary corrode and crack at video frame rates is a powerful tool to link SCC behaviour to the underlying mechanisms behind the process. In this study, the atomic-scale chemical characterisation capability of APT is utilised on crack tips of a sensitised AISI type 304 stainless steel that was observed cracking in an in-situ HS-AFM experiment in an aggressive thiosulphate solution. An APT liftout was obtained from a region close to the crack tip using a specimen preparation method adapted from that used to lift out site-specific grain boundaries in silicon [4]. This preparation method was able to site the crack interface routinely within the APT region of interest, and APT data of the metal-oxide interface showed is a depletion of Cr and Ni enrichment at the boundary, with a thin porous oxide rich in sodium. This was confirmed by focused ion beam cross-sectioning showing large voids at grain boundaries below the surface with a thin Na-rich oxide only at the edges of the voids, indicating a cracking mechanism dominated by the stress. The preparation process will be detailed, as well as correlative data between the two techniques to further the understanding of SCC behaviour in steels.

The Quest for Nanometric Clouds and Clusters in Modern Engineered Materials Stephan Gerstl[1,2], Robin Schäublin[1,2], Lijuan Cui[3], Yong Dai[3], Severin Küchler[2], Vladimir Vojtech[2], Leonardo Pierobon[2] and Jörg F. Löffler[2]; [1]ETH Zurich, Switzerland; [2]ETH Zürich, Switzerland; [3]Paul Scherrer Institut, Switzerland

In this contribution, we review and demonstrate various methods by which we push our characterization limits to better understand nanometric features in the smallest – possibly the most influential – features in nanostructurally engineered materials. Oxide dispersion strengthening of steels for example and, more generally, materials relying on multi-phase strengthening, precipitation hardening, and cluster-strengthening all require an initial catalytic core for the formation of the desired precipitates or mesoscale phases. There is thus a thrust in looking for these pre-precipitation clusters and nano-clouds, which occur in a wide variety of materials research projects. For their analysis we take advantage of correlative techniques between Atom Probe Tomography (APT), Transmission Electron Microscopy, and electron backscatter diffraction, some in

combination with modeling & simulation and others utilizing our original cryo-transfer enabling developments.
We will first focus on FeCr alloys, which model ferritic steels relevant for the fusion community. Here we find intriguing details in the cluster and interfacial chemistry in its α/α' decomposed high-purity binary system [1]. We applied multiple analysis methods to determine their precipitate core compositions, as their structurally coherent boundaries have often shown to be relatively broad compared to other matrix/precipitate systems.
In the field of ferritic steels for advanced nuclear facilities, the nascent irradiation induced clustering and precipitation of nuclear transmutation byproducts is generally investigated to better understand the alloys' evolution of mechanical properties over extended lifetimes and thus irradiation doses. In our near-atomic-scale study we are able to identify the isotopic specificity and thus the particular ions of interest that influence the steel's mechanical properties.
Focusing on SmCo high-temperature supermagnets, we are able to determine the geometry, packing density and local chemistry between Zr-rich nano-platelets and Cu-rich cells, which prove to strongly influence the magnetic properties, such as coercivity [2]. Among these phases, even the finest clustering features may have a strong impact on the macroscopic magnetic properties. With respect to light metals, we show results of room-temperature ('natural') aging of Al alloys, where we have also investigated further alloy classes in Al and Mg that require specimens to remain at cryogenic temperatures from after their creation – to focused ion beam sharpening of the APT tips – to transferring them to the atom probe and enable interrogating their arrested nanostructures [3,4,5].
These examples demonstrate the impact of near-atomic to nano-scale analyses not only to better understand the initial 'gatherings' of atoms (nano-clouds) within a structure, but to stress the continued need for pushing boundaries of highest-resolution characterization methods, the correlation amongst each other, and deploying cryo-vacuum transfer methods.

Navigating the Forest Through the Trees via Machine Learning—Detecting Morphology from Atom Probe Images Krishna Rajan; University at Buffalo, The State University of New York, United States

A paradox in APT is that while on the one hand, it provides an unprecedented level of imaging resolution in three dimensions, it is very difficult to obtain an accurate perspective of morphology or shape outlined by atoms of similar chemistry and microstructure. Hence, unlike scattering techniques such as electron microscopy, interfaces appear diffuse, not sharp. This, in turn, makes it challenging to visualize and quantitatively interpret the microstructure at the "meso" scale, where one is interested in the shape and form of the interfaces and their associated chemical gradients. In this presentation we provide an overview of the computational and machine learning approaches to characterize interface chemistry and morphology directly from atom probe images.

5:30 AM *F.MT05.01.03
Automation Advancements in Atom Probe Tomography Katherine Rice, Brian Geiser, Timothy Payne, Gard Groth, Edward Oltman and Daniel Lenz; CAMECA Instruments, Inc., United States

CAMECA's recent innovations in the areas of automated acqusition, reconstruction, and data analyis have greatly increased the throughput and utilizaton of the Local Electrode Atom Probe™ [1]. These advances position the commercial atom probe as a process monitoring tool for nanoscale devices, providing routine characterization for suitable applications for the microelectronics industry.
CAMECA's Chain Acquisition module enables atom probe data to be acquired from multiple samples, without user intervention, using a recipe-based architecture [2]. Image processing technology is used to do automatic alignment of specimens on a microtip coupon, enabling the user to build a list of specimens that can be analyzed according to individal experimental plans. Live calibration and automated ranging can be perfomed as the instrument is acquiring data, enabling both accurate charge state ratios and reduced user input to mass spectrum assignments. Automated local electrode testing can be performed between analyses, preventing a compromised electrode from affecting the quality of planned experiments, keeping a record of the electrode condtion over time, and notifying a user when an electrode may have decreased in quality.

The experimenal conditions can also be dynamically changed with CAMECA's Scripted Acqusition module. Triggers can be defined to modify acqusition conditions in response to composition, background level, number of ions, or a variety of other experimental outputs. Scripted Acqusition can be used in conjunction with Chain Acqusition to further increase throughput; for example, the acqusition can be stopped after the region of interest is collected and automatically begin acquisition from the next specimen in the chain. This decreases acquisition overall time and increases the value of the dataset by only collecting the necessary volumes. Project management allows scripts to easily be shared between users so that repeatable experiments can be conducted in laboratories around the world.
In addition to automated acqusitions, CAMECA's Atom Probe (AP) Suite enables recipe-based reconstructions and analysis. Reconstructions are completed automatically via user-entered parameters, so that the data is ready for review shortly after collection. Automated reconstruction parmeters can also be selected from a pre-existing list of experiment recipes. Further automated analysis can be queued with application of standard or custom analysis recipes applied to the finished reconstructions. This allows the analyst to repeatably extract the most important information from a dataset without manually applying the analysis steps. Together, these advances have made it faster and easier to collect data and reduce the experience requirements for new users to successfully collect and analyze data with atom probe tomography and reduce time-to-knowledge in the experimental process.

Cluster Analysis Using Machine Learning and Spatial Statistics Galen B. Vincent, Andrew P. Proudian and Jeramy D. Zimmerman; Colorado School of Mines, United States

Clustering of atoms and molecules significantly impacts material properties and is therefore important to characterize accurately. In this work, we use machine learning and spatial statistics to quantify clustering behavior in simulated and experimental APT data. We base our technique on Ripley's K-function analysis, *K(r)*, which is a sensitive measure of spatial correlation (*e.g.* clustering). We use features from the *K(r)* analysis to train a Bayesian regularized neural network (BRNN) to extract radius metrics, intra-cluster density, and background density.

For our test case, training data was simulated for a fixed solute density with clusters of various mean radius, radius variance, intra-particle density, background density, and number of particles. The system was verified on a set of similarly generated data sets, with over 90% of the BRNN-based estimates falling within 10% of the true radius values. Comparing the accuracy of our model against values obtained from the maximum separation algorithm (MSA) in our simulated APT data, we find that the MSA algorithm exhibits large variations based on user-defined inputs while the BRNN model quantifies morphologies accurately. We also apply this analysis to an experimental APT reconstruction with MgZn clusters in a 7000 series aluminum alloy, easily extracting cluster parameters from real APT data.

Measuring Nanosized Void Chemistry at High Accuracy Using Atom Probe Tomography Xing Wang[1,2], Constantinos Hatzoglou[3,4], Yanwen Zhang[2,5], Baptiste Gault[6,7], Karren More[2], Francois Vurpillot[3] and Jonathan Poplawsky[2]; [1]The Pennsylvania State University, United States; [2]Oak Ridge National Laboratory, United States; [3]Normandie Université, France; [4]Norwegian University of Science and Technology, Norway; [5]The University of Tennessee, Knoxville, United States; [6]Max-Planck-Institut für Eisenforschung, Germany; [7]Imperial College London, United Kingdom

Nanosized voids, including pores and bubbles, are a common type of defects that can either improve or degrade the material properties. Voids are essentially empty cavities. Accurate measurement of the material chemistry around voids is important for understanding the void-material interactions. Atom probe tomography (APT) is a promising technique for this task because of its capability to reconstruct 3D positions of elements in materials with a high spatial resolution and chemical sensitivity. However, there has been a knowledge gap regarding how voids are imaged using APT. By performing a correlative scanning transmission electron microscopy (STEM) and APT analysis on void-containing materials, we demonstrated that voids could lead to obvious aberrations in APT reconstructions. Specifically, the local atomic density near voids in an APT dataset can either increase or decrease compared to the matrix. Field evaporation simulations combined with experiments revealed the physical mechanisms for these aberrations and identified the key factors that determined the nature of the aberrations. Based on this study, a general approach for quantifying elemental concentrations near voids using APT has been proposed that has higher accuracy than traditional STEM-based techniques. This approach has been applied to characterize elemental segregations near bubbles in medium and high-entropy alloys (HEAs). The accurate APT measurement shows that in Ni-based HEAs, both Cr and Fe become depleted near bubbles, but Cr depletes more, indicating higher vacancy mobility via Cr. This finding is consistent with the defect energies calculated based on density functional theory and explains the faster bubble growth rate in Ni-based HEAs containing Cr.

Atom Probe Tomography Using a Wavelength-Tunable Femtosecond-Pulsed Coherent Extreme Ultraviolet Light Ann

Chiaramonti-Debay[1], Luis Miaja[1], Benjamin W. Caplins[1], David R. Diercks[2], Brian P. Gorman[2] and Norman A. Sanford[1]; [1]National Institute of Standards and Technology, United States; [2]Colorado School of Mines, United States

Atom probe tomography (APT) is a powerful tool for 3D materials characterization due to its desirable combination of high spatial resolution and high analytical sensitivity. In state-of the-art laser-pulsed APT, a near ultraviolet (NUV) laser (E ≈ 3.5 eV to 3.6 eV; $\lambda \approx$ 355 nm to 343 nm) incident on the specimen provides the thermal energy to overcome the activation barrier for field ion evaporation. NUV laser-pulsed APT has been used to successfully analyze a wide range of materials including metals, semiconductors, insulators, biological materials, and even liquids. However, the data quality is often degraded due to artifacts from the thermal pulsing mechanism. These various artifacts manifest in the form of increased uncertainty in the quantification of specimen composition from the time-of-flight mass spectrometry measurement.

Photon energies in the extreme ultraviolet region of the electromagnetic spectrum (E ≈ 10 eV to 100 eV; $\lambda \approx$ 124 nm to 12 nm) are significantly higher than those in the near ultraviolet and as such, have the potential to trigger entirely new ionization and desorption mechanisms that are not possible with the much lower photon energies in the NUV band. These include various athermal ionization pathways and/or highly local heating that is entirely unlike that achieved using NUV sources.

Initial results from the world's first EUV (41.85 eV; λ = 29.6 nm) radiation-pulsed atom probe microscope will be presented. This instrument uses wavelength-tunable femtosecond-pulsed coherent EUV radiation from phase-matched high harmonic generation in a hollow-core capillary waveguide. EUV radiation-pulsed field ion emission in a variety of materials types will be discussed with respect to the quality of the mass spectrometry data and compared to results obtained using NUV sources. Specifically, the measured composition, time-independent background, time-delayed evaporation, charge state ratios, and multiple hit counts will be compared and related.

This project was made possible with material support from CAMECA Instruments through a Cooperative Research and Development Agreement.

Using a Laser-Pulsed Atom Probe Instrument for Thermal Processing David R. Diercks, Akansha Singh, Rajesh Jha, cristian ciobanu and Aaron Stebner; Colorado School of Mines, United States

Heat treatment of materials to improve performance has been employed for thousands of years. Control of the final size, composition, and distribution of the material's phases is of paramount importance and can be influenced by small changes in initial compositions, temperature, and annealing time. Therefore, knowing what occurs at the earliest stages of the transformation process would shed insight into how to modify the materials for better control of their properties. It has been only within the last one hundred years that the characterization technologies for probing the nanometer-scale mechanisms behind the improved material performance resulting from heat treatments have been developed. While these tools have immensely expanded our understanding of materials and the mechanisms acting on them during thermal processing, there are still aspects that remain challenging to evaluate. In particular, sensitive quantitative compositional measurement with the combination of nano-scale spatial resolution and fractions of a second temporal resolution would provide needed insights into the earliest steps in diffusional processes.
Presented here is a demonstration of how the laser in a laser-pulsed atom probe instrument has been used to thermally induce crystallization and subsequently probe the resulting material structure for a Fe-Si-Nb-Cu-B alloy. Methods of estimating the laser induced temperature profile, determining the cumulative annealing time, and evaluating the resultant three-dimensional nanoscale crystallization are explored. Correlated transmission electron microscopy imaging and diffraction are used to supplement the atom probe results. The distribution of copper-rich cluster sizes and cluster densities measured by atom probe tomography are compared with Thermo-Calc modeling results. Through this example, advantages and limitations of using the atom probe as a processing tool are evaluated.

Surface Dynamics Studies at the Nanoscale by Atom Probe Microscopy—Oxygen Atoms Tracking on Rh, Pt and PtRh Surfaces During H_2+O_2 Reaction Sten V. Lambeets[1], Thierry Visart de Bocarmé[2], Sylwia Owczarek[3], Norbert Kruse[4,1] and Daniel Perea[1]; [1]Pacific Northwest National Laboratory, United States; [2]Univsersité Libre de Bruxelles, Belgium; [3]University of Wroclaw, Poland; [4]Washington State University, United States

Metallic surfaces undergo a series of surface and subsurface structural and chemical transformations that drastically change their surface and mechanical properties. Understanding such dynamics from a fundamental science standpoint is particularly

important in the case of heterogeneous catalysis, as such fundamental understanding is needed to build rational links between chemical/structural surface properties and the desired catalytic performance. This work addresses the dynamics of O_2 hydrogenation over rhodium (Rh), platinum (Pt) and PtRh alloy (10% wt Rh) revealed with Field Emission/Ion Microscopy (FIM/FEM). A comparative study is conducted with the use of other oxygen carrier gases: N_2O, CO and CO_2. Finally, Atom Probe Tomography (APT) is used to map the path of the oxygen atoms on and through the Rh surface.
FIM and FEM are capable to image the apex of sharp needles with nanometric lateral resolution. At the nanoscale, this apex is in the form of a hemisphere with a variety of exposed atomic planes and facets that can be simultaneously probed. Moorphology of such sample mimicks a single metal nanoparticle by its size and shape. FEM exhibits image contrast which is mainly determined by crystallographic plane-dependent variations of the work function. Local brightness variations on video-FEM is used to probe dynamic surface reactions[1]. The APT in turn provides a 3D atom-by-atom map of the entire apex volume with near atomic scale spatial resolution and part per million chemical sensitivity. By mapping the 3D distribution of Rh oxide and the morphology of the oxide/metal interface within the bulk after a controlled O_2(g) exposure, APT is used to explore the nature of oxygen atom penetration in the bulk.
Crystallographically-dependent chemical and structural dynamics of Rh and Pt surface oxidation during an ongoing oxygen exposure is directly observed with FIM/FEM. Focusing on Rh, we observe a mechanism of inter-facet cooperation between Rh{012} and Rh{113} crystallographic surface facets. Clean Rh surface (i.e. no oxide) exhibits bright contrast over {012} facets while {113} facets remain dark. However, upon exposure to oxygen originating from O_2, N_2, or CO_2, we observe simultaneously, an increase brightness over the {113} facets and a decrease in brightness over the {012} facets. This tells us that dissociative adsorption of O_{ads} occurs on the {012} and is followed by oxygen penetration into the subsurface through the {113}. Similar dynamics are observed on Pt and PtRh with exposure to other oxygen carrier gases of N_2O and CO_2. Additionally, the addition of H_2 recovers the original FEM pattern reflecting the reaction between H_{ads} and O_{ads}. This mechanism of inter-facet cooperation leads to a unique distribution of oxygen atoms within the bulk, which can be directly observed by APT. Following a 600s exposure of O_2 (2.0×10^{-2}Pa) at 700K of a pristine Rh needle (i.e. no native surface oxide), APT analysis reveals an anisotropic distribution of Rh oxides (RhO_x) and the complex morphology of the oxide/metal interface reflecting a specific crystallographic dependence[2]. An enhanced density of RhO_X^{n+} (x = 1 or 2 and n = 1 or 2) species are found both under the (111) central plane and along only one of the two three-fold symmetric crystal zones comprising the {113} facets. An iso-density surface of the APT reconstruction reveals a central accumulation of RhO_X species along the [111] direction, connected to the {113} vicinal facets. In summary, we conclude O_{ads} occurs on the {012} and is followed by oxygen penetration into the subsurface through the {113} towards the [111].
The combination of FEM and APT analysis delivers new insight into the Rh oxide formation and offers exciting perspectives leading a better and more fundamental understanding of the heterogenous catalysis as well as corrosion dynamics.

Estimating Evaporation Fields and Specific Heats with Atom Probe Tomography Andrew P. Proudian and Jeramy D. Zimmerman; Colorado School of Mines, United States

Estimations of evaporation field values in atom probe tomography are sparse in the literature despite their importance in the reconstruction and data analysis process. This work describes a method for estimating the zero-barrier evaporation field (ZBEF) using a straightforward measurement series of voltage versus laser pulse energy at a constant evaporation rate. This estimate depends on the sample radius of curvature and its specific heat. If a similar measurement is made of the voltage versus base temperature for a given evaporation rate, direct extraction of the material's specific heat can be made, leaving only the sample radius of curvature as an input parameter.

The method is applied to extract ZBEF in a previously published voltage versus laser pulse energy dataset for CdTe (18.07(87) V/nm).[1] Furthermore, using the published voltage versus base temperature sweep of CdTe permits extraction of a specific heat (11.27(254) J/K/mol @ 23.1 K) in good agreement with the literature (11.14 J/K/mol @ 22.17 K).[2] This method is then applied to a number of organic small molecules to understand how ZBEF depends on molecular properties.

Nanoscale Visualization of Carbon Deposits and Magnesium Clusters in Zeolites Active in the Methanol-to-Olefins Process Sophie H. van Vreeswijk[1], Jonathan Poplawsky[2], Irina Yarulina[3] and Bert M. Weckhuysen[1]; [1]Utrecht University, Netherlands; [2]Center for Nanophase Materials Sciences, United States; [3]BASF Corporation, Netherlands

In the methanol-to-hydrocarbons (MTH) process, methanol is converted to more valuable products, such as olefins and aromatics, using zeolite or zeotype catalysts. Methanol can be obtained from conventional as well as from more renewable sources, such as biomass, carbon containing waste and CO_2, which explains the great commercial interest of this catalytic process. [1][2] The exact end-product of the process is determined by the zeolite pore structure and the number and nature of the acidic active sites. A key step in this MTH mechanism is the formation of a so-called hydrocarbon pool in which olefins and aromatic compounds function as activating and deactivating reaction intermediates. [3] Most of the unmodified proton form zeolites are extensively studied for their performance and deactivation in the MTH process. However, protons can be exchanged by other cations, which can drastically influence catalytic performance. [3] These influences on the catalytic behaviour are nonetheless not well understood.

In this work, magnesium was introduced in the chabazite structure SSZ-13 to (partially) replace the protons in the zeolite framework. This resulted in differences in both catalytic performance as well as catalyst deactivation. Using *operando* UV-Vis spectroscopy and *operando* X-ray diffraction, differences between reaction intermediates and catalyst characteristics can be linked to the catalytic performance.

Zeolites are notoriously difficult to study at the nano-scale, because of their instability under e.g. electron beams. [4] Atom probe tomography (APT) is uniquely positioned among all tomographic techniques; it can provide 3D chemical information with sub-nm resolution, making it the only technique capable of finding nanometre scale relationships in these materials, and especially for studying elements that offer no significant z-contrast differences (e.g. Al and Si). With this technique we were able to visualize magnesium clusters, obtain information about the distribution of the magnesium with respect to the aluminium, as well as the correlation between magnesium and coke molecules after the MTH process.

To conclude, in this work both *operando* as well as APT studies on (un)-modified zeolites are described to be able to contribute to the unravelling of the MTH mechanism in the presence of e.g. Mg.

Atomic-Level Investigation of Preferential Impurity Segregation to Grain Boundaries in Y-TZP Through a Graph-Based Structure Olivia G. Licata[1], Parth Desai[1], Olga Wodo[1], Jonathan Poplawsky[2] and Baishakhi Mazumder[1]; [1]University at Buffalo, SUNY, United States; [2]Oak Ridge National Laboratory, United States

Yttria-stabilized tetragonal zirconia polycrystal (Y-TZP) is of great interest due to its superior corrosion, wear-resistance, and high flexural strength. Y-TZP exhibits a unique toughening mechanism when a stimulus is applied, in which it transforms from tetragonal (t) to monoclinic (m) phase. Over time, this transformation can lead to an aging phenomenon known as low-temperature degradation (LTD)[1]. The aging process is influenced by microstructural features, such as porosity, impurities, grain size, and stabilizer content. These features are also interlinked with one another, making the route for process optimization less clear. Grain boundaries (GBs) are thought to serve as the nucleation site for t-m transformation as well as the path for transformation propagation [2,3]. In an attempt to strengthen the GBs and limit LTD, commercial processing methods have introduced dopants and varying stabilizers to the zirconia microstructure. For every pair of yttria ions in Y-TZP, one oxygen vacancy is introduced (to neutralize the excess charge of Y^{3+})[4]. The annihilation of oxygen vacancies is widely accepted as the root cause of hydrothermal aging in Y-TZP; however, the underlying mechanism and its connection to the destabilization of the tetragonal phase is not fully understood. In this work, we will combine atomic-level insights on

chemical distribution from atom probe tomography (APT) with graph-based materials representation to quantify the extent of elemental heterogeneity influence on microstructural features linked with the t-m transformation.

APT analysis was performed on a set of commercial 3Y-TZP ceramics (3 mol.% Y_2O_3), revealing trace levels of Aluminum (Al), Hafnium (Hf), and Silicon (Si), which were introduced in the raw material and during processing steps. The three-dimensional atom maps from APT demonstrated Y-rich GBs, with a limited number of GBs exhibiting preferential segregation of Al impurities, as well. Concentration profiles taken perpendicularly across the GBs indicated 5 at.% Y and 2 at.% Al within the GB and ~1.5 at.% Y throughout the matrix. APT analysis provides the three-dimensional positions and chemical identity for each atom. The positional data from regions of interest were converted to a graph representation, allowing for the definition and extraction of descriptors to understand the underlying physical phenomena. For example, the nearest neighbor distance between ions of the same species was used to define a descriptor that helps identify the number and distribution of phases present within the sample. Another descriptor was based on the shortest path consisting of Al to help assess the propensity of diffusion. These methods were further extended to understand the likelihood of an O vacancy in a particular region.

Our combined approach utilizes rigorous materials characterization techniques and informatics to quantify critical variations in microstructure related to the t-m transformation. Through graph-based representation, we define new metrics to correlate the microstructure with potential routes for degradation. These understandings will aid in the improved design and processing of zirconia-based ceramics to limit the susceptibility to LTD aging while maintaining their valuable mechanical properties. Our method enhances the capabilities of APT data to quantify the underlying phenomena of material degradation.

Quantification of Carbon in Implanted Silicon Using Atom Probe Tomography Paul Dumas[1,2], Sébastien Duguay[2], Julien Borrel[1], Fanny Hilario[1] and Didier Blavette[2]; [1]STMicroelectronics, France; [2]GPM Rouen, France

Quantification of carbon in materials using Atom Probe Tomography (APT) is a common issue. Large underestimation in the carbon content is often observed [1,2]. One well known reason arises from multiple events that occur when several ions strike the detector nearly simultaneously and close to each other. When this happens, a part of ions may be lost due to the so-called electronic “dead time” and “dead zone” existing between each hit. This phenomenon is very likely when analyzing carbon because the high electric field needed to induce its evaporation promotes correlated departures of carbon ions at the tip surface. Dissociation of molecular ions during their flight from the tip to the detector is another source of carbon multiple events.

Carbon biases can also arise from mass-to-charge ratio overlaps in APT mass spectra. For example, $(^{12}C^{12}C)^{2+}$ and $^{12}C^{+}$ ions are overlapped as they share the same mass-to-charge ratio (12 Da). In this case, the proportion of each overlapped ion is needed to make a correct quantification. These quantities can sometimes be derived using isotopes abundance. In the above example, the true number of $(^{12}C^{12}C)^{2+}$ counts at 12 Da can be derived from $(^{12}C^{13}C)^{2+}$ counts at 12.5 Da. However, since the stable isotope ^{13}C only account for 1.07% of the total carbon amount, ions containing^{13}C are not systematically detected. This issue arises in materials containing a low amount of carbon (less than 1%), for instance in the matrix of steels or in semicondcutors.

The overlap issue faced in materials containing a low carbon content was addressed in this study using $(^{12}C)^{+}$ and $(^{13}C)^{+}$ implanted in equal proportion. Doses, energies and tilts used to introduce $(^{12}C)^{+}$ and $(^{13}C)^{+}$ in a 300 mm silicon wafer were $1 \pm 0.01 \times 10^{15}$ cm^{-2}**,** 30 keV and 3° respectively. The wafer was then annealed to restore silicon crystallinity (750°C for 5 hours). Carbon solubility in slicon being very low (~2 ppb at 750°C) compared to the implanted content (~0.2 at. %), carbon clusters were found by APT. Most peaks were indeed related to molecular ions originating from these clusters. Statistics was successfully used to identify these peaks and quantify the contribution of molecular ions to the carbon content.

Carbon quantification using APT was found more accurate using low electric fields conditions (high laser powers applied at

the tip surface). This was attributed to the hindering of molecular ion dissociation at low electric fields. Furthermore, the atomic fraction of carbon in clusters was found close to that of the expected SiC phase, only when using low electric field conditions (high laser power). This gives a mean number of trapped self-interstitials per carbon atom close to one, in agreement with other studies [3,4].

Stacking Order Dependent Elemental Diffusion Between STO/LMO/LASO Layers Revealed by Atom Probe Tomography Jith Sarker[1,2], Wei Guo[2], Manual Roldan[3], Hans Christen[2], Baishakhi Mazumder[1] and Jonathan Poplawsky[2]; [1]University at Buffalo-SUNY, United States; [2]Oak Ridge National Laboratory, United States; [3]Arizona State University, United States

Perovskite metal oxides (ABO_3) are highly promising for artificial superlattice fabrications due to their exceptional physical properties and chemical stabilities. Among perovskite metal oxide superlattice, $SrTiO_3$ (STO) and $LaMnO_3$ (LMO) based heterostructures has gained significant attention due to enhanced magnetic properties compared to bulk LMO, which is desirable for spintronic devices. Previous scanning transmission electron microscopy (STEM) results demonstrated that the oxygen octahedral rotation (the angle between Mn-O-Mn bonding) at the STO/LMO interface plays a vital role in tuning the magnetic moments in the LMO/STO superlattice. Diffusion of elements across these interfaces can also play a role in the magnetic properties; however, diffusion across these interfaces has not been well documented. STEM has been heavily used to study these materials because it is ideal for observing interfacial structure, but a small amount of interfacial elemental diffusion is difficult to quantify using analytical STEM techniques, such as electron energy loss spectroscopy (EELS). Atom probe tomography (APT) is a good candidate for quantifying the chemistry through these interfaces because it is a sub-nm resolution technique with a maximum sensitivity of ~10 ppm. To this end, APT was employed to map the interfacial chemistry of the STO/LMO superlattice structure. Two different superlattice structures were tested to isolate the top and bottom STO/LMO interfaces. STO/LMO/LASO (5x) and LASO/LMO/STO (5x) superstructures were grown by atomic layer deposition (ALD) on STO supstrates to isolate LMO grown on top of STO (LMO→STO) and STO grown on top of LMO (STO→LMO). The saturation magnetic moment per Mn ion was significantly higher for LMO→STO (M_S~1.67 μ_B per Mn ion) compared to STO→LMO (M_S~1.23 μ_B per Mn ion). Other samples grown in the same manner showed the same behavior. The APT results reveal differences in interfacial elemental diffusion that can explain the observed differences in magnetic behavior. In this presentation, the impact of growth order on elemental diffusion using ALD and how elemental diffusion influences magnetic properties will be discussed. This study provides a direct insight on how changes in interfacial structure and chemistry of LMO/STO superlattice can modify the subsequent magnetic functionalities when the growth sequence is reversed. This information is crucial for understand the ALD growth technique of complex oxides and how to optimize ferromagnetism in future spintronic devices. APT was conducted at ORNL's Center for Nanophase Materials Sciences (CNMS), which is a U.S. DOE Office of Science User Facility.

ODS Steels—The Ideal Case to Study Biases Occurring During APT Analysis of Nanoparticles Constantinos Hatzoglou[1,2], Bertrand Radiguet[1], Gerald Da Costa[1], philippe Pareige[1] and Francois Vurpillot[1]; [1]Groupe de Physique des Materiaux (GPM), France; [2]Norwegian University of Science and Technology (NTNU), Norway

Oxide Dispersion Strengthened (ODS) steels are promising candidates for future nuclear reactors, partly due to the fine and

dense dispersion of the nanoparticles they contain. Until now, there was no consensus as to the nature of the nanoparticles, because their analysis pushed the techniques to their limits and in consequence, introduced some artefacts.
Atom probe tomography (APT) analysis of an ODS steel reveal a dense dispersion (10^{23}–10^{24} m^{-3}) of small (≈ 2 nm) nanoparticles enriched in Y, Ti and O. There are also numerous evidences of APT artefacts: high amount of matrix atoms in the particles (*i.e.* Fe and Cr), reconstructed morphology variations and so atomic density fluctuations, all depending of particles size. It appears that the current understanding of APT artefacts cannot explain all these observations. According to field evaporation simulations, composition and morphological biases result from a cross-over of ions trajectories. It then appears that the particles are pures in Y, Ti and O and therefore all the Fe and Cr atoms, observed in the particles (> 80 at.%), are coming for trajectories aberrations. This conclusion is supported by an analytical model (CCC), that can be applied to other materials, and by complementary experimental analysis (TEM measurements on extractive replica). Moreover, the proportion of Fe and Cr, artificially introduced in the particles, provides the composition of the Cr rich shell around the particles.
From this observation, a literature review shows a significant dispersion of the APT measurement in Y, Ti and O in the particles (considering only those elements), which makes precise characterization difficult. Several factors may be at the origin of this dispersion: the ODS steel (14YWT, MA957, 12YWT, MKCR…), the particles size, the data treatment protocol (and so the user), the APT used (ECOWATAP, LAWATAP, LEAP…) and its analysis conditions (pulse type, pulse fraction, temperature…). One of the objectives is to understand this measurement dispersion by limiting itself to the influence of the APT used. To do this, selected ODS steels was analyzed on different APT, available to the Material Physics Group and to the Norwegian University of Science and Technology and the data was processed by a single user with a quasi-automatic data treatment protocol.

Alloying for Corrosion Resistance—The Effect of Manganese and Silicon on a Polycrystalline Nickel-Based Superalloy Stella Pedrazzini; Imperial College London, United Kingdom

Nickel superalloys are employed in the hottest part of jet engines and industrial gas turbines for power generation. In these harsh environments, sulphur contamination can occur in-service, causing reductions in the predicted component lifetime. Our work uses environmental exposures and state of the art characterisation to explore the effect of low-level silicon (0.5 wt%) and manganese (1 wt%) additions on the sulphidation and type-2 hot corrosion response of a polycrystalline nickel superalloy.

Silicon was added promote formation of a compact dual-layer chromia-alumina scale that reduced oxidation rate in long-term experiments. The silicon-containing alloy was more resistant to hot corrosion from coupled NaCl + SOx exposure.

Manganese improved oxidation resistance by creating MnCr2O4, which reduced the oxidation rate but did not change the oxide scale morphology. The presence of Mn (a known sulphur scavenger) proved less effective than silicon, reducing the sulphidation and corrosion damage extent but not the overall depth.

5:30 AM *F.MT05.04.03
Atom Probe Tomography for Steel Product Development Rosalia Rementeria; ArcelorMittal Global R&D, Spain

When it comes to structures, steel has an ability like no other material to provide outstanding and versatile combinations of strength and toughness, but also to boast with durability and cost efficiency. The properties of steel, as in most structural materials, are attainable by selection of the composition and adjustment of thermomechanical sequence and heat treatment. The migration and final distribution of solute atoms into the iron lattice and its inherent defects determines the performance of the end product. Atom probe tomography (APT) allows to image and quantify nano-scale phenomena relevant to steel metallurgy that have been known to exist for long but could not be directly observed, such as the first stages of tempering in carbon steels or solute decoration of dislocations, the so-known as Cottrell atmospheres. From the viewpoint of the properties, APT helps to understand in deep detail the mechanisms leading to precipitation strengthening, improved ductility, grain boundary pinning, toughness maximization or deterioration and grain boundary embrittlement, among others.
Steel is fun to play with due to its infinite combinations of interstitial and substitutional alloying elements, the various equilibrium and non-equilibrium reactions of the matrix and its complex and sometimes abundant lattice defect substructure. We will review here application cases of APT in steel product development carried out by ArcelorMittal in collaboration with leading institutions.

5:45 AM *F.MT05.04.04
Improving the Strength of Grain Boundaries in Molybdenum by Segregation Engineering S. Jakob[1], K. Leitner[1,2], A.

Lorich[3], W. Knabl[3], Helmut Clemens[1] and V. Maier-Kiener; [1]Montanuniversitaet Leoben, Austria; [2]voestalpine BÖHLER Edelstahl GmbH, Austria; [3]Plansee SE, Austria

Combining mechanical properties with chemical information on the nanometer scale have become a key approach in recent characterization techniques of metals and their alloys. The application of advanced high-resolution characterization techniques such as local electrode atom probe tomography enables a detailed investigation of the material's interfaces on an atomic level. Molybdenum has advantageous structural as well as functional properties leading to a broad range of applications. As a structural material, however, the application of technically pure molybdenum at low temperatures is limited because of its tendency for brittle intergranular failure. The direct correlation of strength and ductility with segregation content at the boundaries significantly helps to understand the intergranular fracture of molybdenum. The deliberate introduction of cohesion enhancing elements lead to a change in fracture mode, a lower brittle-to-ductile transition temperature and a higher ductility of the material. In this work, the site-specific preparation of the region of interest for atom probe measurement is performed using focused ions and so-called transmission Kikuchi diffraction. The grain boundaries of molybdenum alloys, which are showing a fracture mode change, are analyzed and compared to pure molybdenum. An outlook for improved ductility of molybdenum focusing on segregated elements is given.

Exploring New Science Domains with Atom Probe Tomography Enabled by an Environmental Transfer Hub Daniel Perea; Pacific Northwest National Laboratory, United States

It is well known that environmental exposure of materials can lead to alteration, such as for example, the formation of an unintended surface oxide layer, that in some cases can affect the intended analysis. To prevent unwanted morphological or chemical alteration of specimens prior to analysis, control of the specimen environment during transfer between instruments is required for specimens sensitive to air or thermal exposure. At PNNL, we have developed a suite of hardware and experimental protocols for the preparation and handling of environmentally sensitive materials centered around the combination of a unique environmental transfer hub chamber, modified specimen suitcase device, and modified cryo FIB/SEM capabilities. The hub chamber design also allows the connection of ancillary tools, such as a gas phase reactor chamber for controlled surface reaction studies and UHV specimen transfer. The ability to prepare, manipulate, and transfer specimens under either cryogenic or vacuum conditions provides a means to uniquely apply APT analysis to address new science domains in biological, nuclear, and catalytic materials. Here I will describe in detail the design of our system and our developed workflows focusing on specific examples of APT analysis applied to *temperature sensitive* material systems requiring cryo specimen preparation and transfer, as well as *air sensitive* materials systems requiring vacuum or inert vacuum transfer.

Cryogenic Atom Probe Tomography for Hydrogen Characterisation in Steel Microstructures Eason Chen and Julie Cairney; The University of Sydney, Australia

The presence of hydrogen in steels can lead to catastrophic embrittlement/early-fracture. This is a serious issue for hydrogen transportation and storage. However, consensus has not been reached on the exact mechanism of hydrogen embrittlement, mainly due to the difficulty to provide direct evidence of the hydrogen-materials interactions that underpins the hypotheses [1]. In addition, a proposed solution to hydrogen embrittlement by using steels that contain hydrogen traps such as carbide precipitates [2], is limited in its effectiveness, due to the inability to directly observe the proposed hydrogen trapping at microstructural features.
As such, we used atom probe to study the hydrogen distribution at key features, including dislocations [3], grain boundaries [3], and both incoherent [3] and coherent [4] carbide precipitates in BCC/BCT iron matrix. To enable these studies, we charged the sample with deuterium (a hydrogen isotope) to avoid ambiguity from background hydrogen, and utilised a cryogenic sample transfer protocol to allow sufficient signal to be retained for observations. These efforts lead to the confirmations of: i) hydrogen enrichment at dislocations, providing a concrete validation of the hydrogen-enhanced

dislocation mobility theory of embrittlement; ii) hydrogen enrichment at grain boundaries, underpinning the hydrogen-enhanced grain boundary decohesion theory; iii) the hydrogen at the interface between large, incoherent precipitates and the surrounding steel matrix, settling a long-standing debate around whether hydrogen trapping is an interfacial effect; and iv) the hydrogen at the interior of small, coherent carbides, suggesting hydrogen can internalise into carbides under certain conditions.

Correlative Microscopy of Stress Corrosion Cracking Using Atom Probe Tomography and High Speed Atomic Force Microscopy Tomas Martin[1], Stacy Moore[1], Robert Burrows[2], Loren Picco[3,1] and Oliver Payton[1]; [1]University of Bristol, United Kingdom; [2]National Nuclear Laboratory, United Kingdom; [3]Virginia Commonwealth University, United States

Stress corrosion cracking (SCC) is an important degradation mechanism in a number of key engineering applications, including water-cooled nuclear reactors. The mechanism behind SCC requires a susceptible material, a local stress and a corrosive environment, but the local behaviour and chemistry at the crack tip is complex and still not fully understood. For improved understanding of the SCC mechanism, it is necessary to better characterise the mechanical behaviour of the material during the formation of cracks, as well as the local chemistry at the crack tip. Atom probe tomography (APT) has been used previously to image the chemical composition of the grain boundary ahead of a crack tip in SUS316 stainless steel, showing that segregation of Ni plays an important role in sensitising the grain boundary to corrosive attack [1]. The high-speed atomic force microscope (HS-AFM) is a contact mode form of atomic force microscopy that can image the topography of surfaces at frames-per-second acquisition rates, enabling live images of chemical processes. Recent work with HS-AFM has observed real-time formation of cracks in 20Cr-25Ni-Nb stabilised stainless steel [2] and AISI Type 304 stainless steel [3] in a corrosive solution known to accelerate SCC. The ability to watch a grain boundary corrode and crack at video frame rates is a powerful tool to link SCC behaviour to the underlying mechanisms behind the process. In this study, the atomic-scale chemical characterisation capability of APT is utilised on crack tips of a sensitised AISI type 304 stainless steel that was observed cracking in an in-situ HS-AFM experiment in an aggressive thiosulphate solution. An APT liftout was obtained from a region close to the crack tip using a specimen preparation method adapted from that used to lift out site-specific grain boundaries in silicon [4]. This preparation method was able to site the crack interface routinely within the APT region of interest, and APT data of the metal-oxide interface showed is a depletion of Cr and Ni enrichment at the boundary, with a thin porous oxide rich in sodium. This was confirmed by focused ion beam cross-sectioning showing large voids at grain boundaries below the surface with a thin Na-rich oxide only at the edges of the voids, indicating a cracking mechanism dominated by the stress. The preparation process will be detailed, as well as correlative data between the two techniques to further the understanding of SCC behaviour in steels.

An Atom-Probe Tomography Study of High-Nickel Steel Weld Deposits with a Hierarchical Microstructure Amir R. Farkoosh[1], Daniel H. Bechetti[2], Matthew F. Sinfield[2], Jeffrey D. Farren[2] and David N. Seidman[1,3]; [1]Northwestern University,

United States; [2]Carderock Division, Naval Surface Warfare Center, United States; [3]Northwestern University Center for Atom-Probe Tomography (NUCAPT), United States

Fabrication of steel structures requires joining by fusion welding. As requirements for weight and cost savings drive increased demand for advanced high-strength, high-toughness structural steels, the ability to balance mechanical performance and microstructural robustness of steels for the spectrum of welding processes poses a significant challenge. One aspect of this challenge is material responses to reheating during multi-pass welding. Thermal transients induce extensive microstructural changes in prior weld passes, whose nature and magnitude are highly dependent on the specifics of the chosen welding processes and the steel's composition. Herein, we present a new high-nickel steel, developed at the Naval Surface Warfare Center Carderock Division, which exhibits a positive response to the intrinsic heat treatment imposed during multi-pass welding processes. Because of the non-equilibrium solidification conditions, the weldments exhibit a hierarchical microstructure with several unique features, including: (i) cellular/dendritic substructure due to constitutional super-cooling; (ii) micro-segregation; (iii) high oxygen and hydrogen concentrations; and (iv) different amounts of lath martensite, and retained austenite across the fusion zone. Here, site-specific atom-probe tomography has become an essential tool that enables us to study the different regions of this hierarchical microstructure in great detail. The atom-probe tomography experiments are complemented by differential interference contrast optical microscopy, TEM, X-ray diffraction, and EBSD to study the microstructural features over hierarchical length scales. We have demonstrated that it is possible to produce a fine martensitic microstructure, which is reinforced by a high number density of V(N,C) nanoprecipitates, without post-weld heat treatments, leading to both high-strength and toughness. The presence of the V(N,C) nanoprecipitates has a twofold benefit: (i) provides dispersion strengthening; and (ii) removes nitrogen and diffusible hydrogen from the microstructure, which improves the ductility of the weldments and increases resistance against hydrogen embrittlement. The fundamental knowledge acquired in this study is also utilized to optimize the alloy system for the fabrication of structural components through additive manufacturing processes.

Dose Rate and Temperature Effect on the Alpha Prime Precipitation in Ion Irradiated Ultra-High Purity Fe-Cr Alloys Yajie Zhao[1], Arunodaya Bhattacharya[2], Caleb Massey[2], Pengcheng Zhu[1], Cristelle Pareige[3], Philip Edmondson[2], Jean Henry[4] and Steven Zinkle[1]; [1]the University of Tennessee, United States; [2]Oak Ridge National Laboratory, United States; [3]Université et INSA de Rouen, France; [4]CEA, France

Cr-rich alpha prime (α') precipitates are detrimental to the mechanical properties of FeCr based ferritic-martensitic steels. Understanding α' precipitation under irradiation conditions is essential for the application of this steel in nuclear reactor environments. To study the effect of dose rate (ballistic dissolution) and irradiation temperature (radiation-enhanced diffusion) on α' formation, ultra-high purity Fe-Cr alloys with 18 wt.% Cr (in either solid solution or thermally aged to form pre-existing α'precipitates) were irradiated with 8 MeV Fe ions to a midrange (~1 um) dose of 0.35-3.5 displacements per atom (dpa) between 300-450 °C at 10^{-3}, 10^{-4} and 10^{-5} dpa/s. Following irradiation, atom probe tomography (APT) was employed to characterize the number density, radius and Cr concentration of Cr-rich clusters. Homogeneously distributed α' precipitates were revealed when radiation-enhanced diffusion dominates over ballistic dissolution (>300°C). All clusters are identified and quantified through the maximum separation method. The cluster Cr concentrations decrease as irradiation temperature decreases or dose rate increases. This is consistent with the less solute enrichment revealed by the proxigram across the iso-concentration interface. However, despite the irradiation conditions, all of the measured values are well below the equilibrium Cr concentration for α' phase suggested by the phase diagram. The radius and number density of α' clusters are similar and within statistical errors for different specimens. The segregation of Cr, C and N atoms to dislocation loops was also observed.

This research was sponsored by the Office of Fusion Energy Sciences, U.S. Department of Energy under contract DE-AC05-00OR22725 with UT-Battelle, LLC and grant # DE-SC0006661 with the University of Tennessee. The fabrication of the Fe-Cr binary alloys has been carried out within the framework of the EUROfusion Consortium and has received funding from the Euratom research and training program 2019–2020 under Grant Agreement No. 633053.

F.MT05.06.03
High-Yield Cryo-APT Workflow Using a Low-Temperature Microgripper Lorenz G. Lechner[1], Andrew Smith[2] and Stephan Kleindiek[2]; [1]Kleindiek Inc., United States; [2]Kleindiek Nanotechnik, Germany

Focused-ion beam (FIB) target preparation is the gold standard for creating site-specific specimen for atom probe tomography (APT). However, FIB preparation can introduce artifacts, such as contamination, amorphization, and heating. One way to minimize sample damage is the usage of cryo-FIB. Cooling the specimen during FIB milling reduces heating

related damage and limits the diffusion of Ga. Cryo-FIB sample preparation as part of a complete cryo-APT workflow enables the study of soft and unstable materials, e.g., organic solar cells or high-mobility hydrogen impurities.
However, FIB lift-out preparation requires modifications to succeed at low temperatures. Conventional techniques for in-situ lift-out use beam induced deposition to temporarily attach the specimen to a manipulator and permanently mount the specimen on a sample support structure. These "soldering" techniques use metal-organic precursor gases injected into the microscope chamber and locally decomposed using the electron or ion beam. Unfortunately, these gas-phase deposition processes do not work at low temperatures because the precursors form thick condensates on all cold surfaces. Alternative techniques, like beam cured adhesives, are also not feasible at cryogenic temperature.
Here, we demonstrate a gas-free cryo-liftout workflow using a low-temperature microgripper. The gripper assembly consists of a 3-axis micromanipulator equipped with an insulated gripper thermally anchored to the microscope's cold shield. Piezo motors position the system and actuate the gripper jaws with nanometer precision. The specimen is mounted inside the microscope on a cryo-stage. The region of interest is partially released from the bulk material using FIB cutting. The gripper grabs the specimen and — after a final release cut — maneuvers it onto a micro-post. After the specimen is attached to the post using redeposition welding, the gripper releases the specimen. In the last preparation step, annular FIB milling gives the sample its final shape.
In contrast to using conventional manipulation, there is no need to temporarily join the probe and specimen and subsequently cut them free. This simplification makes the process faster and more reliable, overall increasing its yield.

F.MT05.06.05
Atom Probe-Aided Design of Additively Manufactured High-Temperature Aluminum Alloys Richard A. Michi, Amit Shyam, Alex Plotkowski and Jonathan Poplawsky; Oak Ridge National Laboratory, United States

Conventional aluminum alloys cannot be utilized in the 250–450 °C temperature range due to a lack of microstructural stability, creating a technological gap currently filled by steels, titanium alloys, and Ni-base superalloys. Replacement of these materials with aluminum alloys has significant implications for the energy and transportation sectors (e.g., increased engine operating temperature and efficiency, lightweighting, cost reduction), but has yet to be achieved. In this talk, we will give examples of APT analysis aiding in the design of new generations of high-temperature, additively manufactured aluminum alloys specifically targeted for use in the 250–450 °C temperature range. In particular, we will show how APT analysis reveals Zr and Mn segregation to the coherent and semi-coherent interfaces of θ’ precipitates in a novel additively manufactured Al-Cu-Zr-Mn alloy, leading to thermal stability up to 350 °C. We will also discuss how the accurate measurement of matrix solute supersaturations facilitated by APT aid in the design of heat treatments for precipitation-strengthened alloys with thermally stable phases and the observations of refined, nanoscale microstructural features formed during the additive manufacturing process. APT was conducted at ORNL's Center for Nanophase Materials Sciences (CNMS), which is a U.S. DOE Office of Science User Facility.

Tracking Coincident Pair Separation with Varying Concentration Reveals Insights on Nitride Field Evaporation Olivia G. Licata and Baishakhi Mazumder; University at Buffalo, SUNY, United States

The unique ability of Atom probe tomography (APT) to study three-dimensional atomic distribution relies on the field evaporation of ions onto a position-sensitive detector. Multiple ion events reaching the detector within the same pulse period can result in compositional and spatial inaccuracies. Ideally, in APT analysis, acquisition parameters and conditions are modified so that the occurrence of multi-hit events is limited. Some material systems have a higher tendency for multi-hit events during field evaporation in APT, such as those containing boron, carbon, oxygen, nitrogen, and compound semiconductor materials. Under these unavoidable circumstances, these unique events have shown the potential to provide insight on field evaporation and material structure [1, 2]. Here, we define a metric by tracking the distance between coincident detector events within a heterostructure to gain insight on the unique evaporation behavior and crystallographic origin of nitride species. The distributions of pair distances are investigated for each species and region, to understand the influence of elemental composition on evaporated ion separation.

$Al_{0.3}Ga_{0.7}N$/AlN/GaN heterostructures, grown via molecular beam epitaxy (MBE) and metal-organic chemical vapor deposition (MOCVD), were utilized as test structures. Trends in mean and median pair separation distances were consistent between the two preparation methods. Additionally, individual pair species showed agreement within 0.2 mm in detector space. This finding allows for the distinction of Al-x and Ga-x events based on their pair separation. Interestingly, Al-x events show higher separation values than Ga-x events. This is in disagreement with the known lattice constants of Al-N and GaN. This result suggests that crystallographic spacing is not the dominant influence on pair separation. A more likely mechanism is related to the unique field evaporation of the species as well as characteristics of the surface field during

acquisition. The crystallographic orientation upon evaporation may also play a role in the resulting pair separation. Distributions of pair separation distance were utilized to investigate variability in the spread of multi-hit events across heterostructure layers. The most prominent feature was the consistent bimodality of Al^{2+}-N_2, suggesting two separate evaporation phenomena. This unique behavior may originate from a combination of dissociation events and correlated events occurring for the same species.

This in-depth analysis presents a statistical protocol for interpreting multi-hit events from APT data. The reported findings help define species-specific evaporation trends within a compound semiconductor heterostructure in an aim to expand the application of APT to complex systems. Defining the relation between multi-hit events and structural chemistry will extend the current capabilities of APT to gain insight on atomic spacing that was previously unattainable without the aid of additional characterization methods. Furthermore, this methodology can be applied to other material systems to qualify the likelihood of correlation, potential dissociation trends, and crystallographic nature.

Atom Probe Tomography and First Principal Calculation to Study N-Type Doping in $(Al_xGa_{1-x})_2O_3$ Jith Sarker, Ankit Sharma, Uttam Singisetti and Baishakhi Mazumder; University at Buffalo, The State University of New York, United States

Efficient n-type doping in ultra-wide bandgap $(Al_xGa_{1-x})_2O_3$ is a key for the realization of high frequency transistors with theoretical performance limit. Group IV elements (Si, Sn and Ge) are being considered as efficient donors in $(Al_xGa_{1-x})_2O_3$ as they are predicted to substitute in cation sites and contribute in conductivity [1]. First principal calculations by density functional theory (DFT) proposed that Si is the most promising candidate for achieving n-type conductivity in $(Al_xGa_{1-x})_2O_3$ as it remains a shallow donor at the highest range of Al composition while other donors are likely to transform into deep level defects at high Al-$(Al_xGa_{1-x})_2O_3$ [1]. Incorporation of Si in $(Al_xGa_{1-x})_2O_3$ has been reported experimentally. The dopant behavior in these films including dopant distribution, layer homogeneity, segregation/clustering with varying alloy composition is not reported so far. It has been reported for similar wide bandgap system, AlGaN that n-type doping introduces point defects such as cation vacancies (V_{Ga} and V_{Al}). These defect sites act as charge trapping centers by interacting with dopants and forms complex defects (V_{Ga}-Si_{Ga} or V_{Al}-Si_{Al}) [2]. This results in reduced carrier mobility at high doping regime and is termed as "compensating knee" [2]. Similar investigation on dopant behavior in $(Al_xGa_{1-x})_2O_3$ is not reported yet. It is crucial to have in depth understanding of dopant interaction down to atomic level structural chemistry of $(Al_xGa_{1-x})_2O_3$ films is pivotal to achieve excellent doping profile.

Atom probe tomography (APT) was employed to investigate the atomic level dopant behavior and dopant interaction in $(Al_xGa_{1-x})_2O_3$ with varying Al content (x = 0.10-1.0). APT reveals that at low Al content, Si distribution is homogeneous while some high Si density island-like regions appears at high Al content (x80%). The statistical radial distribution function (RDF) was used to understand the dopant interaction in by exploring the nearest neighbor chemistry in the bulk regions of each $(Al_xGa_{1-x})_2O_3$ layer. RDF in layers with low Al contents (x = 10-20%) showed high Ga concentration in regions surrounding the Si atoms with Al concentration being very low, indicating Si is substituting in Ga sites. Ga concentration drops at the position of Si atoms implying the presence of V_{Ga}. This result indicates the potential V_{Ga}-Si_{Ga} defect complex formation. At high Al (x = 60-100%), high Al concentration was observed around Si atoms with Al concentration dropping at the location where Si atoms reside, indicating Al site occupancy with possible V_{Al}-Si_{Al} complexes. The initial interpretation of APT results coincided with what was observed in case of GaN, AlGaN and Ga_2O_3 and would account for compensating effect in $(Al_xGa_{1-x})_2O_3$.

The information obtained from APT would provide a guide to the first principal DFT study of Si doped $(Al_xGa_{1-x})_2O_3$. DFT calculation will be performed to confirm the site specific substitution of dopants in $(Al_xGa_{1-x})_2O_3$ at low and high Al content. DFT will confirm the vacancy, interstitial or vacancy-interstitial complex defects by evaluating the formation enthalpy of these defects and defect complexes at different Al contents that would explain carrier compensation in wide bandgap semiconductors.

We acknowledge Dr. Hongping Zhao's group in Dept. of ECE at the Ohio State University for providing the samples.

APT Revels the Synergistic Role of Mn and Zr/Ti in Producing θ'/$L1_2$ Co-Precipitates in Al-Cu Alloys Jonathan Poplawsky[1], Brian Milligan[2,1], Lawrence Allard[1], Dongwon Shin[1], Patrick Shower[1], Matthew Chisholm[1] and Amit Shyam[1]; [1]Oak Ridge National Laboratory, United States; [2]Colorado School of Mines, United States

Typical AlCu-alloys used for automotive applications can only withstand temperatures up to 250 ºC. Increasing this temperature will improve fuel efficiency. The presence of the θ' (Al_2Cu) precipitate in these alloys is critical for the alloy hardness; however, θ' is a metastable precipitate that disappears (transforms) at higher temperatures, destroying the alloy properties. Recently, an affordable and castable Al-Cu alloy that retains θ' and maintains its strength after a lengthy exposure to 350 ºC was developed (> 200 Hrs). The addition of Mn in combination with Zr and their segregation to precipitate interfaces play a significant role in stabilizing the metastable θ' precipitates, while adding Zr and Mn separately only improves the stability to 200 °C and 300 °C, respectively. A series of atom probe tomography (APT) and scanning transmission electron microscopy (STEM) experiments on Al-Cu-Mn-Zr/Ti-containing alloys subjected to long-term annealing (up to 2,100 h) in the critical temperature range, 300 °C and 350 °C, were performed to reveal how Mn and Zr work synergistically to stabilize the strengthening phase (θ'). The experimentally observed solute segregation to θ' precipitate interfaces (APT) and atomic structure at the interfaces (STEM) were used to guide density functional theory (DFT) simulations to understand how Mn and Zr additions change the energetics of θ' in an Al-matrix. The APT and STEM results reveal that Mn additions reduce interfacial energy, and thus, stabilize θ' long enough for the slower diffusing Zr atoms to segregate to coherent θ' interfaces that eventually create a θ'/ $L1_2$-$Al_3(Zr_x,Ti_{1-x})$ co-precipitate structure. The co-precipitate is highly stable, is a key factor that governs microstructural stability beyond 300 °C. This study reveals how solute additions with different stabilization mechanisms can work in concert to stabilize a desired microstructure, and the results provide insights that can be applied to other high-temperature alloy systems.

This research was supported by the DOE Office of Energy Efficiency and Renewable Energy, Vehicle Technologies Office, Propulsion Materials Program and the DOE Basic Energy Sciences, Materials Sciences and Engineering Division. APT was conducted at ORNL's Center for Nanophase Materials Sciences (CNMS), which is a US DOE Office of Science User Facility. The authors appreciate the support provided by the Oak Ridge Leadership Computing Facility at the ORNL. The authors thank Ray Unocic and Allen Haynes (ORNL) for reviewing the manuscript. The authors would also like to thank Dana McClurg for heat treatments and hardness measurements and James Burns for APT sample preparation and APT operation.

F.MT05.06.10

Late News: Specimen Preparation of Environmentally Sensitive Materials for Compositional and Structural Analysis at the Atomic Scale by Correlative APT and TEM Studies Cecile Bonifacio[1], Daniel Perea[2], Pawel Nowakowski[1] and Paul Fischione[1]; [1]E.A. Fischione Instruments, Inc., United States; [2]Pacific Northwest National Laboratory, United States

Atom probe tomography (APT) is a powerful characterization technique for obtaining three-dimensional structure and materials composition at the atomic scale and is complementary to transmission electron microscopy (TEM). In tandem, the two techniques provide detailed characterization of structure, composition, and chemistry. However, the full potential of both of these techniques is typically hindered by artifacts from specimen preparation (e.g., Ga implantation and amorphization) and environmental conditions that degrade the specimen's surface (e.g., surface oxidation). Dual beam FIB (DB-FIB), which is an efficient tool for removing a substantial amount of material and in situ electron beam imaging, allows more control when shaping the APT specimen tip and is typically used to prepare APT specimens. However, Ga-induced damage and amorphization from FIB milling can result in ambiguous results, especially for Al/Al alloys and Ga-containing materials. In fact, it was recently shown that amorphization due to the high energy Ga beam during FIB milling dramatically affected the shape of the mass spectrum due to tip heating during APT acquisitions in Si APT specimens. Studies such as this provoke this study of using low energy Ar ion milling post-FIB milling to obtain high-quality APT specimens. Low energy (< 1 keV) Ar ion milling has been shown to improve TEM specimen quality by removing amorphization and Ga implantation from FIB prepared specimens. We present a post-FIB specimen preparation of APT specimens under controlled environments using concentrated beam (< 1 μm), low energy Ar^+ milling for the removal of manufacturing damage, oxides and FIB-induced damage for TEM and APT analyses. This controlled environment is integrable to current APT environmentally controlled transfer system.

Al and Mg metals and their alloys were chosen as test specimens due to their highly oxidizing properties. The APT specimens were prepared in a FIB system using standard lift-out methods and annular milling. The APT specimen

preparation workflow from FIB to an Ar^+ milling system using a FIB vacuum transfer system was interfaced with a glovebox in between transfers. For ease of specimen handling and transfer, the half-grid with the APT specimens was secured in the cartridge of a TEM vacuum transfer specimen holder that is compatible with the ion milling system. Ar^+ milling was performed by using a concentrated ion beam that is rastered longitudinally within a defined area on the APT specimen at decreasing milling energies. TEM, energy dispersive X-ray spectroscopy (EDS), and APT characterization were performed under controlled environments before and after ion milling to determine the removal of surface oxides and FIB-induced damage. Quantification of the removal of FIB-induced damage and the workflow's ability to prevent specimen oxidation and contamination will be presented.

F.MT05.06.11
Late News: Atom Probe Tomography and Model-Free Methods for Analysis of Kinetics of a Binary Co-Sn Alloy
Muna S. Khushaim[1], Fatimah Alahmari[2], Delphine Chassaing[3] and Torben Boll[3]; [1]Taibahu University, Saudi Arabia; [2]Imam Abdulrahman bin Faisal University, Saudi Arabia; [3]Karlsruhe Institute of Technology, Germany

Recent studies of lithium-ion batteries suggest that the use of binary *CoSn* alloys as anodes should provide an improvement over currently used anode materials [1]. However, the implementation of *CoSn* alloys is challenging due to uncertainties regarding the phase transformations within this system. In order to understand these, we evaluate the compositions of different intermetallic compounds produced via the peritectic reactions, nucleate and grow within the microstructure of binary *Sn* -25 at.% *Co* by employing atom probe tomography (APT). Owing to its capability, APT with its exceptional capabilities of spatially resolution and quantitative chemical analyses is presented as a sophisticated analytical tool to elucidate the underlying process of the phase transition behaviour of different *Co-Sn* intermetallic compounds and the local structure of the solid solution. The APT results revealed the presence of *Co* clusters with (54.1 ± 0.1) at.% *Co* , (23.34 ± 0.3) at.% *Co* and (0.6 ± 0.1) at.% *Co* in pure Sn phase [2], which is consistent with the equilibrium phase diagram that indicates there is limited solubility of *Co* in *Sn* (up to 0.6%) at a temperature of 1196 °C . This limited solubility of *Co* atoms induced the formation of different observed intermetallic phases that are *CoSn* and $CoSn_3$. This study demonstrates the unique capabilities of APT to characterize a series of peritectic reactions within the binary *Co-Sn* alloy. Moreover, crystallization kinetics of the crystallization reactions in *Co-Sn* alloy system were investigated under non-isothermal as well as isothermal conditions. These investigations were performed by using of model -free (isoconversion) methods. The results show decreasing on the activation energy for the crystallization kinetics for *CoSn* and $CoSn_3$ phases with increasing temperature, which reveals the involvement of two processes of nucleation and diffusion during the crystallization of these intermetallic phases.

Stretching 2D Materials—Freestanding or on a Stretchable Substrate Yong Zhu; North Carolina State University, United States

2D materials are predicted to possess outstanding mechanical and electromechanical properties. It is of great interest to measure the elastic properties, fracture properties, and multiphysical properties (e.g., elastic strain engineering) of 2D materials. Mechanical testing of 2D materials is, however, challenging. Several mechanical testing methods of 2D materials have emerged recently such as indentation or pressurization induced stretching, stretching using a micro-device, and stretching through shear stress transfer from a substrate or matrix. This tutorial will provide a brief overview of these materials and related testing results.

Compressive Strain Tuning of 2D Material Properties in a High Pressure Jung-Fu Lin; The University of Texas at Austin, United States

This tutorial will show how to use compressive strain in a diamond anvil cell to tune physical properties of 2D transition metal dichalcogenides, graphene, and their heterostructures. The use of soft, inert pressure medium in a diamond cell can produce hydrostatic pressure and strain rate up to 10-20%. Such a compressive strain can significantly shorten the interlayer van der Waals bonds of 2D materials. When coupled with time-resolved laser spectroscopy and physical property measurement systems, electronic, optical, thermal transport properties of 2D materials can be effectively tuned, resulting in semiconductor-metal transition, enhanced thermal conductivity, direct-indirect band gap transition, charge transfer, and carrier density and mobility change.

Modeling and Testing the Mechanical Behavior of Single-Crystal and Polycrystalline Graphene James Hone; Columbia University, United States

This tutorial will review the following topics: (1). Experimental methods for mechanical testing of graphene and 2D materials using nano-indentation. (2). Non-linear finite element modeling based on ab initio calculations at large strain. (3). Mechanical testing of polycrystalline graphene and grain boundaries. (4). Detailed multiscale modeling of failure in polycrystalline graphene. In particular, we construct a multiscale model using a cohesive zone element at the grain boundaries, and use this model to establish a relationship between the failure load and the grain boundary distance. This allows us to calculate a semi-analytical probability density function (PDF) to allow for direct comparison with experiments.

Interlayer Excitons in van der Waals Heterostructures Philip Kim; Harvard University, United States

A pair of electron and hole across the interface of semiconductor heterostructure can form a bound quantum state of the interlayer exciton. In a coupled interface between atomically thin van der Waals layers (vdW), the Coulomb interaction of the interlayer exciton increases further. In this presentation, we will discuss observing interlayer exciton formation in semiconducting transition metal dichalcogenide (TMDC) layers. Unlike conventional semiconductor heterostructures, charge transport in of the devices is found to critically depend on the interlayer charge transport, electron-hole recombination process mediated by tunneling across the interface. We demonstrate the enhanced electronic, optoelectronic performances in the vdW heterostructures, tuned by applying gate voltages, suggesting that these a few atom thick interfaces may provide a fundamental platform to realize novel physical phenomena. Furthermore, complete experimental control of density, displacement and magnetic fields in our graphene double layer system enables us to explore the rich phase diagram of several superfluid exciton phases with the different internal quantum degrees of freedom.

2:15 PM *F.MT06.03/EL04.13.02
Tunable Quantum Transport High Mobility 2D Materials Jeanie Lau; The Ohio State University, United States

One of the most alluring features of 2D materials is their tunability, as their carrier density, effect mass, band gap, and electronic phases can be tuned in situ by external parameters such as electric field, magnetic field and strain. Here we will present transport studies of high quality 2D materials. For instance, we demonstrate large tunable SOC and zero-field spin-splitting in atomically thin InSe with unprecedented mobility. From beating patterns in quantum oscillations, we establish that the SOC parameter *a* is thickness-dependent; it can be continuously modulated over a large range by an out-of-plane electric field, achieving zero-field splitting tunable between 0 and 20 meV. Surprisingly, *a* could be enhanced by an order of magnitude in some devices, suggesting that SOC can be further manipulated by variations in interlayer spacing induced by stacking and/or electrostatic compression. Our work highlights the extraordinary tunability of SOC in 2D materials, which can be harnessed for *in operando* spintronic and topological devices and applications.

Electron Interactions in 2D Materials—Correlated Multi-Particle Excitations and Optical Field Driven ARPES Steven G. Louie[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Many-electron interaction effects dominate many spectroscopic properties of reduced-dimensional systems, leading often to manifestation of novel phenomena not seen in the bulk. In this talk, I present some of our recent work on electron interaction effects in atomically thin quasi 2D materials: (1) strongly bounded correlated multi-particle excitations, such as trions and bi-excitons, in quasi 1D and 2D materials; (2) giant excitonic effects in shift currents, a nonlinear optical phenomenon, in non-centrosymmetric quasi 2D semiconductors; and (3) excitons and band renormalization in optical field driven angle-resolved photoemission spectroscopy (ARPES). Studies of these novel phenomena are made possible because of newly developed theoretical methods which incorporate higher-order many-electron correlation effects from first principles, using an interacting Green's function approach.

Quantum Confined-Photon Emission in Layered Materials Andrea C. Ferrari; University of Cambridge, United Kingdom

Layered Materials (LMs) have potential for quantum technologies, as scalable sources of single photon emitters (SPEs)[1,2].

LM heterostructures can be built with tuneable properties depending on the constituent materials and their relative crystallographic orientation[3,4]. Quantum emitters in LMs hold potential in terms of scalability, miniaturization, integration. Generation of quantum emission from the recombination of indirect excitons in heterostructures made of different LMs is a path with enormous potential. I will discuss how LM combinations can be used to generate SPEs and confinement of interlayer excitons[5].

Moire Superpotentials and Quantum Calligraphy of Single Photon Emitters in van der Waals Heterostructures Berend T. Jonker; Naval Research Laboratory, United States

Single photon emitters (SPEs), or quantum emitters, are key components in a wide range of nascent quantum-based technologies. A solid state host offers many advantages for realization of a functional system, but creation and placement of SPEs are difficult to control. We describe here a novel paradigm for encoding strain into 2D materials to create and deterministically place SPEs in arbitrary locations with nanometer-scale precision [1]. We demonstrate the direct writing of SPEs in 2D semiconductors based on a materials platform consisting of a WSe_2 monolayer on a deformable substrate using an atomic force microscope nano-indentation process. This quantum calligraphy allows deterministic placement and real time design of arbitrary patterns of SPEs for facile coupling with photonic waveguides, cavities and plasmonic structures.

The weak interlayer bonding in van der Waals heterostructures (vdWh) enables one to rotate the layers at arbitrary azimuthal angles. For transition metal dichalcogenide vdWh, twist angle has been treated solely through the use of rigid-lattice moiré patterns. No atomic reconstruction has been observed to date, although reconstruction can be expected to have a significant impact on all measured properties, and its existence will fundamentally change our understanding of such systems. Here we demonstrate via conductive AFM and TEM that vdWh of $MoSe_2/WSe_2$ and MoS_2/WS_2 undergo significant atomic level reconstruction at twist angles $\leq 1°$ leading to discrete commensurate domains divided by narrow domain walls [2], rather than a smoothly varying rigid-lattice moiré pattern as has been assumed in prior work. We show that this occurs because the energy gained from adopting low energy vertical stacking configurations is larger than the accompanying strain energy [3]. Such reconstruction impacts both the local conductivity and the optical properties.

Understanding Tunability in the Electronic and Optical Response of Two-Dimensional Materials with Defects by Computational Analysis Ruth Pachter and Jie Jiang; Air Force Research Laboratory, United States

The ability to tune the electronic and optical properties of 2D materials by induced defects has wide-ranging applications. For example, patterned graphene surfaces can be used for biosensing, while strained 2D transition metal dichalcogenides (TMDs) could enable the control of excitons for quantum emitters. Here, we first report on electronic band structure calculations of periodically patterned graphene, which can be fabricated using electron-beam chemistry with radiolyzed water (Islam, et al. *Carbon* **2020**, *166*, 446-455). Analysis of the effects of alternating strips in the graphene surface, which are pristine or with epoxide defects, illustrate electronic confinement in the graphene ribbon, which leads to one-dimensional quasi-metallic or semiconducting response, dependent on the strip's width. Electron transport calculations demonstrate electron

transmission along the graphene strip direction, minimized in the direction perpendicular to edges terminated by oxygen atoms, while intrinsic current-voltage (*I-V*) characteristics indicate comparable performance to graphene nanoribbons with perfect edges. The electron transport in a device setting with gold electrodes shows improved conductivity in comparison to a graphene-based device. Next, in an effort to move towards controlled emission properties, such as for single-photon emission applications, we consider strained 2D WSe_2 monolayers with varying wrinkle structures. The tunability we demonstrate in the optical response of the mechanically deformed nanostructures is described in detail. Our results on exciton tunability by wrinkle structure could motivate experimental fabrication.

Weakened Interlayer Interaction of Incommensurate Graphene as a Key Factor for Superior Lithium Intercalation Tereza Paronyan; HeXalayer, LLC, United States

Carbon/graphite-based energy storage devices, such as lithium-ion batteries (LIBs), are the most reliable energy storage devices for portable electronics, electric vehicles (EV) and electric grid storage due to their high-power density, stability, low cost, and safety. Despite the wide use of LIBs, the graphitic anode has limited capacity (372 $mAh.g^{-1}$) due to the limited rate of lithium diffusion within the commensurately stacked layered structure.
Here we discuss the unique superior capacity of Lithium intercalation of multilayered graphene structures, named as an Incommensurate Multilayer Graphene (IMLG), that consists of closely packed rotated graphene layers. In-plane and out-plane features of graphene are studied by Raman spectroscopy, High-Resolution Transmission Electron Microscopy (HRTEM), and X-ray Diffraction. The commensurate-incommensurate transition of layered graphene is analyzed by Raman spectroscopy and the range of the key parameters is discussed as a significant for efficient Lithium intercalation.
The structural and binding features of graphene anode before and after Lithium insertion is studied, and a new lithium intercalation model is considered. We revealed that weakened interplanar Van der Waals interaction as it occurs within rotated graphene layers enables easy and full penetration of lithium, followed by flexible adjustment of layers for stable and reversible stable cycling without affecting graphene in-plane features. Superior Lithium intercalation provides reversible and stable long-term charge/ discharge of IMLG anodes reaching up over 1500 $mAh.g^{-1}$ capacity of LiBs.
Our recent development of IMLG confirms the feasibility of the synthesis technique which allows us the development of high energy density and powerful lightweight secondary batteries in the nearest future.

Piezoelectricity and Exotic Nonlinearities in Monolayer TMDC Resonators Horacio Espinosa, Shiva Nathamgari and Siyan Dong; Northwestern University, United States

Monolayer transition metal dichalcogenides (TMDCs), with the general chemical formula MX_2 (M = Mo or W and X = S, Se and Te), are a class of 2D materials that have been predicted to be piezoelectric using Density Functional Theory (DFT) calculations. In addition, some of the TMDCs possess certain advantages in monolayer form – such as a direct bandgap and better Q-factors – over graphene. Here, we present resonance and piezoelectric measurements on monolayer transition metal dichalcogenides (TMDCs) using cavity-interferometry. We also demonstrate that TMDCs are promising candidates for Nanoelectromechanical Systems (NEMS) due to their low mass and intrinsic piezoelectricity.

Cavity-interferometry refers to a displacement transduction technique in nanoelectromechanical systems (NEMS). Most fabrication protocols for NEMS naturally render an optical cavity where the NEMS structure and the underlying substrate constitute the two mirrors. The modulation in the cavity depth due to the motion of the NEMS translates to intensity variations of the reflected light from the optical cavity, which can be measured on an appropriate detector. By optimizing the cavity depth, wavelength of the probe laser and the back-end electronics, exquisite displacement sensitivity (sub pico-meter/$Hz^{1/2}$) can easily be achieved [1].

Device fabrication is challenging; hence, we explored various fabrication methods for creation of suspended 2D material devices and established working protocols for both exfoliated and chemical vapor grown TMDCs. We also developed a new transfer method driven by water wettability to facilitate fabrication efforts. To perform device characterization, we developed an integrated in-vacuum Raman/Interferometer setup [1]. By exploiting the cavity formed between suspended 2D TMDC "bridges" and underneath substrates, resonance frequencies of various modes were characterized including exotic line shapes arising due to 1:1 internal resonance coupling in the nonlinear regime. Using a combined experimental-computational approach and the measured shift of fundamental resonance frequencies, induced by applied bias, we extracted piezoelectric

properties of monolayer WS_2 and MoS_2. The exfoliated samples display piezoelectric coefficients that are in good agreement with DFT predictions. By contrast, CVD grown monolayers, exhibit a 10-fold reduction in piezoelectricity, likely due to the existence of atomic defects such as vacancies.

Additionally, by driving resonance in the nonlinear regime, we revealed internal resonance pairs in monolayer WS_2. Discovery of Hopf bifurcations linearly varying with driving forces inspired novel sensing modality with ultrahigh force sensitivity (aN) at room temperature [2]. Our efforts in fabricating and experimenting on suspended 2D TMDC devices will support further development in applying 2D materials to sensors and NEMS applications.

Single Photon Emitters Using Strained Low-Dimensional Materials Hong Gyu Park; Korea University, Korea (the Republic of)

The quantum confinement in atomically-thin transition metal dichalcogenides (TMDCs) has been investigated for single photon emission based on naturally or artificially occurring defects. In particular, the precise control of the position of a single photon emitter by applying mechanical strains to the TMDC is feasible. Strains have been induced in TMDCs using various nanostructures including dielectric pillars, nanobubbles, optical waveguide, metal nanogaps, and metal nanoparticles. However, polarization control and integration with a high-quality (Q) cavity to increase the Purcell factor remain elusive in TMDC-based single photon sources.
In this talk, I will present the deterministic control of both the position and polarization of single photon emitters in atomically thin WSe_2 placed on a nanogap array. Manipulation of the band structure by a local strain gradient generates a potential well at the nanogap site, and position-controlled single photon emission is subsequently achieved. Additionally, directional elongations of the potential well, which are tuned by changing the nanogap size, allow polarization-controlled single photon emission. Moreover, single photons with a $g^{(2)}$ of ~0.1 are generated at 4-20 K. To take a full advantage of such deterministic control of the position and polarization of single photon emitters, the emitters are integrated with one-dimensional photonic crystal cavities. Therefore, this approach is a unique way to develop next-generation, deterministic, controllable single photon emitters based on TMDC materials, which outperform the present single photon sources with random occurrence and uncontrolled polarization properties.

2D Material Based Electronics Under High Mechanical Strain Jong-Hyun Ahn; Yonsei University, Korea (the Republic of)

Rapid advances in synthesis of graphene and 2D materials, and fabrication methods for functional devices enable sophisticated types of functionality and their application to various emerging electronics, such as flexible, wearable and optoelectronic applications, that cannot be addressed with conventional materials. In this talk, I present that graphene and 2D materials can play critical roles in this context, through demonstrations of complex, mechanically assembled electronic and optoelectronic devices for flexible and wearable applications. Specifically, the mechanics of graphene and MoS_2 can yield various devices in distinct, engineered flexible geometries that cannot be easily reproduced with conventional materials and/or conventional device layouts. Examples of devices include touch, tactile sensors and wearable OLED display.

8:47 AM *F.MT06.04.03
Defect and Strain Engineering of Two-Dimensional Materials Jun Lou; Rice University, United States

Two-dimensional (2D) materials, such as Graphene, hBN and MoS_2, are promising candidates in a number of advanced functional and structural applications, owing to their exceptional electrical, thermal and mechanical properties. To better meet

the requirements of practical applications, property modification and regulation are oftentimes desired. Defect and strain engineering strategies are powerful tools to modulate electronic, optoelectronic and other functional properties of 2D semiconductors.
In this talk, we will report our efforts to employ such strategies to tune functional properties of 2D semiconductors. We first demonstrated how substrate interfacial chemistry can be utilized to tailor the physical properties of single-crystalline molybdenum disulphide (MoS_2) monolayers. We use self-assembled monolayers with a variety of end termination chemistries to functionalize substrates and systematically study their influence on the physical properties of MoS_2. Our data shows that combined interface-related effects of charge transfer, built-in molecular polarities, varied densities of defects, and remote interfacial phonons strongly modify the electrical and optical properties of MoS_2. Tunable friction behavior of the heterostructure of monolayer MoS_2 and different self-assembled organic molecules (SAMs) were also demonstrated, which was attributed to the charge transfer from SAMs to MoS_2 influencing the electron concentration and thus the carrier-mediated friction in MoS_2. In another example, we systematically characterize chemical vapor deposition (CVD)-grown MoS_2 by photoluminescence spectroscopy and mapping and demonstrate non-uniform strain in single-crystalline monolayer MoS_2 and strain-induced bandgap engineering. We further modified our CVD process to create a Janus SMoSe monolayer and demonstrated high basal plane hydrogen evolution reaction (HER) activity in such samples and DFT calculation implies that the activity originates from the synergistic effect of the intrinsic defects and structural strain inherent in the Janus structure.

8:52 AM *
Conformal, Area-Specific and Switchable Graphene Nanowrinkles Teri W. Odom; Northwestern University, United States

Selective patterning and functionalization of graphene can produce spatially-defined properties. Buckling or wrinkling of graphene on polymeric substrates enables a direct approach to tune the physical properties without lithographic steps, and the resulting curvature of the wrinkles can control local chemical reactivity. However, most buckling methods have been limited by the range of wavelength tunability, only global control of the wrinkled patterns, and delamination and cracks in the graphene. This talk will describe a scalable approach to achieve area-specific reactivity and patterning of conformal graphene wrinkles. We will discuss how a fluoropolymer layer sandwiched between graphene and different polymer substrates can facilitate crack-free and switchable graphene nanostructures. Such patterned areas with different curvatures show different reactivities based on a plasma fluorination reaction. Our approach for large-area, fine control over graphene wrinkle topographies has prospects for other two-dimensional electronic materials and optoelectronics and plasmonics applications.

8:57 AM BREAK

9:04 AM *F.MT06.04.01
Chemical Properties and Applications of 2D TMDCs Mediated by Defects Qing Hua Wang; Arizona State University, United States

The two-dimensional transition metal dichalcogenides (2D TMDCs) tend to have basal planes that are chemically relatively inert. Many approaches and reaction schemes have been demonstrated to modify the chemical nature of TMDCs, resulting in new chemical properties and applications. This talk will highlight our recent work on the chemical properties of 2D TMDCs mediated by point defects and edges, which subsequently enable applications in water treatment and antimicrobial treatment. We have shown robust and versatile covalent functionalization of materials across the metal chalcogenides including MoS_2, $MoSe_2$, WS_2, WSe_2, Bi_2S_3, and Sb_2S_3 using aryl diazonium salts. The reaction mechanism is initiated at point defect sites and edges, but propagates across the chalcogenide surfaces in a chain-like step growth. We have also shown the ability for MoS_2 to remove Pb contamination from water via a reaction with the surface sites to form sulfate precipitates. The reaction mechanism is again initiated at defect sites in the MoS_2. Finally, we have used single stranded DNA to encapsulate $MoSe_2$ nanosheets and shown their broad-spectrum antimicrobial properties against multidrug resistant bacteria. The choice of ssDNA sequence influences the conformal coating, and the ability for the edges of $MoSe_2$ to cut through bacterial cell membranes.

9:10 AM *F.MT06.04.02
Chemical Trends of Deep Levels in van der Waals Semiconductors Penghong Ci[1], Xuezeng Tian[2], Jun Kang[3], Sefaattin (Sef) Tongay[4], Wladek Walukiewicz[1], Jianwei (John) Miao[2], Oscar Dubon[1] and Junqiao Wu[1]; [1]University of California, Berkeley, United States; [2]University of California, Los Angeles, United States; [3]Beijing Computational Science Research Center, China; [4]Arizona State University, United States

Properties of semiconductors are largely defined by crystal imperfections including native defects. Van der Waals (vdW) semiconductors, a newly emerged class of materials, are no exception: defects exist even in the purest materials and strongly affect their electrical, optical, magnetic, catalytic and sensing properties. However, unlike conventional semiconductors where energy levels of defects are well documented, they are experimentally unknown in even the best studied vdW semiconductors, impeding the understanding and utilization of these materials. We directly evaluate deep levels and their chemical trends in the bandgap of MoS_2, WS_2 and their alloys by transient spectroscopic study. One of the deep levels is found to follow the conduction band minimum of each host, attributed to the native sulfur vacancy. A switchable, DX center - like deep level has also been identified, whose energy lines up instead on a fixed level across different host materials, which explains the chemical trend of native electron density in the hosts as well as a persistent photoconductivity up to 400K.

9:15 AM *F.MT06.04.04
Emerging Electron Microscopy Techniques for 2D Materials Kayla Nguyen, Edmund Han, Chia-Hao Lee, Jeffrey Huang and Pinshane Y. Huang; University of Illinois at Urbana-Champaign, United States

The study of atomic-monolayer materials has been extremely popular within the last decade due to the emergence of a family of two-dimensional (2D) materials with expansive mechanical, electrical and magnetic properties. Subtle changes in these 2D materials at the atomic length scales, ranging from strain fields and dislocations, have large effects for tuning the electronic and mechanical properties, especially when used in real devices. Electron microscopy can provide the insight needed to visualize these effects [1-2]. Recent advancements in detector technology have already pushed the limits of resolution using 2D bilayer molybdenum disulfide using ptychographic reconstruction [3-4]. In my talk, I will discuss ways electron microscopy can provide opportunities for sensitive strain and magnetic measurements of 2D materials, with an emphasis on emerging techniques provided by the electron microscope pixel array detector (EMPAD), a state-of-the-art, high-dynamic range and high-speed electron diffraction detector.

Exotic Spin Transport in Two-Dimensional Materials Stephan Roche[1,2] and Jose H. Garcia Aguilar[1]; [1]Catalan Institute of Nanoscience and Nanotechnology, Spain; [2]ICREA--Institució Catalana de Recerca i Estudis Avançats, Spain

The field of spin transport in two-dimensional has flourished in the past couple of years. Some remarkable features are the reports of large charge-to-spin in graphene-based heterostructures [1], the discovery of the quantum spin Hall effect [2], and ultra-clean spin transport measurements within the ballistic regime [3]. In this talk, we will present predictions on diffusive and ballistic spin transport in different two-dimensional materials. Using complementary large-scale numerical transport methods, we developed a theory showing that contacts have a dramatic effect on the spin transport in systems with a size comparable to the spin relaxation length, leading to underestimating the latter [4]. We then apply this theory and bulk transport methods to unveil the role of broken symmetries in the spin transport of transition metal dichalcogenides in their 1T' and 1Td structural phases, showing they can promote an unconventional spin transport regimen. We believe our predictions will lead to a better understanding of the recent measurements of the quantum spin Hall effect in WTe2 and will help optimize experimental setups for its harvesting.

Study of Thermal and Magnetic Transport in Functional Materials Enabled by Ultrafast Optical Metrology Xiaojia Wang; University of Minnesota Twin Cities, United States

Transport phenomena play an important role in designing and engineering materials with tailored functionalities. Thermal conductivity and spin precession damping, as basic transport properties of materials, can provide a wealth of information on

the fundamental scattering processes of phonons and magnons with structural defects and interface imperfection. In this talk, I will share our group's recent progress on utilizing time-resolved magneto-optical Kerr effect (TR-MOKE) metrology to study the thermal and magnetic properties of functionalized materials spanning a wide range of applications. This will include: (1) revealing the 3D anisotropic thermal transport in black phosphorus, as the next-generation of "wonder materials" for the semiconductor industry; (2) developing low-damping and high-thermal stability materials with perpendicular magnetic anisotropy for spintronic applications; and (3) manipulating spin precession using optically launched acoustic strains via a strong magnon-phone coupling at ultra-high frequencies (~60 GHz). The structure-property relationships of functional materials revealed by the ultrafast pump-probe technique open up opportunities of tailoring material properties by structural engineering at the atomic and molecular levels. Ultimately, such an understanding can be leveraged to guide the design and optimization of materials, as promising building blocks for high-performance electronics, thermal management, hard-disk data storage, and magnetoacoustic devices.

9:33 AM *F.MT06.05.03
Strain Induced Tuning of Physical Properties of Materials Abhishek K. Singh; Indian Institute of Science, India

Tuning physical properties of materials by applying strain opens up wide range of applications. In this presentation, sensitivity of these properties on application of strain will be illustrated for the case of TMDs. Using first principles calculations, the effect of normal compressive (NC), bi-axial compressive (BC), and bi-axial tensile (BT) strain on the electronic properties of few layered MoS_2 has been investigated. Regardless of the type of strain, a reversible semiconductor-to-metal transition is observed MoS_2. The effect of strain as a function of number of layers on the transport properties is investigated. It is found that the 3L and 2L-MoS_2 emerge as the most efficient thermoelectric materials under NC and BT strain, respectively. The study was further extended to semi-metallic TMD TiS_2, which has been in focus due to its application in energy storage and thermoelectric materials. Upon application of uniform biaxial strain, TiS_2 transforms from semi-metal to semiconducting phase. The transport calculations show three-fold enhancement in thermopower for both *p*- and *n*-type doped TiS_2. Further, the effect of strain on thermal conductivity of bulk MoS_2 is explored, wherein an increase of cross-plane thermal conductivity from 3.5 to about 25 W/m-K. The giant enhancement arises from the increase in interlayer interaction on application of strain and decrease in phonon lifetimes due to the unbundling effect along the cross-plane direction. The concepts proposed from our studies can be extended to other semiconducting and metallic TMDs.

Towards Room-Temperature Magnetic Semiconductors in van der Waals Layered Materials Seok Joon Yun, Jinbao Jiang, Dinh Loc Duong and Young Hee Lee; Sungkyunkwan University, Korea (the Republic of)

The ferromagnetic state in van der Waals two-dimensional (2D) materials has been reported recently in the monolayer limit. Intrinsic CrI_3 and $CrGeTe_3$ semiconductors reveal ferromagnetism but the Tc is still low below 60K. In contrast, monolayer VSe_2 is ferromagnetic metal with Tc above room temperature but incapable of controlling its carrier density. Moreover, the long-range ferromagnetic order in doped diluted chalcogenide semiconductors has not been demonstrated at room temperature. The key research target is to realize the long-range order ferromagnetism, Tc over room temperature, and semiconductor with gate tunability. Here, Ferromagnetic order is manifested using magnetic force microscopy up to 360K, while retaining high on/off current ratio of ~10^5 at 0.1% V-doping concentration. The V-substitution to W sites keep a V-V separation distance of 5 nm without V-V aggregation, scrutinized by high-resolution scanning transmission-electron-microscopy. More importantly, the ferromagnetic order is clearly modulated by applying a back gate. We also observe a ferromagnetic hysteresis loop together with oscillatory behavior at room temperature in diluted V-doped WSe_2, while maintaining the semiconducting characteristic of WSe_2 with a high on/off current ratio of five orders of magnitude. Our findings open new opportunities for using two-dimensional transition metal dichalcogenides for future spintronics.

Phonons in van der Waals Solids for Thermal Management Devices Sina Najmaei; US Army Research Lab, United States

Active thermal management devices often lack the efficacy and energy efficiency of electronic switches. This is mainly because of the bosonic nature of phonons and the type of interactions they have with external forces. As a result, discovery of materials with unique vibrational properties that provide better control of thermal carriers is necessary. Our research shows that the phonons in group IVB transition metal dichalcogenides such as hafnium disulfide have distinct characteristics and provide remarkable mechanism for control of thermal careers. This is caused by the intermixing of van der Waals forces and covalent bonds in the material structure combined with their highly anisotropic bond properties. In this talk we present our results on vibrational and thermal transport properties of a member of this group, hafnium disulfide (HfS_2). The highly asymmetric bond properties in HfS_2 dominate the structure and vibrational properties of this material. We explore the physics of HfS_2 by developing a comprehensive computational model to study its phonon behavior, anharmonic properties, and phonon transport characteristics. Our findings demonstrate a unique phonon behavior in the material where the absence of a phonon-gap between the acoustic and optical branches grant a more prominent and unique role to the optical modes of HfS_2. As a result HfS_2 has a low thermal conductivity, ranging between 0.3-5W/mK. In additional only one acoustic phonon branch, the ZA branch, contributes up to 80% to the thermal transport of the material in both out-of-plane and in-plane crystal orientations. Our experiments confirm and support the theory and add further insight into an anomalous behavior in the optical modes. Our quasi-harmonic model reveals a structural phase transformation at around room temperature that leads to unique anharmonicity, discernible in the experimental results of the zone center out-of-plane optical mode. This unique phase transformation contributes to both changes in the phonon decay properties and thermal transport behavior. The structural phase transformation combined with the constricted ZA branch phonon carriers and the distinct scattering physics in optical branches of HfS_2 provide unique means for control of thermal transport. We explore a few strategies for control of thermal properties in HfS_2 based on fundamental vibrational properties of the material. We demonstrate that a successful approach for dynamic control of thermal conductivity is the control of van der Waals gap properties. We demonstrate that through intercalation and modification of these gaps a 4-fold control of cross-plane thermal conductivity in hafnium disulfide from $0.35 Wm^{-1}K^{-1}$ to $1.45 Wm^{-1}K^{-1}$ is achievable. We also demonstrate that an out-of-plane strain can be used to make thermal regulators based on HfS_2. This research unveils a unique class of 2D layers with vibrational properties suitable for development of thermal management devices

Thermal Conductivities of 2D MoS_2 Under Mechanical Strains Annie Xian Zhang; Stevens Institute of Technology, United States

In recent years, transition metal dichalcogenides become emergent thermoelectric materials with potential wide spread in wearable electronics applications. Considering the extensive applications of transition metal dichalcogenides, many research efforts have been paid and good progresses have been made. So far, all of the researches in this field focus on the electrical properties of them. It has not been reported about the transition metal dichalcogenides' thermal transport properties under mechanical strains. Due to their potential applications, it is of significance to discover the thermal transport properties of transition metal dichalcogenides at large mechanical strains, and thus develop the novel thermoelectric platforms which can sustain the extreme environments in wearable electronics.

In this work, we demonstrate using Raman optothermal technique to measure the thermal conductivities of two dimensional (2D) MoS_2. We first utilize more direct measurements of the optical absorption, and then by comparing the response of the samples using different laser spot sizes, we are able to measure the thermal conductivities of the 2D MoS_2. Then thermal conductivities at large mechanical strains are obtained providing more scientific merits.

The Raman optothermal technique has been the most successful method for measurement of thermal conductivity of 2D materials, and was used to measure the 2D materials at large mechanical strains for the first time in this work. In this technique, a laser is focused at the center of a thin film and used to measure the peak position of a Raman-active mode. As the laser power is increased, the sample is heated which enables red-shift Raman mode due to thermal softening. Another comparison experiment is conducted by placing the samples on a heating platform and monitor the change of Raman-active mode peak position shift. Combining these two sections of experiments provide us the thermal modeling can then be used to extract the thermal conductivity from the measured shift rate. We have used a refined version of the optothermal Raman technique to study thermal conductivity of 2D MoS_2, at large mechanical strains. It is the first thermal measurement on 2D

materials at large mechanical strains. This work also addresses several important issues in the measurement of thermal conductivity of 2D materials at large strains using Raman spectroscopy.

In conclusion, we have used Raman optothermal technique to study thermal transport properties of 2D MoS_2 at large mechanical strains. This work addresses several important issues in the measurement of thermal conductivity of the 2D materials MoS_2 using Raman spectroscopy. We derive the thermal conductivity values at large mechanical strains. These results are of significance to discover the thermal transport properties of 2D transition metal dichalcogenides at large mechanical strains, and thus develop the efficient 2D thermoelectric materials which can sustain the large mechanical strains and in turn to use strains to tune their thermal properties.

Late News: Controlling Defects in Continuous 2D GaS Films for High-Performance Electronic and Optoelectronic Devices Yang Lu[1] and Jamie Warner[2]; [1]University of Oxford, United Kingdom; [2]The University of Texas at Austin, United States

A chemical vapor deposition method is developed for thickness-controlled (one to four layers), uniform, and continuous films of both defective gallium(II) sulfide (GaS): $GaS_{0.87}$ and stoichiometric GaS. The unique degradation mechanism of $GaS_{0.87}$ with XPS and HAADF-STEM is studied, and it is found that the poor stability and weak optical signal from GaS are strongly related to photo-induced oxidation at defects. Photodetectors based on the two materials are fabricated with short response time (<66 ms), excellent UV photoresponsivity. An enhanced stability of the stoichiometric GaS is demonstrated under laser and strong UV light, and by controlling defects in GaS, the photoresponse range can be changed from vis-to-UV to UV-discriminating.
Besides the role in degradation mechanism, defects in $GaS_{0.87}$ also contributed to the formation of a new band sitting within its bandgap, which is confirmed by cathodoluminescence results. As a result, controlling defects in GaS turns the band alignment of the bilayer GaS-WS_2 van der Waals heterostructure from type I to type II. XPS and KPFM characterization demonstrates that the defect band can facilitate the charge transfer from WS_2 to GaS. Devices based on the type-II heterojunction further show that the defect band greatly assisted the carrier transport by lowering the contact resistance, and also demonstrate superior photodetector properties with a large linear dynamic range (>73 dB) at a R of 13 A/W for green light.

Quantum Confined-Photon Emission in Layered Materials Andrea C. Ferrari; University of Cambridge, United Kingdom

Layered Materials (LMs) have potential for quantum technologies, as scalable sources of single photon emitters (SPEs)[1,2]. LM heterostructures can be built with tuneable properties depending on the constituent materials and their relative crystallographic orientation[3,4]. Quantum emitters in LMs hold potential in terms of scalability, miniaturization, integration. Generation of quantum emission from the recombination of indirect excitons in heterostructures made of different LMs is a path with enormous potential. I will discuss how LM combinations can be used to generate SPEs and confinement of interlayer excitons[5].

Moire Superpotentials and Quantum Calligraphy of Single Photon Emitters in van der Waals Heterostructures Berend T. Jonker; Naval Research Laboratory, United States

Single photon emitters (SPEs), or quantum emitters, are key components in a wide range of nascent quantum-based technologies. A solid state host offers many advantages for realization of a functional system, but creation and placement of SPEs are difficult to control. We describe here a novel paradigm for encoding strain into 2D materials to create and deterministically place SPEs in arbitrary locations with nanometer-scale precision [1]. We demonstrate the direct writing of SPEs in 2D semiconductors based on a materials platform consisting of a WSe_2 monolayer on a deformable substrate using an atomic force microscope nano-indentation process. This quantum calligraphy allows deterministic placement and real time design of arbitrary patterns of SPEs for facile coupling with photonic waveguides, cavities and plasmonic structures.

The weak interlayer bonding in van der Waals heterostructures (vdWh) enables one to rotate the layers at arbitrary azimuthal angles. For transition metal dichalcogenide vdWh, twist angle has been treated solely through the use of rigid-lattice moiré patterns. No atomic reconstruction has been observed to date, although reconstruction can be expected to have a significant impact on all measured properties, and its existence will fundamentally change our understanding of such systems. Here we demonstrate via conductive AFM and TEM that vdWh of $MoSe_2/WSe_2$ and MoS_2/WS_2 undergo significant atomic level reconstruction at twist angles $\leq 1°$ leading to discrete commensurate domains divided by narrow domain walls [2], rather than a smoothly varying rigid-lattice moiré pattern as has been assumed in prior work. We show that this occurs because the energy gained from adopting low energy vertical stacking configurations is larger than the accompanying strain energy [3]. Such reconstruction impacts both the local conductivity and the optical properties.

Understanding Tunability in the Electronic and Optical Response of Two-Dimensional Materials with Defects by Computational Analysis Ruth Pachter and Jie Jiang; Air Force Research Laboratory, United States

The ability to tune the electronic and optical properties of 2D materials by induced defects has wide-ranging applications. For example, patterned graphene surfaces can be used for biosensing, while strained 2D transition metal dichalcogenides (TMDs) could enable the control of excitons for quantum emitters. Here, we first report on electronic band structure calculations of periodically patterned graphene, which can be fabricated using electron-beam chemistry with radiolyzed water (Islam, et al. *Carbon* **2020**, *166*, 446-455). Analysis of the effects of alternating strips in the graphene surface, which are pristine or with epoxide defects, illustrate electronic confinement in the graphene ribbon, which leads to one-dimensional quasi-metallic or semiconducting response, dependent on the strip's width. Electron transport calculations demonstrate electron transmission along the graphene strip direction, minimized in the direction perpendicular to edges terminated by oxygen atoms, while intrinsic current-voltage (*I-V*) characteristics indicate comparable performance to graphene nanoribbons with perfect edges. The electron transport in a device setting with gold electrodes shows improved conductivity in comparison to a graphene-based device. Next, in an effort to move towards controlled emission properties, such as for single-photon emission applications, we consider strained 2D WSe_2 monolayers with varying wrinkle structures. The tunability we demonstrate in the optical response of the mechanically deformed nanostructures is described in detail. Our results on exciton tunability by wrinkle structure could motivate experimental fabrication.

Visualizing Twisted Bilayer Graphene in Momentum- and Real-Space—Flat Electronic Band and Moiré Lattices Iqbal B. Utama[1], Roland Koch[2], Kyunghoon Lee[1], Nicolas Leconte[3], Hongyuan Li[1], Sihan Zhao[1], Lili Jiang[1], Jiayi Zhu[1], Kenji Watanabe[4], Takashi Taniguchi[4], Paul Ashby[5], Alexander Weber-Bargioni[5], Alex Zettl[1], Chris Jozwiak[2], Jeil

Jung[3], Eli Rotenberg[2], Aaron Bostwick[2] and Feng Wang[1]; [1]University of California, Berkeley, United States; [2]Advanced Light Source, United States; [3]University of Seoul, Korea (the Republic of); [4]National Institute for Materials Science, Japan; [5]Molecular Foundry, United States

Stacking two-dimensional layers with slightly different lattice vectors produces a new periodic structure known as moiré lattices. As one of such moiré system, twisted bilayer graphene (tBLG) has been predicted to host a moiré miniband with flat dispersion if the layers are stacked at the 'magic angles'. Recently, magic angle tBLG was reported to exhibit correlated transport phenomena, where the presence of the flat miniband in the system is thought to be essential. Although STM and compressibility measurements in tBLG have found a van Hove singularity consistent with the presence of the flat band, a direct observation of the flat dispersion in the momentum-space of such a moiré miniband in tBLG is still lacking. Here, we report the visualization of this flat moiré miniband by using angle-resolved photoemission spectroscopy with nanoscale resolution (nanoARPES) **[1]**. Meanwhile, we probed the real-space structure of the moiré lattice with scanning microwave impedance microscopy (sMIM), where the sub-5 nm spatial resolution has also allowed us to image the strain-related inhomogeneity and defect structures in various graphene-based moiré lattices **[2]**. Our measurements demonstrate the existence of the flat moiré band near the charge neutrality for tBLG close to the magic angle at room temperature.

***Ab Initio* Strain-Dependent Valley Dynamics in Monolayer Transition Metal Dichalcogenides** Christopher J. Ciccarino, Chitraleema Chakraborty and Prineha Narang; Harvard University, United States

Two-dimensional transition metal dichalcogenides (TMDCs) have unique optoelectronic properties in part because of their spin- and valley-selective carrier dynamics at the band edges. However, limited valley coherence times represent a major challenge for application. Here we comprehensively investigate electron-phonon interactions at valleys in both the valence and conduction band edges using a first-principles, spin-resolved approach. We capture the effects of strain by introducing ±2% biaxial strain to each of the four monolayer TMDCs (MoS_2, $MoSe_2$, WS_2 and WSe_2) studied. We find that the strength of the spin-orbit splitting is strongly sensitive to strain for tungsten-based monolayers relative to molybdenum-based compounds. Additionally, our results show that the direct nature of the bandgap of monolayer TMDCs is sensitive to less than 1% compressive strain. Our results detail the relevant mode- and wavevector-resolved electron-phonon processes responsible for scattering involving valley states, which we find to be highly tunable by strain. Most notably, we find up to an order of magnitude increase in conduction-band lifetimes under tensile strain. Overall we find significant potential in engineering valley dynamics and optoelectronic properties of monolayer TMDCs through the use of applied strain.

Temperature-Resolved Observations and Predictions of Phonon-Mediated Hydrodynamic Flow of Electrons in WTe_2 George Varnavides[1,2], Uri Vool[1], Yaxian Wang[1], Assaf Hamo[1], Polina Anikeeva[2,2], Amir Yacoby[1] and Prineha Narang[1]; [1]Harvard University, United States; [2]Massachusetts Institute of Technology, United States

Recent measurements of spatially-resolved current flows have revealed that electrons in condensed matter can behave hydrodynamically, exhibiting classical fluid phenomena such as vortices and Poiseuille flow[1,2,3]. This occurs when microscopic scattering processes conserve momentum over time- and length-scales significantly exceeding those of the experimental probe[4]. In contrast with graphene, where the hydrodynamic regime persists well into room-temperature, other materials exhibit hydrodynamic flow only within a finite low-temperature window, and as such require temperature-resolved measurements. Here, we report direct observation of temperature-dependent electron hydrodynamic flow in the van der Waals solid WTe2, via measurements of the associated stray magnetic field using nitrogen vacancy echo magnetometry. At low-enough temperatures the onset of ballistic flow competes with the hydrodynamic regime, eventually resulting in a flat current profile.

In this work, we predict temperature-resolved lifetimes for various electron scattering mechanisms in WTe2 from first principles[5]. We use our ab initio microscopic lifetimes as inputs to the electronic Boltzmann transport equation[6], capturing the non-monotonic behavior in the experimental data. This provides a quantitative estimate for the electron interaction length in WTe2, which seems to be robust against a wide range of impurity concentrations. We find that these results cannot be explained using a direct Coulomb effect alone and that the major contributing momentum-conserving process is a Frohlich-like phonon-mediated electron interaction. We then investigate the effect of strain on the hydrodynamic regime in WTe2, concluding both the temperature-window and the magnitude of the hydrodynamic flow vary.

Dynamical Modulation of Defect-Phonon Coupling in Transition Metal Dichalcogenides Chitraleema Chakraborty, Christopher J. Ciccarino and Prineha Narang; Harvard University, United States

The formation of atomic defects is unavoidable in 2D materials with currently available growth techniques 1 . Nevertheless, there is a myriad of functionalities in modern optoelectronic and nanophotonic devices that leverage quantum defects including the recent demonstration of single photon emitters in 2D materials 2,3 . In parallel, advances in atomic-resolution imaging techniques provide new opportunities to directly create, manipulate and characterize defects down to the atomic scale in low-dimensional materials 4 . Therefore, we present theoretical calculations and analysis of optically active quantum defects in 2D materials. We study the electron-phonon interactions 5,6 of electronic transitions in defects and quantify their optical efficiency by calculating the Huang-Rhys factor. This presents a pathway for maximizing the optical efficiency of designer defect and provides a deterministic choice for defect creation at the atomic scale using scanning probe techniques 2 .

Weakened Interlayer Interaction of Incommensurate Graphene as a Key Factor for Superior Lithium Intercalation Tereza Paronyan; HeXalayer, LLC, United States

Carbon/graphite-based energy storage devices, such as lithium-ion batteries (LIBs), are the most reliable energy storage devices for portable electronics, electric vehicles (EV) and electric grid storage due to their high-power density, stability, low cost, and safety. Despite the wide use of LIBs, the graphitic anode has limited capacity (372 $mAh.g^{-1}$) due to the limited rate of lithium diffusion within the commensurately stacked layered structure.
Here we discuss the unique superior capacity of Lithium intercalation of multilayered graphene structures, named as an Incommensurate Multilayer Graphene (IMLG), that consists of closely packed rotated graphene layers. In-plane and out-plane features of graphene are studied by Raman spectroscopy, High-Resolution Transmission Electron Microscopy (HRTEM), and X-ray Diffraction. The commensurate-incommensurate transition of layered graphene is analyzed by Raman spectroscopy and the range of the key parameters is discussed as a significant for efficient Lithium intercalation.
The structural and binding features of graphene anode before and after Lithium insertion is studied, and a new lithium intercalation model is considered. We revealed that weakened interplanar Van der Waals interaction as it occurs within rotated graphene layers enables easy and full penetration of lithium, followed by flexible adjustment of layers for stable and reversible stable cycling without affecting graphene in-plane features. Superior Lithium intercalation provides reversible and

stable long-term charge/ discharge of IMLG anodes reaching up over 1500 $mAh.g^{-1}$ capacity of LiBs.
Our recent development of IMLG confirms the feasibility of the synthesis technique which allows us the development of high energy density and powerful lightweight secondary batteries in the nearest future.

Piezoelectricity and Exotic Nonlinearities in Monolayer TMDC Resonators Horacio Espinosa, Shiva Nathamgari and Siyan Dong; Northwestern University, United States

Monolayer transition metal dichalcogenides (TMDCs), with the general chemical formula MX_2 (M = Mo or W and X = S, Se and Te), are a class of 2D materials that have been predicted to be piezoelectric using Density Functional Theory (DFT) calculations. In addition, some of the TMDCs possess certain advantages in monolayer form – such as a direct bandgap and better Q-factors – over graphene. Here, we present resonance and piezoelectric measurements on monolayer transition metal dichalcogenides (TMDCs) using cavity-interferometry. We also demonstrate that TMDCs are promising candidates for Nanoelectromechanical Systems (NEMS) due to their low mass and intrinsic piezoelectricity.

Cavity-interferometry refers to a displacement transduction technique in nanoelectromechanical systems (NEMS). Most fabrication protocols for NEMS naturally render an optical cavity where the NEMS structure and the underlying substrate constitute the two mirrors. The modulation in the cavity depth due to the motion of the NEMS translates to intensity variations of the reflected light from the optical cavity, which can be measured on an appropriate detector. By optimizing the cavity depth, wavelength of the probe laser and the back-end electronics, exquisite displacement sensitivity (sub pico-meter/$Hz^{1/2}$) can easily be achieved [1].

Device fabrication is challenging; hence, we explored various fabrication methods for creation of suspended 2D material devices and established working protocols for both exfoliated and chemical vapor grown TMDCs. We also developed a new transfer method driven by water wettability to facilitate fabrication efforts. To perform device characterization, we developed an integrated in-vacuum Raman/Interferometer setup [1]. By exploiting the cavity formed between suspended 2D TMDC "bridges" and underneath substrates, resonance frequencies of various modes were characterized including exotic line shapes arising due to 1:1 internal resonance coupling in the nonlinear regime. Using a combined experimental-computational approach and the measured shift of fundamental resonance frequencies, induced by applied bias, we extracted piezoelectric properties of monolayer WS_2 and MoS_2. The exfoliated samples display piezoelectric coefficients that are in good agreement with DFT predictions. By contrast, CVD grown monolayers, exhibit a 10-fold reduction in piezoelectricity, likely due to the existence of atomic defects such as vacancies.

Additionally, by driving resonance in the nonlinear regime, we revealed internal resonance pairs in monolayer WS_2. Discovery of Hopf bifurcations linearly varying with driving forces inspired novel sensing modality with ultrahigh force sensitivity (aN) at room temperature [2]. Our efforts in fabricating and experimenting on suspended 2D TMDC devices will support further development in applying 2D materials to sensors and NEMS applications.

5:30 AM *F.MT06.02.04
Single Photon Emitters Using Strained Low-Dimensional Materials Hong Gyu Park; Korea University, Korea (the Republic of)

The quantum confinement in atomically-thin transition metal dichalcogenides (TMDCs) has been investigated for single photon emission based on naturally or artificially occurring defects. In particular, the precise control of the position of a single photon emitter by applying mechanical strains to the TMDC is feasible. Strains have been induced in TMDCs using various nanostructures including dielectric pillars, nanobubbles, optical waveguide, metal nanogaps, and metal nanoparticles. However, polarization control and integration with a high-quality (Q) cavity to increase the Purcell factor remain elusive in TMDC-based single photon sources.

In this talk, I will present the deterministic control of both the position and polarization of single photon emitters in atomically thin WSe_2 placed on a nanogap array. Manipulation of the band structure by a local strain gradient generates a potential well at the nanogap site, and position-controlled single photon emission is subsequently achieved. Additionally, directional elongations of the potential well, which are tuned by changing the nanogap size, allow polarization-controlled single photon emission. Moreover, single photons with a $g^{(2)}$ of ~0.1 are generated at 4-20 K. To take a full advantage of such deterministic control of the position and polarization of single photon emitters, the emitters are integrated with one-dimensional photonic crystal cavities. Therefore, this approach is a unique way to develop next-generation, deterministic, controllable single photon emitters based on TMDC materials, which outperform the present single photon sources with random occurrence and uncontrolled polarization properties.

5:45 AM *F.MT06.02.07
2D Material Based Electronics Under High Mechanical Strain Jong-Hyun Ahn; Yonsei University, Korea (the Republic of)

Rapid advances in synthesis of graphene and 2D materials, and fabrication methods for functional devices enable sophisticated types of functionality and their application to various emerging electronics, such as flexible, wearable and optoelectronic applications, that cannot be addressed with conventional materials. In this talk, I present that graphene and 2D materials can play critical roles in this context, through demonstrations of complex, mechanically assembled electronic and optoelectronic devices for flexible and wearable applications. Specifically, the mechanics of graphene and MoS_2 can yield various devices in distinct, engineered flexible geometries that cannot be easily reproduced with conventional materials and/or conventional device layouts. Examples of devices include touch, tactile sensors and wearable OLED display.

Interlayer Excitons in van der Waals Heterostructures Philip Kim; Harvard University, United States

A pair of electron and hole across the interface of semiconductor heterostructure can form a bound quantum state of the interlayer exciton. In a coupled interface between atomically thin van der Waals layers (vdW), the Coulomb interaction of the interlayer exciton increases further. In this presentation, we will discuss observing interlayer exciton formation in semiconducting transition metal dichalcogenide (TMDC) layers. Unlike conventional semiconductor heterostructures, charge transport in of the devices is found to critically depend on the interlayer charge transport, electron-hole recombination process mediated by tunneling across the interface. We demonstrate the enhanced electronic, optoelectronic performances in the vdW heterostructures, tuned by applying gate voltages, suggesting that these a few atom thick interfaces may provide a fundamental platform to realize novel physical phenomena. Furthermore, complete experimental control of density, displacement and magnetic fields in our graphene double layer system enables us to explore the rich phase diagram of several superfluid exciton phases with the different internal quantum degrees of freedom.

5:15 AM *F.MT06.03/F.EL04.13.02
Tunable Quantum Transport High Mobility 2D Materials Jeanie Lau; The Ohio State University, United States

One of the most alluring features of 2D materials is their tunability, as their carrier density, effect mass, band gap, and electronic phases can be tuned in situ by external parameters such as electric field, magnetic field and strain. Here we will present transport studies of high quality 2D materials. For instance, we demonstrate large tunable SOC and zero-field spin-splitting in atomically thin InSe with unprecedented mobility. From beating patterns in quantum oscillations, we establish that the SOC parameter *a* is thickness-dependent; it can be continuously modulated over a large range by an out-of-plane electric field, achieving zero-field splitting tunable between 0 and 20 meV. Surprisingly, *a* could be enhanced by an order of magnitude in some devices, suggesting that SOC can be further manipulated by variations in interlayer spacing induced by stacking and/or electrostatic compression. Our work highlights the extraordinary tunability of SOC in 2D materials, which can be harnessed for *in operando* spintronic and topological devices and applications.

Electron Interactions in 2D Materials—Correlated Multi-Particle Excitations and Optical Field Driven ARPES Steven G. Louie[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Many-electron interaction effects dominate many spectroscopic properties of reduced-dimensional systems, leading often to manifestation of novel phenomena not seen in the bulk. In this talk, I present some of our recent work on electron interaction effects in atomically thin quasi 2D materials: (1) strongly bounded correlated multi-particle excitations, such as trions and bi-excitons, in quasi 1D and 2D materials; (2) giant excitonic effects in shift currents, a nonlinear optical phenomenon, in non-centrosymmetric quasi 2D semiconductors; and (3) excitons and band renormalization in optical field driven angle-resolved photoemission spectroscopy (ARPES). Studies of these novel phenomena are made possible because of newly developed theoretical methods which incorporate higher-order many-electron correlation effects from first principles, using an interacting Green's function approach.

Quantum Anomalous Hall Effect in Intrinsic Magnetic Topological Insulator $MnBi_2Te_4$ Yuanbo Zhang; Fudan University, China

In a magnetic topological insulator, nontrivial band topology conspires with magnetic order to produce exotic states of matter that are best exemplified by quantum anomalous Hall (QAH) insulators and axion insulators. Up till now, such magnetic topological insulators are obtained by doping topological insulators with magnetic atoms. The random magnetic dopants, however, inevitably introduce disorders that hinder further exploration of topological quantum effects in the material. We resolve this dilemma by probing quantum transport in $MnBi_2Te_4$ thin flake—a topological insulator with intrinsic magnetic order. In this layered van der Waals crystal, the ferromagnetic layers couple anti-parallel to each other, so bulk $MnBi_2Te_4$ is an antiferromagnet. Atomically thin $MnBi_2Te_4$, however, becomes ferromagnetic when the sample has odd number of septuple layers (a septuple layer represents a single structural unit in the out-of-plane direction). We observe zero-field QAH effect in a five-septuple-layer specimen; an external magnetic field further enhance the QAH quantization by forcing all layers to align ferromagnetically. $MnBi_2Te_4$ therefore becomes the first intrinsic magnetic topological insulator exhibiting QAH effect.

THz-Driven Irreversible Topological Phase Transition in Monolayer $MoTe_2$ Keith A. Nelson; Massachusetts Institute of Technology, United States

The availability of intense tabletop terahertz-frequency pulses and simple field-enhancement structures that enable peak electric fields of tens of MV/cm have ked to demonstrations of highly nonlinear THz-induced responses from a wide variety of materials. THz-driven electronic, magnetic, and structural phase transitions and domain switching have illustrated novel possibilities for control over collective properties and dynamics. In experiments on single-layer and few-layer $MoTe_2$, we have found that irradiation with just one sufficiently strong THz pulse induces an irreversible phase transition [1]. The initial, noncentrosymmetric 2H phase disappears, as shown by the disappearance of characteristic Raman lines and second harmonic generation. After further THz irradiation, the topological insulator phase appears, revealed by its distinct Raman spectrum. Single-shot measurements of the $MoTe_2$ evolution as a function of time after THz irradiation reveal complex dynamics over many-picosecond time scales. Theoretical calculations show that the transition is induced through THz-induced liberation of carriers which stabilize the new phase and reduce the energy barrier between the two phases. The result illustrates the prospects for THz control over complex multiphase landscapes in quantum materials.

Conformal, Area-Specific and Switchable Graphene Nanowrinkles Teri W. Odom; Northwestern University, United States

Selective patterning and functionalization of graphene can produce spatially-defined properties. Buckling or wrinkling of graphene on polymeric substrates enables a direct approach to tune the physical properties without lithographic steps, and the resulting curvature of the wrinkles can control local chemical reactivity. However, most buckling methods have been limited

by the range of wavelength tunability, only global control of the wrinkled patterns, and delamination and cracks in the graphene. This talk will describe a scalable approach to achieve area-specific reactivity and patterning of conformal graphene wrinkles. We will discuss how a fluoropolymer layer sandwiched between graphene and different polymer substrates can facilitate crack-free and switchable graphene nanostructures. Such patterned areas with different curvatures show different reactivities based on a plasma fluorination reaction. Our approach for large-area, fine control over graphene wrinkle topographies has prospects for other two-dimensional electronic materials and optoelectronics and plasmonics applications.

Chemical Properties and Applications of 2D TMDCs Mediated by Defects Qing Hua Wang; Arizona State University, United States

The two-dimensional transition metal dichalcogenides (2D TMDCs) tend to have basal planes that are chemically relatively inert. Many approaches and reaction schemes have been demonstrated to modify the chemical nature of TMDCs, resulting in new chemical properties and applications. This talk will highlight our recent work on the chemical properties of 2D TMDCs mediated by point defects and edges, which subsequently enable applications in water treatment and antimicrobial treatment. We have shown robust and versatile covalent functionalization of materials across the metal chalcogenides including MoS_2, $MoSe_2$, WS_2, WSe_2, Bi_2S_3, and Sb_2S_3 using aryl diazonium salts. The reaction mechanism is initiated at point defect sites and edges, but propagates across the chalcogenide surfaces in a chain-like step growth. We have also shown the ability for MoS_2 to remove Pb contamination from water via a reaction with the surface sites to form sulfate precipitates. The reaction mechanism is again initiated at defect sites in the MoS_2. Finally, we have used single stranded DNA to encapsulate $MoSe_2$ nanosheets and shown their broad-spectrum antimicrobial properties against multidrug resistant bacteria. The choice of ssDNA sequence influences the conformal coating, and the ability for the edges of $MoSe_2$ to cut through bacterial cell membranes.

Chemical Trends of Deep Levels in van der Waals Semiconductors Penghong Ci[1], Xuezeng Tian[2], Jun Kang[3], Sefaattin (Sef) Tongay[4], Wladek Walukiewicz[1], Jianwei (John) Miao[2], Oscar Dubon[1] and Junqiao Wu[1]; [1]University of California, Berkeley, United States; [2]University of California, Los Angeles, United States; [3]Beijing Computational Science Research Center, China; [4]Arizona State University, United States

Properties of semiconductors are largely defined by crystal imperfections including native defects. Van der Waals (vdW) semiconductors, a newly emerged class of materials, are no exception: defects exist even in the purest materials and strongly affect their electrical, optical, magnetic, catalytic and sensing properties. However, unlike conventional semiconductors where energy levels of defects are well documented, they are experimentally unknown in even the best studied vdW semiconductors, impeding the understanding and utilization of these materials. We directly evaluate deep levels and their chemical trends in the bandgap of MoS_2, WS_2 and their alloys by transient spectroscopic study. One of the deep levels is found to follow the conduction band minimum of each host, attributed to the native sulfur vacancy. A switchable, DX center - like deep level has also been identified, whose energy lines up instead on a fixed level across different host materials, which explains the chemical trend of native electron density in the hosts as well as a persistent photoconductivity up to 400K.

5:30 AM *F.MT06.04.03
Defect and Strain Engineering of Two-Dimensional Materials Jun Lou; Rice University, United States

Two-dimensional (2D) materials, such as Graphene, hBN and MoS_2, are promising candidates in a number of advanced functional and structural applications, owing to their exceptional electrical, thermal and mechanical properties. To better meet the requirements of practical applications, property modification and regulation are oftentimes desired. Defect and strain engineering strategies are powerful tools to modulate electronic, optoelectronic and other functional properties of 2D semiconductors.
In this talk, we will report our efforts to employ such strategies to tune functional properties of 2D semiconductors. We first demonstrated how substrate interfacial chemistry can be utilized to tailor the physical properties of single-crystalline

molybdenum disulphide (MoS_2) monolayers. We use self-assembled monolayers with a variety of end termination chemistries to functionalize substrates and systematically study their influence on the physical properties of MoS_2. Our data shows that combined interface-related effects of charge transfer, built-in molecular polarities, varied densities of defects, and remote interfacial phonons strongly modify the electrical and optical properties of MoS_2. Tunable friction behavior of the heterostructure of monolayer MoS_2 and different self-assembled organic molecules (SAMs) were also demonstrated, which was attributed to the charge transfer from SAMs to MoS_2 influencing the electron concentration and thus the carrier-mediated friction in MoS_2. In another example, we systematically characterize chemical vapor deposition (CVD)-grown MoS_2 by photoluminescence spectroscopy and mapping and demonstrate non-uniform strain in single-crystalline monolayer MoS_2 and strain-induced bandgap engineering. We further modified our CVD process to create a Janus SMoSe monolayer and demonstrated high basal plane hydrogen evolution reaction (HER) activity in such samples and DFT calculation implies that the activity originates from the synergistic effect of the intrinsic defects and structural strain inherent in the Janus structure.

Emerging Electron Microscopy Techniques for 2D Materials Kayla Nguyen, Edmund Han, Chia-Hao Lee, Jeffrey Huang and Pinshane Y. Huang; University of Illinois at Urbana-Champaign, United States

The study of atomic-monolayer materials has been extremely popular within the last decade due to the emergence of a family of two-dimensional (2D) materials with expansive mechanical, electrical and magnetic properties. Subtle changes in these 2D materials at the atomic length scales, ranging from strain fields and dislocations, have large effects for tuning the electronic and mechanical properties, especially when used in real devices. Electron microscopy can provide the insight needed to visualize these effects [1-2]. Recent advancements in detector technology have already pushed the limits of resolution using 2D bilayer molybdenum disulfide using ptychographic reconstruction [3-4]. In my talk, I will discuss ways electron microscopy can provide opportunities for sensitive strain and magnetic measurements of 2D materials, with an emphasis on emerging techniques provided by the electron microscope pixel array detector (EMPAD), a state-of-the-art, high-dynamic range and high-speed electron diffraction detector.

6:00 AM F.MT06.04.06
Quantifying Peak Profile Analysis of 2D Tellurium Nanostructures by 4D-STEM Alejandra Londono-Calderon[1], Darrick Williams[1], Colin Ophus[2] and Michael Pettes[1]; [1]Los Alamos National Laboratory, United States; [2]Lawrence Berkeley National Laboratory, United States

Tellurium nanostructures are promising candidates for functional electronic and optical nanomaterials. The anisotropic helical crystal structure of trigonal tellurium (t-Te) and the weak van der Waals stacking of its layers; allows the formation of a variety of 1D nanostructures such as nanowires and nanobelts. A kinematically driven growth can promote the formation of 2D tellurium known as tellurene. This recent realization of 2D tellurium has allowed scientists to demonstrate an air-stable monoelemental van der Waals material with remarkable potential for applications in electronics and optoelectronics. The chiral-chain structure of ultrathin Te allows controllable electronic and optical properties due to the non-monotonic carrier mobility and an increase in electronic band-gap as the thickness is reduced. Scalable and accurate production of 2D Te-based functional devices will require detailed knowledge of structural defects and strain field distributions that can be linked to transport properties.
Standard HRTEM images provide localized crystallographic information, which usually leaves out larger-scale structural components. Precise quantification of lattice parameters and additional structural features is often not fully captured in this type of analysis. Modern single electron detectors allow the rapid collection of 2D diffraction patterns of a 2D set of probe positions in the so-called 4D Scanning Transmission Electron Microscopy (4D-STEM). 4D-STEM provides a remarkable tool for structural analysis across many length scales, and enables extracting the crystalline structure, orientation, virtual images, and strain information at the nanometer scale.
In this presentation, we will demonstrate a new microwave-assisted synthesis method for 1D and 2D tellurium nanostructures and the analysis of the micro/nanostructure using conventional XRD and the new 4D-STEM technique. Fast collection of nano beam electron diffraction (NBED) patterns of beam sensitive Te nanowires and flakes was performed using a Gatan K3 direct electron detector, and these data sets were used to perform peak profile analysis over the thousands of NBED patterns to quantify the nanostructure of 1D and 2D Te including chirality and grain boundary analysis.

6:10 AM F.MT06.04.07
Ultra-High-Resolution Imaging of Moiré Lattices and Superstructures under Ambient Conditions Kyunghoon Lee[1,2,3], Iqbal Bakti Utama[2], Salman Kahn[2], Appalakondaiah Samudrala[4], Nicolas Leconte[4], Birui Yang[2], Shuopei Wang[5], Kenji Watanabe[6], Takashi Taniguchi[6], Guangyu Zhang[5], Alexander Weber-Bargioni[1], Michael Crommie[2,1,3], Paul Ashby[1], Jeil Jung[4], Feng Wang[2,1,3] and Alex Zettl[2,1,3]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]Kavli Energy NanoScience Institute, United States; [4]University of Seoul, Korea (the Republic of); [5]Institute of Physics, Chinese Academy of Sciences, China; [6]National Institute for Materials Science, Japan

A moiré lattice is produced by stacking lattice-mismatched 2D materials or by introducing misalignment. The moiré lattices generate the periodic potential that can strongly modify the electronic properties of the constituent 2D layers. In addition, superstructures of moiré lattices can emerge from multiple misaligned lattice vectors or inhomogeneous strain distribution, which offers an extra degree of freedom in engineering electronic band structure. Thus, a high-resolution imaging moiré lattices and superstructures is critical to correlate the moiré structure with the resulting material behavior. Here we report the versatility of ultra-high-resolution implementation of scanning impedance microwave microscopy (sMIM) in imaging the moiré superlattices in various graphitic systems at ambient conditions. We show that an ultra-high spatial resolution better than 5 nm can be achieved although the scanning probe tip has a gross radius of ~100 nm. The high sensitivity of sMIM allows the imaging of the intricate nanostructural details in the superlattice. Furthermore, the imaging capability of sMIM enables the characterization of various composite moiré designs, including the super-moiré pattern and Kagome-like superlattice.

SESSION F.MT06.05: Transport Properties
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020

5:00 AM *F.MT06.05.01
Study of Thermal and Magnetic Transport in Functional Materials Enabled by Ultrafast Optical Metrology Xiaojia Wang; University of Minnesota Twin Cities, United States

Transport phenomena play an important role in designing and engineering materials with tailored functionalities. Thermal conductivity and spin precession damping, as basic transport properties of materials, can provide a wealth of information on the fundamental scattering processes of phonons and magnons with structural defects and interface imperfection. In this talk, I will share our group's recent progress on utilizing time-resolved magneto-optical Kerr effect (TR-MOKE) metrology to study the thermal and magnetic properties of functionalized materials spanning a wide range of applications. This will include: (1) revealing the 3D anisotropic thermal transport in black phosphorus, as the next-generation of "wonder materials" for the semiconductor industry; (2) developing low-damping and high-thermal stability materials with perpendicular magnetic anisotropy for spintronic applications; and (3) manipulating spin precession using optically launched acoustic strains via a strong magnon-phone coupling at ultra-high frequencies (~60 GHz). The structure-property relationships of functional materials revealed by the ultrafast pump-probe technique open up opportunities of tailoring material properties by structural engineering at the atomic and molecular levels. Ultimately, such an understanding can be leveraged to guide the design and optimization of materials, as promising building blocks for high-performance electronics, thermal management, hard-disk data storage, and magnetoacoustic devices.

Exotic Spin Transport in Two-Dimensional Materials Stephan Roche[1,2] and Jose H. Garcia Aguilar[1]; [1]Catalan Institute of Nanoscience and Nanotechnology, Spain; [2]ICREA--Institució Catalana de Recerca i Estudis Avançats, Spain

The field of spin transport in two-dimensional has flourished in the past couple of years. Some remarkable features are the reports of large charge-to-spin in graphene-based heterostructures [1], the discovery of the quantum spin Hall effect [2], and ultra-clean spin transport measurements within the ballistic regime [3]. In this talk, we will present predictions on diffusive and ballistic spin transport in different two-dimensional materials. Using complementary large-scale numerical transport methods, we developed a theory showing that contacts have a dramatic effect on the spin transport in systems with a size comparable to the spin relaxation length, leading to underestimating the latter [4]. We then apply this theory and bulk transport methods to unveil the role of broken symmetries in the spin transport of transition metal dichalcogenides in their 1T' and 1Td structural phases, showing they can promote an unconventional spin transport regimen. We believe our predictions

will lead to a better understanding of the recent measurements of the quantum spin Hall effect in WTe2 and will help optimize experimental setups for its harvesting.

5:30 AM *F.MT06.05.03
Strain Induced Tuning of Physical Properties of Materials Abhishek K. Singh; Indian Institute of Science, India

Tuning physical properties of materials by applying strain opens up wide range of applications. In this presentation, sensitivity of these properties on application of strain will be illustrated for the case of TMDs. Using first principles calculations, the effect of normal compressive (NC), bi-axial compressive (BC), and bi-axial tensile (BT) strain on the electronic properties of few layered MoS_2 has been investigated. Regardless of the type of strain, a reversible semiconductor-to-metal transition is observed MoS_2. The effect of strain as a function of number of layers on the transport properties is investigated. It is found that the 3L and 2L-MoS_2 emerge as the most efficient thermoelectric materials under NC and BT strain, respectively. The study was further extended to semi-metallic TMD TiS_2, which has been in focus due to its application in energy storage and thermoelectric materials. Upon application of uniform biaxial strain, TiS_2 transforms from semi-metal to semiconducting phase. The transport calculations show three-fold enhancement in thermopower for both *p*- and *n*-type doped TiS_2. Further, the effect of strain on thermal conductivity of bulk MoS_2 is explored, wherein an increase of cross-plane thermal conductivity from 3.5 to about 25 W/m-K. The giant enhancement arises from the increase in interlayer interaction on application of strain and decrease in phonon lifetimes due to the unbundling effect along the cross-plane direction. The concepts proposed from our studies can be extended to other semiconducting and metallic TMDs.

Towards Room-Temperature Magnetic Semiconductors in van der Waals Layered Materials Seok Joon Yun, Jinbao Jiang, Dinh Loc Duong and Young Hee Lee; Sungkyunkwan University, Korea (the Republic of)

The ferromagnetic state in van der Waals two-dimensional (2D) materials has been reported recently in the monolayer limit. Intrinsic CrI_3 and $CrGeTe_3$ semiconductors reveal ferromagnetism but the Tc is still low below 60K. In contrast, monolayer VSe_2 is ferromagnetic metal with Tc above room temperature but incapable of controlling its carrier density. Moreover, the long-range ferromagnetic order in doped diluted chalcogenide semiconductors has not been demonstrated at room temperature. The key research target is to realize the long-range order ferromagnetism, Tc over room temperature, and semiconductor with gate tunability. Here, Ferromagnetic order is manifested using magnetic force microscopy up to 360K, while retaining high on/off current ratio of ~10^5 at 0.1% V-doping concentration. The V-substitution to W sites keep a V-V separation distance of 5 nm without V-V aggregation, scrutinized by high-resolution scanning transmission-electron-microscopy. More importantly, the ferromagnetic order is clearly modulated by applying a back gate. We also observe a ferromagnetic hysteresis loop together with oscillatory behavior at room temperature in diluted V-doped WSe_2, while maintaining the semiconducting characteristic of WSe_2 with a high on/off current ratio of five orders of magnitude. Our findings open new opportunities for using two-dimensional transition metal dichalcogenides for future spintronics.

6:00 AM F.MT06.05.05
Thermal Conductivities of 2D MoS_2 Under Mechanical Strains Annie Xian Zhang; Stevens Institute of Technology, United States

In recent years, transition metal dichalcogenides become emergent thermoelectric materials with potential wide spread in

wearable electronics applications. Considering the extensive applications of transition metal dichalcogenides, many research efforts have been paid and good progresses have been made. So far, all of the researches in this field focus on the electrical properties of them. It has not been reported about the transition metal dichalcogenides' thermal transport properties under mechanical strains. Due to their potential applications, it is of significance to discover the thermal transport properties of transition metal dichalcogenides at large mechanical strains, and thus develop the novel thermoelectric platforms which can sustain the extreme environments in wearable electronics.

In this work, we demonstrate using Raman optothermal technique to measure the thermal conductivities of two dimensional (2D) MoS_2. We first utilize more direct measurements of the optical absorption, and then by comparing the response of the samples using different laser spot sizes, we are able to measure the thermal conductivities of the 2D MoS_2. Then thermal conductivities at large mechanical strains are obtained providing more scientific merits.

The Raman optothermal technique has been the most successful method for measurement of thermal conductivity of 2D materials, and was used to measure the 2D materials at large mechanical strains for the first time in this work. In this technique, a laser is focused at the center of a thin film and used to measure the peak position of a Raman-active mode. As the laser power is increased, the sample is heated which enables red-shift Raman mode due to thermal softening. Another comparison experiment is conducted by placing the samples on a heating platform and monitor the change of Raman-active mode peak position shift. Combining these two sections of experiments provide us the thermal modeling can then be used to extract the thermal conductivity from the measured shift rate. We have used a refined version of the optothermal Raman technique to study thermal conductivity of 2D MoS_2, at large mechanical strains. It is the first thermal measurement on 2D materials at large mechanical strains. This work also addresses several important issues in the measurement of thermal conductivity of 2D materials at large strains using Raman spectroscopy.

In conclusion, we have used Raman optothermal technique to study thermal transport properties of 2D MoS_2 at large mechanical strains. This work addresses several important issues in the measurement of thermal conductivity of the 2D materials MoS_2 using Raman spectroscopy. We derive the thermal conductivity values at large mechanical strains. These results are of significance to discover the thermal transport properties of 2D transition metal dichalcogenides at large mechanical strains, and thus develop the efficient 2D thermoelectric materials which can sustain the large mechanical strains and in turn to use strains to tune their thermal properties.

6:10 AM F.MT06.05.06
Strain-Induced Effects on Transport in 2D Materials Jennifer Coulter and Boris Kozinsky; Harvard University, United States

Understanding the influence of strain on transport properties, such as piezoresistive effects, is important for device applications of 2D materials. Accurate predictions of transport in materials depend on detailed knowledge of electron-phonon interactions, calculations of which have only recently become feasible due to algorithmic improvements. In particular, we can now apply the Electron-Phonon Averaged approximation to reduce the cost of such calculations and automate the prediction of resistivity with respect to variations in strain. Using first-principles electron-phonon calculations, we explore the specific mechanisms underlying piezoresistive effects in systems such as graphene and transition metal dichalcogenides, and provide additional understanding of how to manipulate these effects for practical use.

6:20 AM *F.MT06.05.07
Phonons in van der Waals Solids for Thermal Management Devices Sina Najmaei; US Army Research Lab, United States

Active thermal management devices often lack the efficacy and energy efficiency of electronic switches. This is mainly because of the bosonic nature of phonons and the type of interactions they have with external forces. As a result, discovery of materials with unique vibrational properties that provide better control of thermal carriers is necessary. Our research shows that the phonons in group IVB transition metal dichalcogenides such as hafnium disulfide have distinct characteristics and provide remarkable mechanism for control of thermal careers. This is caused by the intermixing of van der Waals forces and covalent bonds in the material structure combined with their highly anisotropic bond properties. In this talk we present our results on vibrational and thermal transport properties of a member of this group, hafnium disulfide (HfS_2). The highly asymmetric bond properties in HfS_2 dominate the structure and vibrational properties of this material. We explore the physics of HfS_2 by developing a comprehensive computational model to study its phonon behavior, anharmonic properties, and phonon transport characteristics. Our findings demonstrate a unique phonon behavior in the material where the absence of a phonon-gap between the acoustic and optical branches grant a more prominent and unique role to the optical modes of HfS_2.

As a result HfS_2 has a low thermal conductivity, ranging between 0.3-5W/mK. In additional only one acoustic phonon branch, the ZA branch, contributes up to 80% to the thermal transport of the material in both out-of-plane and in-plane crystal orientations. Our experiments confirm and support the theory and add further insight into an anomalous behavior in the optical modes. Our quasi-harmonic model reveals a structural phase transformation at around room temperature that leads to unique anharmonicity, discernible in the experimental results of the zone center out-of-plane optical mode. This unique phase transformation contributes to both changes in the phonon decay properties and thermal transport behavior. The structural phase transformation combined with the constricted ZA branch phonon carriers and the distinct scattering physics in optical branches of HfS_2 provide unique means for control of thermal transport. We explore a few strategies for control of thermal properties in HfS_2 based on fundamental vibrational properties of the material. We demonstrate that a successful approach for dynamic control of thermal conductivity is the control of van der Waals gap properties. We demonstrate that through intercalation and modification of these gaps a 4-fold control of cross-plane thermal conductivity in hafnium disulfide from $0.35 Wm^{-1}K^{-1}$ to $1.45 Wm^{-1}K^{-1}$ is achievable. We also demonstrate that an out-of-plane strain can be used to make thermal regulators based on HfS_2. This research unveils a unique class of 2D layers with vibrational properties suitable for development of thermal management devices

Direct Correlation of Structure and Optical Properties of Defect Related Colour Centres in Hexagonal Boron Nitride Soumya Sarkar, Sinu Mathew, Manohar Lal, T. Venky Venkatesan and Silvija Gradecak; National University of Singapore, Singapore

Hexagonal boron nitride (h-BN) has recently emerged as a prominent nanophotonic material due to observation of several unique optoelectronic phenomena such as natural hyperbolicity, strong second order non-linearities and robust deep UV emission. Specifically, its ultra wide bandgap ~ 6eV can host midgap defects that often exhibit intense room temperature quantum emission. Understanding the origin of such defect related emission is crucial to harness their technological potential. Here, we report controlled tailoring of defect states in hBN by focussed helium ions using a helium ion microscope and present a direct correlation of their structural and optical properties using a combination of Raman, photoluminescence (PL), cathodoluminescence (CL) and high resolution electron microscopy. We observe that while end of range defects cause an evolution of sp^3 phase in the otherwise sp^2 hBN leading to bright and previously unreported near infrared emission, near surface defects contribute to strong visible emitters often attributed to single photons. Our results provide a comprehensive overview of defect related colour centres in hBN across a wide spectral range that would serve as a platform to realize next generation quantum optoelectronic devices.

F.MT06.06.02
Late News: Controlling Defects in Continuous 2D GaS Films for High-Performance Electronic and Optoelectronic Devices Yang Lu[1] and Jamie Warner[2]; [1]University of Oxford, United Kingdom; [2]The University of Texas at Austin, United States

A chemical vapor deposition method is developed for thickness-controlled (one to four layers), uniform, and continuous films of both defective gallium(II) sulfide (GaS): $GaS_{0.87}$ and stoichiometric GaS. The unique degradation mechanism of $GaS_{0.87}$ with XPS and HAADF-STEM is studied, and it is found that the poor stability and weak optical signal from GaS are strongly related to photo-induced oxidation at defects. Photodetectors based on the two materials are fabricated with short response time (<66 ms), excellent UV photoresponsivity. An enhanced stability of the stoichiometric GaS is demonstrated under laser and strong UV light, and by controlling defects in GaS, the photoresponse range can be changed from vis-to-UV to UV-discriminating.
Besides the role in degradation mechanism, defects in $GaS_{0.87}$ also contributed to the formation of a new band sitting within its bandgap, which is confirmed by cathodoluminescence results. As a result, controlling defects in GaS turns the band alignment of the bilayer GaS-WS_2 van der Waals heterostructure from type I to type II. XPS and KPFM characterization demonstrates that the defect band can facilitate the charge transfer from WS_2 to GaS. Devices based on the type-II

heterojunction further show that the defect band greatly assisted the carrier transport by lowering the contact resistance, and also demonstrate superior photodetector properties with a large linear dynamic range (>73 dB) at a R of 13 A/W for green light.

FAIR Data Infrastructures Towards New Horizons for Materials Research Claudia Draxl[1,2]; [1]Humboldt-Universität zu Berlin, Germany; [2]Fritz-Haber-Institut Berlin, Germany

Novel approaches of Artificial Intelligence (AI) can find patterns and correlations in data that cannot be obtained from individual calculations or experiments and not even from high-throughput studies. In fact, data-driven research is adding a new research paradigm to the scientific landscape. For a real breakthrough, *Open Data* and sharing, as well as an efficient data infrastructure is key [1]. In other words, for shaping this forth paradigm and contributing to the development or discovery of improved and novel materials, data must be what is now called FAIR - Findable, Accessible, Interoperable, and Reusable [2].

The NOMAD Laboratory [3,4] is a living example for such infrastructure in computational materials science, comprising the NOMAD *Repository* (raw data) and its *Archive* (normalized, i.e. code-independent data). The NOMAD *Encyclopedia* is a web-based public platform that visualizes the results of this vast amount of calculations. The NOMAD Analytics Toolkit provides a collection of examples and tools to demonstrate how materials data can be turned into knowledge by AI approaches (e.g. [5,6]). I will give a guided tour through this data lab and discuss successes and challenges [7] ahead of us for exploiting the whole wealth of materials data – including experiment and sample synthesis.

5:15 AM F.MT07.01.02
The Perovskite Database Project—How Do We Get Experimentalists to Share All Their Data in a Form Useful for Others? Tor J. Jacobsson[1,2] and Eva Unger[1]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Uppsala University, Sweden

Lead halide perovskites have in the last decade gained a large interest as a promising solar cell material and the number of published papers has now surpassed 15000. The sheer amount of papers makes it increasingly difficult to keep track of the field, and the lack of standards for describing, reporting, and sharing device data is something that seriously limit the pace of discovery. To deal with those problems, we have initiated the Perovskite Database Project where we aim at collecting all past and future perovskite device data in one place in a standardised machine-readable format. The project includes a web app, interactive graphics enabling anyone to explore and learn from the data, open source code, and mechanisms for collecting new data. The project is scheduled to go online during the autumn of 2020. In this talk we will discuss challenges and insights gained during this project including: how to motivate volunteers to gather previously published data, how do we get a sufficiently large part of a research community to share all their new data, how to organise data in a way that is simple to collect and robust to reporting errors, how do we ensure that the data is useful for as many as possible, and what can we really do with the data once we have it?

5:25 AM F.MT07.01.03
Accuracy, Uncertainty, Inspectability—Learning with Compositionally-Restricted Attention-Based Networks Steven K. Kauwe[1], Anthony Y. Wang[2] and Taylor D. Sparks[1]; [1]The University of Utah, United States; [2]Technische Universität Berlin, Germany

The materials science community has established that data-driven modeling, based on chemical composition, generates accurate and actionable results. Tools for performing this task have evolved from simple statistical methods to large endeavors containing complex neural-networks with millions of parameters. With each successive work, we have seen a marked improvement in property predictions with a trend towards raw model accuracy. However, model performance often includes additional considerations such as uncertainty quantification or interpretability.

In this talk, I will present our new model architecture, the Compositionally-Restricted Attention-Based Network (CrabNet). CrabNet generates high-fidelity predictions based on the self-attention mechanism, a fundamental component of the transformer architecture which revolutionized natural language processing. The transformer encoder uses self-attention to encode the context-dependent behavior for the components within a system. In physical environments, elements contribute differently to a material's property based on the materials system itself. For example, boron behaving as an electrical dopant in one system while behaving as a mechanical strengthening bond modification in another. CrabNet's ability to potentially capture this type of context-dependent behavior allows for highly accurate model predictions.

CrabNet does not stop there. Our modeling approach uses a robust loss function and model ensembling techniques to provide uncertainty values along with the property predictions. Importantly, we achieve this with a model architecture that generates simple and inspectable self-attention maps. These attention maps govern the learned material property by representing element importance and interactions. The visualization and analysis of these attention maps are available during training and inference periods.

As a result, CrabNet provides property prediction, uncertainty estimation, and the governing element interactions for every prediction. We expect that the ideas and capabilities of CrabNet will encourage additional research and discussion around the uses and benefits of our community's maturing data-driven approaches.

5:35 AM F.MT07.01.04

Late News: Uncertainity-aware microstructural database to accelerate data consolidation in organic electronics Christopher W. Hong[1], Snigdha Motadaka[2], Boris Glavic[1], Oliver Kennedy[2] and Olga Wodo[3]; [1]Illinois Institute of Technology, United States; [2]University at Buffalo, The State University of New York, United States; [3]State University of New York at Buffalo, United States

Stimulated by the Materials Genome Initiative (MGI), more databases with materials and materials properties are becoming publicly available. Among them, the databases are the Materials Project and the Harvard Clean Energy Project. Databases at the next scale - microstructure - are relatively less explored and consist of various application-specific and sparse datasets. This is because, among others, microstructural datasets are relatively expensive to obtain due to the high cost of sample preparation, limitations of imaging instruments, simulation cost, and individual labs' capabilities to generate a large volume of data. This limits machine learning's applicability and necessitates some form of data consolidation between various labs with the following challenges:
(i) data consolidation is hindered by the inherently diverse nature of materials data (as most data repositories focus on a specific subset of materials data) but also lab effects (e.g., different protocols of data processing or sample preparation);
(ii) microstructural data is sparse and noisy data due to incomplete observations or imprecise measurements.
In this talk, we present the microstructural database build on the principles of probabilistic and incomplete databases. Unlike a classic database, the probabilistic database can deal with uncertain, incomplete information-missing values or uncertain information (value of an attribute represented as probability density function over the set of possible value instead of a single value). They inherently handle problems that emerge from data integration from various sources that are diverse and often incompatible. We show two frameworks: vizier and mimir that are used to integrate and store the datasets, respectively.
To demonstrate our database's effectiveness, we showcase the integration of three data sets generated through three projects aimed to improve the efficiency of organic solar cells. In each project, the microstructures were analyzed to predict the solar cell efficiencies. However, the microstructures were annotated with a different set of descriptors. Moreover, different types of microstructures were analyzed (i.e., dendritic, spinodal, and wavy). We illustrate how the integrated, although incomplete, data is used to impute the missing data in the respective datasets. Finally, we showcase the framework's capabilities to mark database entry or imputed values in conflict with other entries or violating the physics-based constraints.

5:45 AM F.MT07.01.05
Late News: Data Automation and Data Intelligence for Data-Driven R&D Max Petersen and Rob Brown; Dotmatics, United States

Data-driven R&D, especially machine learning (ML) and artificial intelligence (AI), are receiving lots of attention as avenues to accelerate new product development and to avoid/supplement costly lab experimentation. The pre-requisite for all these approaches is of course the availability of reliable high-quality data. However in real-life AI/ML projects an excess of time is spent aggregating and curating data, leading inevitably to dirty datasets and poor prediction results. Sadly, the IT infrastructure required to automate the provision of clean and properly contextualized data is often an afterthought.

This presentation gives an overview on our recent progress on an R&D IT infrastructure that solves the data provisioning problem in process-driven R&D. We will focus on three key areas: the automation of instrument data acquisition and their mass storage, combined querying across semantic and highly structured data, and the application of graph searching across chemistry experiments for reaction pathway mapping.

Managing instrument data is challenging not only because of their volume, but also because of their variability in data formats. Commonly, R&D IT systems capture incomplete data, e.g. by only saving processed files, or by placing them in inaccessible data silos where they can only provide limited use to data science efforts. We will discuss our approach that retains the full information content of all instrument data generated, while at the same time providing a framework to automate data processing and streamline lab operations.

Scientific data are notorious difficult to deal with in data modeling contexts. This is because of the combination of highly structured data, e.g. structure-property relationships, and unstructured semantic data that is generated as part of analyses, observations, conclusions, etc. Here, we will discuss an approach to embed semantic technologies into our scientific data platform to solve this complex problem.

Finally, we will discuss an application of graph technologies to mining reaction data that allows analysis of reaction pathways that span a multitude of experiments. This functionality is useful to compile information for patent submissions, or to optimize and discover synthetic routes based on existing IP.

SESSION F.MT07.02: Analysis of Experimental Data
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-MT07

5:00 AM *F.MT07.02.01
FAIR Digital Object Framework and High Throughput Experiment Zachary T. Trautt[1], Raymond L. Plante[1], Gretchen Greene[1], Jason R. Hattrick-Simpers[1], Brian L. DeCost[1], Gilad Kusne[1] and Andriy Zakutayev[2]; [1]National Institute of Standards and Technology, United States; [2]National Renewable Energy Laboratory, United States

With the increasing use of data-driven methodologies, concerns around data discovery, data access, and data interoperability have come to the forefront. Beginning in August 2019, communities have convened to work towards convergence of three complementary visions: (1) Digital Object Architecture, (2) Linked Data and Semantic Web, (3) FAIR Data Principles. This convergence has established the FAIR Digital Object Framework. This talk will overview these developments, summarize work within the NIST Material Measurement Laboratory to support adoption of the FAIR Digital Object Framework within the materials science and engineering community, and provide practical examples of how researchers can leverage these developments.

5:15 AM F.MT07.02.02
Automated Prediction of Crystal Lattice Parameters from Powder Diffraction Data Sathya R. Chitturi[1,2], Daniel Ratner[1,2], Kevin Stone[1,2], Richard Walroth[1,2], Vivek Thampy[1,2], Mike Dunne[1,2] and Christopher Tassone[1,2]; [1]SLAC National Accelerator Laboratory, United States; [2]Stanford University, United States

X-ray powder diffraction (powder XRD) is an important experimental characterization technique used to determine crystal structure. Current powder XRD analysis involves several time-consuming and error-prone human intervention steps including peak identification and indexing. In this work, we use one-dimensional Convolutional Neural Networks (1D CNNs) to perform the task of lattice parameter prediction, a critical step in the analysis pipeline.

We train independent regression models for each of the six crystal systems in order to take advantage of specific symmetry constraints on the lattice parameters. We perform simulations based on allowed Bragg angles for each crystal system in order to quantify best-case performance under conditions of perfect information. We show that, with sufficient data, it is possible to meet arbitrarily low mean percentage error (MPE) thresholds. Furthermore, the amount of data needed for perfect prediction scales directly with the number of independent lattice parameters in each crystal system. We also present results for simulated data based on the Cambridge Structural Database (CSD), containing over one million unique entries which span a very wide range of lattice parameter space. We achieve an MPE value of less than 10% for the cubic crystal system and MPE values of less than 20% for all other crystal systems. Validation of these results is performed in GSASII using standard refinement procedures.

This analysis builds on previous works focusing on classification tasks such as crystal system and space group prediction from powder XRD data. We hope that our results will further the eventual goal of high-throughput, real-time crystal structure analysis.

5:25 AM F.MT07.02.03
Accelerating Structural Investigation in $InGaO_3(ZnO)_m$ Using Rapid and Cost-Effective Optical Pre-Screening Vidit Gupta[1], Aine Connolly[1], Duncan Sutherland[1], Max Amsler[1,2], Sebastian Ament[1], R. B. Van Dover[1] and Michael O. Thompson[1]; [1]Cornell University, United States; [2]University of Bern, Switzerland

We have investigated structural transformations in the $InGaO_3(ZnO)_m$ (IGZO) homologous series using optical and X-ray techniques. Following thermal processing via lateral gradient Laser Spike Annealing (lgLSA), structural transformation kinetics were observed as a function of composition ($1<m<12$), processing time (250 us - 10 ms), and peak temperature (500-1400°C). The high dimensionality of this composition and processing space dictates the use of automation in both sample generation and data analysis. Two complementary high-throughput and low-cost spatially resolved optical techniques were initially used to identify optical transitions that correlate strongly with structural transformations. As these samples are thin transparent films, the optical techniques are sensitive to extremely small changes in the optical path length due to physical

thickness and optical index (phase) variations. This ability to efficiently prescreen the experimental phase space enabled automated and accelerated determination of structural transformations (if any) associated with these optically determined boundaries using X-ray diffraction. We propose a model for structural evolution along this IGZO pseudo-binary based on the ordering of In-O and (Ga,Zn)-O layers.

5:35 AM F.MT07.02.04
Image Similarity Latent Manifolds for Materials Microscopy Tri N. Nguyen, Yichen Guo and Joshua Agar; Lehigh University, United States

Instruments of scientific discovery (e.g., electron microscopes, scanning probe microscopes, and others) acquire vast collections of images that contain physical insight. Humans, however, struggle to search and draw correlations from enormous databases of images; thus, only a small fraction of the data collected is translated into knowledge. Researchers need an analytical toolbox that can create an image similarity latent manifold and allow visual interaction in an informative, comprehensive, and intuitive way. Here, we develop machine learning algorithms to create image similarity projections using a dataset of 25,000 piezoresponse force microscopy images. We implement a variety of pre-trained convolutional neural networks optimized on the ImageNet dataset to extract latent features of size [1x1x4096]. We extend this concept by updating the pre-trained model by classifying wallpaper group symmetries to create physics-informed latent representations. We use manifold learning techniques [e.g., t-Distributed Stochastic Neighbor Embedding (t-SNE) and Uniform Manifold Approximation and Projection (UMAP)] to generate interpretable 2D projections of these features. We demonstrate how this tool can be used for recursive image similarity searching and exploration accelerating discovery of trends in materials microscopy. Our algorithms are capable of identifying microstructure in diverse microscopy images across length scales. We will discuss how this concept can be integrated with structured scientific databases containing images and metadata as well as interactive graphical user interfaces to enable the rapid extraction of actionable information from materials microscopy data. While we demonstrate the aptitude of this approach on piezoresponse force microscopy images, this approach is amenable to other forms of microscopy and imaging techniques.

5:45 AM F.MT07.02.05
Combining Experiment, Physics-Based Modeling and Bayesian Inference to Enhance Voltammetric Characterization Alexis M. Fenton Jr. and Fikile Brushett; Massachusetts Institute of Technology, United States

Voltammetry is a ubiquitous electroanalytical technique used for qualitative and quantitative characterization of redox-active species for a range of purposes (e.g., materials development, detection).[1,2] For dilute electrolyte solutions, known fundamental relationships, based on the mathematical treatment of reaction-transport processes, can be used to discern key physical and electrochemical properties of deterministically prepared electrolytes.[1,3] Further, voltammetry may be readily performed *in-situ* or *in-operando*, making it a minimally invasive and rapid diagnostic technique. However, many studies seek to track the chemical evolution of redox-active species in non-deterministically generated electrolytes, often by identifying the chemical by-products of this evolution.[4,5] Voltammetric methods alone are inadequate to uniquely identify compounds, as multiple species may have similar electrochemical properties; as a result, electrolyte characterization also includes suites of *ex-situ* techniques (e.g., mass spectrometry, UV-Vis spectroscopy). Advanced labeling protocols – potentially involving machine learning (ML) methods – may enable voltammetry to uniquely identify more compounds, which, in turn, may streamline characterization workflows. Indeed, ML methods have already been shown to enhance voltammetric capabilities,[6,7] but, to our knowledge, no studies have combined ML methods and electrochemical descriptors to identify compounds.

In this presentation, we describe a framework to identify solution-phase redox couples using experimental voltammetry, electrochemical descriptors from physics-based simulations, and Bayesian inference. This protocol references a library of candidate compounds comprised of molecular property sets (e.g., diffusion coefficient, redox potential) and compares it to experimental data to characterize the electrolyte being examined. The compound identities and the associated probabilities are then reported, enabling targeted follow-up experiments. We discuss the development and the validation of this protocol using a model set of redox-active molecules, demonstrating viability and motivating further development. We also explore possible expansions of this Bayesian framework, and we conclude by discussing potential applications (e.g., electrolytes for energy storage technologies). As a result, this protocol may extend the capabilities of voltammetric analysis, thereby accelerating the materials development pipeline for systems involving redox-active compounds.

SESSION F.MT07.03: Constitutive Modeling
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-MT07

5:00 AM *F.MT07.03.01
Scientific AI in Materials Science—Reproducibility, Trusting Archival Data and Single Scalar Labels Jason R. Hattrick-Simpers[1], Brian L. DeCost[1], Zachary T. Trautt[1], Gilad Kusne[1], Eva Campo[2] and Martin L. Green[1]; [1]National Institute of Standards and Technology, United States; [2]National Science Foundation, United States

Scientists are increasingly turning to the power of artificial intelligence (AI) to increase the rate of knowledge extraction, provide insight into new materials and discover unexpected correlations. In some cases, robust AIs have even been coupled with experimental (or theoretical) automation to generate autonomous scientific platforms capable of planning and executing experimental designs without human intervention. With the excitement around AI rapidly increasing it is time to begin thinking about the bursting of the AI bubble and what are the actions we can take as a community to mitigate its severity. Here scientific-AI and the opportunities and paths forward for creating a sustainable and scalable paradigm within materials science will be discussed. Of particular note will be issues with the reproducibility of AI model results, the use of archival data to build models, and the common usage of single scalar labels to summarize data sets. We will show building the same model using the same data set using a different implementation of the same algorithm does not result in statistically identical results. Next we will discuss the importance of preserving a record of primary data underlying archival labels, by highlighting the impact of a using a fuzzy metric to classify the state of a material. Finally, we will discuss the issue of labeling uncertainty with the idea that an AI will not always be presented with pristine data for evaluation and make recommendations for possible methods to capture disagreement between experts in the literature.

5:15 AM F.MT07.03.02
Neural Network Approach for Predicting Organic Molecular Properties from Core-Loss Spectroscopy Kakeru Kikumasa[1], Shin Kiyohara[2], Kiyou Shibata[1] and Teruyasu Mizoguchi[1]; [1]The University of Tokyo, Japan; [2]Tokyo Institute of Technology, Japan

Core-loss spectroscopy observed by electron, electron energy loss spectroscopy (EELS), and X-ray, X-ray adsorption spectroscopy (XAS), are analytical techniques used for wide variety of materials, including battery, catalysis, and functional oxides. In particular, electron energy loss near edge structure (ELNES) and x-ray adsorption near edge structure (XANES) correspond to the electronic transition from a core orbital to conduction bands and contain various information on local atomic structures and electronic states.
In general, ELNES/XANES spectra of target samples are interpreted through comparison with reference spectra which are often obtained with time-consuming theoretical calculations. However, the interpretation of these spectra is very difficult because of the ambiguous relationship between the spectral features and the properties of target materials. Moreover, up to tens of spectra can be obtained in an experiment due to time-resolved and/or space resolved observation by high performance experimental equipment. For these reasons, individual interpretation of the spectra by the conventional approaches is becoming unrealistic.
In recent years, machine learning (ML) approaches, which can overcome obstacles to handling multidimensional big-data,

have spread in materials science. ML has been applied to spectroscopic data including ELNES/XANES spectra and succeeded in predicting local chemical environment and properties including bond length, bond angle and Mulliken charge [1]. However, few studies have attempted to utilize ML on carbon-K edge ELNES/XANES spectra of functional organic molecules for investigating local chemical properties.
In this research, ML was applied to carbon-K edge dataset generated by theoretical calculations. A neural network model was adopted to extract information about properties of organic molecules from carbon-K edges. Moreover, we added some data about molecules as input data to improve the accuracy of prediction.

Input data of neural network was composed of 240-dimensional vector data of spectral intensities, which were referred to range of 24 eV in 0.1 eV steps. For output data, several molecular properties were selected. Hyperparameters, including the number of hidden layers, the number of neurons and the weight decay parameter, were tuned through cross validation.
To construct the carbon-K edge dataset, 7,941 structural data of organic molecules were extracted from the QM9 database [2,3]. Carbon-K edges were calculated from these data by a first principle pseudopotential method using CASTEP code [4].

Several properties such as HOMO-LUMO gap were successfully predicted, whereas the regression accuracy of internal energy remained at a low level. Careful investigation suggested that it was difficult to accurately predict the extensive properties when only spectral data was used as the input data. We found that the prediction accuracy of these extensive properties could be drastically improved using additional input data about molecules.

In summary, we clarified that carbon-K edges contained sufficient information on organic molecular properties. Our neural network model enebles fast, accurate, and direct prediction of molecular properties from ELNES/XANES, which contributes to a new way to investigate materials properties beyond the conventional comparison approach.

Assessing the Predictive Power of the Pauling Rules Using Modern Data Analysis Janine George, David Waroquiers, Davide Di Stefano, Guido Petretto, Gian-Marco Rignanese and Geoffroy Hautier; Université catholique de Louvain, Belgium

Materials scientists are trying to accelerate the discovery of new materials, for example, by using high-throughput computations and machine learning. Chemical heuristics such as the Pauling rules[1] have long served as the only guide for experimentalists to discover and understand new materials. The Pauling rules promised to be a structure-stability relationship that could accelerate the discovery of stable materials. They relate the coordination environments and their connections to the stability of materials. Despite being a corner-stone of solid-state chemistry and materials science, the Pauling rules have not been systematically and statistically evaluated. Here, we will present such a systematic assessment using modern informatics tools and a recently developed code which automatically detects coordination environments and their connections.[2] Using a database of 5000 known oxides, we will report on the quality of the different Pauling rules and provide a general assessment of their predictive power.[3] Our work shows how traditional empirical rules can now be tested and challenged using modern tools of data analysis and available structural databases.

A Bayesian Approach to Quantify the Single-Crystal Elastic Constants in a Polycrystalline β Metastable Titanium Alloy Ravi raj purohit Purushottam Raj Purohit[1,1], Thiebaud Richeton[1,1], Lionel Germain[1,1], Stephane Berbenni[1,1], Nathalie

Gey[1,1] and Olivier Castelnau[2]; [1]Université de Lorraine, France; [2]Arts et Métiers ParisTech/ CNRS 8006, France

The identification of single-crystal elastic constants (SEC) of a high strength near-β titanium alloy, used in aeronautical applications, has been investigated with a Bayesian approach. The literature on the identified SEC of the cubic β phase in the Ti-alloys shows no substantial agreement, with anisotropic index (Zener ratio) extending from 1.6 to 8 [1]. The directional elastic moduli (DEM) from the X-ray diffraction (XRD) analysis are often used to identify the SEC following the method of Kröner (inverse identification) [2,3]. However, several studies [3,4] have reported that the DEM for Ti-alloy can be insensitive to the bulk modulus, thus resulting in several possible SECs that satisfy the lattice strain evolution. This is addressed by evaluating the SEC at a fixed bulk modulus. In the current study, the high energy XRD and elastic self-consistent modeling [5,6] is revisited with a Bayesian framework and applied to a near-β Ti–10V–2Fe–3Al alloy in its as-forged state (dual phase: 15% of primary hexagonal α_p nodules embedded in a cubic β matrix). The effect of each phase elastic anisotropy was systematically investigated along with different parameters of the micro-mechanical model and also the biases introduced by the XRD data on the identification of the SEC of the β phase. The grain aspect ratio in the self-consistent model, which is often simplified in the literature was found to be the most significant parameter affecting the identification of SEC. The grain shape should therefore be taken into account in the micro-mechanical model when identifying the SEC from diffraction data.

Automatic Generation of Computational Reaction Networks for Unbiased Exploration of Chemical Pathways Evan W. Spotte-Smith[1,2], Samuel M. Blau[1], Xiaowei Xie[1,2], Brandon Wood[1], Hetal Patel[1,2], Shyam Dwaraknath[1] and Kristin A. Persson[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Reaction networks, graph-based representations of the reactions occurring between chemical species, have long served as tools for the identification of chemical pathways and for the study of chemical dynamics. In recent years, high-throughput first-principles calculations have been used to generate computational reaction networks (CRNs) consisting of hundreds of molecules and thousands of chemical reactions. However, the systems thus far considered in CRN literature have been limited by insufficient automation. Specifically, automating calculations involving complex chemistries (ions, open-shell molecules, metal-coordinated molecules, solvated molecules, etc.) remains a challenge.

Here, we present a computational framework for the automatic generation of massive CRNs based on density functional theory (DFT) calculations. Using a robust and accurate level of theory and automated error handling, we have achieved a 95% success rate for DFT calculations of electrochemically relevant molecules. Using graph theory, we can generate CRNs consisting of all possible elementary reactions between the chemical species that we have studied without the use of complex pre-defined mechanisms. Our framework can also automatically identify optimal reaction pathways in massive CRNs based on reaction thermodynamics or energy barriers. As a demonstration of these automated tools, we present a CRN for the formation of the solid-electrolyte interphase in Li-ion batteries consisting of over 8,000 species and over 100,000 chemical reactions, the largest CRN based on reaction thermodynamics yet reported. Using shortest path algorithms, we have recovered critical pathways for electrolyte decomposition in a fully automated fashion, indicating the power of unbiased pathway detection for enhancing chemical understanding.

Microscope is a Laboratory—Supervised and Unsupervised Automated Experiment in Scanning Probe and Electron Microscopy Sergei V. Kalinin, Maxim Ziatdinov, Kyle Kelly, Ondrej Dyck, Stephen Jesse, Andrew Lupini and Rama Vasudevan; Oak Ridge National Laboratory, United States

Discovery, optimization, and design of novel materials is the primary challenge facing civilization in the XXI century. The transition from simple functionalities in structural, optical, and semiconductor materials to complex intertwined functionalities in batteries, fuel cells, information technology and sensor devices renders the classical paradigm of serendipitous discovery and sequential optimization impractical and necessitates alternative pathways for materials discovery and optimization. One, actively explored at present, paradigm is automated experimentation and guided or combinatorial synthesis combined with rapid throughput characterization. However, a second pathway can be developed based on modern imaging tools including scanning probes and electron microscopy that allow us to not only visualize and probe functionalities of materials on the nanometer and atomic scales, but also to introduce controllable modifications in materials. Effectively, we aim to discover the defined mesoscopic and atomic structures and probe their functional properties, establish the pathways towards controllable creation of these structures, and ideally extend these towards macroscopic assemblies. Here, we discuss possible strategies towards autonomous experimentation (AE) in STEM and SPM. We demonstrate the examples of Bayesian optimization-based workflows for AE SPM and STEM using prior data sets, and discuss the development of the acquisition and pathfinder functions. We further discuss opportunities for the development of self-training AE workflows in microscopy, where the features of interest are unknown a-priori and are discovered during the experiment. The experimental realization of these concepts is demonstrated for ferroelectric domain manipulation and electron-beam induced chemical reactions.

Contrasting Error Cancellation in *Ab Initio* and Machine Learning Predictions of Thermodynamic Stability Christopher Bartel[1], Amalie Trewartha[1], Qi Wang[2], Alexander Dunn[2,1], Anubhav Jain[2] and Gerbrand Ceder[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

The realization of autonomous materials discovery depends critically on the ability to predict whether a given material will be synthesizable. This problem is generally addressed *in silico* by calculating the thermodynamic stability of candidate materials using density functional theory (DFT). There have been many recent claims that this step can be greatly accelerated using machine learning instead of DFT to predict the formation energy of inorganic solids. However, thermodynamic stability is ultimately dictated by relative formation energies between chemically similar competing phases, and not by the absolute formation energy of any single compound. It is therefore essential to assess how well these machine learning predictions of intrinsic thermodynamic quantities generalize to the problem of relative materials stability. In this work, we systematically probe this question by testing a diverse set of materials representations and learning algorithms on a variety of problems that simulate real applications of materials discovery. Our findings emphasize the value of including structure in materials representations and suggest that error cancellation plays a critical role in the prediction of thermodynamic stability.

6:20 AM F.MT07.03.09
Automated Calculation and Convergence of Defect Transport Tensors Thomas D. Swinburne[1] and Danny Perez[2]; [1]CNRS / CINaM, France; [2]Los Alamos National Laboratory, United States

Defect transport is a key process in materials science and catalysis, but as migration mechanisms are often too complex to enumerate a priori, calculation of transport tensors typically have no measure of convergence and require significant end user intervention. These two bottlenecks prevent high-throughput implementations essential to propagate model-form uncertainty from interatomic interactions to predictive simulations. In order to address these issues, we extend a massively parallel accelerated sampling scheme[1], autonomously controlled by Bayesian estimators of statewise sampling completeness, to build atomistic kinetic Monte Carlo models on a state space irreducible under exchange and space group symmetries. Focusing on isolated defects, we derive analytic expressions for defect transport tensors and provide a convergence metric by calculating the Kullback-Leiber divergence across the ensemble of diffusion processes consistent with the sampling uncertainty. The autonomy and efficacy of the method is demonstrated on surface trimers in tungsten and hexa-interstitials in magnesium oxide, both of which exhibit complex, correlated migration mechanisms[2].

Machine-Learning Approaches to Elucidate Structure-Property Relationships in 2D Materials Siyu I. Tian[1], Alexandra Carvalho[2], Zekun Ren[1], Mohammed AlEzzi[2], Antonio H. Castro Neto[2], Kostya S. Novoselov[2] and Tonio Buonassisi[1,3]; [1]Singapore-MIT Alliance for Research and Technology, Singapore; [2]National University of Singapore,

Singapore; [3]Massachusetts Institute of Technology, United States

Over the past decade, the family of 2D crystals increased dramatically, with 2D materials now covering a huge range of properties: metallic, semiconducting, ferromagnetic, superconducting… As the field attempts to engineer materials properties by design, an outstanding challenge is to develop high-accuracy predictive models that reversibly connect material structure with their properties. Herein, we adapt the recently-proposed Fourier Transform of Crystal Properties (FTCP) framework [1] to 2D materials, toward generating an invertible crystallographic representation of 2D materials suitable for materials search and inverse design tasks. When we train on ~2000 2D materials in the publicly available 2DMatPedia database, we can predict simple ground-state properties such as formation energy with mean average errors of 281 meV/atom. When a transfer-learning approach is employed, whereby ~51,000 3D materials from MaterialsProject are used, the mean average error of formation energy predictions improves to 209 meV/atom. We believe this framework presents a promising approach to predict certain ground-state properties of 2D materials, and may potentially extend to other properties in the near future.

Jump Planner for Autonomous Materials Discovery Chiwoo Park[1], Peihua Qiu[2], Jennifer Carpena-Núñez[3], Rahul Rao[3], Michael Susner[3] and Benji Maruyama[3]; [1]Florida State University, United States; [2]University of Florida, United States; [3]Air Force Research Laboratory, United States

We propose an autonomous AI planner that recommends the next experiments based on the outcomes of all past experiments with the goal of materials discovery in accelerated paces. We are particularly interested in accelerating an experimental campaign for mapping out an unknown relation of experimental conditions to the experimental outcomes of interest, e.g. resulting material properties and kinetic rates of reaction. The relation often has discontinuities in that there are abrupt changes in the experimental outcomes for a small change in the experimental conditions over some boundary regions such as boundaries of reaction equilibrium or chemical regime changes. In such cases, many conventional experimental planners, exploiting the continuity and smoothness of the relation, cannot be applicable. We propose a jump planner to optimize the experimental planning under discontinuities of the underlying relation to discover. Its application will be illustrated with carbon nanotube growth experiments with various catalysts.

5:15 AM F.MT07.04.02
Autonomous Discovery of Materials for Intercalation Electrodes Felix Tim Bölle, Tejs Vegge, Juan Maria Garcia Lastra and Ivano E. Castelli; Technical University of Denmark, Denmark

The development of automated computational tools is required to accelerate the discovery of novel battery materials. In this work, we design and implement a workflow, based on Density Functional Theory calculations, to autonomously identify materials to be used as intercalation electrodes in batteries. The materials selection is based on thermodynamic and kinetic descriptors, such as adsorption energies and diffusion barriers. A substantial acceleration for the calculations of the kinetic properties is obtained thanks to the recent implementation of the Nudged Elastic Bands (NEB) method, which takes into consideration the symmetries of the system to reduce the number of images to calculate. We have applied this workflow to discover new cathode materials for Mg batteries, where two of these materials display a threefold increase in the potential of the Chevrel phase, the state of the art cathode in commercial prototype Mg batteries. In addition to the discovery of new materials, the dataset produced with this workflow has been used to train a machine-learning algorithm to accelerate and generalize the discovery of electrodes, beyond Mg-ion batteries.

Largest Possible Mobility of Molecular Semiconductors and Strategies to Achieve It Tahereh Nematiaram, Daniele Padula, Alessandro Troisi and Alessandro Landi; University of Liverpool, United Kingdom

A large database of known molecular semiconductors is used to define a plausible physical limit to the charge carrier mobility achievable within this materials class. From a detailed study of the desirable properties in a large dataset, it is possible to establish whether such properties can be optimized independently and what would be a reasonably achievable optimum for each of them. All relevant parameters are computed from a set of almost five thousand known molecular semiconductors, finding that the best known materials are not ideal with respect to all properties. These parameters in decreasing order of importance are the molecular area, the nonlocal electron-phonon coupling, the 2D nature of transport, the local electron-phonon coupling, and the highest transfer integral. It is also found that the key properties related to the charge transport are either uncorrelated or "constructively" correlated (i.e., they improve together) concluding that a tenfold increase in mobility is within reach in a statistical sense, on the basis of the available data. It is demonstrated that high throughput screenings, when coupled with physical models of transport produce both specific target materials and a more general physical understanding of the materials space.

5:35 AM F.MT07.04.04
Crystal Synthesis Prediction Using Deep Learning Ali Davari and Sara Kadkhodaei; University of Illinois at Chicago, United States

Predicting the synthesizability of hypothetical crystals has proven to be challenging due to the wide range of parameters that govern the crystalline materials synthesis. In this work, we convert the atomic structures of known synthesized or observed crystals in databases into three-dimensional pixel-wise images color-coded by chemical species and electronegativity and use them to train a deep-network convolutional autoencoder(CAE). We extract the latent features of synthesizability hidden in structural and chemical arrangements of crystalline materials embedded in the auto-encoder. The accurate classification of materials into synthesizable crystals vs. crystal anomalies based on these features across a broad range of crystal structure types and chemical compositions confirms the validity of our model.

5:45 AM F.MT07.04.05
Physically Informed Deep Learning for Accelerated Photosensitizer Discovery Jiali Li, Shidang Xu, Pengfei Cai, Xiaoli Liu, Bin Liu and Xiaonan Wang; National University of Singapore, Singapore

Photodynamic therapy is arising as a non-invasive treatment modality for cancer and other diseases. One of the key factors to determine the therapeutic function is the efficiency of photosensitizers (PSs). According to the latest studies, reducing the energy gap (ΔE_{ST}) between the lowest excited singlet state (S_1) and lowest excited triplet state (T_1) was an effective approach to yield highly efficient PSs, and ΔE_{ST} could be fine-tuned through precise molecular donor-acceptor engineering. There is a growing literature where small families of small-ΔE_{ST} PS compounds are explored experimentally, or purely computationally at a slightly broader scale. Here, we report a large-scale data-driven search for novel PSs, with a special focus on red PS. This work comprehensively integrates computational quantum chemistry, machine learning, organic synthesis, and nanoagent fabrication and testing.

By providing the list of commonly used donors, acceptors and bridges, there is a chemical design space of more than 7 million possible PSs. Such a vast search space can hardly be explored by chemical intuitions or Edison's approaches. Even performing quantum calculations of this vast space can take infeasibly long time. A data-driven approach by screening the ΔE_{ST} of 7 million PSs with a well-trained deep learning model provides a possible solution. Herein, we have created a high-throughput quantum calculation toolset for the construction of a novel dataset of 10k PSs with ΔE_{ST} information. This training dataset contains representative donors, acceptors and bridges with both Donor-Acceptor and Donor-Acceptor-Donor structures. A molecular graph convolutional neural network with molecular structure as features is trained on this dataset. In combination with a high-throughput PS generator, we could efficiently predict the ΔE_{ST} of possible PSs within the chemically intuited design framework. In order to further improve the performance of the predictive model, we have also employed a transfer learning approach. In addition to this physically informed design model, we utilize a motif-based hierarchical encoder-decoder (hgraph2graph) as another deep learning method for the direct generation of possible PS candidates. These two approaches will be compared with results discussions. Furthermore, the experimental validation of chosen PSs with low ΔE_{ST} is conducted and presented. Finally, the potentials and limitations of this work will be discussed.

5:00 AM *F.MT07.05.01
Machine Learning of Experimental Databases for Predictions and Discovery of Novel Functional Materials Ichiro Takeuchi; University of Maryland, United States

Combinatorial experimentation has become a well-established technique to explore new compounds with enhanced physical properties in a variety of functional materials fields. High-throughput experiments are particularly effective when designs and layouts of combinatorial libraries are guided by predictions. With the advent of high-throughput computational screening, it is now possible to come up with a large list of possible new compounds quickly. In many areas of functional and quantum materials, however, it remains a formidable challenge to make accurate predictions through computational means. When properly curated experimental databases are available, it is also possible to mine such databases in order to identify trends among known materials compositions and make predictions of new materials. As an example, we have previously developed machine learning models of superconductors based on the SuperCon database within MatNavi (NIMS, Japan) which contains over 29,000 experimental entries. Although SuperCon lacks structural property information, random forest regression was able to build models, which can decipher key distinctions between different families of superconductors. In many materials areas, such an approach is unfortunately hampered by the lack of sufficiently large experimental databases with very few exceptions. I will discuss our recent work where we have combined structural property predictions using ICSD with compositional information in order to identify trends in materials discoveries and make predictions based on clustering of known compounds through neural network. This work is carried out in collaboration with Valentin Stanev, Haotong Liang, and A. Gilad Kusne, and is funded by NIST.

Platform for Polymer Inverse-Design by Graph Generative Algorithms Seiji Takeda[1], Toshiyuki Hama[1], Hsianghan Hsu[1], Victoria Piunova[2], Dmitry Zubarev[2], Daniel Sanders[2] and Daiju Nakano[1]; [1]IBM Research - Tokyo, Japan; [2]IBM Almaden Research Center, United States

1. Introduction
Designing “tailored” material that possesses desired characteristics is a long-awaited technology. Especially molecular design is important across broad industrial domains. It is to solve a complex combinatorial problem in terms of molecule’s atomistic configuration patterns, that significantly exceeds 10^{60}. In this extra-vast parameter space, human SMEs (Subject-Matter-Experts) can only explore around a tiny space by trial-and-error relying on their experience and knowledge. To accelerate their design speed and expand the structural variety of molecules, AI can play a key role. Several AI molecular design tools and algorithms exist [1,2], but following issues in practical use are unaddressed; (1) deep learning - based methods rely on extremely large amount of material data, (2) models are black box, therefore hard to tune for chemists, (3) customization for specific material domains is not supported, (4) a certain level of IT skill is required to use. To address those issues, we developed a platform for small organic molecules [3]. In this paper, we exhibit customization of the tool for polymer domains and demonstrate to design new acrylic polymers having specific Tg (glass transition temperature).
2. Method
The fundamental workflow of our tool consists of sequential 5 steps; (1) data input, (2) feature encoding, (3) property prediction, (4) solution search, and (5) structure generation. First, a data set listing pairs of chemical structures and target properties is input as a training dataset. Structures are encoded to a set of feature vectors, by which a regression model to predict target properties is built. After the model is built, a user inputs target property values. The system performs the solution search to identify candidate feature vectors that satisfy the target property values. Finally, the feature vectors are decoded to concrete molecular structures by improved Mckay’s Canonical Costruction Path algorithm, that builds up a molecular graph by connecting atoms and substructures indicated in the feature vector. That process is called “inverse-design”; to solve a model inversely starting from target properties.
We further customized the tool for polymer domain; first, the tool identifies monomer’s main chain and extract only side chain structures as a part to design. Second, structure generation algorithm is reinforced by structural constraints to avoid chemically unrealistic structures.
3. Results
To demonstrate inverse-design of polymers, from PolyInfo we extracted acrylic polymer data consisting of 378 pairs of SMILES and Tg. Side chain structures are extracted from the acrylic main chain, and encoded to about 50 dimensional feature vectors, in which each element represents a number of substructures. Regressions were carried out on the feature vectors to predict Tg. The best regression model exhibited determination coefficient R^2~ 0.68 corresponding to RMSE~ 30 C°. Inverse-design was carried out on the model targeting Tg ~ 150 C°. Running several hours, more than 100 structures were generated, that is significant acceleration in design speed compared with typical SMEs. The generated structures were

reviewed by a polymer SME for screening, and some of the candidates were successfully synthesized in the lab.

Platform in Service

The above platform is running on the cloud of IBM. They are provided as-a-service to our client companies for research purpose. Two interfaces; Python-based command line interface and GUI-based web application are provided to cover broad range of user's IT-skills. In the presentation, we will also demonstrate the web application.

Navigating Chemical Composition Spaces Using Gaussian Processes and Representation Learning Jens S. Hummelshoej, Muratahan Aykol, Joseph H. Montoya, Linda Hung and Santosh Suram; Toyota Research Insititue, United States

Rapid experimentation and discovery of materials has typically centered around high throughput screening of materials in high-dimensional composition settings. Machine learning assisted selection of composition spaces is expected to significantly accelerate the experimental materials discovery process. To achieve this, frameworks that enable learning across composition spaces are necessary. A central aspect of such a framework is digital representation of compositions that are tuned for the composition-property mapping task of interest. While generic descriptors of elements exist we show that a framework that learns these representations for a specific task significantly outperforms generic representations.

Specifically, in this talk we present methodologies to learn composable digital representations of the chemical elements that enable learning about composition-property relationships across composition spaces. We demonstrate these methodologies by predicting formation energy, band gap in compositional spaces that cannot be interpolated from the training composition spaces. We also demonstrate that digital representations learned from simulation data can be transferred to predict experimental data.

Further, we demonstrate large scale predictions of formation energy by combining digital representation of elements, physical constraints into a Gaussian process framework. We demonstrate that using physical constraints and clustering based on covariances we can address the scalability limitations of Gaussian processes, allowing their deployment for large scale discovery applications. Finally, this work provides a framework to accelerate extrapolative exploration of composition spaces for materials discovery.

5:35 AM F.MT07.05.05

Machine Learning Based Design of Transition Metal Catalysts Gabriel dos Passos Gomes[1], David Balcells[2], Alán Aspuru-Guzik[1] and Pascal Friederich[3,3]; [1]University of Toronto, Canada; [2]University of Oslo, Norway; [3]Karlsruhe Institute of Technology, Germany

Homogeneous catalysis using transition metal complexes is ubiquitously used for organic synthesis, as well as technologically relevant in applications such as water splitting and CO_2 reduction. Automatic selection and optimization of catalysts also plays a very important role for automated and autonomous experimental synthesis platforms. The key steps underlying homogeneous catalysis require a specific combination of electronic and steric effects from the ligands bound to the metal center. Finding the optimal combination of catalysts and ligands is a challenging task due to the exceedingly large number of possibilities and the non-trivial ligand–ligand interactions. We show how quantum mechanical calculations and machine learning (ML) methods can be combined to enable the prediction of reactivity within large chemical spaces containing thousands of complexes. We illustrate our approach using the classic examples of the Vaska's complex [1] as well as a gold catalyzed cyclization reaction. We compare multiple different machine learning methods based on their accuracy, interpretability as well as their ability to learn from small amounts of data. In contrast to experiments and calculations requiring several days to be completed, the ML models were trained and used on a laptop on a time-scale of minutes.

5:45 AM *F.MT07.05.06

Accelerating Materials Discovery Using Autonomous Experimentation R. B. Van Dover[1], Michael O. Thompson[1], Carla

Gomes[1], Bart Selman[1], John Gregoire[2] and Max Amsler[1]; [1]Cornell University, United States; [2]California Institute of Technology, United States

High throughput combinatorial methods have accelerated searches for new materials, but most remain constrained by experimental limitations and human decisions. We are developing fully autonomous methods that enable discovery of functional materials, especially non-equilibrium materials that have yet to be synthesized by traditional techniques. To achieve this goal, we use a hierarchy of closed-loop processing/characterization agents (systems) to identify and execute an experimental strategy that optimizes the deployment of experimental resources (time, money, and access). This results in extremely efficient exploration of broad composition and processing spaces leading to the rapid and autonomous discovery of new metastable phases.

At the experimental level, we employ lateral-gradient Laser Spike Annealing to process amorphous thin film composition-spread libraries prepared on standard Si wafers. A variety of optical and X-diffraction (XRD) techniques are used to identify regions in the high-dimensional space {composition fractions {xi}, temperature T, dwell/quench time, t} that are associated with distinct crystal structures and/or microstructures. While optical characterization alone cannot label crystal structures or crystallographic texture, these low cost optical techniques are very sensitive and can rapidly identify transitions that provide valuable prior knowledge for structural XRD studies, either asynchronously through subsequent follow-up autonomous investigations at synchrotron sources, or synchronously in a fully coupled autonomous experimental loop.
Intelligent exploration of the high-dimensional space requires effective active learning—using the results of initial and accumulated characterization of the phase space to decide the next [{xi},T,t] condition to be explored. This involves real-time interaction of the experiments with a community of AI-based agents that must: (a) interpret optical or XRD patterns to create a model of the evolving “processing phase diagram,” (b) identify the conditions that, when characterized, are most likely to decrease uncertainty in the boundaries of this map, (c) direct automated equipment to execute the chosen processing, and (d) complete the loop by managing and controlling optical or XRD characterization. To tackle this challenge, we employ various Gaussian Process (GP) models with carefully designed kernels that capture subtleties of the physics associated with the transformations.

This approach enables us to identify regions with distinct structures. To determine the particular crystal structure(s) associated with each region, we apply novel computational techniques that we have developed and that have proven to be highly effective at automated crystal structure phase mapping. Example results from several systems will be used to demonstrate the current state of these agents and the overall process.

As these methods are fully realized, we will achieve the key goals of:
* developing a methodology for real-time closed-loop autonomous synthesis/process/characterization experiments using active learning
* identifying opportunities and demonstrating examples where state-of-the-art AI methods offer unique advantages for scientific experimentation
* creating new materials with superior functional properties, and advancing our understanding of the fundamentals of phase transformation in rapid-thermal-processed materials.

6:00 AM F.MT07.05.07
Automatic Cyclometalated Iridium(III) Complex Design Using a Data-Driven Fragmentation Representation of Molecules Hsianghan Hsu[1], Seiji Takeda[1], Toshiyuki Hama[1], Jed Pitera[2] and Daiju Nakano[1]; [1]IBM Research - Tokyo, Japan; [2]IBM Almaden Research Center, United States

Data is a resource to drive discovery, fueled by multiple factors such as new funding, open source, and AI. Inspired by demands from the materials industry, an inverse design solver accompanied with an end-to-end AI-based tool for small organic molecule design is developed. Our published studies show good correspondence between predicted properties and calculated values [1]. In this report, we extend the scope of our tool, ensuring that the newly generated ligands form optimized Ir(III) complex structures, and finally perform validation through DFT simulations confirming energy gaps large enough to blue light LED material candidates.

Cyclometalated Ir(III) complexes are a well-established class of metal-organic compounds with attractive photophysical properties [2]. The design of the ligands around the Ir ion dominates the performance. By using open data sets and reliable models, a vast number of ligand candidates can be generated. However, considering the complexity of the three-fold symmetric structure, it is still difficult to effectively calculate representative characteristics even when subject matter expert insight is included. An automatic, high throughput workflow is discussed in the followings.

Initial searches extracted 1400 samples with CIE 1931 color coordinates and SMILES information. For deep blue emission the target values are (0.15, 0.12). This corresponds to a calculated energy gap larger than 2.5 eV according to experience. Multiple fused rings in the ligands leads to encode features with atom count, ring count, substructures, and fingerprints. In the prediction step, the hyper-parameters are further optimized by exhaustive grid search algorithm. The model with highest cross validation score is input to estimate new features and ligand generation.

In parallel, another framework is established to inherit the generated results. Newly generated ligands are converted to 3D structures and optimized by force field. Although the tris-heteroleptic Ir(III) complex is the more general use case, the detail of dealing with tris-homoleptic ones is described here. The two coordinating ions (A and B) to Ir ion are identified by a rule-based algorithm with more than 90 % accuracy. The three ligands coordinates are put in a 3D space without interference and Ir ion is located at the origin. The atom and bonding information are updated and do 2nd structure optimization. Because the ligand structures are optimized prior to the attachment, the degrees of freedom can be reduced to only three for the purpose of finding energy in global minimum. Three ligands are rotated simultaneously along the vector sum of Ir-A and Ir-B. By using genetic algorithm with many enough iterations, the angle combination with the lowest total energy is obtained. Finally, the hydrogen atoms are attached and ready for DFT simulation.

The workflow is validated by reproducing the numbers in [3]. There are 100 samples with tabulated values of LUMO, HOMO, dipole moment, S1, and T1 wavelength. Different software and parameters (G98 vs. GAMESS) are used. The results show good correspondence with R-square scores: 0.98, 0.98, 0.74, 0.71, and 0.89. With this framework, we can validate the newly generated ligands also have large enough band gap energy such as c1cnc2ccn3cc(C4CCCCC4)nc3c2c1 (4.20 eV), c1ccc2c(c1)ncn1c3ccccc3nc21 (3.64 eV).

The framework is capable of forming facial and meridional coordination geometries by adjusting the fitness in the optimization algorithm. Multiple dockerized packages provide such workflow automation. The potential of the developed tool is still increasing by adapting the customization for other functional materials.

Extracting Relevant Features For Understanding and Predicting Metal-Insulator Materials from Machine Learning Models Alexandru Georgescu[1], Aubrey R. Toland[2], Peiwen Ren[1], Nicholas Wagner[1], Elsa Olivetti[2] and James Rondinelli[1]; [1]Northwestern University, United States; [2]Massachusetts Institute of Technology, United States

Metal-insulator transition (MIT) compounds are both of high technological interest, with potential applications to low-power computation and transistors, glass coatings and of broad general scientific interest, as the metal-insulator transition is due to a rich interplay of complex electronic and atomic degrees of freedom. This interplay makes it difficult for high-throughput, first-principles approaches to find potential MIT candidates, while machine-learning approaches can be difficult to implement and understand due to the limited number of known MIT compounds. In this work we show that, using a gradient boosted decision tree, we can nonetheless obtain a surprisingly strong model to predict which materials may or may not exhibit thermally driven MITs. By comparing a model in which the most important features of the materials are extracted automatically, to one in which they are added gradually and physically informed using domain knowledge, we extract novel insights into the physics of metal-insulator transition materials, as well as into how best to search for improved MIT material candidates.

Inferring Physical Laws of Material Degradation in Perovskite Solar Cells Using Machine Learning Richa R. Naik,

Armi Tiihonen, Shijing Sun, Zhe Liu and Tonio Buonassisi; Massachusetts Institute of Technology, United States

To date, most applications of machine learning (ML) in materials science have focused on process optimization and improving engineering parameters of merit. Inferring physical laws directly from data has a great potential to accelerate materials research by allowing us to extract generalizable scientific information from the data. In this study, we explore the use of ML algorithms to study perovskite degradation, with the aim of gaining knowledge of the underlying degradation mechanisms. The environmental instability of halide perovskite materials hinders the commercialization of perovskite solar cells. The degradation mechanisms are still not fully understood due to the complexity of degradation phenomena. The functional space of feasible physics equations capturing these mechanisms is enormous [1]. Furthermore, experimental data is noisy and often sparse, making inference of quantitative analytic descriptions even more challenging.

We show a case study of perovskite degradation to infer physical laws from data and we interpret them in the context of proposed theoretical degradation pathways for perovskites [1]. We analyze simulated datasets for the degradation of perovskites under heat and continue to experimental data: Methylammonium lead iodide (MAPI) films subjected to degradation in our in-house environmental chamber at various temperatures, low humidity, and 0.15 sun illumination. We monitor their degradation using an optical camera extracting color versus time, capturing the transition from black MAPI to yellow lead iodide (PbI_2). Utilizing experimental and modeled data, we conduct a systematic study modeling degradation processes using a (1) traditional regression approach, (2) fitting parameters to partial differential equations (PDEs), and finally shifting to (3) symbolic regression of PDEs [2, 3, 4].

We find that the regression approaches extract variables of interest with relative errors as low as 2%, even with 5% Gaussian noise superimposed upon the simulated datasets. However, this requires knowledge of the equation form. We demonstrate that sparse regression [2] identifies the underlying equation from noiseless data with errors less than 10%. We have PDE extraction calculations underway, with preliminary results, governing physical laws for MAPI degradation using a genetic programming algorithm for symbolic regression [3]. We examine three data-driven algorithms for learning differential equations and find that they are generally challenged to fit exponential equations (common to many materials-science problems) and handle noise. We conclude that the study of materials degradation can be rendered more quantitative, by including inference of physical laws of degradation, using regression and potentially ML-based PDE extraction techniques. We also opine about the gap that exists between ML-based tools today and common materials science challenges.

Learning to Electrodeposit Corrosion-Resistant Alloy Coatings Through Autonomous Electrochemical Experimentation Brian L. DeCost[1], Howie Joress[1], Bruce Ravel[1], Suchismita Sarker[2], Apurva Mehta[2], Najlaa Hassan[1], Trevor Braun[1] and Jason R. Hattrick-Simpers[1]; [1]National Institute of Standards and Technology, United States; [2]SLAC National Accelerator Laboratory, United States

Autonomous laboratory systems continually learn by adaptively planning and executing campaigns of physical and/or in silico experiments to achieve a scientific or engineering goal without requiring direct human intervention. The current research community is demonstrating new opportunities in accelerated materials synthesis, evaluation, and optimization, but major challenges remain for application of robotic systems for broader scientific discovery in materials and chemistry. Foremost, current AI systems used in robotic science applications make and test predictions, but lack the mechanistic modeling components needed for formulating and evaluating scientific hypotheses that explain these predictions in terms of generalizable physical principles. Furthermore, learning to reliably synthesize materials, and reconciling multiple structure and property data streams make it difficult to comprehensively explore complex and multiscale structures that determine the performance of engineering materials.

This talk will focus on technical and methodological aspects of building AI agents that drive closed-loop synthesis and characterization platforms and deploying them for scientific discovery. We explore these issues using an autonomous scanning droplet cell (ASDC) platform designed for on-demand alloy electrodeposition and real-time electrochemical characterization. Our initial studies seek to jointly optimize electrochemical deposition of binary ZnNi alloys while maximizing their corrosion resistance properties. We present exploratory research incorporating mechanistic transport models into the Gaussian Process modeling framework we use for surrogate modeling and active selection of experiments. We also discuss the challenge of disentangling the effects of chemistry, crystal structure, and microstructure on material properties, focusing on corrosion resistance within a ternary NbTiTa refractory alloy system that we have characterized with a multimodal X-ray diffraction and corrosion study.

As the materials community surmounts the challenge of incorporating mechanistic modeling components into our machine learning systems, automated materials synthesis and characterization platforms offer much more than black-box optimization of engineering materials: they offer the potential to develop and deploy new algorithms for generating and testing scientific hypotheses.

Late News: Representations for Data-Driven Material Discovery Kiran Vaddi and Olga Wodo; University at Buffalo, United States

Representations play a crucial role in building predictive models using data driven approaches. In this work we present a representation based approach to high-throughput experimental data analysis of X-ray diffraction (XRD) and Cyclic Voltammetry (CV)--where the input is systematically swept and the response is collected for all the materials screened. A common data representation in above cases is to use the output as an n-dimensional vector with discrete inputs as corresponding dimensions/components. In this talk, we present a couple of other representations namely a metric space and a function space representation with a goal to encode known physical knowledge. We evaluate the representations in two different case studies with applications involving material discovery and cyclic voltammetry. Our first case study involves using a metric space representation where topology of the sampled data is captured using a physics based metric. Metric space representation presented in this talk is an automated way of computing distance measure and achieves comparable accuracy to computationally complex, expert defined distance measures. A second case study involves a function space representation tailored for CV data analytics. We use covariance functions of Gaussian process (GP) as basis functions to encode the two dimensional CV curve onto a vector space represented by the basis functions. We show that the GP based methodology presented here is analogous to using images with each pixel represented using a Gaussian distribution thus allowing us to use well developed image analysis techniques for downstream analysis. We present two case studies of function space representations 1) iterative design of experiments to identify materials with fast kinetics in a electro-chemical environment with application to catalyst discovery of oxygen reduction and evolution reaction 2) iterative identification of an optimal mechanism from a set of postulated mechanisms by combining experiments with a physics based model. Approaches presented here will also highlight the importance of building a physics based representation of data for downstream analysis.

Topology-Driven Completion of Chemical Data Dmitry Zubarev and Petar Ristoski; IBM Research - Almaden, United States

Efficient discovery of novel functional materials strongly relies on development of the exploration strategies in the chemical space. In this contribution we are describing an approach that helps to identify lacunae in the existing data and complete the missing pieces in a targeted manner. The proposed approach consists of 2 main steps.

Step 1: We perform topological data analysis on the set of molecules. Molecular set is treated as a point cloud with pair-wise distances defined using standard chemoinformatic approaches. We apply the Mapper algorithm [1] to produce a simplified description of the data in a form of a graph G=(C,E), where C is a set of clusters represented as nodes, and E is the set of all edges. Each node in the graph represents a cluster of molecules, and an edge between 2 clusters indicates that the clusters overlap. Mapper graph directly visualizes such aspects of the data shape as holes and branches (loops and flares on the Mapper graph, respectively), which indicate that there is missing data. Our task, therefore, is to generate new molecules that fill out the loops (elimination of the branches can be done in a similar fashion). First, we search for the scaffolds in the dataset that are most promising for the molecule generation. Operationally, we prioritize scaffolds found in small clusters along big loops on the Mapper graph. For each cluster we identify the smallest (in terms of hops) loop l using the Dijkstra's algorithm [2], then we calculate the length of the cycle w_l, which is the sum of the length of each edge in the loop. For each

molecule in each cluster we calculate the Bemis-Murcko scaffolds $S=\{s_1,s_2,...s_n\}$. For each scaffold s we introduce the generative potential $g_s = \Sigma_{cs}\ mean(|C|)\ w_{lc}\ /|c_i|$ where c_s are all the clusters where the scaffold appears, and the w_{lc} is the length of the cycle for that cluster. A high g_s value indicates that the scaffold appears in small clusters with large cycle length, meaning they are part of bigger loops, and have a higher potential for generating novel molecules. We normalize the g_s values between 0 and 1.

Step 2: To generate novel molecules that complete loops on Mapper graph we adapt an existing graph-generative model for scaffold-based molecular design, using variational autoencoders (VAE). Here, the input scaffold is extended by sequentially adding atoms and bonds, i.e., the generation is conditioned on the existing scaffolds, making sure that all generated molecules contain the input scaffold. We modify the standard VAE loss function to take in consideration the generative potential of the scaffolds: $L = (1 - g_s)\ (L_r + L_{KM} + \alpha\ (g_s - g_{sn}))$, where α is a hyperparameter between 0 and 1, g_{sn} is the generative potential of the scaffold of the newly generated molecule, L_r is the reconstruction error of the input s and generated scaffold s_n and L_{KL} is the Kullback-Leibler divergence between the prior and approximate posterior distribution. With this loss function we reduce the influence of the scaffolds with low generative potential and penalize the model when it generates molecules with low generative potential g_{sn}. To calculate the g_{sn} of a new scaffold, we include the newly generated molecule in the Mapper analysis after each iteration.

We will discuss the application and performance of the described approach to the exploration of the space of photo-acid generators.

Molecule Representation Governs Predictive Accuracy—Case Study on Predicting Minimum Inhibitory Concentration of Large Molecules
Armi Tiihonen[1], Sarah J. Cox-Vazquez[2], Harry Q. Liang[1], Zekun Ren[3], Noor Titan Putri Hartono[1], Shijing Sun[1], Guillermo Bazan[2] and Tonio Buonassisi[1]; [1]Massachusetts Institute of Technology, United States; [2]National University of Singapore, Singapore; [3]Singapore-MIT Alliance for Research and Technology, Singapore

Much progress in molecular property prediction has been made by generating and curating datasets, and developing machine-learning (ML) models. However, to increase predictive accuracy of machine-learning-driven research, combining these two with improved data representations (which capture the structural and chemical features relevant for property prediction) remains an outstanding challenge. This is especially true for large, non-rigid molecules containing more than 30 atoms. Proper data representation maximizes the probability that an ML algorithm will successfully infer correlations between molecular structure and chemistry and output properties of interest.

There are a multitude of successful molecule representations in literature [1-2], but a remaining limitation especially in understanding large molecules is the ability to efficiently capture both chemistry and three-dimensional (3D) structure. Molecular fingerprint sets can be designed as a combination of features reflecting the 3D structure and chemistry of the molecule but may have a limited generalizability. SMILES strings provide a straightforward method for mapping the molecular structure into 1D, and graph representations develop the idea further to capture bonds between the molecules, albeit using a dimensionless representation.

We investigate molecule representations from the viewpoint of capturing both chemistry and 3D structure. We show a case study of predicting antibiotic potential of large (20–100 carbon atoms) antibiotic molecule candidates via an experimentally measured indicator, minimum inhibitory concentration. Our consistent investigation involves comparison of different representations ranging from chemistry only to ones attempting to integrate 1D – 3D structure (chemistry-only and structure-capturing features downselected automatically from a set of 5000 potential features, SMILES, and molecular bond graph with combinations of the previous ones), compared in traditional and complex models (including random forest regression and directed message passing neural network [3]).

We demonstrate the power of improving model predictions by focusing on optimum representation, show that representation can be tuned utilizing models with faster ramp up time, and find that structure-capturing representation improves predictive accuracy especially when the data consists of large, non-rigid molecules. Our systematic case study highlights the importance

of data representation when optimizing for predictive accuracy.

Active Learning Guided Online Materials Synthesis and Full-Map Understanding Xiaonan Wang; National University of Singapore, Singapore

The rapid development of deep learning enabled artificial intelligence (AI) has brought new opportunities to accelerate conventional experimental design in materials science. The discovery of high-dimensional synthesis recipes that yield desired material properties used to be costly and time-consuming, while advances in machine learning (ML) driven high-throughput experiments are able to rapidly achieve optimal conditions to produce the target materials. I will introduce our recently developed online active learning approaches that can effectively guide experiments and achieve full-map understanding of the design space.

The first case study demonstrates a two-step active learning framework that combines Bayesian Optimization (BO) and Deep Neural Network (DNN) in a loop with a high-throughput microfluidic platform, to optimize the synthesis of silver nanoparticles with the desired absorbance spectrum. In Step I, the optimization process is accelerated by the offline introduction of DNN after a few runs of targeted sampling through BO with a Gaussian Process. In step II, the DNN is allowed to sample the parameter space using grid optimization to test its regression function. The fully trained DNN can then predict absorbance spectra around the target and possibly optimize the synthesis towards a new target.

The second case study further extends the active learning method to a hierarchical AI framework, which is tested for strain sensor material synthesis. The challenge to obtain customized sensing devices with designated working windows comes from the complex and unclear structure-composition-property relationships that are hard to predict and pre-design. A feasibility classifier using support vector machine (SVM) is first constructed as the screening layer towards the material design. An active machine learning loop is then designed to perform full-map exploring and learning by sampling the “most informative” data points to perform explorations. Besides, comprehensive algorithm optimization is performed for better AI prediction performance. The framework enables a full-map understanding to the system and provides new insights and principles for sensor design.

Moreover, we have developed a series of interpretation and visualization approaches to understand "black-box" ML models and make them more favoured by domain experts to extract knowledge of complex systems that embed a huge amount of hidden information. Although promising opportunities are identified, many challenges exist this highly interdisciplinary field, such as construction of valuable and open datasets, in-depth understandings of descriptors, lack of standard algorithms workflow and fully autonomous experimental platforms, which will be briefly discussed as future directions.

Meta-Reinforcement Learning as the Driver of Data Acquisition in Autonomous Polymer Discovery Sarathkrishna Swaminathan, Chinyere Agunwa, Victoria Piunova, Krystelle Lionti, Daniel Sanders and Dmitry Zubarev; IBM Research, United States

Discovery and development of polymer materials is strongly driven by experimental data acquisition. Polymer materials have

to be prepared and characterized in order to be patentable. The immediate outcome of the polymerization reaction can be transformed into multiple materials with strikingly different properties by means of formulation and processing. Potential for IP development increases sharply as the polymerization product evolves via formulation and processing into the final material. Experimental data acquisition, therefore, unfolds under conditions of delayed rewards on incredibly rich landscapes shaped by access to multiple experimental degrees of freedom that can be both continuous (concentration, temperature, radiation, time) and categorical (monomers, catalysts, initiators, solvents) [1,2].

In the presented contribution, we report results of the ongoing effort in the development of an end-to-end reinforcement learning (RL) approach to the experimental data acquisition in the polymer material domain. The application is the development of a simple spin-on-glass. It starts with the acquisition of initial experimental data, proceeds to training a RL agent to search for the experimental settings (generating experimental hypothesis) that produce materials with desired properties, then to applying a trained RL agent to design the experimental plan, and finally to executing the experimental plan using the existing robotic platform. We identify and discuss the following factors that we are systematically addressing:

- Direct access to the lab equipment during the training phase is impractical; given the complexity of the polymer synthesis and processing, therefore, the most viable option is to prepare a surrogate model of the system and use it to set up the RL environment. The optimal choice of the surrogate as well as handling the uncertainties deserves systematic investigation.

- The task of materials discovery often comprises a search for multiple promising solutions, both search and enumeration, but not necessarily global optimization. The search task can be learned in the narrow context of the specific experimental project (cf. navigation of one specific maze); a significantly stronger result is to train a RL agent to navigate experimental landscapes *as such* (cf. learning general strategies of maze navigation). This brings meta-learning to the top of the priority list [3].

- RL is notoriously data-greedy; meta-learning further amplifies the need for abundant and diverse training data. Therefore, data augmentation is necessary, particularly around creating families of the surrogate models. The specifics of the data augmentation, that leads to optimal performance, needs careful observation.

- As is generally the case with RL, the reward system plays a big role. One possible (and informative) approach is to develop reward systems that mimic effective “rewards” and “penalties” for human researchers solving similar data acquisition tasks.

On the artificial intelligence angle, we describe the specifics of the implementation (OpenAI Gym based environment, and RL algorithms) and discuss obtained performance metrics and approaches to the diagnostics of the RL agent behavior.

Model-Based Reinforcement Learning for Predictive Synthesis of MoS_2 Pankaj Rajak[1], Aravind Krishnamoorthy[2], Ankit Mishra[2], Ye Luo[1], Rajiv Kalia[2], Aiichiro Nakano[2] and Priya Vashishta[2]; [1]Argonne National Laboratory, United States; [2]University of Southern California, United States

Scalable synthesis of two-dimensional (2D) materials is a major bottleneck to more widespread adoption of layered material-based devices. Chemical vapor deposition (CVD) has emerged as a viable method for large-scale synthesis of 2D materials. However, neither experiment nor theory has been able to decipher mechanisms and selection rules for different growth scenarios or make predictions of optimized growth parameters. Here, we have designed a workflow using model-based reinforcement learning (RL) and neural autoregressive density estimator (NADE-CVD) to generate the optimal synthesis condition for the prototypical two-dimensional semiconductor, monolayer MoS_2 with high 2H-phase fraction in minimum time from MoO_3 crystal. Here, the NADE-CVD models the probability density function of CVD-synthesis and is trained using 15,000 reactive molecular dynamics (RMD) simulation trajectories each for 20 ns of MoS_2. After training, NADE-CVD serves as a dynamics model of CVD-synthesis and interacts with the RL agent. Using the reward singles from the dynamics model, the RL agent is able to propose synthesis conditions (such as temperature profile and S_2, H_2 and H_2S partial pressures) and their dependencies among each other that generates MoS_2 crystal with maximum 2H phase fraction quickly, thus paving the way toward rational design of CVD synthesis techniques for MoS_2 and other layered materials.

This work was supported as part of the Computational Materials Sciences Program funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, under Award Number DE-SC0014607. Simulations were performed at the Argonne Leadership Computing Facility under the DOE INCITE program and Aurora Early Science programs and at the Center for High Performance Computing of the University of Southern California.

5:35 AM F.MT07.06.04
Accelerating Inverse Design of Conjoined Photovoltaic and Thermoelectric Generator Systems via Physics-Driven Machine Learning Aleks Siemenn, Tonio Buonassisi and Zhe Liu; Massachusetts Institute of Technology, United States

Humanity is accumulating magnitudes of data for many discrete components — but how do we best utilize these data to improve complex systems? The world of "big data" begins to intersect "systems engineering." In this contribution, we contemplate a model system — conjoined photovoltaic and thermoelectric generators (PV+TEG) — which has tens of design variables and corresponding response curves [1]. However, with such voluminous design and response data (in machine-learning parlance, "vast state space"), it is unclear how we can inversely map the response data back to our design variables to improve system energy yield under a given set of operating conditions. Therefore, to leverage the supply of big data coming from our simulated and experimental systems such as PV+TEG, we propose a framework for system optimization via supervised surrogate models (*e.g.*, neural networks) and model-free optimization (Bayesian optimization, BO), which combines the advantages of embedded physics domain knowledge and adaptability to complex action-responses outside the model.

Conducting system optimization using this framework promotes high-throughput iterative design cycles for faster rates of learning [2]. There is great importance in optimizing new or existing systems using high-throughput iterative design because by informing a new design based on learning data trends rather than experimentally building a new system each iteration, significant savings are seen in time, energy, and material costs [2]. In the example of solar energy, photovoltaics and thermoelectric modules are both well-established technologies individually, however, by drilling down to the design components of each device, the thermoelectric module can be better optimized to improve the energy yield of a photovoltaic device, in turn, requiring a smaller area to generate the same power. The working principle of this system improvement framework is that: (1) physics-driven models establish the fundamental relationship between PV+TEG design variables and response outputs; (2) experimental response curves provide ground-truth relationships for a narrow band of design variables and outputs; (3) physics-fusion neural networks combine simulated and experimental response data to build robust inferences of feasible PV+TEG designs [3]; (4) the manifold of PV+TEG design variables is searched by BO to generate operational system designs that maximize energy yield. We demonstrate that with large volumes of operational system data, neural networks and Bayesian optimization are used to accelerate the convergence on optimal photovoltaic and thermoelectric generator designs by 10x relative to the state of the art Multiphysics simulation while allowing more parameter customization [4]. By reducing design time, fiber laser-powered gallium arsenide PV+TEGs will be explored in a gamut of small-scale applications to maximize energy transmission efficiency.

5:45 AM F.MT07.06.05
Inverse Design of Nanoporous Crystalline Reticular Materials with Deep Generative Models Zhenpeng Yao[1,2], Benjamín Sánchez-Lengeling[1], N. Scott Bobbitt[3], Benjamin Bucior[3], Tom Woo[4], Omar Farha[3], Randall Snurr[3] and Alán Aspuru-Guzik[1,2]; [1]Harvard University, United States; [2]University of Toronto, Canada; [3]Northwestern University, United States; [4]University of Ottawa, Canada

Reticular frameworks are crystalline porous materials that form *via* the self-assembly of molecular building blocks (*i.e.*, nodes and linkers) in different topologies. Many of them have high internal surface areas and other desirable properties for gas storage, separation, and other applications. The notable variety of the possible building blocks and the diverse ways they can be assembled endow reticular frameworks with a near-infinite combinatorial design space, making reticular chemistry both promising and challenging for prospective materials design. Here, we propose an automated nanoporous materials

discovery platform powered by a supramolecular variational autoencoder (SmVAE) for the generative design of reticular materials with desired functions. We demonstrate the automated design process with a class of metal-organic framework (MOF) structures and the goal of separating CO_2 from natural gas or flue gas. Our model exhibits high fidelity in capturing structural features and reconstructing MOF structures. We show that the autoencoder has a promising optimization capability when jointly trained with multiple top adsorbent candidates identified for superior gas separation. MOFs discovered here are strongly competitive against some of the best-performing MOFs/zeolites ever reported. This platform lays the groundwork for the design of reticular frameworks for desired applications.

AMANDA—An Autonomous Materials and Device Application Platform for the Laboratory of the Future and the Next Generation Materials Research Christoph J. Brabec[1,2]; [1]FAU, Germany; [2]Forschungszentrum Jülich GmbH, Germany

The development of high performance, stable solar cell materials poses a multi-objective optimization problem in a considerable multidimensional parameter space. Solving it requires reproducible, user independent laboratory work and intelligent preselection of conducted experiments. However, research on organic photovoltaics (OPV) is a field where manual routines are still predominant, although other domains like pharmacy have long used robotics and automation.
To better utilize automation in materials science, we introduce AMANDA (Autonomous Materials and Device Application Platform), a generic software framework for distributed materials research and its research line LineOne (L1), a robotic facility for the production and characterization of solution processed solar cells.
We integrated pipetting and transport robots with spin coating and evaporation units as well as characterization tools like spectrometers and electrical measurements into LineOne. With this setup, the AMANDA Platform automatically produces and measures OPV cells without human interaction while it is capable of rapidly screening large materials and processing parameter spaces in a combinatorial approach at high precision. The current hardware configuration is fully scalable and allows the high throughput screening of up to 270 variations per day on LineOne. The output comprises the complete fabrication of solar cells, full characterization and comprehensive documentation of all applied process steps as well as compiled results for each individual solar cell. We demonstrate the capabilities of AMANDA by the process development for OPV solar cells based on PM6:Y6 with 13.7% efficiency when processed in air and through the detailed investigations of the impact of subtle process parameters, like solution concentration and volume of solution deposited for spin coating, on film quality and performance.

5:15 AM F.MT07.07.02
An Automated Formulation System to Accelerate Development of Printed Thin-Film Materials Kane L. Scipioni[1], Amir H. Khalighi[1], Kuya Takami[1], James A. Corson[1], Colin J. McNeece[1], Michael C. Heiber[1], Christopher L. Farrow[1], Roger T. Bonnecaze[2] and Eric Jones[1]; [1]Enthought, United States; [2]The University of Texas at Austin, United States

Formulation chemistry is big business for a wide variety of industries, where formulated fluids cover a market worth hundreds of billions of dollars per year. Formulations for printing applications represent one of many components of this market and include a diverse range of products from consumer inks to advanced electronic materials. Industrial ink formulations can be extremely complex with a wide range of specifically selected components to impart multifunctionality on the final dry film. Film materials have important requirements for optical, electrical, and mechanical properties as well as longer-term chemical, temperature, and UV stability. In addition, formulations must meet specific surface tension and viscosity criteria to be printable. Meeting these complex requirements requires optimization over many dimensions. In our experience working with various specialty chemical companies, we have observed that, most often, these formulation optimization experiments are still performed using slow, labor-intensive workflows. This dramatically limits what can be explored given realistic budget constraints.

In recent years, advances in machine learning together with greater accessibility of robotic automation tools have enabled a new paradigm of accelerated materials development using autonomous research systems. In the printed electronics space, several exemplary autonomous research systems have been recently created.[1,2] However, these systems have been designed to create thin films by spin-coating or drop-casting, which are less applicable to large-area, high-throughput industrial

manufacturing processes. Previous systems have also used robotic pipetting to measure out different formulations in a slow batch-based process.

To tackle real industry problems with our clients, we have developed a modular automated system for rapid flow-based microfluidic formulation, fluid characterization, inkjet printing, and film characterization. As opposed to the methods used in previous autonomous systems, inkjet printing is a key enabling additive manufacturing technology that is mature and widely used for high volume manufacturing. The system includes multiple characterization modes along the workflow, including shear-rate-dependent viscosity, complex jetting behavior, and final film quality. Where possible, we have also been developing low-cost hardware modules to help alleviate the sticker shock that often occurs when new automated systems are proposed to business units with tight R&D budgets.

In our first case study, the system was able to improve upon an existing manual process used to develop polymer films for display applications. The legacy process took around 35 person-hours per recipe, including slow ink formulation, printing, characterization, and cleaning. The new system reduced that worker time to almost zero and features automated cleaning, freeing up skilled researchers' time to work on other tasks. The system now takes about 15 minutes to investigate each recipe with minimal human interaction and is also able to rapidly map out the multidimensional printability window. One of the key enablers of this was the inkjet stroboscopic imaging setup. There is a wealth of information in the dynamic shape of jetted droplets which correlates strongly with the viscoelasticity, surface chemistry, and microstructure of the fluid. We are currently implementing an experiment planning and scheduling system that can execute various strategies for hierarchical optimization. With this in place, the system will not simply maximize sample throughput but also focus on performing experiments where the likelihood of knowledge gain is the highest.

Applications and Development of an Autonomous Alloy Electrochemical Deposition and Corrosion Platform Howie Joress[1], Brian L. DeCost[1], Bruce Ravel[1,2], Suchismita Sarker[3], Najlaa Hassan[1], Trevor Braun[1], Apurva Mehta[3] and Jason R. Hattrick-Simpers[1]; [1]National Institute of Standards and Technology, United States; [2]Brookhaven National Laboratory, United States; [3]SLAC National Accelerator Laboratory, United States

We present our work on the development and application of a mesofluidic electrochemical deposition and analysis platform. Our scanning droplet cell (SDC), coupled with a bank of syringe pumps is capable of serial electrodeposition and electrochemical corrosion measurements on millimeter scale areas. We have also demonstrated integration of our platform into the 6-BM end-station at NSLS-II to add in situ x-ray fluorescence and diffraction capabilities. In addition to describing this platform in detail, we will present two validation studies: In the first we use this system for serial corrosion measurements of sputtered combinatorial thin-film metallic glass and high-entropy alloy libraries. Second, we will discuss our on-going efforts to combine synthesis and characterization, controlled by an autonomous AI agent. In this work we look at the effect of electrodeposition processing parameters for Ni-Zn plating, such as solution concentration and bias, on alloy corrosion resistance, composition, and structure. Our goal here is to experimentally generate a machine learning based model to describe optimal deposition conditions for an arbitrary alloy composition in its most corrosion resistant state and describe the corrosion behavior of that alloy. In this way, we hope that this system can transcend simple optimization and can begin to decouple the interplay of deposition, structure, and corrosion resistance in order to generate new knowledge.

Accessing Creativity and Institutional Knowledge of Polymer Chemists via Expert-in-the-Loop AI—Case of Acrylic Polymer Design Victoria Piunova[1], Dmitry Zubarev[1], Petar Ristoski[1], Anna Lisa Gentile[1], Linda Kato[1], Seiji Takeda[2], Toshiyuki Hama[2], Hsianghan Hsu[2], Daiju Nakano[2], Daniel Gruhl[1], Seteve Welch[1] and Daniel Sanders[1]; [1]IBM Almaden Research Center, United States; [2]IBM Tokyo Research Laboratory, Japan

With ever increasing demand of the modern world for the materials with advanced properties, we are facing the pressure to accelerate the discovery through a paradigmatic shift. One of the major practical bottlenecks – actionability bottleneck - is majority of the computationally generated hypotheses fail to transition to the experimental phase. In this case, the target properties are expected to meet project requirements, but the candidates fail to satisfy broader project-specific constraints. The most problematic constraints represent institutional knowledge, broadly defined. Institutional knowledge is not systematically captured in publications, but rather carried by subject matter experts (SMEs). This explains fundamental

difficulty of capturing institutional knowledge, introducing it into the training phase of statistical modeling, and propagating into the hypothesis generation phase.
This contribution addresses resolution of the actionability bottleneck via capture and instantiation of SME's creativity and institutional knowledge in the form of AI models. This is accomplished using a two-tiered expert-in-the-loop (EITL) approach [1,2]. Specifically, we considered monomer design for acrylic polymers. The first tier of EITL AI included training a discriminator that was reproducing SME's decision-making in the adjudication of the candidate monomers. The candidate monomers were generated using recently developed system for molecular inverse-design [3]. The SME – a polymer chemist responsible for the polymerization experiments – accepted or rejected the candidates as they answered the question: "Is it practical to synthesize this monomer?" The question, as discussed with the SME, implied subjective assessment of the synthetic accessibility, expected behavior during polymerization, and novelty. The second tier of EITL AI leveraged the adjudication results and the trained discriminator to train a generative model producing monomer candidates that were likely to be accepted by the SME. We trained 2 sequential neural network models and 3 generative adversarial networks (GANs); generative models were refined via separate adjudication of their output until acceptable performance was reached. At this point the generative form of EITL AI combined implicit models of SME's knowledge and creativity as both these components informed the adjudication processes.
The trained generative component of EITL AI was queried by the SME to identify candidates for the experimental phase. The generated structures were evaluated on the basis of novelty and synthetic complexity. Selected structures were additionally assessed based on the following criteria:

- the ease of synthesis or commercial availability for the monomer precursor
- the number of transformations, their difficulty, commercial availability and price of starting materials and reagents
- the ease of polymerizable handle installation on the monomer precursor
- the ability of the obtained monomer to be polymerized in a free radical polymerization process

Five monomers were selected to produce acrylic polymers. Performance metrics of the AI models, experimental procedures, and polymer characterization results will be discussed along with existing challenges and potential extensions.

Robot-Accelerated, Data-Enabled Investigation into Metal Halide Perovskite Reaction Networks Zhi Li[1], Jakob Dahl[2,1], Mansoor Ani N. Nellikkal[3], Joshua Schrier[4], Alexander Norquist[3] and Emory Chan[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]Haverford College, United States; [4]Fordham University, United States

We present the development of high-throughput, data-enabled strategies for understanding the crystallization and chemical transformations of metal halide perovskites in the form of macroscopic single crystals and nanocrystals. These approaches combine robotic synthesis workflows developed at the Molecular Foundry with data-driven approaches that can predict crystallization outcomes and elucidate reaction networks. We will first discuss our Robot-Accelerated Perovskite Investigation and Discovery (RAPID) workflow, which we used to rapidly identify and optimize synthesis conditions for the formation of high quality single crystals via inverse temperature crystallization (ITC). A total of 8172 metal halide perovskite synthesis reactions were performed using 45 organic ammonium cations. Robotic screening increased the number of metal halide perovskite materials accessible by an ITC synthesis route by more than five-fold and resulted in the formation of two new phases. The resulting dataset enabled the construction and evaluation of machine learning models that were able to predict the formation of a diverse range of crystal compositions and morphologies with >85% accuracy after only 100 reactions. We used the same robotic apparatus to systematically explore the reaction networks that produce cesium lead bromide nanocrystals. Deploying automated spectroscopy and a custom deconvolution algorithm to extract the relative populations of each reaction product (i.e. molecular clusters, nanoplatelets, and nanocubes), we generated phase maps of the high-dimensional Cs-Pb-Br synthetic space. Based on these maps, we attempted chemical transformations from each of the as-synthesized products to all other species. The resulting transformation data revealed a dynamic equilibrium between species and allowed us to construct chemical reaction network that provides a holistic view of this weakly reversible system. This work demonstrates the concept that combining high throughput experimentation, machine learning, and data-enabled approaches accelerates and enhances the study of metal halide perovskite crystallization, and that this approach is generalizable across different synthetic routes, materials, and their length scales.

6:00 AM F.MT07.07.07
A Framework Enabling AI-Assisted High-Throughput Experimentation Linda Hung[1], Brian Rohr[1], John Gregoire[2], Li Cheng Kao[3], Jens S. Hummelshoej[1], Wenhui Li[3], Junko Yano[3], Steven Torrisi[4] and Santosh Suram[1]; [1]Toyota Research Institute, United States; [2]California Institute of Technology, United States; [3]Lawrence Berkeley National Laboratory, United

States; [4]Harvard University, United States

The acceleration of high-throughput experimental discovery involves several recurring challenges such as data ingestion, visualization, analysis, and recommendation. In this talk, we describe how the ACE (AI-assisted Catalyst Experimentation) framework addresses these challenges and enables scientists to improve decision-making in high-throughput experimentation.

We highlight the following aspects of our framework:

1. Data Ingestion: We describe an experimental database schema that has minimal built-in assumptions, follows FAIR principles, and is expected to generalize to a wide variety of scientific applications using one of the largest experimental datasets as an example.[1]

2. Data Visualization: Scientists can easily navigate the database by using a domain specific language as part of the UI. These queries are bolstered with visual aids about metadata. In addition, the UI automatically provides a set of useful visualizations for dataset statistics, trends, and details of individual samples and processes.

3. Analysis: Analysis of materials characterization data remains one of the critical bottlenecks for high-throughput experimental materials discovery. We present specific examples for AI-assisted analysis of X-ray spectroscopy to demonstrate the capabilities of our framework to address this bottleneck.

4. Recommendation: The current recommendation capabilities of our framework include a) sequential recommendation for accelerated discovery within a composition space, b) recommendation of composition spaces for experiments using representation learning. We demonstrate these capabilities for learning formation energy, band gap, and catalytic properties. We also show human and machine benchmarks for sequential learning within a specific composition space.

These components that make up ACE are designed to be modular and generalizable; and aim to provide foundational infrastructure for accelerated adoption of machine learning for diverse high-throughput experimental applications.

Benchmarking the Performance of Bayesian Optimization Across Multiple Experimental Domains Harry Q. Liang[1], Aldair E. Gongora[2], Zekun Ren[3], Zhe Liu[1], Armi Tiihonen[1], Shijing Sun[1], Flore C. Mekki-Berrada[4], Saif A. Khan[4], Daniil Bash[5], Kedar Hippalgaonkar[5], Keith A. Brown[2], John W. Fisher[1] and Tonio Buonassisi[1]; [1]Massachusetts Institute of Technology, United States; [2]Boston University, United States; [3]Singapore-MIT Alliance for Research and Technology, Singapore; [4]National University of Singapore, Singapore; [5]Agency for Science, Technology and Research (A*STAR), Singapore

High-throughput autonomous research has recently emerged as the new frontier of accelerated materials discovery. This success has sparked efforts to improve not only lab automation infrastructure but also optimization algorithms. In materials optimization campaigns, sequential learning approaches such as Bayesian Optimization (BO) have gained great popularity due to their ability to improve parameters of merit with fewer number of experiment cycles in comparison to brute-force approaches. Previous attempts to quantitatively evaluate the acceleration of research through sequential learning have been limited to specific materials systems [1]. Therefore, two open questions that remain are: (a) how does performance of BO in sequential learning approaches vary across multiple experimental domains and manifold complexities. (b) how we could improve upon current optimization algorithms and attend to the needs of a broader materials science community.

In this work, we benchmark the performance of sequential learning approaches within the BO framework across four experimental domains. Each focusing on a different materials system, four experimental datasets with varying sizes, dimensionalities and dataset manifold complexities are used to build representations of ground truths, where we draw from these to simulate optimization campaigns. We compare the performance of BO algorithms employing one of three surrogate models and five myopic acquisition functions. The performance of each surrogate model and acquisition function pair is benchmarked against random acquisition, and further quantified via learning rate metrics designed to measure different research objectives.

It is observed that BO consistently reduces the number of experiment cycles necessary to reach superior materials response by factors of 5 to 15 across all experimental systems. Random forest surrogate model paired with a lower confidence bound acquisition function of balanced mean and standard deviation shows higher-ranking performance for research tasks such as finding any or all of the candidates with top 5% response. Interestingly, in the case of surrogate models, random forests outclass gaussian processes in optimization tasks when using the same acquisition functions across all datasets, likely due to their nature of making fewer structural assumptions about manifold landscapes. In addition, we further explore the benefits of utilizing look-ahead decision policies as an alternative to the traditional myopic acquisition functions in the BO framework. Complementary to our findings, our benchmarking effort has yielded many useful insights on how experimentalists interested in novel materials systems could select the most suitable BO methods prior to embarking on an optimization campaign. These can be utilized by a broader materials science community in further progressing the field of autonomous research.

Reassessing High-Dimensional Optimization Strategies Using Interpretable Machine Learning For Perovskite Solar Cell Manufacturing Zhe Liu[1], Nicholas Rolston[2], Zekun Ren[3], Felipe Oviedo[1], Harry Q. Liang[1], Reinhold H. Dauskardt[2] and Tonio Buonassisi[1,3]; [1]Massachusetts Institute of Technology, United States; [2]Stanford University, United States; [3]Singapore-MIT Alliance for Research and Technology, Singapore

Developing novel scalable fabrication processes for perovskite PV devices involves optimizing many process variables, which is challenging for human intuition alone to solve the problem efficiently. Autonomous high-throughput experimentation has recently demonstrated a very encouraging outcome to aid rapid materials development[1–3]. Preliminary success has also been demonstrated by introducing machine learning (ML) in the loop to guide the experiments[4] for developing a fabrication process. However, the black-box nature of machine learning is a key limitation that hinders wide adoption in physical science research[5]. Although ML is a powerful statistical tool to navigate and optimize in a high-dimensional space, rigorously-trained materials scientists are not able to easily understand the decisions made by ML algorithms. Due to this lack of model interpretability, researchers usually find it difficult to intellectually engage with ML-driven optimization.

In this work, we investigate how we can work cooperatively with an ML algorithm and maximize the acceleration of the optimization process. To do so, we revisit a historical dataset of perovskite devices with open-air spray deposition, and then adopt commonly used sequential learning methods to navigate the process optimization of perovskite solar cells. Based on this case study, we find three generalizable points to better utilize machine learning tools for materials research. **First, initial sampling is crucial to ensure rapid optimization.** We compare different initial sampling methods, *e.g.*, chronological, random, and Latin hypercube sequences, and find the initialization method plays an important role to facilitate the subsequent optimization. Without a good initial design of experiments guided by domain knowledge, the acceleration benefits with an ML algorithm is very limited. **Second, the acquisition and objective functions need to be tuned for different research objectives of optimizing device performance or building a predictive regression model.** By assigning different weights to "exploitation" and "exploration", we evaluate the optimization outcomes for various acquisition functions with different regression models. Echoing previous findings by Rohr *et al.*[6], we also observe that acceleration in building a predictive model is not necessarily easy with sequential learning algorithms, but it could significantly accelerate the process optimization of device efficiency (where up to 2x acceleration could be found). **Third, the algorithm interpretability allows researchers to engage with the ML model and avoid mistakes**. At each step, our framework helps visualize how sampling decisions are made by the ML algorithm: whether an acquisition decision is influenced more by the predicted mean or the predicted uncertainty, whether it favors exploration in the unsampled regions or exploitation in the known regions, or which process variable has the highest impact on the decision. We envision the impact of this work as a human-in-loop machine-learning platform where researchers can understand the framework of ML and utilize ML algorithms to accelerate the research of novel materials.

Accelerated Quantum Dot Development in Flow—Convergence of Flow Chemistry, Colloidal Synthesis and Machine Learning Milad Abolhasani; North Carolina State University, United States

Metal halide perovskite quantum dots (QDs) have recently emerged as an exciting class of semiconducting materials, outperforming conventional II-VI, IV-VI, and III-V semiconductor nanocrystals in QD-based optoelectronic devices.[1] Despite the substantial improvement in performance of perovskite QD-based optoelectronic devices over the past five years, two major obstacles hinder their development: **(i)** Edisonian (trial and error)-based QD synthesis, discovery, and optimization methods, and **(ii)** poor size dispersity of batch-synthesized colloidal nanocrystals, resulting in surface trap states. Existing material development strategies very often fail to overcome the demands of colloidal QDs' vast colloidal synthesis and processing universe, resulting in time- and cost-intensive QD development efforts.
Recent advances in machine learning (ML),[2] including deep neural networks (DNNs) and reinforcement learning algorithms, provide an exciting opportunity for reshaping the synthesis and development of perovskite QDs, through the machine-based direction of a high-throughput QD synthesis bot. Capitalizing on the recent progress of ML-based optimization algorithms, *smart* QD manufacturing strategies relying on DNNs trained on experimentally measured QD properties can be envisioned to accelerate the discovery, synthesis, and manufacturing of metal halide perovskite QDs with application-guided optoelectronic properties.
In this talk, I will present an *Artificial Chemist*,[3] a modular intelligent fluidic microprocessor[4] capable of autonomous synthesis, optimization, and end-to-end manufacturing of colloidal QDs for direct utilization in high-performance and low-cost optoelectronic devices. The Artificial Chemist can rapidly and efficiently **(i)** explore the massive parameter space of colloidal perovskite QDs, **(ii)** learn their synthesis and processing schemes, **(iii)** identify the composition and relevant synthesis route(s) of perovskite QDs to achieve specific optoelectronic properties, and **(iv)** continuously manufacture the rapidly optimized perovskite QDs at a fraction of time/cost of batch techniques. The reconfigurable Artificial Chemist technology utilizes a multimodal *in-situ* material diagnostic probe (absorption/photoluminescence (PL) spectroscopy) in conjunction with a real-time, ensemble DNN adaptive sampling algorithm to enable simultaneous optimization of PL quantum yield and emission linewidth of colloidal QDs for any desired peak emission energy. The Artificial Chemist technology can be readily adapted for accelerated development and autonomous end-to-end manufacturing of other solution-processed nanomaterials.

6:45 AM F.MT07.07.11
Using Quantified Uncertainty to Guide Efficient Phase Diagram Determination via Sequential Learning Theresa Davey[1], Brandon J. Bocklund[2], Zi-Kui Liu[2] and Ying Chen[1]; [1]Tohoku University, Japan; [2]The Pennsylvania State University, United States

Phase diagrams are a fundamental tool in materials design, but thorough experimental determination is challenging, expensive, and time consuming. Phase diagrams calculated entirely from first-principles may reduce time and expense, providing information at the prediction stage. Our previous work demonstrated a methodology to obtain a first-principles only CALPHAD-type solid phase diagram reproducing all major features, with little or no prior knowledge of the system [1]. This can guide reduced experiments needed for database validation.

Considering the quantified uncertainty of the first-principles phase diagram using PDUQ [2] and ESPEI [3], a sequential

learning approach is taken to systematically add thermodynamic and phase boundary data in regions of highest uncertainty. This simulates how the first-principles only phase diagram can most efficiently guide experimental investigation towards a thorough understanding of a materials system. This convergence towards a target phase diagram will be quantified and compared to the chronological introduction of experimental data.

6:55 AM F.MT07.07.12
A Unified Bayesian Approach to Learning Many-Body Potentials Jonathan Vandermause and Boris Kozinsky; Harvard University, United States

A number of competing frameworks for learning interatomic potentials have been proposed in the last decade, including Gaussian Approximation Potentials (GAP), Spectral Neighbor Analysis Potentials (SNAP), and the Atomic Cluster Expansion (ACE). We here present a Bayesian approach that unites these three frameworks, allowing uncertainty estimates on many-body energies, forces, and stresses to be rigorously computed. We first show how a multi-species generalization of the 3-body ACE descriptor can be used to define an efficient many-body kernel similar to the Smooth Overlap of Atomic Positions kernel used in GAP models. We use this kernel to construct Gaussian process (GP) models of the potential energy surface, and show that uncertainties derived from the predictive posterior distribution of the GP correlate with true model error on independent test sets. Mean predictions of the GP are shown to be linear in an integer power of the descriptor, eliminating the expensive loop over training points required in GP regression and establishing a connection to the SNAP framework. The resulting linear models are implemented in the molecular dynamics program LAMMPS, and shown to achieve competitive performance for a range of molecular and extended systems.

The predictive uncertainties of our Gaussian process models open the door to automated training during molecular dynamics simulations, allowing a wide range of material compositions to be explored in a closed-loop fashion. In this approach, training structures are selected with active learning by making calls to density functional theory only when the predictive uncertainty on a force component exceeds a threshold value. We apply this on-the-fly molecular dynamics method to the shape memory alloy nitinol, and show that we accurately capture the martensite/austenite phase transition that occurs in this material at ambient pressure. Guided by model uncertainties, we systematically expand the training set to examine the effects of dopants, defects, and nonequiatomic compositions on the martensitic transition temperature.

Automated Workflows for Surface Generation and 0D and 2D Structural and Electronic Optimisation and Analysis via WASP@N and SAINT Helen Duncan and Scott Woodley; University College London, United Kingdom

Automating materials calculations to populate a searchable and curated web-accessible database is non-trivial problem. Moreover, we are interested in enabling the model creation, initialisation of simulations and control of the workflow (as well as the content of the database) from a webpage interface which unfortunately leads to an additional conflict between increasing the desirable accessibility/functionality whilst maintaining security to prevent malicious cyber-attacks. Over a period of 10 years we have developed and implemented a combined hardware (housing the webserver, database and dedicated compute node) and software solution to handle such workflows. To date, we have applied our approach to assisting two different communities: those interested in research based on the atomic structure of clusters, or small sized nanoparticles; and those interested in simulations of surfaces and their reactivity with probe molecules. The former is part of the WASP@N project, whereas the latter is part of the UK's Materials Chemistry HEC Consortium's SAINT project. Both offer access to a database of their respective models, which users can also contribute, and include useful tools for analysis via their web-interfaces.

WASP@N (Web-Assisted Structure Prediction at the Nanoscale) was developed to support the dissemination and comparison of atomic configurations found from global optimisation studies of energy landscapes, which can subsequently be used as models for further studies (their electronic and physical properties or their interaction with other media). All uploaded structures are automatically optimised using the FHI-aims electronic structure code and hyperlinks – based on either composition, energy, and connectivity – that users can follow are created between both the original and refined structures and other entries in the database (all uploaded structures are also linked via DOI to their original publication).

SAINT (The Surface and Interface Toolkit) was developed to support researchers' day-to-day surface simulations, by

providing tools for generating surface models and enabling automatic calculation of surface energies using the CRYSTAL electronic structure code. SAINT offers fully relaxed surface models for a range of metal oxides and maps of their reactivity to three probe molecules; the ability to generate surfaces and then download input files for a range of different DFT and IP codes; and a method of dissemination of published surface models.

Here we will first discuss our insights into hardware and software solutions for such automation and database population along with the need to balance security of the data with ease of accessibility and how this can be applied to other databases and automation. Next, we will demonstrate a case-study using SAINT to produce reactivity maps of non-polar surfaces for a range of compounds with respect to three probe molecules, and how this information can streamline simulations of surfaces with more complex reaction species.

Applying Automated Process Analytical Technology to Challenges in Material Synthesis Jason Hein; University of British Columbia, Canada

Optimizing multicomponent chemical processes is a challenge which lends itself well to automation due to the large number of experiments usually required. In addition to classic high throughput and Design of Experiment methodologies, the application of online analytical tools provides real-time feedback and therefore acute control over the chemistry in question. This approach enables fundamental insights to be translated into practical application at an unprecedented pace, particularly when coupled to machine learning capabilities. Herein we present two examples of automated process analytical technology designed to resolve bottlenecks in materials R&D and chemical manufacturing.

The supply of specific, high-performance molecular conductors is critical to the development of organic photovoltaic devices. Unfortunately, the gold-standard molecule used almost ubiquitously (Spiro-OMeTAD) is notoriously expensive as its synthesis remains underdeveloped. To address this challenge, we have developed a range of automated tools capable of formulating reactions, taking samples, and performing online HPLC analysis. Our versatile platforms are also compatible with air sensitive chemistry occurring in an inert atmosphere. We use these tools to generate temporal reaction profiles and rapidly optimize the synthesis of key materials such as Spiro-OMeTAD.

As a second case study, we apply advanced crystallization methodologies inspired by the pharmaceutical industry to access battery-grade lithium carbonate from waste brines. The dynamic nature of crystallization requires the continuous assessment of sample purity and the corresponding manipulation of crystallization parameters. Our suite of process analytical technology provides comprehensive data on sample composition (IC, FTIR), turbidity (computer vision), and crystal growth (microscopy) to enable feedback control and consistently isolate high-purity product.

5:15 AM F.MT07.08.02
Transferable Nonlocal Exchange Density Functionals via Machine Learning Kyle W. Bystrom and Boris Kozinsky; Harvard University, United States

Due to its computational efficiency compared to other quantum mechanical methods, semi-local density functional theory (DFT) is a popular tool for simulating large, complex systems like surfaces, interfaces, point defects, and battery cathode materials. However, the complex electronic structure of these systems cannot be described accurately by the approximate exchange-correlation (XC) functionals used in semi-local DFT. More accurate methods, such as exact exchange and post-Hartree Fock, are prohibitively expensive for large systems. To remedy this problem, we introduce nonlocal exchange density functionals that are fit via machine learning (ML) and can be computed more efficiently than the exact exchange energy. We build on work in both analytical and ML functionals to perform feature engineering that enables the use of lightweight, smooth, and transferable machine learning models. We explore how Gaussian Processes can be used to construct uncertainty estimates of the exchange energy and assess the performance of different kernels. To construct large training

databases, we also develop code to evaluate the exchange energy density on real-space grids. To benchmark this new class of functionals, we implement the functional derivatives to find the exchange potential and use it in self-consistent field calculations on a diverse set of small molecules.

5:25 AM F.MT07.08.03
Quantifying Uncertainty in High-Throughput Density Functional Theory Vinay Hegde[1], Christopher K. Borg[1], Zachary del Rosario[1,2], Yoolhee Kim[1], Maxwell Hutchinson[1], Erin Antono[1], Julia Ling[1], Paul Saxe[3], James E. Saal[1] and Bryce Meredig[1]; [1]Citrine Informatics, United States; [2]Olin College of Engineering, United States; [3]Virginia Tech, United States

The completely automated nature of high-throughput density functional theory (HT-DFT) creates unique challenges, such as how to choose DFT parameters and post-processing techniques that work across all materials classes, and strike an effective balance between computational cost and accuracy. These challenges have been tackled in different ways by the several large HT-DFT databases that have emerged so far. However, the effect of the different approaches on the calculated materials properties is as yet unclear. Here, we quantify the uncertainty in the HT-DFT properties resulting from such different-yet-reasonable parameter choices, by consolidating three large HT-DFT databases: Automatic-FLOW (AFLOW), Materials Project, and the Open Quantum Materials Database (OQMD), onto a common data platform and analyzing comparable records. Overall, we find the variance in reported properties between HT-DFT databases to be comparable to that between DFT and experiment. We identify the underlying physical factors responsible for some of the larger discrepancies, and outline paths toward further standardization of HT-DFT.

5:35 AM F.MT07.08.04
Two-Tier Machine Learning Acceleration of Molecular Dynamics with Enhanced Sampling—Predicting Reaction Rates of Hydrogenation Reactions on Metal Catalysts Lixin Sun, Simon L. Batzner, Steven B. Torrisi, Yu Xie, Jin Soo Lim, Jonathan Vandermause and Boris Kozinsky; Harvard University, United States

Aldehydes, in particular formaldehyde (CH_2O), are key precursors of many important chemical compounds. Cu-based catalysts are attractive for its production since they allow anhydrous alcohol dehydrogenation that does not need expensive distillation and produces a valuable byproduct, H_2.

However, the fundamental mechanism of alcohol dehydrogenation on Cu is not yet fully understood. Static DFT calculations fail to predict the nonlinear dependency of the dehydrogenation reaction rates on the size of the alkoxy molecule [1]. To address this problem, we use molecular dynamics to directly model the dehydrogenation process on the Cu(110) surface, which can capture the dynamical effects that are missed in static DFT calculations.

But due to the slow reaction rates, it is prohibitive to directly compute these reactions with *ab initio* molecular dynamics. Therefore, we use a two-step approach to accelerate molecular dynamics simulations. First, DFT force calculations are replaced by machine learning force fields. We train two different models, Tensor-Field neural networks and mapped Gaussian processes[2]. Both models can reach near DFT level accuracy at much lower computational cost. Second, we use nonlinear dimensionality reduction to learn reaction coordinates and employ them to explore the free energy landscape around the reaction path, speeding up sampling of rare transition events and obtaining reaction rates from free energy barriers.

Late News: End-to-End Automatic Differentiation for Experimentally-Informed Molecular Dynamics Wujie Wang, Simon Axelrod and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States

Molecular dynamics simulations use statistical mechanics at the atomistic scale to enable both the elucidation of fundamental mechanisms and the engineering of matter for desired tasks. The behavior of molecular systems at the microscale is typically simulated with differential equations parameterized by a Hamiltonian, or energy function. The Hamiltonian describes the state of the system and its interactions with the environment. In order to derive predictive microscopic models, one wishes to infer a molecular Hamiltonian that agrees with observed macroscopic quantities. From the perspective of engineering, one wishes to control the Hamiltonian to achieve desired simulation outcomes and structures, as in self-assembly and optical

control, to then realize systems with the desired Hamiltonian in the lab. In both cases, the goal is to modify the Hamiltonian such that emergent properties of the simulated system match a given target. We demonstrate how this can be achieved using differentiable simulations where bulk target observables and simulation outcomes can be analytically differentiated with respect to Hamiltonians, opening up new routes for parameterizing Hamiltonians to infer macroscopic models and develop control protocols.

Autonomous Materials Discovery with Boundless Objective-Free Exploration Koji Tsuda; The University of Tokyo, Japan

Materials chemists develop chemical compounds to meet often conflicting demands of industrial applications. This process may not be properly modeled by black-box optimization because the target property is not well defined in some cases. Herein, we propose a new algorithm for automated materials discovery called BoundLess Objective-free eXploration (BLOX) that uses a novel criterion based on kernel-based Stein discrepancy in the property space. Unlike other objective-free exploration methods, a boundary for the materials properties is not needed; hence, BLOX is suitable for open-ended scientific endeavors. We demonstrate the effectiveness of BLOX by finding light-absorbing molecules from a drug database. Our goal is to minimize the number of density functional theory calculations required to discover out-of-trend compounds in the intensity–wavelength property space. Using absorption spectroscopy, we experimentally verified that eight compounds identified as outstanding exhibit the expected optical properties. Our results show that BLOX is useful for chemical repurposing, and we expect this search method to have numerous applications in various scientific disciplines.

Accelerated Search and Optimization of Uniform Pseudo-Magnetic Fields and Magnetic Edges in Strained Monolayer Graphene Using Artificial Intelligence Stefan Sorescu[1], Jason Inirio[1], Zhuofa Chen[1], Mounika Vutukuru[1], Paul Hanakata[2] and Anna Swan[1]; [1]Boston University, United States; [2]Harvard University, United States

Pseudo-magnetic fields (PMFs) in graphene are an intriguing strain-emergent phenomenon that lead to exciting physics such as Landau level quantization and zero-field quantum Hall effect. PMFs have been demonstrated experimentally first on small nanostructures such as nanobubbles [1]. Experimentally, generating uniform PMF of sufficiently large magnitude is of interest. However, as the strength of the generated PMF is inversely related to the size of the strained region, only small dimensions of graphene have been explored for this purpose. Of more technological interest are larger structures with engineered PMFs [2].

In this work, we are interested in the strain-induced uniform PMF and PMF-zero edges in various geometries in the scale of micrometers. From finite element simulations of strained graphene shapes with varying PMF distributions, we utilize a variational autoencoder that learns the pseudo-magnetic field emergent from geometric images. Our aim is to discover hitherto novel geometries by learning over the geometry-PMF possibility space (a generative approach). We further analyze geometries that will have optimal, robust PMF-zero edges under uniaxial strain via advanced graphing theory algorithms. Finally, we train an auxiliary neural network to rapidly classify large batch, simulated images of strained graphene to arrive at optimally strained graphene geometries that would produce well-defined pseudo-Landau levels for use in advanced electronic devices, such as transistors.

Efficient Uncertainty Estimation of Neural Network Potentials with Atomic-Level Resolution Enabled by Replica Ensemble Wonseok Jeong, Dongsun Yoo, Kyuhyun Lee, Jisu Jung and Seungwu Han; Seoul National Univ, Korea (the Republic of)

Neural network potentials (NNPs) are gaining much attention as they enable fast atomic simulations for a wide range of systems while maintaining the accuracy of density functional theory calculations. Since NNP is constructed by machine learning on training data, its prediction uncertainty increases drastically as atomic environments deviate from training points. Therefore, it is essential to monitor the uncertainty level during the simulations to judge the soundness of the results. In this presentation, we present an uncertainty estimator based on the replica ensemble in which NNPs are trained over atomic

energies of a reference NNP that drives the target simulations. The replica ensemble is trained efficiently and its standard deviation provides atomic-resolution uncertainties. We apply this method to a silicidation process of Ni deposited on Si(001) and confirm that the replica ensemble can spatially and temporally trace simulation errors at the atomic resolution, which in turn guides on augmenting the training set. The refined NNP completes a 3.6-ns molecular dynamics simulation without any noticeable defects. The efficient and atomic-resolution uncertainty indicator suggested in this presentation will contribute to achieving reliable NNP simulations.

Machine Learning as a Solution to the Electronic Structure Problem Beatriz Gonzalez del Rio, Christopher B. Kuenneth, Huan Tran and Rampi Ramprasad; Georgia Institute of Technology, United States

An essential component of materials research is the use of simulations based on density functional theory (DFT), which imposes severe limitations on the size of the system under study. A promising development in recent years is the use of machine learning (ML) methodologies to train surrogate models with DFT data to predict quantum-accurate results for larger systems. Many successful ML models have been created to predict higher-level DFT results such as the total potential energy and atomic forces, and initial steps have been taken to create deep-learning based ML methodologies that can predict fundamental DFT outputs such as the charge density, wave functions and corresponding energy levels [1]. Here, we explore the applicability of this latter methodology using convolutional and recurrent neural networks to learn and predict the electronic charge density and the density of states of carbon, for a large variety of allotropes spanning from metallic to insulating behavior. Further improvements to the speed, accuracy and versatility of this DFT-emulation methodology will also be presented.

Prediction on Electron Density of States in Metal Nanoclusters by Atomic Configuration via Machine Learning Kiyou Shibata and Teruyasu Mizoguchi; The University of Tokyo, Japan

For understanding and design of functional materials, density of states (DOS) is an important property. DOS hosts an essential information on various materials properties such as stability, thermal property, magnetism and catalytic activities [1]. The DOS projected on orbitals, so-called projected DOS (proDOS), provides site-specific properties and is closely related to the local physical property and chemical activity. The DOS is also used for understanding experimental data such as core-loss spectroscopy and X-ray photoelectron spectroscopy. Generally, the DOS and proDOS is obtained by a first-principles calculation, which requires a high computational cost. If a lower-cost computational method can alternate the first-principles calculation, search for new functional materials and extraction of information from huge experimental data can be accelerated.

In recent years, Materials Informatics, a combination of materials science and informatics methods, has been attracting great attention as a way for realizing the search for substances that exhibit excellent physical properties and the extraction of information from experimental data. In principle, the DOS is a quantity that is uniquely determined by an atomic arrangement, although its distribution drastically changes in various ways by a splitting and a shift of states due to a formation of bonded/anti-bonded states according to the atomic arrangement. Regarding the application of informatics on DOS, predictions on DOS of bulk crystals and surface using principal component analysis have been reported [2], which focuses on the composition dependence of alloys with a certain specific structure and the plane orientation dependence of surface DOS. from the viewpoint of atomic coordinates, however, the machine learning prediction on DOS has not been investigated well so far. In this research, we have tried to predict the DOS of metal nanoclusters from their atomic arrangements using the machine learning.

The nanocluster structures composed of several metal atoms were randomly sampled with a constraint on an interatomic distance. The first-principles calculation was performed using VASP code [3] for the generated atomic arrangements without a structural relaxation by PAW method with a planewave cutoff energy of 500 eV and a generalized gradient approximation with considering a spin polarization. Each ProDOS data for the analysis was extracted as two 64-dimensional vectors for each spin up and down, 128-dimensional vectors in total. In order to predict ProDOS, we first trained a variational auto-encoder (VAE) to extract features of ProDOS as latent vectors.
The trained VAE reproduces ProDOS to the extent that the physical property values, such as a d-band center, are roughly reproduced. Interestingly, we found that latent variables are one-dimensionally distributed as a function of interatomic

distance in the latent variable space. We then trained another neural network for regression of the encoded latent vectors by atomic configurations. The predicted ProDOS obtained by decoding predicted latent vector from atomic configurations with the trained VAE shows good agreement of the calculated ProDOS.

In summary, we constructed the combination of the VAE and the neural network in order to predict the ProDOS of the metal nanoclusters. In the presentation, we will show examples of the ProDOS prediction performance, the model details, the distribution of the VAE latent variables, the generalization performance, and the examples of the diatomic molecules composed of different atoms.

Real-Time Control and Analysis in Autonomous Materials Synthesis Kristofer G. Reyes[1], Soojung Baek[1], Kevin Yager[2], Frank Alexander[2], Jennifer Carpena[3], Rahul Rao[3] and Benji Maruyama[3]; [1]University at Buffalo, The State University of New York, United States; [2]Brookhaven National Laboratory, United States; [3]Air Force Research Laboratory, United States

Many current autonomous materials platforms employ Bayesian optimization or active learning techniques, in which synthesis and processing parameters are sequentially considered in a search for the growth conditions that optimize some material response. While these techniques optimize within a closed-loop framework, each experiment done considers the input parameter settings as fixed and treats the synthesis and characterization of the material as a black-box, with input parameters ultimately yielding characterized output properties. We can, however, take advantage of the ability to perform in-situ characterization to provide yet another level of control in the search for optimized parameters by allowing strategically selected changes to real-time-controllable parameters such as temperature or gas flow rates within an experiment. In this talk, we describe the modeling framework and decision-making policies needed to take advantage of real-time control and characterization currently available in many autonomous materials platforms. We provide examples of how such a system can be used to dynamically control and optimize synthesis pathways in chemical kinetics, and show how to overcome hurdles in characterization resolution associated to in-situ measurements.

An Autonomous Experimentation System with Multiple Information Sources Aldair E. Gongora[1], Emily Whiting[1], Patrick Riley[2], Kristofer G. Reyes[3], Elise F. Morgan[1] and Keith A. Brown[1]; [1]Boston University, United States; [2]Google, United States; [3]University at Buffalo, The State University of New York, United States

By combining automated experimentation and active learning, autonomous experimentation systems have accelerated the pace of research in fields such as materials science, chemistry, biology, and mechanics. While advancements in automated experimentation such as robotic platforms can increase the throughput of experiments to further accelerate the pace of research, an alternative path to accelerating learning is to utilize multiple information sources, with varying predictive power and cost, to evaluate the property of interest in the active learning loop. For example, a property of interest can be evaluated via a computational model or experimental measurement. This is particularly salient in the field of mechanics where both computational tools such as finite element analysis (FEA) and experimental characterization such as mechanical testing offer measurements of mechanical properties with varying fidelity. While imperfect and limited to mechanical properties that can be reasonably predicted, FEA encompasses useful information that can be utilized to explore vast design spaces for optimal designs. Conversely, for properties that cannot be reliably simulated, such as toughness, autonomous experimentation systems have emerged to efficiently search the design space for high-performing structures.[1] An open question that remains, however, is how to accelerate learning by utilizing multiple information sources available to an autonomous experimentation system.

In this work, we present a multi-information source optimization (MISO) framework for autonomous experimentation systems by incorporating simulated mechanical responses from FEA in the learning campaign. In this way, the learning campaigns become physics-informed instead of proceeding as a strictly black-box approach. We evaluate this MISO approach by simulating physics-informed learning campaigns and compare the resulting performance to that of black-box learning campaigns. From this study, we observed that including physics-based simulations, in our case FEA, leads to a decrease in both the number of experiments and time necessary to find optimal mechanical designs. Additionally, we evaluate the utility of these approaches in autonomous experimental campaigns. The development of this MISO framework by combining machine learning, physics-based simulations, and physical experimentation presents an approach for incorporating and leveraging numerous information sources available to accelerate research.

Combining Synthetic and Experimental Data in Multi-Fidelity Machine Learning Models to Accelerate Glass Discovery Kai Yang and Mathieu Bauchy; University of California, Los Angeles, United States

Developing novel glasses with new, improved properties and functionalities is key to address some of the Grand Challenges facing our society. Although machine learning offers a unique opportunity to accelerate the discovery of novel glasses with exotic functionalities, it faces the "curse of dimensionality." This is especially significant for glass discovery, since glasses can virtually accommodate the entire periodic table, which, in turn, results in highly dimensional models. Such high dimensionality must be matched with high numbers of glass property data, which is presently lacking. Here, to address this issue, we present a new machine learning pipeline that simultaneously leverages experimental and simulation-based (synthetic) data by means of multi-fidelity Gaussian process regression (GPR) models. We show that our hybrid model systematically outperforms models relying solely relying on experimental data.

Optimization of Multiple Physical Properties by Machine Learning Incorporating the Concept of Deviation Value Kokin Nakajin[1,2], Takuya Minami[1], Toshio Fujita[1,2], Masaaki Kawata[3], Katsumi Murofushi[1], Hiroshi Uchida[1], Kazuhiro Omori[1] and Yoshishige Okuno[1]; [1]Showa Denko, Japan; [2]Research Association of High-Throughput Design and Development for Advanced Functional Materials(ADMAT), Japan; [3]National Institute of Advanced Industrial Science and Technology (AIST), Japan

Machine leaning (ML) [1,2] has become popular method in materials design, and came to be used in various fields nowadays, especially in metal material [3,4] and organic material [5]. Actually, so far it was reported that ML have the effect of shorting the lead time of product development. By contrast, at the development site, there are multiple required characteristics. Because there is a trade-off relationship for multiple characteristics, it is difficult to achieve all of them in same time. Therefore, researchers will conduct experiments on the combinations of various ingredients and their compound ratios, and search for the optimal synthesis method by trial and error. However, it is not easy to find out optimum conditions breaking the trade-off from an enormous number of combinations, even if you use existing ML.
In this study, we verified the effectiveness of machine learning in developing thermosetting transparent flexible films. The thin films were obtained by cross-linking the pre-polymers synthesized by using the mixture of three diol ingredients and a single isocyanate ingredient. Here, we explored the optimum experimental conditions for maximizing transparency, elongation, and elastic modulus.
The predictive model was trained using 27 data obtained by the experimentalist. The hydroxyl values and Extended-connectivity fingerprints (ECFP) of pre-polymers were employed as the explanatory variables X [6,7], and the film properties were used as the objective variables y. The ECFP of each pre-polymers was calculated by summing up the ECFPs of all ingredients with weighted by mixing ratio.

We compared the number of trials required for improving the performance of thin films between that performed by the experimentalist and that by machine learning. As a result, the predictive model successfully found the high-performance films by a lower number of trials compared to the experimentalist.
Additionally, we also report the results by the above model applying Bayesian optimization.

Charting Lattice Thermal Conductivity of Inorganic Crystals Taishan Zhu[1,1], Sheng Gong[1], Tian Xie[1], Prashun Gorai[2] and Jeffrey C. Grossman[1]; [1]Massachusetts Institute of Technology, United States; [2]Colorado School of Mines, United States

Thermal conductivity is a fundamental material property but challenging to predict, with less than 5% out of about 10^5 synthesized inorganic materials being documented. In this work, we extract the structural chemistry that governs lattice thermal conductivity, by combining graph neural networks and random forest approaches. We show that both mean and variation of unit-cell configurational properties, such as atomic volume and bond length, are the most important features, followed by mass and elemental electronegativity. We chart the structural chemistry of lattice thermal conductivity into extended van-Arkel triangles, and predict the thermal conductivity of all known inorganic materials in the Inorganic Crystal Structure Database (stoichiometric). For the latter, we develop a transfer learning framework extendable for other applications.

F.MT07.10.05
Authoring Interactive and Extensible Visualizations from a Materials Knowledge Graph Michael Deagen[1], James P. McCusker[2], Sam Stouffer[2], Tolulomo Fateye[3], Linda S. Schadler[1] and L. Catherine Brinson[3]; [1]The University of Vermont, United States; [2]Rensselaer Polytechnic Institute, United States; [3]Duke University, United States

Effective data visualization accelerates the analysis and communication of data-driven science by enabling humans to interpret, comprehend, and form hypotheses around complex datasets. A large number of high-quality data visualization tools have emerged in recent years, however the adoption of proprietary formats or stand-alone software can hinder interoperability in the pursuit of FAIR data principles. We have developed a visualization authoring tool for the NanoMine knowledge graph (KG) database that combines the query language for RDF data (SPARQL) with a high-level specification for transforming raw data into interactive charts (Vega-Lite). This combination of open-source tools provides a glimpse into the broad collection of experimental materials data curated from the polymer nanocomposites literature into the NanoMine KG. Charts created using this tool are saved to the KG along with provenance information and made accessible via a Gallery on the NanoMine website. The Gallery allows visitors and new users to assess the available data in NanoMine, while advanced users can use the source code (SPARQL query, Vega-Lite spec) behind these charts as inspiration for their own contributions to the Gallery. The reusability of charts created with this approach allows a community of users to learn, build upon examples, and realize the rich expressiveness of SPARQL and Vega-Lite. Together, this data visualization authoring tool provides an interoperable, reusable, and extensible mechanism for users of NanoMine to inspect data quality, perform their own analyses, and pursue new research questions.

F.MT07.10.06
Data-Driven Thermoelectric Modelingš—Prospects and Current Challenges Mamadou T. Mbaye, Sangram K. Pradhan and Messaoud Bahoura; Norfolk State University, United States

Recent advancements in computing technologies coupled with the need to make sense of large amounts of raw data have renewed much interest in data-driven materials properties modeling and prediction. Traditional materials science research relies heavily on experimental data to gauge the properties of materials. However, this paradigm is purely based on trial and

error and ongoing research can take decades to discover new materials. Data-driven modeling tools such as machine learning and its proven libraries can help speed up the materials discovery process through the implementation of powerful algorithms on readily available materials datasets mined from the ever-increasing privately and government-funded materials databases. In this work, we applied various machine learning models on tens of hundreds of thermoelectric compounds obtained from Density Functional Theory (DFT) calculation results. In our preliminary analysis, we made use of pymatgen and the powerful materials science library matminer to add and explore key materials features that have the propensity to accurately predict our achievable target output. We evaluated the accuracy and performance of our models with K-Fold cross-validation estimators and identified the most important descriptors for our materials. Finally, we reviewed the current state-of-the-art in data-driven materials research, its prospects, and current challenges.

Inverse Design of Colossal Permittivity Materials with Crystal Graph Convolutional Neural Networks Dillon C. Yost, Sheng Gong, Tian Xie and Jeffrey C. Grossman; Massachusetts Institute of Technology, United States

Colossal permittivity dielectric materials exhibit great potential as essential building blocks for future electronic devices and energy storage applications. Recent research has demonstrated that a giant dielectric constant could be achieved for certain materials with perovskite-like crystal structure (e.g. CaCu3Ti4O12) or by co-doping the transition metal oxides (e.g. In and Nb doped in TiO2). This opens up tremendous opportunities for inventing and tailoring materials with desired dielectric properties, while it also comes with significant challenges including a gigantic high-dimensional materials design space and unclear colossal permittivity mechanisms. Here, we leverage first-principles calculations and deep learning via the crystal graph convolutional neural network (CGCNN) method to predict and understand dielectric properties of a diverse array of materials. In doing so, we greatly accelerate the exploration and screening of candidate materials for colossal permittivity, and we clarify some of the complex relationships between dielectric properties and material structure and composition.

F.MT07.10.10

Automated Cluster Analysis of 2-Dimensional X-Ray Diffraction for Composition Spread Oxide Thin Film Fabricated by Combinatorial Synthesis, Aiming to Visual Information-Guided Material Discovery Akihiro Yamashita[1,2], Takahiro Nagata[2], Shinjiro Yagyu[2], Toru Asahi[1] and Toyohiro Chikyow[2]; [1]Waseda University, Japan; [2]National Institute for Materials Science, Japan

Data-driven material research can radically shorten time to discover new materials compared to traditional methods. However, collecting and classifying materials data is time consuming. A number of researchers focus on automation methods, however automated analysis of 2-dimensional X-ray diffraction (2D-XRD), which contains various information on structure and is beneficial to thin film research, is not well researched compared to conventional 1D-XRD. We consider automated cluster analysis of 2D-XRD with non-negative matrix factorization (NMF) and also visualization method with variational autoencoder (VAE). In this work, we analyzed 2D-XRD of $(Ga_xIn_{1-x})_2O_3$ composition spread film fabricated on various crystal growth conditions.
For X-ray diffraction (XRD) data, which is the basic analysis method for structural analysis, identification of each peak in a XRD data and classifying each XRD data into some group are essential to understand the correlation between crystal structures and physical properties, but tough work. NMF is already reported to separate XRD dataset into clusters and, consequently, identifying few XRD patterns which are characteristic to each cluster is enough to understand the cluster analysis result [1]. However, the reported XRD data is from one composition spread film, so the cluster analysis result is based on the effects of composition differences on the crystal structure. Effects of crystal growth conditions such as substrates, growth temperatures, and reactive gases on cluster analysis result are still unknown. Also, for thin films, properties such as high oriented, mosaicity, and grained structures affect physical properties, which can be identified by 2D-XRD. Therefore, we have applied NMF to 2D-XRD, and as a case study, the 2D-XRD data of $(Ga_xIn_{1-x})_2O_3$ composition spread samples fabricated by pulsed laser deposition varying composition ratio, substrate, oxygen partial pressure, and substrate temperature were analyzed. We confirmed that NMF can automatically separate the 2D-XRD data into some clusters corresponding to single crystalline, oriented polycrystalline, grained structures, etc. In addition, we applied VAE for converting differences among 2D-XRD data into a graphical image according to physical properties and growth conditions. VAE can convert input data into latent variables following some probability distribution, so differences in the input data is represented as the different positions in the distribution. Analyzing relationships among probability distribution of converted 2D-XRD data, cluster analysis result from NMF, and physical condition will guide us to improved fabrication process based on the obtained graphical image.

Machine Learning Materials Properties for Small Datasets Pierre-Paul De Breuck, Geoffroy Hautier and Gian-Marco Rignanese; Université catholique de Louvain, Belgium

In order to make accurate predictions of crystalline materials properties, current machine-learning approaches generally require large amounts of data. However, in practice, problems that could benefit from machine learning are intrinsically slow and thus small in data size. In this work, a novel all-round framework is presented which relies on a feedforward neural network and the selection of a limited set of physically-meaningful and property-relevant descriptors. Moreover, it enables the prediction of multiple properties, such as temperature or pressure curves, by using a novel tree-like architecture. This does slightly improve accuracy by taking advantage of information stored across different properties, known as joint transfer learning.
Next to being faster in terms of training time, this approach is shown to outperform current graph-network models on small datasets.
Furthermore, excellent accuracy is found when using the composition only, very helpful for identifying experimental candidates. In particular, the vibrational entropy at 305K of crystals is predicted with a mean absolute error of 0.01 meV/K/atom (four times lower than previous studies).
Finally, next to improving prediction performances, the selection algorithm highlights the most important features and thus helps understanding the underlying physics.

F.MT07.10.14
Development of All-Atom and Coarse-Grained Embedded Atom Method Potentials for Gold Using Particle Swarm Optimization Gaurav Anand, Troy Gustke, Abhishek T. Sose, Soumil Joshi, Fangxi Wang and Sanket A. Deshmukh; Virginia Tech, United States

New embedded atom method (EAM) potentials have been developed to describe the interatomic interaction for face-centered cubic (FCC) gold represented by all-atom and coarse-grained (CG) models using particle swarm optimization (PSO) algorithm. These EAM potentials show good physical properties such as lattice constant, bulk modulus, and elastic constant, in agreement with the experimental and computational data. The reliability of each EAM potential is assessed using Gaussian Process (GP) regression and Bayesian statistical framework. The GP model predicted quantities of interest (QOI) such as surface energies, density, and vacancy formation energy, show good consistency with QOI obtained from molecular dynamics simulation, which indicates the GP model is good to reduce the computational cost significantly. Further, the GP model is used to develop 10,000 data points for the Bayesian framework. The Bayesian analysis shows that this EAM can predicate the physical properties with a high confidence level. The above optimization framework will be extended to develop the interatomic potentials for other metals and their alloys in a more efficient way.

Mechanical Characterization of Ceramic Nanocomposites *via* Multi-Fidelity Neural Networks Christos E. Athanasiou, Xing Liu, Lu Lu, Nitin Padture, Huajian Gao and Brian Sheldon; Brown University, United States

Nanocomposites are at the forefront of materials research as they could meet the challenges and growing needs of diverse strategic fields from energy storage to transportation to advanced manufacturing. The investigation of the mechanical properties of such materials requires the combination of novel experimental microscale testing combined with labor/time-intensive finite element computations. In this talk, we will present a new approach for ceramic nanocomposite materials characterization based on the latest developments in deep learning. Specifically, we will discuss how multi-fidelity deep learning can significantly accelerate fracture toughness characterizations at small scales, without the need for large finite element-generated datasets. The predictive capabilities of this method will be accessed by direct comparisons with single-fidelity machine learning.

F.MT07.10.16
Adaptive Spectral Graph Convolutional Neural Network in Crystal Property Prediction Jiali Li[1], Lingtong Chen[2], Zekun Ren[3], Xiaoli Liu[1], Qian Xie[4] and Xiaonan Wang[1]; [1]National University of Singapore, Singapore; [2]University of Southern California, United States; [3]Singapore MIT Alliance for Research and Technology, Singapore; [4]Anhui University of Technology, China

Machine Learning (ML) has been more and more widely used in accelerating the design of new materials due to its close accuracy and less computational cost in predicting material properties compared to simulation methods. However, existing ML methods for designing crystalline materials are usually not flexible to handle different crystal types or hard to interpret

because of the arbitrary size. Although there are more generalized models such as Crystal Graph Convolutional Neural Networks (CGCNN) that utilize graph CNN to encode the structure of a crystal, they are over-localized and impossible to learn beyond the bond connectivity. Here we show a stronger and more adaptive framework, based on spectral convolutional neural network, which is not only capable for arbitrary crystal structure but also learns a unique graph representation based on both global and local topology of each crystal.

First a crystal graph is produced base on the cif file of the crystal similar to CGCNN, and each node is encoded with its atomic properties such as electronegativity, covalent radius, etc. The connectivity is determined based on the distance between each atom. The graph Laplacian *L* is then obtained by performing graph Fourier transformation on the crystal graph. The transformation process can be decomposed by a complete set of eigenvectors U and the eigenvalue matrix LAMBDA(λ), which represents the topology of the graph. The spectral filter $g_\theta(\lambda)$ generates a customized convolution kernel on the graph in space which can be formulated by:

$g_\theta(\lambda) =$(from k=0 to k=k-1)$\sum\theta_k\lambda^k$
Where *k* can be interpreted as the number of convolutions in space.

However, this graph convolution cannot exploit the topological property of the graph. It is possible that the disconnected nodes have larger correlation than those connected nodes. To achieve the capability to learn from the geometric structure, we adapted a new spectral filter from Li et al.[1] which takes a non-Euclean metric so that it learns a residual graph apart from the intrinsic crystal graph by making a correction on the original graph Laplacian *L*:

$L_{new} = L + \alpha L_{res}$

The overall intrinsic plus residue graph is trained with the spectral graph convoluted neural network to predict chemical properties of crystal and results are compared with various existing models. The proposed method has achieved better prediction accuracy especially in larger crystals with more than 4 elements.

Further work has been done by encoding the momentum space feature of the crystal with a graph of reciprocal lattice. Both graphs in real space and momentum space are trained with spectral graph convoluted neural network, but with their own parameters. The outcomes are concatenated and used to make predictions with a neural network. The results are further improved than the model with only the real space graph trained.

Computational Structure Prediction for Discovery of Novel Crystalline Phases Lauren McRae and Scott Warren; University of North Carolina Chapel Hill, United States

Many next-generation technologies rely on increasing the capacity of batteries. Although lithium-ion batteries have attracted the most attention, batteries that shuttle anions like fluoride remain relatively unexplored. Anion shuttle batteries may offer high capacity to enable next-generation technologies and may be made from abundant materials. The promise of anion shuttle batteries warrants a comprehensive investigation of phase-space to discover new materials that can intercalate anions. In the past, materials discovery was done exclusively through experiment, often tedious and time-consuming work. Within the past 20 years, many methods have been developed to explore phase-space more efficiently by computationally predicting structures and calculating properties. With the goal of predicting new materials for anion intercalation, we have developed a computational method of rapid stable and metastable structure prediction using known chemical intuition rules and well-established structure prediction methods. This method uses an evolutionary algorithm to predict complete phase diagrams combined with density functional theory calculations to optimize each predicted structure and obtain an accurate energy. Stable and metastable phases of similar chemical systems can then be predicted based on the calculated phase diagram, with similarity of systems quantified using a previously published measure of atomic similarity. Using this method, we can rapidly predict novel, synthesizable structures that have desirable properties for various applications, including next-generation batteries.

F.MT07.10.18
Tackling Data Scarcity in Materials Research—Augmentation of Training Data for Classification of X-Ray Diffraction (XRD) Patterns Shreyaa Raghavan, Zhe Liu and Tonio Buonassisi; Massachusetts Institute of Technology,

United States

When applying deep learning in material characterization tasks, generating and manually labeling experimental data can be expensive and time-consuming [1]. Especially, this is not an option when large amounts of data are necessary to obtain accurate results from a machine learning model. For this reason, the idea of training deep learning models with simulated data is appealing to tackle data scarcity, particularly when the simulation data can be generated easily and cheaply. A recent study about XRD pattern classification [2] found that the simulated XRD patterns provide some but a limited improvement on accuracy due to the differences between simulated data and experimental data. To close this gap, we explore a Generative Adversarial Network (GAN) [3] to augment the simulated XRD patterns with "realistic" features from experimental data, so that the training of the highly-accurate classifier can be completed with the simulation data only. The GAN consists of a refiner network and a discriminative network with an adversarial loss, where the refiner network reintroduces those realistic features, and the discriminative network penalizes large changes between the original simulated data and the refined data. To avoid the instability of two competing networks in the refined XRD patterns, the discriminative network in our study uses a history of the refined patterns rather than only ones from the current batch. By doing this, our GAN model has a longer-term memory to prevent the refiner network from reintroducing errors. First, we are building and testing this GAN model for data augmentation with 2000 simulated data with labels and 88 unlabeled experimental data, generated following the protocol established in Ref. [2]. Second, we will compare the prediction accuracy of classifying the space groups of the XRD patterns with the model training model using three types of training data: the original simulation data only, the original simulation and experimental data, and the refined simulation data. Third, following the protocol established in Ref. [2], we will adopt the class activation map (CAM) method to identify and understand the root causes of classification error when trained by different training datasets. We envision the method is generalizable to tackle the data scarcity in materials research, where large labeled experimental datasets are not readily available, and further accelerate many characterization tasks with machine learning.

Monte Carlo Simulations of Materials with Autoregressive Generative Models James K. Damewood, Daniel Schwalbe Koda and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States

Monte Carlo simulation is a standard tool for the investigation of the thermodynamic properties of materials. However, the usage of these methods in a high-throughput framework is limited by the efficiency of the current algorithms. The problem becomes even more challenging when considering the difficulty of modeling the multi-component systems at the forefront of many materials disciplines. Recent advances in autoregressive generative models have introduced new sampling methods to optimize the simulation of spin systems through Neural Markov Chain Monte Carlo (NMCMC) and Neural Importance Sampling (NIS). We will demonstrate the applicability of these methods to the study of lattice models in materials science. In particular, we will present the performance of these approaches on benchmark systems, including Copper-Gold and Nickel-Gold. Furthermore, we will discuss results when extending the model's possible state-space beyond two components. Finally, we will evaluate the potential for using these machine learning led simulations in high-throughput screening platforms for perovskites.

Boltzmann Sigmoidal Modeling Analysis of Patterned GaAsSbN Nanowires Sean Johnson, Rabin Pokharel, Michael Lowe, Hirandeep Kuchoor, Surya Nalamati and Shanthi Iyer; North Carolina A&T State University, United States

The first reports of the application of the Boltzmann Sigmoidal model on pitch-dependency in patterned nanowires (NWs) of dilute nitride GaAsSbN on p-Si (111) substrates by self-catalyzed plasma-assisted molecular beam epitaxy are presented in this study. Sizeable bandgap tuning of ~75 meV, as ascertained from 4K photoluminescence (PL), over a pitch length variation of 200 nm to 1200 nm has been demonstrated. Axial and radial growth rates reveal a logistic sigmoidal growth

trend with respect to pitch, which differs from those commonly observed in other patterned non-nitride III-V NWs. Sigmoidal modeling offers additional insight into the shift of the PL spectral arising from differences in Sb and N incorporation from pitch induced variation in secondary fluxes. Results signal that sigmoidal fitting can be a valuable tool to ascertain optimal pitch length for patterned NW arrays of dilute nitrides, and other highly mismatched alloys.

Accelerating Materials Development and Discovery via the Signac Data Management Framework Brandon L. Butler, Bradley Dice, Vyas Ramasubramani, Carl Simon Adorf and Sharon C. Glotzer; University of Michigan, United States

High-throughput data generation and analysis via automation and applications of machine learning offer incredible potential for accelerating materials discovery and development, especially if used in conjunction with well-managed computational workflows. The open-source *signac* data management framework* (signac.io) enables researchers to maintain well-formed, reusable data spaces from early exploration through automated production runs and analysis on platforms ranging from laptops to supercomputers. This is achieved through a transparent data and workflow model combined with a simple and unobtrusive programmatic interface. The framework is application-agnostic, and has been applied in molecular simulations, quantum chemistry, photonics, computational fluid dynamics, machine learning, graph mining, and even organizing experimental data. Recently, the framework has been extended significantly with the addition of FlowGroups and aggregation to signac's workflow model. We have added the ability to group operations on the data space for larger throughput on computer clusters and multiple independent resource specifications allowing for different resource requests on different computing platforms. In addition, we generalized operations from working with individual data points to operating on arbitrary subsets of an arbitrarily large data space. In this presentation, we show examples of applications of these new additions to signac that demonstrate the efficacy and versatility of *signac* in materials discovery and development.

*The signac framework is a NumFOCUS affiliated project.

Self-Supervised Graph Representation Learning for Cell-Penetrating Peptides Ting-Chi Liu, Wei-Han Hui, Chia-Ching Chou and Shu-Wei Chang; National Taiwan University, Taiwan

Scientists have used deep learning algorithms to accelerate drug screening and design in the past few years. For example, transforming the organic compound structure into SMILES notation and leveraging the n-gram model have been used to compute the embedding for the downstream task. Most of these models are based on heavily hand-craft rules to preprocess the training data, and it remains challenging to encode the molecular property. In order to solve these problems, we propose a self-supervised method to learn the molecular representation from the molecular graph directly. We develop a novel approach to encode the information of bond rather than the node and use this embedding for membrane penetrating predictions. The self-supervised graph representation learning method is used to learn the molecular representation both hierarchically and as a whole, to understand the influence of the molecular size. Our model is evaluated with membrane-penetrating peptide database and our results show that this model can successfully predict the cell-penetrating peptides with less human heuristics.

Excitonic Effects in Absorption Spectra of Carbon Dioxide Reduction Photocatalysts Tathagata Biswas; Arizona State University, United States

We study the quasiparticle bandstructure and excitonic properties of 52 materials, which were recently shortlisted for their potential as a catalyst for CO photo-reduction through rigorous firstprinciples computation-based screening strategy. Many body perturbation theory within GW approximation has been used to explore the electronic structure of these materials. To inspect the excitonic effects we use state-of-the-art Bethe-Salpeter formalism. A high-throughput computational workflow using the "atomate" package was used to perform the GW-BSE calculations and analyze the results. We validate our results with 10 previously studied (using both theoretical and experimental methods) materials found in literature and report the results for 42 promising unexplored materials. In addition to providing a more accurate quasiparticle description of the

electronic structure, our study further investigates the suitability of these materials in applications such as CO photo-reduction, efficient solar cells, etc. by examining their absorption spectra and excitonic properties.

F.MT07.10.24
Prediction of Change of DOS Associated with Bond Formation Using Machine Learning Eiki Suzuki, Kiyou Shibata and Teruyasu Mizoguchi; The University of Tokyo, Japan

The density of states (DOS) is a diagram to describe the electronic structure of the material and provides direct information on chemical bonding and materials properties. For example, electronic and photonic properties are mainly correlated to the DOS profiles around bandgap, and catalytic activity is also known to be correlated to the DOS profile of d-band[1]. The DOS is usually obtained by a density functional theory (DFT) simulations which are often time-consuming, especially in a large system. Machine learning (ML) methodologies have been used to create alternative models to predict some DFT outputs for overcoming this problem[2]. Besides, while a bond formation is a fundamental phenomenon in materials and molecules, changes in the orbital interactions and DOS profiles accompanying the bond formation are often complicated.
In this study, we have predicted the changes in DOS using ML techniques. Artificial neural network models have been developed to predict DOS of the atom combined system using DOS of the corresponding isolated system as inputs. We obtained successful results including prediction of gradual change of DOS with respect to bond distance.
First, the DOS database has been created by DFT computations on isolated atoms, diatomic molecules, and single-atom-adsorbed graphene and ethylene with various bond distances using various elements from H to Kr. Second, the ML models based on the artificial neural network has been developed and trained. Finally, the prediction of DOS has been demonstrated for unseen test species on each database.
All the first-principles DFT calculations are performed with the Vienna Ab-initio Simulation Package (VASP)[3] under the generalized gradient approximation (GGA) of Perdew-Burke-Ernzerhof (PBE). Ion cores are modeled with projector augmented wave (PAW) potentials. Semi-core orbital is included in valence. Cut-off energy of 500 eV is used. Spin polarization is considered. SCAN + rVV10[4] is used for considering van der Waals forces. All the structures and the cells are fixed and only electronic relaxation is performed.
For each system, a feedforward neural network model has been developed for DOS prediction. DOS of isolated atoms or adatom is used as input data and DOS of corresponding diatomic molecules or adsorbed systems is used as output data. the DOS of diatomic molecules is also used as input data only for adsorbed systems. The size of the dataset is 14750, 5694, and 2670 sets for diatomic molecules, adsorbed graphene, and adatom-ethylene system respectively. Each dataset is separated into 8:2 for train data and test data. Note that species used in the train data is not included in the test data. Mean squared error (MSE) is used as a loss function.
The DOS prediction for diatomic molecules which are the unseen test species have shown good agreement with calculated DOS. The prediction model reproduces change in shapes with respect to the bond distance. For instance, in the case of O-O molecule, characteristic changes in the DOS profile depending on the bond length would be predicted sufficiently. Main peaks appear around -14 eV in the most stable model with the bond distance of 1.2Å which is shifted to -10 eV in models with larger bond distance, and then it becomes a double-peak feature in the 4.0Å model. On the other hand, the accurate predictions for the adsorbed graphene and ethylene have achieved only when the DOS of the diatomic molecule (calculated) is served as the additional inputs for the prediction model. We are going to present the details in my presentation.

Data-Driven Approach to the Prediction of Mechanical Properties in Carbon Fiber Reinforced Composites Vade Shah, Steven Zadourian, Charles Yang, Zilan Zhang and Grace Gu; University of California, Berkeley, United States

For decades, fiber-reinforced composite materials have been integral to the aerospace, automotive, and military industries due to their lightweight properties. Fiber-reinforced composite manufacturing process involves the curing of the matrix material, which is typically a resin, polymer, or ceramic. The curing process is dependent on several factors, including humidity, temperature, and cycle time, altogether referred to as the curing environment. Curing environments are known to have a significant impact on the mechanical properties, such as modulus and strength, of the final product. While many studies have focused on predicting the mechanical properties of composites, the curing environment is usually not considered. In this work, a data-driven method is applied to various uni-directional carbon fiber laminates to investigate the effects of curing environments on mechanical properties such as longitudinal/transversal strength and modulus. We have conducted statistical

and exploratory data analyses to identify trends, using data from the National Center for Advanced Materials Performance (NCAMP). Results show that high curing temperatures can yield stronger composites, and that the variability in material property values may be resistant to temperature for some resins but not all. Additionally, using machine learning techniques, we develop and compare regressive models considering varying curing environments to predict the strength and modulus of these materials in both longitudinal and transverse directions. This work establishes a statistical framework to analyze complex empirical data for both inference and insight for optimal designs.

Late News: Inverse Design of Potential Singlet Fission Molecules Using a Transfer Learning Based Approach Akshay Subramanian, Utkarsh Saha, Tejasvini Sharma, Naveen Tailor and Soumitra Satapathi; Indian Institute of Technology Roorkee, India

Singlet fission has emerged as one of the most exciting phenomena known to improve the efficiencies of different types of solar cells and has found uses in diverse optoelectronic applications. The number of discovered singlet fission molecules is however limited, since molecules have to satisfy certain energy conditions in order to make the phenomenon possible. Recent advances in drug and molecular design have made use of state of the art Deep Learning models for inverse design that have enabled the prediction of drugs by optimizing targeted properties of interest.
These techniques have been particularly helpful in uncovering information from large datasets and using the learned information to generate new structures. However, unlike the field of drug discovery, we seldom encounter large datasets linking structures to properties in the field of materials science.
In our work, we tackle this scarcity of materials data with a transfer learning approach and demonstrate the utility of the inverse design approach to the design of singlet fission molecules.
Our approach is based on a deep generative model (Variational Autoencoder (VAE)) which has been inspired from Gomez-Bombarelli et al.'s work on de novo drug design. We attempt to extend the utility of their approach to Materials Science datasets (singlet fission in our case) that are often small in size.
We initially pre-train the VAE on an unsupervised task of SMILES string reconstruction on a large database (ChEMBL) of drug molecules. This pre-training allows the model to learn basic SMILES string grammar and the resulting trained weights can serve as a good initialization for the subsequent fine-tuning task on the singlet fission dataset. This can be thought of as similar to the common approach used in Computer Vision of pre-training models on the large ImageNet dataset and subsequently fine-tuning on various downstream tasks. This pre-training approach has been shown to remarkably improve the performance on downstream tasks, especially when the downstream datasets are small.
An important condition for the Singlet Fission phenomenon to occur is E(S1) - 2 x E(T1) >= 0. This condition ensures that Singlet Fission can proceed without the need for external thermal activation. So, we use E(S1) - 2 x E(T1) as the targeted property to optimize in our fine-tuning task. We fine-tune the pre-trained VAE model and an MLP (Multilayer Perceptron) regression head jointly on SMILES string reconstruction and property (E(S1) - 2 x E(T1)) regression tasks, on the Singlet Fission dataset. This guides the model to learn a latent (encoded) representation that segregates molecules based on the value of E(S1) - 2 x E(T1). We were then able to predict potential optimized molecules by performing targeted sampling from this learned latent space.
A second important condition for Singlet Fission to occur is E(T2) - 2 x E(T1) >= 0. This is to ensure that the generated triplet excitons do not annihilate each other immediately after their formation. We model this condition by training an MLP on the prediction of E(T2) - 2 x E(T1). We apply this trained model to the previously sampled molecules and eliminate the ones with negative valued predictions. Finally, we were left with four molecules that could potentially show Singlet Fission properties.
Our work demonstrates the formulation of a transfer learning based inverse design framework that can significantly minimize the efforts involved in the computational screening of molecules by allowing targeted traversal of a boundless search space. This approach can easily be extended to many classes of materials though we demonstrate it's utility only to Singlet Fission molecules.

F.MT07.10.27
Late News: Multigenerational Crumpling of 2D Materials for Anticounterfeiting Patterns with Deep Learning Authentication Lin Jing and Po-Yen Chen; National University of Singapore, Singapore

Physical unclonable function (PUF) is a cornerstone of anticounterfeiting. However, conventional PUF key-based secure tags encounter several bottlenecks, such as complicated manufacturing, specialized and tedious readout, long authentication time, and insufficient stability. To address these challenges, we utilize various two-dimensional materials (2DMs), including $Ti_3C_2T_x$ MXene and graphene oxide, to construct multigenerational microstructures as PUF anticounterfeiting patterns. Two intermediate treatments, cation intercalation and moisture-induced lubrication, are introduced in between sequential substrate

contractions to *in situ* engineer the multiscale patterns in a transfer-free and scalable fashion. To accelerate the authentication, a deep learning (DL)-facilitated software is developed to pre-categorize the hierarchical topographies with classifiable features. Afterwards, the search-and-compare is conducted within a smaller database to shorten the overall authentication time. The synergy between 2DM tags and DL-facilitated authentication software enables a reliable and environmentally stable anticounterfeiting technology, *DeepKey*, showing superior encoding capacity ($>10^{144,494}$) and short authentication time (~3.5 minutes). Our 2DM anticounterfeiting tag is finally integrated with QR codes to provide two-layer information security.

Late News: Matching Optimal Physical Descriptors of Two-Layer Materials in Search of High Interfacial Thermal Conductance Using Gaussian Process Regression Ainur Koshkinbayeva, Azat Abdullaev and Zhandos Utegulov; Nazarbayev University, Kazakhstan

Prediction of the highest or lowest interfacial thermal conductance (ITC) across dissimilar materials is of high technological importance for effective heat management in nuclear and fusion reactors [1], thermal barrier coatings, nanoelectronics and thermoelectric devices [2]. It might take several decades to discover new materials using traditional methods such as physics-based modeling and testing of the pilot samples. In contrast, newly emerging and dynamically developing machine learning algorithms allow to accelerate this process by minimizing the trial-failure routine thanks to an availability of large number of measurement and simulation data generated over the years of active materials research. Today's industry requires much higher rates of materials improvement in thermal and mechanical properties. In this regard, the application of machine learning algorithms allows to discover high-performance materials and interfaces with sufficient accuracy at the lowest consumption of materials and time to discovery.

In this work we present an application of Gaussian Process Regression (GPR) method applied to earlier published experimental reports of ITCs measured across various *metal-nonmetal* and *nonmetal-nonmetal* two-layer interfaces. The following physical descriptors of both, the film and the substrate, were considered: thermal conductivity k, Debye temperature θ_D, longitudinal sound velocity v_l, melting temperature T_m, mass density ρ, Young's modulus E, molar volume V_μ. These parameters of the corresponding films and substrates were found to be substantially affecting the resulting ITC across them [3, 4].

Pearson correlation coefficient map was built to evaluate the linear correlation of different physical descriptors with the corresponding ITC value. The analysis based on the given data set showed that such film parameters as v_l, E and θ_D have the strongest correlation with the ITC.

The values of G of two-layered structures fell in the range of 1.5 to 1500 W/m^{2}K. The tendency of the parameter's ratio for the 5 cases of G values were compared. The results show that the ITC is maximum if the ratios of the film and the substrate descriptors are in the range of 0.7 - 1.7. Moreover, we see that *matching* of v_l, k , T_m and V_μ between films and substrates is of critical importance to maximize ITC values.

Late News: Improving the Performance of Machine-Learning Models for the Prediction of A*x*A(1-*x*)BX3 Perovskite Bandgaps Heesoo Park[1], Raghvendra Mall[2], Adnan Ali[1], Halima Bensmail[2], Stefano Sanvito[3] and Fadwa El Mellouhi[1]; [1]Qatar Environment and Energy Research Institute, Hamad Bin Khalifa University, Qatar; [2]Qatar Computing Research Institute, Hamad Bin Khalifa University, Qatar; [3]School of Physics, AMBER and CRANN Institute, Trinity College, Dublin, Ireland

Machine-learning-inspired computational approaches have accelerated the chemical composition space exploration hence motivating experimental laboratories to adopt this strategy for novel materials discovery. In this work, we build an extensive

dataset based on density functional theory calculations using 2x2x2 supercells of halide and chalcogenide mixed cation Perovskites () with varying ratios of A/A′-cations mixture to account for the local distortions in the BX_6 octahedra. An automated workflow is employed to handle the DFT calculation, followed by the extraction of relevant physical properties and target features form the converged and verified density functional calculations (DFT) calculations. Subsequently, the dataset is built, curated and prepared using the chemical and structural features of the perovskites. This dataset is divided into two datasets sampled randomly: training and test dataset. Subsequently, this procedure is followed by a series of machine learning training based on a 5-fold cross-validation for each hyper-parameter combination to select the best hyper-parameters set until the model is optimized using the training dataset.
Here, we report the details of building a highly accurate predictor for halide and chalcogenide mixed cation Perovskites () bandgaps that takes into account the subtle structural and octahedral deformation a perovskite structure might experience upon mixing the organic cations. A high level of accuracy could be achieved with a careful investigation of the input features [1]. Our analysis emphasizes how important the feature selection stands for constructing the predictive model as we challenge the robustness of our machine learning predictor in a lab validation setup.
A model-to-lab validation is undertaken by synthesizing mixed-cation $MA_xDMA_{(1-x)}PbI_3$ perovskite thin films while varying the DMA concentration over a broad range, namely, for $(1 - x)$=0.0, 0.005, 0.01, 0.02, 0.05, 0.1, and 0.15. We find that the incorporation of DMA at concentrations of 5, 10, and 15 mol % results in non-perovskites in agreement with earlier findings. This indicates that beyond 2 mol % the local strain of DMA on $MAPbI_3$, due to its size, is too large to be accommodated within the perovskite structure. The experimental bandgaps of $MA_xDMA_{(1\ x)}PbI_3$ thin films, as measured by UV–vis spectrophotometer analysis feature systematic bandgap increase with the DMA concentration, with modest variations of the order of 0.02 eV, which are expected given the small concentration range explored. Hence, the observed bandgap increase upon DMA doping is related to small local distortions of the PbI_6 octahedra and not to volumetric effects. Reverting back to our perovskite band gap predictor that have trained and tested over a limited number of DFT calculations for cation concentrations requiring moderate-sized supercells, the model enables to to map the bandgap of mixed-cation hybrid perovskites over a broad range of chemical and structural compositions not accessible by DFT. In this presentation, we will discuss not only the performances of our model but also the machine-learning training procedure to obtain a robust machine learning model.

Late News: Data-Driven Discovery of the Functional Form of the Superconducting Critical Temperature Stephen R. Xie, Yundi Quan, Gregory R. Stewart, James J. Hamlin, Peter J. Hirschfeld and Richard G. Hennig; University of Florida, United States

Predicting the critical temperature Tc of superconductors is a notoriously difficult task, even for electron-phonon systems. We build on earlier efforts by McMillan and Allen and Dynes [1] to model Tc from various measures of the phonon spectrum and the electron-phonon interaction by using machine learning algorithms. Specifically, we use symbolic regression implemented in the Sure Independence and Sparsifying Operator (SISSO) method [2] to identify a new, physically interpretable equation for Tc as a function of a small number of physical quantities. We show that our model [3], trained using the relatively small Tc < 10K data tested by Allen and Dynes, improves upon the Allen-Dynes fit and can reasonably generalize to superconducting materials with higher Tc such as H3S. We find that recently-discovered superconducting systems with a more two-dimensional electron-phonon coupling are outliers in both the Allen-Dynes equation and our analytical expression, suggesting a need for a descriptor that also characterizes Fermi surface properties. Furthermore, we explore the use of variational autoencoders and Eliashberg theory to augment the data. By incorporating physical insights and constraints into a data-driven approach, we demonstrate that machine-learning methods can identify the relevant physical quantities and obtain predictive equations using small but high-quality datasets.

Exotic Light-Matter Interactions in Metamaterials with Broken Symmetries Andrea Alù; City University of New York, United States

In this tutorial, I will overview emerging sub-fields of electromagnetics and nano-optics showing how suitably tailored meta-atoms and suitable arrangements of them open exciting venues to realize new phenomena and devices for light, radio-waves and sound. In particular, I discuss venues in which broken symmetries play a pivotal role in establishing emerging physical properties in metamaterials, from geometrical asymmetries and generalized forms of chirality, to time-reversal symmetry and parity-time symmetry. The opportunities offered by hybrid metamaterials combining classical photonic material platforms with 2D and quantum materials with exotic lattice symmetries will also be discussed. Our work shows how these concepts can provide interesting tools to largely break Lorentz reciprocity and realize isolation without the need of magnetic bias, based on broken time-reversal symmetry induced by mechanical motion, spatio-temporal modulation and/or nonlinearities. I also discuss how broken symmetries in space and space-time can open the opportunity to induce topological order in metamaterials. In the talk, I will also discuss the impact of these concepts from basic science to practical technology, from classical waves to quantum phenomena.

Optical Meta-Devices—Advances and Applications Din P. Tsai; The Hong Kong Polytechnic University, Hong Kong

Metasurfaces, the 2D counterpart of artificial metamaterials, have attracted much attention because of their exceptional ability to manipulate the electromagnetic wave such as amplitude, phase, polarization, propagation direction, and so on. Different from conventional optical components, meta-devices based on the metasurface optics are truly flat and compact and exhibit superior novel performance. Recent progress in the developments of optical meta-devices will be discussed. First, the working principle and characteristics of optical meta-devices are explored. Then, it is described how the dispersion aberration in optical meta-devices can be used or eliminated to make them suitable for being employed in a range of applications that are difficult or impossible for traditional optical components. In addition, various optical meta-devices based applications are introduced, including imaging, high spectral resolution spectroscopy, and multiplex color routing, etc. Introduction and review of the reconfigurable and tunable optical meta-devices is also included. This talk will be concluded by addressing the future prospects of novel optical meta-devices.

Near-Zero-Index Material Platforms and Dispersion Engineering Nader Engheta; University of Pennsylvania, United States

Materials are often used to manipulate and control photons. As such they play major roles in all aspects of nanophotonics. Mematerials -- specially engineered material structures -- have enabled scientists and technologists to engineer desired dispersion and to construct platforms with unconventional material parameters, thus providing exciting opportunities to manipulate light-matter interaction in unconventional ways that exhibit unprecedented physics and technology for optical devices and components. One such platform is the near-zero-index metamaterials. In such structures, the effective relative permittivity and/or relative permeability is designed to be near zero at operating frequencies, causing the effective refractive index to be near zero. Consequently, in such epsilon-near-zero (ENZ), mu-near-zero (MNZ), and/or near-zero-index (NZI) structures the wavelength is “stretched”, and therefore the phase distribution is effectively uniform throughout this volume. This leads to a variety of unique features including supercoupling, photonic doping, photonic surface states, electric levitation, extreme quantum optics, thermal beaming, and giant nonlinearity, just to name a few. In this tutorial, I will present an overview of some of the fundamental principles and unique physics of wave interaction with such near-zero-index structures and their engineered dispersion. I will then discuss some of the applications of such platforms in photonics and microwave technologies. Possible future directions of research in this field will also be forecasted.

1:00 PM BREAK

Hybrid Nanophotonic Platforms to Control Chiral Light-Matter Interactions Jennifer A. Dionne; Stanford University, United States

Chirality in Nature can be found across all length scales. At the molecular scale, the spatial dissymmetry in the atomic arrangements of pairs of mirror-image molecules, known as enantiomers, gives rise to fascinating and often critical differences in chemical and physical properties. With increasing hierarchical complexity, protein function, cell communication, and organism health rely on enantioselective interactions between molecules with selective handedness. For example, neurodegenerative and neuropsychiatric disorders including Alzheimer’s and Parkinson’s diseases have been linked to distortion of chiral-molecular structure. Moreover, d-amino acids have become increasingly recognized as potential biomarkers, necessitating comprehensive analytical methods for diagnosis that are capable of distinguishing l- from d-forms and quantifying trace concentrations of d-amino acids. Correspondingly, many pharmaceuticals and agrochemicals consist of chiral molecules that target particular enantioselective pathways. Yet, despite the importance of molecular chirality, it remains challenging to sense and to separate chiral compounds. Chiral-optical spectroscopies are designed to analyze the purity of chiral samples, but they are often insensitive to the trace enantiomeric excess that might be present in a patient sample, such as blood, urine, or sputum, or pharmaceutical product. Similarly, existing separation schemes to enable enantiopure solutions of chiral products are inefficient or costly. Consequently, most pharmaceuticals or agrochemicals are sold as racemic mixtures, with reduced efficacy and potential deleterious impacts.

Recent advances in nanophotonics lay the foundation toward highly sensitive and efficient chiral detection and separation methods. In this Tutorial, we highlight efforts of our lab and the broader community to leverage nanoscale chiral light–matter interactions to detect, characterize, and separate enantiomers, potentially down to the single molecule level. Notably, certain resonant nanostructures can significantly enhance circular dichroism for improved chiral sensing and spectroscopy as well as high-yield enantioselective photochemistry. We first describe how achiral metallic and dielectric nanostructures can be utilized to increase the local optical chirality density by engineering the coupling between electric and magnetic optical resonances. While plasmonic nanoparticles locally enhance the optical chirality density, high-index dielectric nanoparticles can enable large-volume and uniform-sign enhancements in the optical chirality density. By overlapping these electric and magnetic resonances, local chiral fields can be enhanced by several orders of magnitude. We show how these design rules can enable high-sensitivity circular dichroism as well as high-yield enantioselective photochemistry. We also show how hybrid nanophotonic platforms can enable structure-sensitive vibrational IR and Raman spectroscopy. The Tutorial will describe both computational and experimental approaches, including methods to sense the structure of molecular monolayers and dynamically detect the structural transformations of chiral molecules. Finally, we discuss future challenges and opportunities spanning fundamental research to technology translation.

8:00 AM INTRODUCTION AND ANNOUNCEMENTS

8:12 AM *F.NM01.04.02
Atomic Layer Deposited VO_2 Thin Films Towards Modulated Infrared Optoelectronic Devices V. D. Wheeler[1], Chase Ellis[1], Marc Currie[1], J.R. Avila[2], Michael A. Meeker[1], Joshua D. Caldwell[3] and Joseph Tischler[1]; [1]U.S. Naval Research Laboratory, United States; [2]ASEE Postdoctoral Fellow, United States; [3]Vanderbilt University, United States

VO_2 is a phase change material that undergoes a first order crystalline phase transition at a critical temperature ($T_c = 68^oC$), resulting in significant changes in intrinsic electrical and optical properties, especially in the infrared. Optical changes with this phase transition are of particular interest as passive and active components of optoelectronic devices, specifically for thermal regulation and modulated signaling. Realizing this type of device often requires the integration of thin, conformal VO_2 films with complex, non-planar structures (like metamaterials). Thus, atomic layer deposition (ALD) is the ideal deposition method in these cases.
Traditional metal-based plasmonic materials suffer from high optical losses, which has promoted research towards alternative low-loss materials that can support plasmonic-like effects. One such approach employs phonon-mediated collective-charge oscillations (surface phonon polaritons, SPhPs) that are supported by nanostructured polar dielectric materials (SiC, AlN, etc), which inherently are low-loss. Geometric design of the nanostructures enables spectral tuning of resonant features between the longitudinal and tranverse optical phonons of the polar material, typically in the infrared regions. However, the spectral position and amplitude of these resonances remain fixed after fabrication. Integrating phase change materials with these structures provides a way to achieve active modulation of resonances.
In this work, we will discuss the ALD process optimization and characterization of thin VO_2 films itself and subsequent integration into different optoelectronic structures for active modulation. In particular we will present a case study where nanopillar arrays were etched into SiC and AlN to create narrowband resonances in the long-wave infrared region. These structures were subsequently coated with ALD VO_2 films with different thicknesses (8-75nm). As-deposited VO_2 films are highly conformal and amorphous, and cause the resonances to shift and broaden due to the different dielectric environment. However, after annealing the films at 525°C in $6x10^{-5}$ Torr, the VO_2 films crystallize resulting in sharper resonances and spectral locations close to the initial uncoated structures. Temperature-dependence reflectance and emission measurements show that by heating through the VO_2 transition temperature, the amplitude of the resonances can be modulated. Full signal modulation (ie. on/off) requires at least a 16nm VO_2 film. This work shows the ability to actively tune surface phonon polariton resonances using ALD phase change materials.

Photonic Designs for Laser Driven Propulsion Ho-Ting Tung and Artur Davoyan; University of California, Los Angeles, United States

In this work we examine principles of laser propulsion for spaceflight in the solar system. We discuss regimes of laser operation, system requirements on acceleration distance and sail-craft dimensions and weight. We show that with laser propulsion small satellites may be injected into various trajectories on a path to other planets. We show that travel times to planets may be as small as one month. We analyze spacecraft trajectory for various laser illumination regimes. Lastly, we discuss sail-craft materials and photonic design. We show that with a proper choice of low-loss materials and photonic engineering highly reflective sails may be crafted to ensure efficient momentum transfer. We further study pathways for radiative heat dissipation to ensure sustainable spacecraft operation and propulsion. We discuss several specific design concepts and demonstrate the feasibility and promise of such laser propulsion with today's technology. Our work shows that laser propulsion may offer an alternative for fast transit time and high velocity missions beyond the reach of conventional chemical rockets and plasma engines.

Miniature Optical Systems Based on Cascaded Metasurfaces Andrew McClung, Mahdad Mansouree, Sarath Samudrala, Mahsa Torfeh, Babak Mirzapourbeinekalaye and Amir Arbabi; University of Massachusetts Amherst, United States

Miniaturized optical systems with planar form factors and low power consumption have many applications in consumer electronics, imaging and spectral sensing systems, and as integral parts of medical and industrial equipment. Flat optical devices based on dielectric metasurfaces introduce a new approach for the realization of such systems at low cost using conventional nanofabrication techniques. In this talk, I will present an overview of our work on the development of various high-performance optical dielectric metasurface components and systems. In particular, I will discuss multi-layer dielectric metasurfaces that enable complete control of wavefront at multiple wavelengths. I will present an on-chip integration platform enabled by vertical or lateral integration of multiple metasurfaces and active optoelectronic components such as laser arrays and image sensors. I will also introduce a novel technique for engineering chromatic dispersion by cascading and discuss various optical systems implemented in this platform and a single-snapshot multispectral imager.

Manipulating Light and Matter at the Nanoscale for Next Generation Solar Energy Conversion Devices Esther Alarcon-Llado; AMOLF, Netherlands

Introducing thin, light-weight and high efficiency photovoltaics will ensure solar cells to be integrated in urban landscapes, small gadgets or even in space. While thinning down of absorber materials is a good strategy to overcome these restrictions, it comes down to the expense of poor light absorption. By contrast, nano-structuring is an effective approach to tackle flexibility, material and weight reduction without compromising absorption through the exploiting of their strong interactions with light.
In this talk I will describe the power of semiconductor nanostructures to capture and trap sunlight, enabling a wide range of new solar cells designs. First, I will introduce the wave guiding effects in semiconductor nanowires. The absorption cross-section in semiconductor nanowires can reach up to x100 their geometrical footprint, so that nanowire arrays can reach to the same absorption as in bulk films with a small fraction (< 3%) of the material. We have seen experimental evidence for the strong extinction in vertically standing GaAs and InAs nanowires, using 3D confocal fluorescence microscopy. We observe how light is perturbed up to few microns away from the nanowires for a broad range of wavelengths. We demonstrate that by probing ordered arrays with this method, the effective absorption coefficient and cross-section can be obtained without the need of a transparent substrate. Because of the absorption cross-section in nanowires is ruled by the efficient incoupling of light to the waveguide modes, absorption is relatively narrow-band (~50 nm) with the central wavelength depending on the nanowire diameter. The coloured appearance in sparse arrays are actually the perfect framework to generate a new class of semi-transparent photovoltaics, that can be used as windows and other urban spaces. We find that the multi-mode absorption in the arrays, result into higher absorbance as compared to the thin film counterpart with the same average visible transparency. Second, I will show that the diffractive power of nanowire arrays can be modulated by the wavelength-selective 1D wave guiding in the nanowires. Using the tailored structural properties in the array, we show that a nanowire array can serve as both solar cell and light in-coupler to a thin film cell underneath. The dual waveguiding effects in GaAs nanowire-Si thin film tandem architectures give rise to a 4-fold light absorption increase in the Si ultrathin bottom cell. This is a significant light trapping scheme that is obtained “for free” when using a nanostructured top cell. As a final remark, I will touch upon emerging fabrication methods for nanostructured semiconductor and conducting metamaterials. In particular, electrochemical deposition is a convenient growth method that allows for control over the growth conditions through combinations of solvents, additives, and pH, in addition to conventional parameters such as heat and pressure. By combining scalable imprint lithography with electrochemical deposition, we demonstrate large-area plasmonic lattices of In,Ga metals that can be electrochemically transformed to dielectric (In,Ga)As.

Linear and Nonlinear Conducting Oxide Epsilon-Near-Zero Nanophotonics Sudip Gurung[1], Jingyi Yang[1], Aleksei Anopchenko[1], Khant Minn[1] and Ho Wai (Howard) Lee[1,2]; [1]Baylor University, United States; [2]University of California,

Irvine, United States

The optical response of epsilon-near-zero (ENZ) materials has been a topic of significant interest in the last few years as the electromagnetic field inside media with near-zero permittivity has been shown to exhibit unique optical properties, including strong electromagnetic wave confinement, non-reciprocal magneto-optical effects, and abnormal nonlinearity.

This talk will review our recent development on the linear and nonlinear properties of conducting oxide epsilon-near-zero materials [1-6]. I will present a method to engineer the nonlinear refraction coefficients and the nonlinear absorption coefficients of Al-doped zinc oxide (AZO) ENZ thin films synthesized by atomic layer deposition (ALD) technique. Our results suggest that ENZ nonlinear refraction and nonlinear absorption properties of AZO films are enhanced by excitation of the ENZ modes and can be engineered by changing the mode-strengths via control over either the excitation angles or by ALD engineering of material dispersion/ film thickness. Measured values as large $n_2^{(eff)} \approx 10^{-9}$ mm^2/W and $\beta_2^{(eff)} \approx -10^{-5}$ mm/W are obtained along with approximately an order of magnitude tunability.

In addition, I will also discuss the first experimental demonstration of optically confined ENZ resonance excitation in a side-polished optical fiber waveguide uniformly coated with AZO nanolayer. We observed a transmission resonance dip in the ENZ regime with on and off resonance difference of ~20 dB in an ENZ-optical fiber with a 30 nm-thick AZO layer, which is attributed to the coupling between the fundamental mode of the optical fiber and ENZ mode supported by the ultrathin AZO film. We also demonstrate the active nonlinear optical and electrical control of the hybrid ENZ resonances in the AZO ENZ optical fibers. The ENZ-optical fiber provides a unique excitation platform of hybrid ENZ resonance with relatively long light-interaction length and eases the complexity of optical configuration without required sophisticated prism/grating coupling, which has potential applications in nonlinear and quantum zero index photonics, in-fiber optical sensing, lasers, and dispersion control.

Designing Tunable Phase-Change Material Based Metasurfaces Using Multiphysics Simulations Dmitry N. Chigrin[1,2]; [1]DWI–Leibniz Institute for Interactive Materials, Germany; [2]RWTH Aachen University, Germany

Tunable metasurfaces allow to control the phase, amplitude and propagation direction of electromagnetic waves. Integrating phase-change materials into metasurface design provide an opportunity to control metamaterial properties at the meta-atom length scale. This could enable full reprogrammability and post-fabrication adjustments of adaptive metasurfaces. A state of phase change material near a meta-atom can be switched by a local deposition of heat using optical, electrical pulses or hot scanning probes. Resulting phase transition process is intrinsically non-stationary and inhomogeneous. The phase transition from crystalline to amorphous state is accompanied by the drastic change of the material properties leading to time-varying and position-dependent refractive index, conductivity, absorption rate and heat conduction. In order to describe local phase transition in metamaterials, a self-consistent numerical treatment of electromagnetic, carrier transport, heat transfer and phase transition processes becomes of primarily importance. Understanding the phase transition process at the meta-atom length scale is essential for a purposeful design of programmable adaptive metasurfaces. Here, we report on a self-consistent multiphysics description of a local phase transition in metasurfaces. The developed model is applied to analyse local phase

transition in different metasurfaces under the application of different mechanism of the local heat deposition.

Metamaterial Computing Machines Nader Engheta; University of Pennsylvania, United States

Metamaterials and metasurfaces have offered exciting platforms for engineering light-matter interaction that can provide desired functionalities. Over the past several years, numerous features and exciting applications of metastrucures have been explored and developed. One of the interesting possibilities in using metamaterials is the development of "metamaterial computing machines", which we have been exploring in my group. In such paradigm, structures are designed in order to perform mathematical operations when waves propagate through them. Effectively, materials become computing machines. We have been investigating various scenarios in which metastructures can solve integral and differential equations and can invert matrices as incoming waves interact with them. In addition to using materials platform for this purpose, we have also investigating how collections of the Mach-Zehnder interferometers (MZIs) can provide another platform for solving equations and doing mathematics with light. In this talk, I will discuss some of our ongoing research projects on this topic and will present an overview of our most recent results.

Lattice Resonances in Arrays of Metallic Nanostructures Alejandro Manjavacas; The University of New Mexico, United States

Periodic arrays are an exceptionally interesting arrangement for plasmonic nanostructures due to their ability to support strong collective lattice resonances, which arise from the coherent multiple scattering enabled by the array periodicity. Thanks to these exceptional properties, periodic arrays are being exploited in a wide variety of applications, including ultrasensitive biosensing, nanoscale light emission, and color printing, to cite a few. In this talk, we will discuss the response

of arrays with multi-particle unit cells using an analytical approach based on plasmon hybridization, which provides a simple and efficient way to design periodic arrays with engineered properties [1]. We will pay particular attention to bipartite arrays and show how, depending on the relative position of the particles within the unit cell, these systems can support super- or subradiant lattice resonances [2]. We will also discuss how the interplay between the response of the individual constituents and the collective interaction determines the ultimate limits of the field enhancement provided by a periodic array [3]. We will finish by addressing the effect that the presence of edges as well as disorder have on the response of these systems [4].

Functional Metasurfaces for Rapid, Colorimetric Cancer Tissue Diagnostics Lisa V. Poulikakos[1,2], Mark Lawrence[1], David R. Barton[1], Stefanie S. Jeffrey[1] and Jennifer A. Dionne[1]; [1]Stanford University, United States; [2]UC San Diego, United States

Hundreds of thousands of patients in the United States are diagnosed with cancer annually. While the accurate determination of disease stage is closely linked to the probability of patient survival, current diagnostic technology presents patients and physicians with trade-offs between duration, precision and cost. Here, we present an all-optical, label-free technology for quantitative, real-time cancer tissue diagnostics on a single, clinically-compatible chip. Periodically-arranged sub-wavelength dielectric nanostructures, known as metasurfaces, are patterned into dielectric layers on glass microscope coverslips, where biopsied tumor tissue sections can be deposited following routine clinical procedure. Specifically, our technique maps the anisotropy and orientation of collagen fibers, a quantitative marker of cancer stage in tissue, onto metasurface structural color.

We pattern a sub-wavelength rectangular lattice of rhombohedral perturbations into stacked layers of silicon nitride (215 nm) and silicon dioxide (75 nm), where < 10 nm bandwidth guided-mode resonances yield a high-purity chromaticity in reflectance, with a polarization-sensitive colorimetric response. With full-field numerical simulations, we demonstrate how selective tuning of the guided-mode resonances maps the orientation angle of collagen fibers onto blue-to-green chromaticity, while changes in refractive index are separately mapped onto red-to-green chromaticity as the sensing medium varies from air to biological tissue. For the example case of breast cancer diagnostics, where the presence and orientation of collagen fibers at the tumor margin can distinguish early-stage from metastasized disease, we quantify the performance of our metasurface via the 1976 CIE Lab color discrimination. We find that our metasurface outperforms polarized light microscopy by unambiguously mapping tissue orientation onto structural color at higher color discrimination values, while enabling the distinction of orientation angles which otherwise yield an identical response. This improved performance is attributed to engineered symmetry-breaking of the metasurface geometry by Stokes parameter analysis of the metasurface-reflected fields. Finally, we experimentally characterize the anisotropic optical properties of planar sheets of ordered synthetic collagen scaffolds using both conventional polarimetry and our metasurface device. Working at the interface of nanoscale optics and medicine, our colorimetric metasurface platform has the potential to set a new benchmark for rapid, quantitative and cost-effective cancer tissue diagnostics.

4:15 PM *F.NM01.05.05
Straintronics and ITO-Photonics—Advances in Heterogeneous Opto-Electronic Devices Volker J. Sorger; George Washington University, United States

Here I discuss our recent demonstrations of ITO-based opto-electronic devices and introduce the concept of 'Strainoptronics'. The presentation includes the following concepts: 1) Here we demonstrate a spectrally broadband, gigahertz-fast Mach–Zehnder interferometric modulator exhibiting a miniscule Vπ L of 95 V-um, deploying a subwavelength short electrostatically tunable plasmonic phase shifter based on heterogeneously integrated indium tin oxide thin films into silicon photonics. This GHz-fast broadband integrated modulator bears relevance since ITO is a foundry-compatible material. Unlike the crystal- orientation-sensitive LN, ITO optoelectronics is synergistic to enhancing electrostatics known from transistor technology. 2) Strain-engineered high-responsivity MoTe2 photodetector for silicon photonic integrated circuits In integrated photonics, specific wavelengths such as 1,550 nm are preferred due to low-loss transmission and the availability of optical

gain in this spectral region. For chip-based photodetectors, two-dimensional materials bear scientifically and technologically relevant properties such as electrostatic tunability and strong light–matter interactions. However, no efficient photodetector in the telecommunication C-band has been realized with two-dimensional transition metal dichalcogenide materials due to their large optical bandgaps. Here we demonstrate a MoTe2-based photodetector featuring a strong photoresponse (responsivity 0.5 A/W) operating at 1,550 nm in silicon photonics enabled by strain engineering the two-dimensional material. Non-planarized waveguide structures show a bandgap modulation of 0.2 eV, resulting in a large photoresponse in an otherwise photoinactive medium when unstrained. Unlike graphene-based photodetectors that rely on a gapless band structure, this photodetector shows an approximately 100-fold reduction in dark current, enabling an efficient noise-equivalent power of 90 pW/Hz^0.5. Such a strain-engineered integrated photodetector provides new opportunities for integrated optoelectronic systems.

4:23 PM *F.NM01.05.08
2.5D Photonics as Engines of Information Manipulation Rajesh Menon; The University of Utah, United States

Micro- and nanostructures have been widely applied to enhance the performance of optical components and systems. Structures whose characteristic dimensions are greater than the wavelength of interest, l, can effectively manipulate the **scalar** properties of light, while nanostructures with dimensions << l/2 can manipulate the **vector** properties of light. By restricting the photonic functionality to a thin plane (i.e., 2.5D photonics), it's possible to create very thin lightweight imaging lenses,[1] spectrum-splitting solar concentrators,[2] and integrated-photonics devices.[3] In this presentation, we will highlight examples of each such device that overcome limitations of conventional implementations (if they exist at all). For example, flat multi-level diffractive lenses (MDLs) have recently shown achromatic bandwidth,[4,5] depth-of-focus[6] and efficient high-numerical aperture focusing[7] far better than their conventional counterparts, all while reducing weight and thickness by several orders of magnitude.
Computational techniques, such as nonlinear optimization, coupled with electromagnetics modeling can drive the *inverse design* of novel optical and photonic components and systems. When guided by manufacturing constraints, such techniques can result in highly practical, low-cost, ultra-compact (on the order of l x l) and multi-functional integrated-photonics components, such as polarization beam-splitters,[3] wavelength splitters,[8] couplers,[9] waveguide bends,[10] etc. We'll also describe a nanophotonic cloak that enables two devices to be placed closer together than is otherwise feasible, leading to an increase in integration density.[11]
When coupled with advanced machine-learning or linear-algebraic methods, 2.5D photonics can engines of information manipulation, enabling highly non-intuitive forms of optical systems such as photography with no lenses[12,13] or microscopy with only a surgical needle[14,15] or multi-spectral imaging with a diffractive element.[16]

SESSION F.NM01.15: Live Keynote II: Optical Nano-Kirigami
Session Chairs: Artur Davoyan and Philip Hon

4:30 PM *F.NM01.07.01
Optical Nano-Kirigami Nicholas Fang[1], Huifeng Du[1], Xinhao Li[1], Zhiguang Liu[1], Jiafang Li[2] and Ling Lu[3]; [1]Massachusetts Institute of Technology, United States; [2]Beijing Institute of Technology, China; [3]Chinese Academy of Sciences, China

Recently, exciting new physics of plasmonics has inspired a series of key explorations to manipulate, store and control the flow of information and energy at unprecedented dimensions. For example, analogous to the familiar description of optical energy and linear momentum, non-local symmetry transformations of photons lead to new degrees of freedoms with respect to optical spin and optical helicities that are controllable at sub-wavelength scales thanks to the emerging nanohelical structures and networks. In this talk I will introduce versatile 3D shape transformations of nanoscale structures by deliberate engineering of the topography-guided stress equilibrium of gold nanostructures. By using the topography-guided stress equilibrium, rich 3D shape transformation such as buckling, rotation, and twisting of nanostructures is precisely achieved, which can be predicted by our mechanical modeling. Benefiting from the nanoscale 3D twisting features, giant optical chirality is achieved in an intuitively designed 3D pinwheel-like structure, in strong contrast to the achiral 2D precursor without nano-kirigami. High-contrast cross-polarized diffractions are successfully observed in both linear and radial configurations, resulting from constant phase difference between the pinwheel structures of opposite handedness. We further demonstrate an on-chip and electromechanically reconfigurable nano-kirigami with optical functionalities. The nano-electromechanical system is built on a CMOS-compatible Au/SiO2/Si substrate and operated via attractive electrostatic forces between the top gold nanostructure and bottom silicon substrate. Large-range nano-kirigami like 3D deformations are clearly observed and reversibly engineered, with scalable pitch size down to 0.975 μm. The demonstrated nano-kirigami, as well as the exotic 3D nanostructures, could be adopted in broad nanofabrication platforms and could open up new possibilities for the exploration of functional micro-/nanophotonic and mechanical devices. Nanoscale control of optical spin and optical helicities with nano-kirigami are promising for numerous technological applications, such as chiral molecular sensing, separation and synthesis, super resolution imaging, nanorobotics, and ultrathin broadband optical components for chiral light.

Advanced Optimization Algorithms for Nanophotonic Design at the Device and System Level Katherine T. Fountaine[1,2], Prachi Thureja[2], Yury Tokpanov[2], Dagny Fleischman[2] and Harry Atwater[2]; [1]Northrop Grumman Aerospace Systems, United States; [2]California Institute of Technology, United States

Nanophotonic design spaces are often highly nonlinear; the large number of parameters (both geometric and material properties) will result in an exceptionally complex and high dimensionality design space that renders an exhaustive parameter sweep computationally insurmountable. Additionally, the design of a full nanophotonic device involves optimization at multiple levels, including material selection/design, device design, and system level design. In this talk, I will discuss multiple optimization frameworks for different design problems, including device level design for multispectral filters and

phase modulation devices and system level design for beamsteering devices and other active metasurfaces. At the device level, we have (1) employed NOMAD (non-linear optimization using mesh adaptive direct search), a hybrid (global +local), derivative free optimization method, and (2) developed a new Bayesian optimization algorithm, MF-MI-Greedy, which uses multiple levels of fidelity, to optimize various nanophotonic structures including dielectric metasurfaces and multispectral filters. At the system level, we have (1) developed a new iterative genetic algorithm and (2) employed neural nets to optimize antenna arrays of active metasurfaces with non-ideal phase and amplitude characteristics. These studies suggest that selection of the correct optimization algorithm at a given design level can significantly reduce computational time for design and improve overall device performance.

7:38 PM *F.NM01.08.04
Investigating and Controlling the Opto-Electronic/Valleytronic/Spintronic Properties of van der Waals Nanomaterials/Heterostructures/Metastructures Nai-Chang Yeh, Wei-Hsiang Lin, Chen-Chih Hsu, Duxing Hao, Deepan Kishore Kumar and Chia-Shuo Li; California Institute of Technology, United States

Thin layers of van der Waals (vdW) materials, ranging from insulators to semiconductors, semi-metals and superconductors, exhibit novel optical, electronic, orbital, magnetic, topological and superconducting properties. Varying the interfacial stacking order of vdW homo/heterostructures further yields Moiré bands and new physical phenomena. Nanoscale strain-engineering of vdW materials (*e.g.*, graphene, transition-metal dichalcogenides, TMDs) can induce novel quantum/topological phenomena, such as giant pseudo-magnetic fields (PMF) and flat bands associated with quantized Landau levels in monolayer graphene, and strain-dependent energy gaps and exciton lifetimes for monolayer 2H-phase TMDs. Quantum confinement due to reduced spatial dimensions and broken symmetry is known to induce new quantum states that are non-existent in the bulk. Spin-orbit coupling of light by optical vortices (*a.k.a.* twisted light, Laguerre-Gaussian beam) and plasmonic vortices produces photons with nontrivial spin/orbital-angular-momentum, which can impart integer and fractional *topological charges* onto condensed matter and atomic/molecular systems through light-matter interactions. Therefore, investigating and controlling the light-matter interactions in vdW nanomaterials/heterostructures/metastructures represents a pathway to explore new quantum phenomena and to advance opto-electronic/valleytronic/spintronic applications.

We employ scalable CVD and PECVD fabrication techniques to synthesize a variety of vdW nanomaterials and their heterostructures, including monolayer and bilayer graphene,[1-3] quasi one-dimensional (1D) graphene nanostripes,[1,4] h-BN,[5] and monolayer-to-multilayer TMDs MX_2 and $MX_{2-y}X'_y$ (M = Mo, W; X, X′ = S, Se, Te; $0 \leq y \leq 2$).[6] We investigate their properties by means of spatially resolved and polarization-dependent photoluminescence (PL), time-resolved PL (TRPL), Raman spectroscopy, x-ray photoelectron spectroscopy (XPS), Kelvin-probe force microscopy, conductive atomic force microscopy (c-AFM), scanning tunneling microscopy/spectroscopy (STM/STS).[6,7] We perform nanoscale strain engineering on monolayer graphene to control the strain-dependent PMF and electronic correlation, and to achieve valley/spin polarization;[7] and on TMDs to control the energy gaps and exciton lifetimes. We develop plasmonic vortices on TMDs by metasurfaces together with circularly polarized light to control the light-matter interaction and valley/spin polarization in TMD and the topological charge. Our approach leads to various interesting findings, including: valley splitting, quantum oscillations, spontaneous symmetry breaking and spin polarization, quantum valley-Hall and quantum anomalous-Hall effects in valley Hall transistors based on nanoscale strain-engineered monolayer graphene;[7] exceedingly long and temperature independent optically excited carrier lifetimes (~ 10 ns) as well as broadband (from IR to UV) photoluminescence in quasi-1D graphene nanostripes; much enhanced valley polarization in monolayer WS_2 by combining plasmonic vortices with circularly polarized light; and compositional dependent opto-electronic/valleytronic properties in $WS_{2-y}Te_y$ ($0 < y < 2$). Based on these experimental findings, we discuss potential applications of van der Waals nanomaterials/heterostructures/metastructures to opto-electronic/valleytronic/spintronic devices.

Dynamically Switchable Photonics Based on Alloyed Metal Hydrides Jeremy N. Munday; University of California, Davis, United States

The ability to control the optical properties of photonic materials on demand is essential for the operation of a variety of devices ranging from active color filters and routers to switchable mirrors and sensors. Here we will present our latest work on actively controllable photonic devices using alloyed metal hydrides. Using our recently developed apparatus for *in situ* measurements of optical and mechanical response upon hydrogenation, we first show how pure metal hydrides containing Pd, Mg, Zr, Ti, and V can be used as tunable photonic elements throughout the visible and near-infrared [1]. A number of devices will be shown including structures that have five orders of magnitude change in reflectivity, as well as planar systems for physical encryption and counterfeit detection. Second, we will show how alloying can not only improve cyclability, but also lead to higher hydrogen fractions than previously obtained as a result of film stresses and microstructuring [2]. These results have led to new insights in the dynamic behavior of metal-hydrides and will help in the design of next-generation hydrogen sensors and tunable photonic devices.

7:53 PM *F.NM01.09.02
Approaches for Tuning of Chalcogenide Glass Dielectric Metasurfaces Jesse Frantz[1], Jason D. Myers[1], Robel Y. Bekele[2], Anthony Clabeau[2], Vinh Nguyen[1], Jiannan Gao[3], Mikhail Shalaev[3], Natalia Litchinitser[3] and Jas Sanghera[1]; [1]U.S. Naval Research Laboratory, United States; [2]University Research Foundation, United States; [3]Duke University, United States

Chalcogenide glasses have recently received attention for their potential use in dielectric metasurfaces for several reasons: They typically possess high linear refractive indexes, enabling high index contrast devices; some compositions exhibit exceptionally high optical nonlinearity (n_2>1000× that of silica) making them good candidates for nonlinear devices; they have wide transmission windows spanning from the visible through the longwave infrared; and some compositions undergo a structural phase transition, enabling devices with switching based on phase-change. We discuss a variety of approaches to achieve tunability in chalcogenide glass metasurfaces from our work and that of others. We review recent progress on the use of the Kerr nonlinearity in As_2S_3 films to achieve power-dependent behavior and the application of this effect for the manipulation of orbital angular momentum. We discuss the design and realization of chalcogenide-based photonic quasicrystals enabling simultaneous phase matching of an arbitrary number of nonlinear optical processes in a single engineered nanostructure. We discuss recent observations that a permanent index change can be induced in As_2Se_3 via thermal tuning and the use of this effect to achieve permanent one-way tuning of the optical resonance of a metasurface. We discuss work being done by a variety of groups on phase-change chalcogenide materials such as germanium-antimony-telluride and gallium-lanthanum-sulfide in order to realize switchable metasurfaces. Finally, we discuss future prospects for the use of chalcogenide glass metasurfaces for applications that require tuning of the optical response.

8:00 PM *F.NM01.05.02
Volumetric Meta-Optics for Novel Device Functionalities Andrei Faraon; California Institute of Technology, United States

Three-dimensional elements, with refractive index distribution structured at subwavelength scale, provide an expansive optical design space that can be harnessed for demonstrating multifunctional free-space optical devices. We present 3D dielectric elements, designed to be placed on top of the pixels of image sensors, that sort and focus light based on its color and polarization with efficiency significantly surpassing 2D absorptive and diffractive filters. The devices are designed via iterative gradient-based optimization to account for multiple target functions while ensuring compatibility with existing

nanofabrication processes, and they are experimentally validated using a scaled device that operates at microwave frequencies. This approach combines arbitrary functions into a single compact element, even where there is no known equivalent in bulk optics, enabling novel integrated photonic applications. We further discuss capabilities enabled by volumetric meta-optical devices for compact on-chip polarimetry and discuss implementations using multi-layer nanofabrication.

Writing and Submitting Your Papers Rachel Won; Nature Photonics, United Kingdom

This talk introduces you to all the existing and new journals in the family of *Nature.* It covers the detailed information and guidelines on scientific manuscript preparation and submission. Tips for writing a good abstract and a good paper will be provided. Editorial and peer-review processes will be discussed.

SESSION F.NM01.02: Advanced Biophotonic Systems, Platforms and Applications
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-NM01

5:00 AM *F.NM01.02.01
Emerging Nanophotonic Platforms for Infectious Disease Diagnostics—Re-Imagining the Conventional Microbiology Toolkit Jennifer A. Dionne, Jack Hu, Jefferson Dixon, John M. Abendroth, Loza Tadesse, Amr Saleh, Mark Lawrence, Michelle Solomon and Fareeha Safir; Stanford University, United States

We present our research controlling light at the nanoscale for infectious disease diagnostics, including detecting bacteria at low concentration, sensing COVID antibodies and antigens, and visualizing in-vivo inter-cellular forces. First, we combine Raman spectroscopy and deep learning to accurately classify bacteria by both species and antibiotic resistance in a single step. We design a convolutional neural network (CNN) for spectral data and train it to identify 30 of the most common bacterial strains from single-cell Raman spectra, achieving antibiotic treatment identification accuracies exceeding 99% and species identification accuracies similar to leading mass spectrometry identification techniques. Our combined Raman-CNN system represents a proof-of-concept for rapid, culture-free identification of bacterial isolates and antibiotic resistance.

Second, we describe resonant nanophotonic surfaces, known as “metasurfaces” that enable multiplexed detection of SARS-CoV-2 antibodies and antigens. Our metasurfaces utilize guided mode resonances excited in high refractive index nanostructures. The high quality factor (“high-Q”) modes ($Q > 1000$) produce a large amplification of the electromagnetic field intensities near the nanostructures that increase the response to minute refractive index changes from targeted binding of an antibody; simultaneously, the optical signal is beam-steered for multiplexed detection. We describe how this platform can be manufactured at scale for portable, low-cost assays.

Finally, we introduce a new class of *in vivo* optical probes to monitor biological forces with high spatial and temporal resolution. Our design is based on upconverting nanoparticles that, when excited in the near-infrared, emit light of a different color and intensity in response to nano-to-microNewton forces. The nanoparticles are sub-30nm in size, do not bleach or photoblink, and can enable deep tissue imaging with minimal tissue autofluorescence. We present the design, synthesis, and characterization of these nanoparticles both in vitro and in vivo, focusing on the forces generated by the roundworm *C. elegans* as it feeds and digests its bacterial food. Chronic cytotoxicity assays are used to confirm biocompatibility. Our force measurements are coupled with electrical measurements of muscle contractions in both wild-type and mutant animals, providing insight into the interplay between mechanical, electrical, and chemical signaling *in vivo*.

5:15 AM F.NM01.02.02
Functional Metasurfaces for Rapid, Colorimetric Cancer Tissue Diagnostics Lisa V. Poulikakos[1,2], Mark Lawrence[1], David R. Barton[1], Stefanie S. Jeffrey[1] and Jennifer A. Dionne[1]; [1]Stanford University, United States; [2]UC San Diego, United States

Hundreds of thousands of patients in the United States are diagnosed with cancer annually. While the accurate determination of disease stage is closely linked to the probability of patient survival, current diagnostic technology presents patients and physicians with trade-offs between duration, precision and cost. Here, we present an all-optical, label-free technology for quantitative, real-time cancer tissue diagnostics on a single, clinically-compatible chip. Periodically-arranged sub-wavelength dielectric nanostructures, known as metasurfaces, are patterned into dielectric layers on glass microscope coverslips, where biopsied tumor tissue sections can be deposited following routine clinical procedure. Specifically, our technique maps the anisotropy and orientation of collagen fibers, a quantitative marker of cancer stage in tissue, onto metasurface structural color.

We pattern a sub-wavelength rectangular lattice of rhombohedral perturbations into stacked layers of silicon nitride (215 nm) and silicon dioxide (75 nm), where < 10 nm bandwidth guided-mode resonances yield a high-purity chromaticity in reflectance, with a polarization-sensitive colorimetric response. With full-field numerical simulations, we demonstrate how selective tuning of the guided-mode resonances maps the orientation angle of collagen fibers onto blue-to-green chromaticity, while changes in refractive index are separately mapped onto red-to-green chromaticity as the sensing medium varies from air to biological tissue. For the example case of breast cancer diagnostics, where the presence and orientation of collagen fibers at the tumor margin can distinguish early-stage from metastasized disease, we quantify the performance of our metasurface via the 1976 CIE Lab color discrimination. We find that our metasurface outperforms polarized light microscopy by unambiguously mapping tissue orientation onto structural color at higher color discrimination values, while enabling the distinction of orientation angles which otherwise yield an identical response. This improved performance is attributed to engineered symmetry-breaking of the metasurface geometry by Stokes parameter analysis of the metasurface-reflected fields. Finally, we experimentally characterize the anisotropic optical properties of planar sheets of ordered synthetic collagen scaffolds using both conventional polarimetry and our metasurface device. Working at the interface of nanoscale optics and medicine, our colorimetric metasurface platform has the potential to set a new benchmark for rapid, quantitative and cost-effective cancer tissue diagnostics.

5:25 AM F.NM01.02.03
Xanthommatin Biophotonics—Fundamental Optical Properties and Squid Skin Optics Richard M. Osgood[1], Sean R. Dinneen[1], Zhuangsheng Lin[2], Camille Martin[2], Amrita Kumar[2], Leila Deravi[2], Yassine Ait-El-Aoud[1], Steven Kooi[3], Elizabeth Welsh[1], Michael Okamoto[1] and Ihsan Uluturk[1]; [1]US Army CCDC-SC, United States; [2]Northeastern University, United States; [3]Massachusetts Institute of Technology, United States

Biomaterials are of increasing interest for photonics applications, including for biophotonics. The size of bioparticles used for nanophotonics can be similar to that of plasmonic nanoparticles; e.g., in the range of 50-500 nm. Some virus simulants scatter light and have been detected by highly sensitive photonic crystals.

Cephalopods are known to have important coloration and camouflage properties. The chromatophores in squid skin can change shape and influence light scattering and color; they are responsible for the bulk color changes (red, yellow, brown) observed in cephalopods. Underneath the chromatophore lie iridocyte cells, multilayered Bragg reflectors that reflect color and can cause iridescence. The chromatophore contains xanthommatin (Xa) pigments confined in nanostructured granules with sizes in the range 300-600 nm and achieves both pancake-like, expanded states and spherical, punctate state. The diameters of these granules are well-sized, and perhaps optimized for nanophotonic scattering of visible light, especially blue-green wavelengths; not absorption. Recently, researchers have succeeded in mimicking chromatophore color and in particular, the light scattering (diameter ~ 500 nm) granules within them, using artificial materials and chemically-synthesized Xa[1]. These novel material platforms can be used for more efficient control of light at the nanoscale.

In the past, our group has discovered that the Xa pigment in cephalopod chromatophores has a very high refractive index (n < 1.92), using fixed-wavelength refractometry (589 nm) and cavity ring-down spectrometry [2]. The latter experiment required drying aerosols. Here we report comprehensive broadband ellipsometric measurements of broadband (300 nm – 3200 nm) optical indices (n and absorption coefficient k) of Xa pigment, using a novel method for extracting natural Xa pigment from the squid's chromatophores and forming smooth, high-quality films. These measurements give a more complete description

of Xa's fundamental optical properties, than previously known. We report a new short wave infrared absorption resonance and its possible origin. These important findings will assist in the design of new lightweight optical components, such as lenses, that can change in response to external stimuli and perhaps even image underwater. Most lenses are designed for a broad spectrum of light, where it is essential to know (n, k) across the entire wavelength range of interest, in order to predict optical system performance.

In this presentation, with a more advanced and quantitative understanding of squid skin optics, we improve on earlier results, that made important breakthroughs but did not have experimental optical constants, to extract scattering and absorption parameters. We use a 4-flux optical model (specular and diffuse light) of the chromatophore, optically coupled to the iridocyte. Armed with fundamental values of n and k, we employ direct experimental data for Xa to better quantitatively assess the optical response (e.g. scattering, reflectivity, transmission, and absorption) of the combined chromatophore-iridocyte optics.

These fundamental findings are important and will aid in the control of nanoscale light, using the novel Xa biomaterial, which can enable new scattering and coloration functionalities due to its unusually high n. Such a high-index material, which may be possible to synthesize in an environmentally-friendly way, may enable new designs of lightweight optical systems that can adapt and change shape, perhaps with an electrical trigger, and may aid in underwater detection or imaging. We discuss possible new designs and new nanophotonic systems, using the interesting Xa biomaterial.

5:35 AM F.NM01.02.04
Surface Plasmon Enhanced Shortwave Infrared Fluorescence for *In Vivo* Imaging of Ovarian Cancer Shengnan Huang, Ching-Wei Lin, Jifa Qi, Archana M. Iyer, Yanpu He, Yingzhong Li, Neelkanth Bardhan, Darrell Irvine, Paula T. Hammond and Angela Belcher; Massachusetts Institute of Technology, United States

Shortwave infrared (SWIR, 900-1700nm) enables *in vivo* imaging with high spatial resolution and penetration depth due to the reduced photon scattering and suppressed tissue autofluorescence at long wavelengths. Recently, small organic SWIR dyes have drawn great interest because SWIR dyes have excellent biocompatibility as compared to their inorganic counterparts. However, the application of SWIR dyes for *in vivo* imaging is hampered by their low quantum yield and photostability. To resolve these issues, in this work, the SWIR dyes are placed in close proximity to gold nanorod (AuNR) for surface plasmon enhanced SWIR fluorescence. The plasmon enhancement is optimized by varying the dye-to-AuNR number ratio and a maximum enhancement factor of ~ 45-fold is achieved. In addition, it is found that the highest dye-to-AuNR number ratio gives the maximum emission on the weight basis and this ratio is used for synthesizing the plasmon enhanced SWIR imaging probes. The outmost surface of the imaging probes is modified with different ligands. Their effect on the targeting capability and intratumor distribution of the imaging probes is investigated and compared in two orthotopic ovarian cancer models. Lastly, it is demonstrated that the plasmon enhanced SWIR imaging probes are able to detect submillimeter-sized ovarian cancer nodules, making them excellent candidates for real-time fluorescence imaging-guided surgery.

5:45 AM F.NM01.02.06
High Quality Factor Metasurfaces for SARS-CoV-2 Antibody Detection Jack Hu, Jefferson Dixon, Mark Lawrence, John M. Abendroth, Lisa V. Poulikakos, Fareeha Safir, Stefanie S. Jeffrey, Scott Boyd and Jennifer A. Dionne; Stanford University, United States

As of June 1st 2020, COVID-19 has impacted 213 countries with over 6 million cases globally. Antibody tests identify individuals who have been infected with SARS-CoV-2 and have developed an immune response; they also identify individuals with anti-SARS-CoV-2 antibodies who are potential donors of convalescent plasma. However, current serologic antibody tests are either qualitative or slow, are unable to correlate viral loads to antibody type and level, and do not offer real-time information about antibody-antigen binding on-rates, off-rates, or affinity constants. Here, we design and fabricate high quality factor (Q) silicon metasurfaces to sensitively detect SARS-CoV-2 antibodies and monitor antigen-antibody interaction dynamics at the few-protein level. Our metasurfaces utilize guided mode resonances excited in high refractive index nanostructures. The high Q modes ($Q > 1000$) produce a large amplification of the electromagnetic field intensities near the nanostructures that increase the response to minute refractive index changes from targeted binding of an antibody. Using a Si-on-Sapphire platform, we fabricate biperiodic array metasurfaces with quality factors exceeding 2500. Next, we functionalize our metasurfaces with the spike receptor-binding domain (RBD) to bind with IgM, IgG, and IgA, and their

subtypes. Importantly, our zwitterionic and PEGylated matrix functionalization minimizes non-specific adsorption and enables oriented antibody attachment. On dried samples, transmission spectroscopy reveals metasurface resonant shifts exceeding the resonant full-width-half-max with varied antibody concentrations from clinical samples. A fluidic platform also allows real-time interrogation of metasurface resonant shifts as the serological samples are introduced. We describe how this platform can be manufactured at scale for portable, low-cost assays, and also how it can be modified to enable point-of-care antigen testing.

SESSION F.NM01.03: Dispersion Engineered Materials and Metamaterials
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-NM01

5:00 AM *F.NM01.03.01
Nonlinear and Hyperbolic Metasurfaces and Applications Augustine Urbas; AFRL, United States

Efforts to examine large optical nonlinear response in structured and novel electromagnetic materials are ongoing. This work is partly motivated by the promise of leveraging structural resonances or regions of exotic materials response, such as the epsilon near zero or ENZ regime to amplify the underlying nonlinear response of component materials. This nonlinear response can in turn be leveraged to explore new device response when incorporated into metasurfaces and metamaterial structures. The mechanisms for this nonlinear response are varied and span the range of traditional nonlinear materials. Leveraging such resonances or narrow response regimes however, leads to limitations in the band width of the response as has been reported previously. In this presentation, we will explore the use of multilayered structures composing so-called hyperbolic metamaterials as nonlinear media with large and broad band optical response. Such structures have been proposed as nonlinear materials as well as for a variety of other applications. We examine the spectrally and temporally-resolved response of multilayer Arsenide semiconductor materials which are constructed to possess hyperbolic metamaterial properties. By controlling the composition and doping of the materials, and then examining their response during optical excitation of free carriers, we can examine the material, structure, and optical effects on the nonlinear response. To analyze ultrafast changes in carrier concentration we use a pump-probe experiment. Pump and probe laser pulses are 85 fs in duration and their center wavelength can be tuned separately with an optical parametric amplifier (OPA) and difference frequency generator (DFG) in either path. Typical wavelengths used were 1300 nm for the pump and 4, 5, or 5.5 μm for the probe. The differential intensity measurements were taken by appropriately positioned detectors to record $\Delta R/R$ for reflection or $\Delta T/T$ for transmission. We have explored the photo-induced change in optical properties of a multilayer semiconductor system constructed so as to generate hyperbolic dispersion under photoexcitation using pump-probe spectroscopy. The response shows characteristics wavelength and polarization dependent features that support the emergence of hyperbolic dispersion at pump excitation that induce sufficient photoinduced carrier responses. This response can serve as a basis for highly nonlinear systems and as a material from which highly nonlinear metasurfaces can be made.

5:15 AM *F.NM01.03.02
Linear and Nonlinear Conducting Oxide Epsilon-Near-Zero Nanophotonics Sudip Gurung[1], Jingyi Yang[1], Aleksei Anopchenko[1], Khant Minn[1] and Ho Wai (Howard) Lee[1,2]; [1]Baylor University, United States; [2]University of California, Irvine, United States

The optical response of epsilon-near-zero (ENZ) materials has been a topic of significant interest in the last few years as the electromagnetic field inside media with near-zero permittivity has been shown to exhibit unique optical properties, including strong electromagnetic wave confinement, non-reciprocal magneto-optical effects, and abnormal nonlinearity.

This talk will review our recent development on the linear and nonlinear properties of conducting oxide epsilon-near-zero materials [1-6]. I will present a method to engineer the nonlinear refraction coefficients and the nonlinear absorption coefficients of Al-doped zinc oxide (AZO) ENZ thin films synthesized by atomic layer deposition (ALD) technique. Our results suggest that ENZ nonlinear refraction and nonlinear absorption properties of AZO films are enhanced by excitation of the ENZ modes and can be engineered by changing the mode-strengths via control over either the excitation angles or by ALD engineering of material dispersion/ film thickness. Measured values as large $n_2^{(eff)} \approx 10^{-9}$ mm^2/W and $\beta_2^{(eff)} \approx -10^{-5}$ mm/W are obtained along with approximately an order of magnitude tunability.

In addition, I will also discuss the first experimental demonstration of optically confined ENZ resonance excitation in a side-

polished optical fiber waveguide uniformly coated with AZO nanolayer. We observed a transmission resonance dip in the ENZ regime with on and off resonance difference of ~20 dB in an ENZ-optical fiber with a 30 nm-thick AZO layer, which is attributed to the coupling between the fundamental mode of the optical fiber and ENZ mode supported by the ultrathin AZO film. We also demonstrate the active nonlinear optical and electrical control of the hybrid ENZ resonances in the AZO ENZ optical fibers. The ENZ-optical fiber provides a unique excitation platform of hybrid ENZ resonance with relatively long light-interaction length and eases the complexity of optical configuration without required sophisticated prism/grating coupling, which has potential applications in nonlinear and quantum zero index photonics, in-fiber optical sensing, lasers, and dispersion control.

5:45 AM *F.NM01.03.04
Lattice Resonances in Arrays of Metallic Nanostructures Alejandro Manjavacas; The University of New Mexico, United States

Periodic arrays are an exceptionally interesting arrangement for plasmonic nanostructures due to their ability to support strong collective lattice resonances, which arise from the coherent multiple scattering enabled by the array periodicity. Thanks to these exceptional properties, periodic arrays are being exploited in a wide variety of applications, including ultrasensitive biosensing, nanoscale light emission, and color printing, to cite a few. In this talk, we will discuss the response of arrays with multi-particle unit cells using an analytical approach based on plasmon hybridization, which provides a simple and efficient way to design periodic arrays with engineered properties [1]. We will pay particular attention to bipartite arrays and show how, depending on the relative position of the particles within the unit cell, these systems can support super- or subradiant lattice resonances [2]. We will also discuss how the interplay between the response of the individual constituents and the collective interaction determines the ultimate limits of the field enhancement provided by a periodic array [3]. We will finish by addressing the effect that the presence of edges as well as disorder have on the response of these systems [4].

Absorption, Nonparabolicity and the Origins of Extreme Nonlinearity in Epsilon-Near-Zero Materials Nathaniel Kinsey[1], Ray Secondo[1] and Jacob Khurgin[2]; [1]Virginia Commonwealth University, United States; [2]Johns Hopkins University, United States

Optical researchers have long sought to develop materials and systems that enable more efficient nonlinear processes. From semiconductors, polymers, organize, and metamaterials, many promising materials, and approaches have been investigated, yet the primary platforms for nonlinear phenomena remain bulk crystals and optical fiber. A new entry into the area of nonlinear materials is epsilon-near-zero materials. In the past few years, these films have been shown to enhance various nonlinear processes from extreme refractive index tuning, phase conjugation, harmonic generation, and adiabatic frequency

shifts in films with a thickness on the order of the wavelength due to unique intrinsic and extrinsic enhancement of the nonlinear response. Despite a variety of experimental successes, the theory of the effect has largely lagged behind. Here we outline a theoretical approach to describing extreme nonlinear index tuning in Drude epsilon-near-zero materials such as transparent conducting oxides. Our approach provides an analytical description suited to estimate the order of magnitude of the nonlinearity given basic properties, as well as a full numerical approach capable of predicting the strength, dispersion, and intensity dependence of the nonlinearity for multiple materials without fitting parameters. We utilize this model to investigate the impact of loss on the nonlinear response and develop a figure of merit to evaluate the performance of up-and-coming material platforms. Ultimately we believe our approach will aid the development and optimization of the promising epsilon-near-zero platform for both free-space and on-chip nonlinear applications.

6:15 AM F.NM01.03.06
Mie-Resonant Three-Dimensional Metacrystals Seokhyoung Kim[1], Cindy Zheng[1], George C. Schatz[1], Koray Aydin[1], Kyoung-Ho Kim[2] and Chad Mirkin[1]; [1]Northwestern University, United States; [2]Chungbuk National University, Korea (the Republic of)

Optical metamaterials are engineered structures that exhibit electromagnetic properties not found in naturally occurring materials. These structures, which can exhibit properties including near-zero or negative refractive indices, very large electric permittivities, and negative permeabilities, may enable new cloaking, metatronic nanocircuitry, and optical computing technologies. While there have been significant advances in the design and fabrication of two-dimensional (2D) metasurfaces, planar structures create nontrivial angular and polarization sensitivities, making omnidirectional operation impossible. Although three-dimensional (3D), isotropic metamaterials have been proposed, including ones that exhibit unnaturally high refraction, they have yet to be made. Here, we report the use of DNA-mediated programmable assembly to prepare isotropic 3D metacrystals from oligonucleotide-modified Au nanocubes. We use finite-element modeling to show such structures could have an effective index as large as ~8 in the mid-infrared, far greater than that of natural materials, and for the first time, experimentally observe multipolar Mie resonances in 3D metacrystals with well-formed habits. Specifically, we synthesized cubic superlattices with effective indices of ~4.7, comparable to the previous record in the optical regime for 2D metasurfaces. These sub-micron cube-shaped metacrystals exhibit mid-infrared Mie resonances, which were characterized by synchrotron infrared microspectroscopy.

Aluminum Plasmonics Naomi Halas; Rice University, United States

While the noble/coinage metals have dominated chemistry research in nanomaterials that support surface plasmons, more recently the quest for sustainable and inexpensive plasmonic media has begun to focus on Aluminum. The nucleation and growth chemistry of Aluminum is unique, however, and few lessons learned from aqueous-based metal nanoparticle nucleation and growth apply to this metal. Aluminum nanocrystal growth is catalyst-driven, and the nucleation event is also strongly influenced by solvent molecules that complex with the catalyst-alane precursor. Studies of this system has led us to discover paths toward size and shape control dependent on the catalyst properties. With both size and shape dependence come new properties, which include new roles as optical antennas in plasmonic photocatalyst complexes. We show that for reactions that are driven by a hot electron mechanism, there is a strong dependence of reaction rate upon nanoparticle shape, for particles with the same plasmon resonant energy.

5:15 AM *F.NM01.04.02
Atomic Layer Deposited VO_2 Thin Films Towards Modulated Infrared Optoelectronic Devices V. D. Wheeler[1], Chase Ellis[1], Marc Currie[1], J.R. Avila[2], Michael A. Meeker[1], Joshua D. Caldwell[3] and Joseph Tischler[1]; [1]U.S. Naval Research Laboratory, United States; [2]ASEE Postdoctoral Fellow, United States; [3]Vanderbilt University, United States

VO_2 is a phase change material that undergoes a first order crystalline phase transition at a critical temperature (T_c = 68°C), resulting in significant changes in intrinsic electrical and optical properties, especially in the infrared. Optical changes with

this phase transition are of particular interest as passive and active components of optoelectronic devices, specifically for thermal regulation and modulated signaling. Realizing this type of device often requires the integration of thin, conformal VO_2 films with complex, non-planar structures (like metamaterials). Thus, atomic layer deposition (ALD) is the ideal deposition method in these cases.
Traditional metal-based plasmonic materials suffer from high optical losses, which has promoted research towards alternative low-loss materials that can support plasmonic-like effects. One such approach employs phonon-mediated collective-charge oscillations (surface phonon polaritons, SPhPs) that are supported by nanostructured polar dielectric materials (SiC, AlN, etc), which inherently are low-loss. Geometric design of the nanostructures enables spectral tuning of resonant features between the longitudinal and tranverse optical phonons of the polar material, typically in the infrared regions. However, the spectral position and amplitude of these resonances remain fixed after fabrication. Integrating phase change materials with these structures provides a way to achieve active modulation of resonances.
In this work, we will discuss the ALD process optimization and characterization of thin VO_2 films itself and subsequent integration into different optoelectronic structures for active modulation. In particular we will present a case study where nanopillar arrays were etched into SiC and AlN to create narrowband resonances in the long-wave infrared region. These structures were subsequently coated with ALD VO_2 films with different thicknesses (8-75nm). As-deposited VO_2 films are highly conformal and amorphous, and cause the resonances to shift and broaden due to the different dielectric environment. However, after annealing the films at 525°C in $6x10^{-5}$ Torr, the VO_2 films crystallize resulting in sharper resonances and spectral locations close to the initial uncoated structures. Temperature-dependence reflectance and emission measurements show that by heating through the VO_2 transition temperature, the amplitude of the resonances can be modulated. Full signal modulation (ie. on/off) requires at least a 16nm VO_2 film. This work shows the ability to actively tune surface phonon polariton resonances using ALD phase change materials.

5:30 AM F.NM01.04.04
Wurtzite Gallium Phosphide Structures for Photonic Applications Bruno da Silva[1], Odilon D. Couto Jr[1], Carlos A. Senna[2], Braulio S. Archanjo[2], Fernando Iikawa[1] and Monica A. Cotta[1]; [1]University of Campinas, Brazil; [2]National Institute of Metrology, Quality and Technology, Brazil

Wurtzite Gallium Phosphide (GaP) nanowires have been intensively studied due to the possibility of finding a new direct band gap material in the green spectral range. However, recent works have suggested a pseudodirect band gap instead. Here, we investigate the optical properties of Au-catalyzed GaP nanowires, obtained by chemical beam epitaxy and nanoparticle crawling-assisted vapor-liquid-solid growth. We discuss how this phenomenon impacts nanowire morphology, and leads to the formation of an asymmetric GaP nanostructure. Using large volume (micron-sized) GaP structures in the wurtzite phase, we were able to carry out absorption measurements to elucidate the exact value of the fundamental band gap, excitonic emissions and valence band splitting energies of the wurtzite phase. Our data indicates the existence of a dipole forbidden (pseudo-direct) band gap at low temperature at (2.19 +/- 0.02) eV. We also discuss how to control the incorporation of unintentional impurities and its effect on the luminescence of this material. Furthermore, we show that high densities of large volume, wurtzite GaP structures (up to 40micra in length and over 2micra in diameter), with sidewalls presenting roughness in nanometer scale, can easily be obtained with our nanoparticle crawling-assisted growth method for antireflective coating in device applications.

5:40 AM F.NM01.04.05
Physical Properties and Formation of Zinc Oxide Nano-Scaled Using Natural Extract from Dry Corn Husk (Zea Mays) via Green Chemistry Assisted by Spin Coating Technique Moussa Bakayoko[1,2,3], Balla Diop Ngom[2], Papa D. Tall[2], Malik Maaza[3,1] and Ibrahima Ngom[1,2,3]; [1]University Of South Africa, South Africa; [2]Université Cheikh Anta Diop de Dakar, Senegal; [3]iThemba Laboratory for Acclerator Based Science, South Africa

Biosynthesis, as an alternative method, sparked an attractive attention in the research world due to its biocompatibility concerning production potential antibacterial agents. However, compared to chemical and physical methods, the main drawback associated with the biological synthesis is the inability to get the size and / or shape desired nanoparticles with a good yield.
In order to overcome this granulometry problem associated with a biological approach, this research work consisted, first step, to synthesize zinc oxide nanoparticles (ZnO NPs), by an entirely ecological chemistry process, simple and profitable using the extract from the dry husk of corn (Zea mays) as an effective chemical reducing agent without the addition of any standard acid or basic component. The physical properties such as structure, size, morphology and elementary composition, as well as the optical properties of the bio-synthesized nanoparticles were determined using the following different characterization techniques: High resolution scanning electron microscopy (HR -MEB), high resolution transmission electron

microscopy (HR-MET), X-ray diffraction (DRX), energy dispersive X-ray spectroscopy, Fourier transform infrared spectroscopy and Raman scattering, UV-Visible spectroscopy, as well as photoluminescence (PL) spectroscopy.
In a second step, we therefore synthesized zinc oxide nanofilms (ZnO NFs) in a biological approach assisted by spin coating technique, and thus studied its main physical properties using the same investigation techniques as mentioned above through a comparative study with the properties of bio-synthesized ZnO nanoparticles (ZnO NPs).
After investigation, the results show that the size of ZnO nanoparticles has been reduced by 20%, thus suggesting that the spin coating technique is an appropriate high quality method for improving the biosynthesis process of oxide-based nanomaterials, by overcoming the size phenomenon linked to this biological approach.

5:50 AM F.NM01.04.07
N-Doping of Quantum Dots by Lithium-Ion Intercalation Woo Je Chang, Kyu-Young Park, Yizhou Zhu, Christopher Wolverton, Mark Hersam and Emily Weiss; Northwestern University, United States

The electronic and optical properties of colloidal quantum dots (QDs) are significantly affected by impurities and doping. Crucial to efficient electronic doping of QDs is suitable charge compensation, but current compensation methods based on surface chemical modification and substitutional impurities have limited controllability and feasibility, respectively. Here, we describe an electronic *n*-type doping method where charge compensation is achieved with Li^+ ions occupying interstitial sites. By controlling the electrochemical potential, Li^+ ions are intercalated into CdSe QDs, allowing compositional control of Li_xCdSe, $x \leq 0.3$. At high lithiation levels, the Fermi energy is shifted into the QD conduction band, resulting in *n*-type degenerate doping characteristics, including bleaching of the band edge optical absorption, activation of intraband transitions, and blue-shifting of the photoluminescence spectrum. By reversing the sweep of the electrochemical potential, the original optical features of undoped QDs are partially recovered, indicating the reversibility of Li^+ ion intercalation. Overall, this work establishes electrochemical interstitial doping as a reversible method for tuning the optical properties of colloidal QDs.

6:00 AM F.NM01.04.08
High Plasmonic Quality Titanium Nitride Films Grown on MgO-Buffered Si (001) Kai Ding[1], Dhruv Fomra[1], Alexander Kvit[2], Hadis Morkoç[1], Nathaniel Kinsey[1], Ümit Özgür[1] and Vitaliy Avrutin[1]; [1]Virginia Commonwealth University, United States; [2]University of Wisconsin–Madison, United States

Titanium nitride (TiN) thin films on Si are very attractive for TiN-based integrated plasmonic devices. However, the heretofore reported TiN films on highly coveted Si substrates typically exhibited only moderate plasmonic properties due in large part to substantial defect densities caused by the large lattice mismatch between Si and TiN (21.9%). Therefore, smaller lattice mismatched substrates such sapphire and bulk MgO have been more commonly used. In this work, we report a comparative study on the structural and optical properties of TiN thin films grown by atomic layer deposition on different substrate materials including Si (001), MgO-buffered Si (001), c-sapphire, and bulk MgO (001). High-resolution X-ray diffraction (XRD), high-resolution scanning transmission electron microscopy (STEM), and variable angle spectroscopic ellipsometry were used to characterize the TiN films on these substrates. We observed that the TiN films grown on Si (001), MgO-buffered Si (001), and bulk MgO (001) substrates are all (001)-oriented possessing four-fold in-plane symmetry, while the films grown on c-sapphire substrate exhibit (111) orientation with six-fold in-plane symmetry. Insertion of a thin (~10 nm) MgO buffer led the intensity of XRD reflections from the TiN films grown on Si (001) to increase significantly, and cube-on-cube epitaxial growth was confirmed by high-angle annular dark-field imaging analysis of STEM. To characterize the plasmonic quality of the TiN films grown on different substrates, we used the traditional figure of merit (FOM) that equals to $-\varepsilon'/\varepsilon''$, which quantifies the tradeoff between dielectric losses (ε'') and metallicity (ε'). The peak FOM values are 2.4, 2.7, 2.8, and 2.9 for TiN films grown on Si (001), c-sapphire, MgO-buffered Si (001), and bulk MgO (001), respectively. As a result of the improved crystalline quality, use of a thin MgO buffer layer enhances the plasmonic quality of TiN films on Si (001) nearly to the level of TiN on bulk MgO (001) substrate. This thin MgO interlayer makes TiN thin films on MgO-buffered Si (001) an attractive material for applications in integrated plasmonic devices such as modulators and resonators based on the silicon platform.

6:10 AM F.NM01.04.11
Titanium Nitride for Plasmonic and Metamaterial Applications Amber N. Reed, Hadley Smith, Zachary Biegler, Krishnamurthy Mahalingam, Kurt Eyink and Augustine Urbas; Air Force Research Laboratory, United States

Titanium nitride (TiN) is a promising material for plasmonic and metamaterials due to its temperature stability, chemical stability, low surface energy, mechanical robustness, and zero-crossover wavelength in the visible region. In this work we demonstrate the reactive magnetron sputtering of heteroepitaxial TiN on (0001)-Al_2O_3, (001)-MgO and (0001)-$LiNbO_3$ substrates. Additionally, we demonstrate the incorporation of TiN in metal-dielectric stacks. We discuss the effect of

substrate material and deposition conditions on the TiN growth, stoichiometry and crystallinity. Coupled x-ray diffraction (XRD) show high quality epitaxial TiN growth on all three substrates. Pendellosung fringes on the (111)-TiN diffraction peak for the coupled XRD of TiN on c-plane sapphire and LiNbO3 and the (001)-TiN diffraction peak on MgO indicate uniform d-spacing and a pristine interface. Further structural characterization, however, reveals differences in crystal defects, strain and surface morphology based on substrate crystal structure and lattice mismatch. A 6-fold symmetry is seen in the pole figure XRD of the TiN grown on sapphire, indicating the presence of stacking faults. These domains, which are also evident in atomic force microscopy (AFM) of the TiN surface, are attributed to different stacking within the TiN domains. Cross-hatching features similar to those on the bare MgO substrate seen in the AFM of the TiN surface. X-ray photoelectron spectroscopy was used to investigate compositional differences between films grown with different deposition conditions. The real (ε_1) and imaginary (ε_2) permittivity for TiN was measured using variable angle spectroscopic ellipsometry. The TiN behaves metallic on all substrates for wavelengths above 470-490 nm. We calculate a quality factor (QLSPR = - $\varepsilon_1/\varepsilon_2$) of 3.34, 3.9 and 4.2 for TiN on $LiNbO_3$, MgO and Al_2O_3 respectively, for a wavelength of 1550 nm.

6:20 AM F.NM01.04.12
Modulating the Phase Transition in VO_2 Nanoparticles Produced by Solid-State Dewetting Samuel T. White, James R. Taylor, Thomas Folland, Joshua D. Caldwell and Richard F. Haglund; Vanderbilt University, United States

Phase-change materials (PCMs) can introduce reconfigurable behavior into metamaterials and optical devices that otherwise have fixed properties. Vanadium dioxide (VO_2) is outstanding among PCMs due to its near-room-temperature transition (T_c~68°C), sharp change in optical properties, and ultrafast (tens of femtoseconds) switching speeds. It has served as the active material in passive thermal control coatings, ultrafast photonic modulators, tunable ring resonators, and reconfigurable hyperbolic metamaterials. Many avenues for tailoring the optical properties and transition behavior of thin-film VO_2 have been explored—doping, strain, and defects being among the most prominent—but adjusting T_c without loss of contrast between the metal and insulating phases remains a challenge. Tungsten doping, for example, can reduce T_c; but heavy doping severely reduces the contrast and degrades the sharpness of the transition, before T_c is even below room temperature.
In contrast to thin films, VO_2 nanoparticles, doped with tungsten and embedded in a silica matrix, can achieve $T_c \sim$ -25°C without significant loss of contrast (1). Here, we investigate the formation of self-assembled VO_2 nanoparticles by solid-state dewetting of VO_2 thin films, and study how the phase transition behavior of those nanoparticles depends on particle size, W-doping, and silica encapsulation. Nanoparticle formation by solid-state dewetting, much simpler and faster than lithographic techniques, is driven by surface energies and statistical mechanics of particle aggregation. The resulting nanoparticles are remarkably consistent across different film deposition techniques (pulsed laser deposition, atomic layer deposition, RF sputtering, and vapor transport); a comparison of results on silicon shows that the average nanoparticle radius is directly proportional (slope ≈ 2.8) to the initial film thickness, regardless of the deposition method. We show how this size dependence, as well as the nanoparticle size distribution, can be predicted with a simple model.
The effect of nanoparticle size on hysteresis in the metal-insulator transition has been studied previously, usually by measuring large groups of particles in aggregate and considering the average particle size. By employing scattering-type scanning near-field optical microscopy, we observe the phase transition in individual nanoparticles with increased sensitivity, spatial resolution, and temperature resolution (across the region of strong correlation) relative to previous work (2). Simultaneously investigating multiple individual nanoparticles allows us to observe precise size and shape effects and to understand the degree of intrinsic particle-to-particle variation. Finally, by comparing the effects of W-doping and SiO_2-encapsulation on these nanoparticles and on corresponding thin films, we elucidate how particle-size effects, strain resulting from encapsulation, and/or a synergistic combination of the two can lead to greater tunability of T_c without loss of switching contrast. Together, these results represent an advancement in our understanding of how VO_2 nanoparticles form via solid-state dewetting and in our ability to tailor their size, shape, T_c, and hysteretic behavior to suit the needs of individual applications, thus further increasing the versatility of VO_2 as an active component for “smart” optical devices.

6:30 AM F.NM01.04.13
Dual-Mode Infrared Absorption by Segregating Dopants within Plasmonic Semiconductor Nanocrystals Stephen Gibbs[1], Christopher Dean[1], Joey Saad[1], Bharat Tandon[1], Corey Staller[1], Ankit Agrawal[2] and Delia Milliron[1]; [1]University of Texas at Austin, United States; [2]Lawrence Berkeley National Laboratory, United States

Degenerately doped metal oxides derive a high free charge carrier population from charge-compensated defects. Spatial

control of the dopant distribution within each nanocrystal allows tuning of the potential energy landscape for charge carriers in a way not possible for conventional metals. Here, we employ a slow-addition approach to nanocrystal synthesis that enables control of radial distribution of substitutional tin dopants within an indium oxide lattice. When dopants are segregated either to the core or surface of spherical indium oxide nanocrystals, the potential established by space-charge build up at the interface between indium oxide and tin-doped indium oxide prevents charge carriers from distributing homogeneously throughout the nanocrystal. The doped region maintains a higher carrier concentration than the undoped region. The dielectric permittivity then varies radially, resulting in two distinct spectral modes in the plasmonic optical response. Spectra reported previously for spherical plasmonic semiconductor nanocrystals have shown hints of this dual-mode response, but the reason for its appearance has remained largely uninvestigated. We developed a simple model employing a core-shell Maxwell-Garnett effective medium approximation that can reliably fit dual-mode spectra and can explain the evolution of the secondary mode in our dopant-segregated system.

Two sample series were synthesized and investigated: one with an undoped core and doped shell of increasing thickness and another with a doped core and undoped shell of increasing thickness. After shell growth of sufficient thickness, a second absorption mode manifested in both series. The effective medium model allowed us to extract intrinsic material properties, in particular the the carrier concentration of both the core and the shell, that supported the experimentally observed trends in both series. Lastly, we proved that the sensitivity of the plasmonic response to the surrounding refractive index depends on dopant distribution, underlining the impact that intra-nanocrystal carrier distribution can have on the interaction between plasmonic nanocrystals and their environment.

Hybrid Photonic Devices Based on Gallium Phosphide and Diamond Kai-Mei Fu; University of Washington, United States

Solid-state defect qubit systems with viable spin-photon interfaces show promise for single-photon generation, metrology and quantum information applications. Photon collection efficiency presents a major challenge for efficient utilization of defect qubits in high refractive index host materials like diamond and silicon carbide. Here we present a flexible inverse-design optimization framework that can reconcile a broad range of design constraints and generate planar dielectric photonic structures operating near the theoretical limit. Our optimized device utilizes a hybrid gallium phosphide (GaP) on diamond structure for photoluminescence (PL) extraction from synthesized NV centers in diamond. The enhancement is fairly insensitive to spatial localization and efficiently extracts photons from all dipole orientations. Additionally, we constrain patterning to the GaP layer, to minimize perturbations of the NV environment due to diamond etching. We fabricate the optimized device and observe efficient PL extraction from shallow (~100 nm) single NVs and near-surface (<100 nm) NV ensembles created by nitrogen ion implantation and annealing. These versatile devices exhibit a broadband PL enhancement for wavelengths in the measured range of 575 nm to 800 nm. We measure up to fourteen fold enhancement of free-space PL collection rate from device coupled NVs over non-device NVs and quantify the effect of fabrication and device integration on defect charge state and spectral stability. We expect such inverse-design hybrid devices will enable realization of scalable arrays of single-photon emitters, rapid characterization of new quantum emitters, high sensitivity metrology and efficient heralded entanglement schemes.

Volumetric Meta-Optics for Novel Device Functionalities Andrei Faraon; California Institute of Technology, United States

Three-dimensional elements, with refractive index distribution structured at subwavelength scale, provide an expansive optical design space that can be harnessed for demonstrating multifunctional free-space optical devices. We present 3D dielectric elements, designed to be placed on top of the pixels of image sensors, that sort and focus light based on its color and polarization with efficiency significantly surpassing 2D absorptive and diffractive filters. The devices are designed via iterative gradient-based optimization to account for multiple target functions while ensuring compatibility with existing nanofabrication processes, and they are experimentally validated using a scaled device that operates at microwave

frequencies. This approach combines arbitrary functions into a single compact element, even where there is no known equivalent in bulk optics, enabling novel integrated photonic applications. We further discuss capabilities enabled by volumetric meta-optical devices for compact on-chip polarimetry and discuss implementations using multi-layer nanofabrication.

5:30 AM *F.NM01.05.03
Van der Waals Material Integrated Nanophotonics Arka Majumdar; University of Washington, United States

Atomically thin van der Waals (vdW) materials have generated strong interest in the community due to its unusual physical properties and possibility of creating high-performance devices. However, the ultrathin nature of these materials limits the achievable light-matter interaction. One promising way to increase such interaction is via nanophotonic confinement of light. In fact, researchers have demonstrated various nanophotonic devices using such vdW materials, including optically pumped lasing, second harmonic generation, cavity enhanced electroluminescence, and exciton-polaritons. In this talk, I will explore the possibility of going to quantum optical regime using this material system integrated with nanophotonic resonators. I will discuss the role of exciton-phonon interaction in the cavity photoluminescence spectrum and present a quantum optical model of the coupled system in presence of the phonons. I will then report the observation of the exciton-polaritons using transition metal dichalcogenides (TMD) coupled with a metasurface structure. This hybrid light-matter system can be used to reach single photon nonlinear regime via further engineering the nanophotonic structure and patterning the TMD material.

5:45 AM *F.NM01.05.04
Ultrafast Semiconductor Dielectric Metasurfaces Igal Brener; Sandia National Laboratories and Center for Integrated Nanotechnologies, United States

Resonant dielectric metasurfaces offer unparalleled degrees of freedom to design flat-optics and study fundamental aspects of light-mater interaction, due to the freedom to use optical resonances of electrical and magnetic character and different symmetries, extremely low loss when operating below the semiconductor band gap, and controlled coupling and interactions between the meta-atoms. Additionally, transient sub-picosecond behavior can be imparted to the metasurface using optical pumping and controlling of carrier dynamics and decay. In this talk I will overview some of our work based on such metasurfaces made from III-V semiconductors. In particular, I will focus on ultrafast switching and diffraction, transient frequency conversion and perfect absorbing metasurfaces for THz emission and detection.

6:00 AM *F.NM01.05.05
Straintronics and ITO-Photonics—Advances in Heterogeneous Opto-Electronic Devices Volker J. Sorger; George Washington University, United States

Here I discuss our recent demonstrations of ITO-based opto-electronic devices and introduce the concept of 'Strainoptronics'. The presentation includes the following concepts: 1) Here we demonstrate a spectrally broadband, gigahertz-fast Mach–Zehnder interferometric modulator exhibiting a miniscule Vπ L of 95 V-um, deploying a subwavelength short electrostatically tunable plasmonic phase shifter based on heterogeneously integrated indium tin oxide thin films into silicon photonics. This GHz-fast broadband integrated modulator bears relevance since ITO is a foundry-compatible material. Unlike the crystal- orientation-sensitive LN, ITO optoelectronics is synergistic to enhancing electrostatics known from transistor technology. 2) Strain-engineered high-responsivity MoTe2 photodetector for silicon photonic integrated circuits In integrated photonics, specific wavelengths such as 1,550 nm are preferred due to low-loss transmission and the availability of optical gain in this spectral region. For chip-based photodetectors, two-dimensional materials bear scientifically and technologically relevant properties such as electrostatic tunability and strong light–matter interactions. However, no efficient photodetector in the telecommunication C-band has been realized with two-dimensional transition metal dichalcogenide materials due to their large optical bandgaps. Here we demonstrate a MoTe2-based photodetector featuring a strong photoresponse (responsivity 0.5 A/W) operating at 1,550 nm in silicon photonics enabled by strain engineering the two-dimensional material. Non-planarized waveguide structures show a bandgap modulation of 0.2 eV, resulting in a large photoresponse in an otherwise photoinactive medium when unstrained. Unlike graphene-based photodetectors that rely on a gapless band structure, this photodetector shows an approximately 100-fold reduction in dark current, enabling an efficient noise-equivalent power of 90 pW/Hz^0.5. Such a strain-engineered integrated photodetector provides new opportunities for integrated optoelectronic systems.

6:15 AM *F.NM01.05.06
Miniature Optical Systems Based on Cascaded Metasurfaces Andrew McClung, Mahdad Mansouree, Sarath Samudrala, Mahsa Torfeh, Babak Mirzapourbeinekalaye and Amir Arbabi; University of Massachusetts Amherst, United States

Miniaturized optical systems with planar form factors and low power consumption have many applications in consumer electronics, imaging and spectral sensing systems, and as integral parts of medical and industrial equipment. Flat optical devices based on dielectric metasurfaces introduce a new approach for the realization of such systems at low cost using conventional nanofabrication techniques. In this talk, I will present an overview of our work on the development of various high-performance optical dielectric metasurface components and systems. In particular, I will discuss multi-layer dielectric metasurfaces that enable complete control of wavefront at multiple wavelengths. I will present an on-chip integration platform enabled by vertical or lateral integration of multiple metasurfaces and active optoelectronic components such as laser arrays and image sensors. I will also introduce a novel technique for engineering chromatic dispersion by cascading and discuss various optical systems implemented in this platform and a single-snapshot multispectral imager.

6:30 AM *F.NM01.05.07
Optical Meta Devices—Eyes to the Future Din-Ping Tsai, Mu-Ku Chen and Yongfeng Wu; The Hong Kong Polytechnic University, Hong Kong

The novel property of optical metasurface which consist of nano-antenna made by artificial nanostructures, has attracted a lot of attention lately. Nano-antenna at the interface can behave like secondary radiation sources after interactions of the incident electromagnetic wave. Various optical devices based on the specific designs of meta-surfaces are called optical meta-devices. The great advantages of meta-devices are their new properties, lighter weight, small size, high efficiency, better performance, broadband operation, lower energy consumption, and CMOS compatibility for mass production. Given the demands of photonics, many optical meta-devices for the applications of controlling of the incident light are developed, such as for beam deflection and reflection, polarization control and analysis, meta-holography, second-harmonic generation, meta-laser, tunability, imaging, absorption, color display, focusing of light, multiplexer of colour routing and light-field sensing, etc. Considering the flexibility, the metasurface with integrated functionalities may be promising for multi-focusing microscopy, high-dimension quantum technology, hyperspectral microscopy, micro robotic vision, automobile sensing, virtual and augmented reality (VR and AR), drones, and miniature personal security systems [1-7].

2.5D Photonics as Engines of Information Manipulation Rajesh Menon; The University of Utah, United States

Micro- and nanostructures have been widely applied to enhance the performance of optical components and systems. Structures whose characteristic dimensions are greater than the wavelength of interest, l, can effectively manipulate the **scalar** properties of light, while nanostructures with dimensions << l/2 can manipulate the **vector** properties of light. By restricting the photonic functionality to a thin plane (i.e., 2.5D photonics), it's possible to create very thin lightweight imaging lenses,[1] spectrum-splitting solar concentrators,[2] and integrated-photonics devices.[3] In this presentation, we will highlight examples of each such device that overcome limitations of conventional implementations (if they exist at all). For example, flat multi-level diffractive lenses (MDLs) have recently shown achromatic bandwidth,[4,5] depth-of-focus[6] and efficient high-numerical aperture focusing[7] far better than their conventional counterparts, all while reducing weight and thickness by several orders of magnitude.
Computational techniques, such as nonlinear optimization, coupled with electromagnetics modeling can drive the *inverse*

design of novel optical and photonic components and systems. When guided by manufacturing constraints, such techniques can result in highly practical, low-cost, ultra-compact (on the order of l x l) and multi-functional integrated-photonics components, such as polarization beam-splitters,[3] wavelength splitters,[8] couplers,[9] waveguide bends,[10] etc. We'll also describe a nanophotonic cloak that enables two devices to be placed closer together than is otherwise feasible, leading to an increase in integration density.[11]
When coupled with advanced machine-learning or linear-algebraic methods, 2.5D photonics can engines of information manipulation, enabling highly non-intuitive forms of optical systems such as photography with no lenses[12,13] or microscopy with only a surgical needle[14,15] or multi-spectral imaging with a diffractive element.[16]

Nonlinear Photonic CMOS Technology for Optoelectronics Integration and Sub-7nm ULSI and ASIC—Is Hybrid Approach or Hybrid Silicon Laser Still Necessary? James Pan[1,2]; [1]Advanced Enterprise and License Company, United States; [2]Northrop Grumman Corporation, United States

A photonic MOSFET includes a low resistance laser or LED in the MOSFET drain region, and a photon sensor or avalanche photo diode (APD) in the well region. MOSFET, laser and APD are fabricated as one integral device. When a voltage is applied to the MOSFET gate, and a voltage is applied to the drain, both MOSFET and laser are on. Light emitted from the laser is absorbed by the APD or photon sensor in the channel / well region right next to the laser, and a light current is triggered. The large light current flows into the drain to contribute to the total output drain current. When the MOSFET is turned off, both laser and APD are switched to off immediately. Photonic CMOS includes a photonic NMOSFET and a photonic PMOSFET.

There are two approaches to fabricate photonic CMOS transistors: (1) The MOS transistor is built in a silicon wafer. Lasing semiconductor films (III-V or II-VI) are selectively deposited in the drain region with low temperature selective CVD or epitaxy. (2) A thin silicon film is deposited on a GaAs (or GaN) substrate. CMOS is built in this thin Si layer. In the drain region, the Si layer is selectively etched with RIE (Reactive Ion Etch or "Dry Etch"). Lasing semiconductor films are selectively deposited on the opened GaAs substrate. Photon sensors or APD are fabricated in the substrate prior to the CMOS process. The process integration is simplified and low cost - compatible to the existing sub-7nm advanced CMOS process flow, including FINFETs.

Nonlinear optical materials are fabricated in the CMOS isolation regions, or buried oxide (BOX) for silicon on insulator (SOI), and in the optical waveguides connected with the photonic CMOS. The nonliear feature enables the photonic CMOS for laser communications, and optical computing. When an external IR laser beam reaches a photonic CMOS, it is converted to a higher frequency light, and processed by the built-in photon sensor or APD in the photonic CMOS. The may also be laser communications among the photonic CMOS transistors.

Since silicon is an indirect bandgap material and can not emit light, a hybrid platform, or hybrid silicon laser, needs to rely on lasers in GaAs, GaN or other II-VI materials bonded or fabricated with silicon. The bonding process often comes with higher resistance, lower speed, and additional costs (due to the system on chip configuration and more expensive packages).

Forming a substrate with both Si and GaAs (InP, GaN..etc.) results in complicated process integration, and is not compatible to advanced CMOS ULSI or ASIC. If a laser is built with GaAs, then connected with a nearby silicon circuit, the process is quite sophisticated and performance may be compromised.

For high power lasers, the hybrid approach could cause more instability and vulnerable to temperature variations.

All such issues can be bypassed or resolved with the photonic CMOS technology. Lasing films are selectively deposited in the drain regions of CMOSFETs. CMOS and lasers are combined for higher speed, drive current, and better performance.

In this paper we would like to present I-V characteristics of photonic CMOS, and the effects of laser quantum efficiency and photon sensor absorption rate on the photon CMOS performance. We will also show several process integration schemes for nonlinear optical effects. Other potential products with photonic CMOS, such as new SRAM, circuit designs, and CMOS imaging applications will be discussed.

Enhancing Methanol Production by Photothermal Desorption in Solid-Gas Phase CO_2 Hydrogenation Siyuan Zhu, Peter Novello and Jie Liu; Duke University, United States

Currently, burning fossil fuels all over the world causes excessive emission of CO_2 accelerating climate change and causing detrimental harm to the environment. The capture of CO_2 and converting it into a high-value fuel has the potential to close the carbon cycle and mitigate harm to the climate in the future. Methanol is widely used in the chemical industry for producing chemicals, such as olefins, formaldehyde, methyl tert-butyl ether, and acetic acid. The reaction which produces methanol by CO_2 hydrogenation favors strict reaction conditions, like low temperature and high pressure. By using indium oxide as catalyst under ambient atmosphere, we found there is the fastest reaction rate at 250C with limited methanol desorption and the fastest methanol desorption at 500C with limited methanol production. Here, we design a two temperature processes for CO_2 hydrogenation reaction to produce methanol by shifting temperature between 250C and 500C. Indium oxide can absorb light from a blue LED efficiently, and allows quick temperature flip from these two temperatures. When using a blue LED to increase the temperature from 250C to 500C, the temperature increases more rapidly with the help of photothermal effect than pure heating, which can save about 1 min in the total desorption process. The study of these two temperature processes and using light as a heating source are investigating the energy efficiency between the pure heating process and the light plus heating process to optimize the energy input in the chemical reaction.

Hot Carrier Photophysics and Thermoplasmonic Response of Water-Soluble Plasmonic HfN Nanocrystals Sven Askes and Erik Garnett; AMOLF, Netherlands

Plasmonic nanostructures feature extraordinary absorption cross sections, highly tunable optical responses, and capability of concentrating the excitation energy in subwavelength volumes. They are furthermore attractive for driving sustainable photochemistry such as selective CO_2-reduction and N_2-fixation under mild conditions due to the presence of an active catalytic surface and the participation of hot electrons and/or phonons upon light excitation. Although Au and Ag nanoparticles have a strong visible range plasmonic response, they are relatively unstable in high-demanding photocatalytic environments due to thermal deformation and oxidation (for Ag). In contrast, the metallic refractory material hafnium nitride (HfN) offers a desirable combination of a visible range plasmonic response, high chemical inertness, catalytically active surface, and an extremely high melting point. Although the merits are clear, the synthesis of nanostructured HfN and the detailed photophysical characterization are still relatively unexplored.

In our work we use ultrafast transient absorption to characterize the photophysical behavior of crystalline, water-soluble HfN nanoparticles with a plasmonic response around 550 nm. We find that the ultrafast response is distinctly different from the noble metals due to the extremely short lifetime of plasmonic hot electrons in HfN. Using a dual-parabolic two-step model, we completely justify the response at short and longer timescales, and predict a phonon outburst directly after pulsed light

excitation. Our results reveal that HfN is highly promising for thermoplasmonic and photocatalytic applications, where material robustness is essential.

Optical Nano-Kirigami Nicholas Fang[1], Huifeng Du[1], Xinhao Li[1], Zhiguang Liu[1], Jiafang Li[2] and Ling Lu[3]; [1]Massachusetts Institute of Technology, United States; [2]Beijing Institute of Technology, China; [3]Chinese Academy of Sciences, China

Recently, exciting new physics of plasmonics has inspired a series of key explorations to manipulate, store and control the flow of information and energy at unprecedented dimensions. For example, analogous to the familiar description of optical energy and linear momentum, non-local symmetry transformations of photons lead to new degrees of freedoms with respect to optical spin and optical helicities that are controllable at sub-wavelength scales thanks to the emerging nanohelical structures and networks. In this talk I will introduce versatile 3D shape transformations of nanoscale structures by deliberate engineering of the topography-guided stress equilibrium of gold nanostructures. By using the topography-guided stress equilibrium, rich 3D shape transformation such as buckling, rotation, and twisting of nanostructures is precisely achieved, which can be predicted by our mechanical modeling. Benefiting from the nanoscale 3D twisting features, giant optical chirality is achieved in an intuitively designed 3D pinwheel-like structure, in strong contrast to the achiral 2D precursor without nano-kirigami. High-contrast cross-polarized diffractions are successfully observed in both linear and radial configurations, resulting from constant phase difference between the pinwheel structures of opposite handedness. We further demonstrate an on-chip and electromechanically reconfigurable nano-kirigami with optical functionalities. The nano-electromechanical system is built on a CMOS-compatible Au/SiO2/Si substrate and operated via attractive electrostatic forces between the top gold nanostructure and bottom silicon substrate. Large-range nano-kirigami like 3D deformations are clearly observed and reversibly engineered, with scalable pitch size down to 0.975 μm. The demonstrated nano-kirigami, as well as the exotic 3D nanostructures, could be adopted in broad nanofabrication platforms and could open up new possibilities for the exploration of functional micro-/nanophotonic and mechanical devices. Nanoscale control of optical spin and optical helicities with nano-kirigami are promising for numerous technological applications, such as chiral molecular sensing, separation and synthesis, super resolution imaging, nanorobotics, and ultrathin broadband optical components for chiral light.

Metamaterial Computing Machines Nader Engheta; University of Pennsylvania, United States

Metamaterials and metasurfaces have offered exciting platforms for engineering light-matter interaction that can provide desired functionalities. Over the past several years, numerous features and exciting applications of metastrucures have been explored and developed. One of the interesting possibilities in using metamaterials is the development of “metamaterial computing machines”, which we have been exploring in my group. In such paradigm, structures are designed in order to perform mathematical operations when waves propagate through them. Effectively, materials become computing machines. We have been investigating various scenarios in which metastructures can solve integral and differential equations and can invert matrices as incoming waves interact with them. In addition to using materials platform for this purpose, we have also investigating how collections of the Mach-Zehnder interferometers (MZIs) can provide another platform for solving equations and doing mathematics with light. In this talk, I will discuss some of our ongoing research projects on this topic and will present an overview of our most recent results.

5:30 AM *F.NM01.07.03
Advanced Optimization Algorithms for Nanophotonic Design at the Device and System Level Katherine T. Fountaine[1,2], Prachi Thureja[2], Yury Tokpanov[2], Dagny Fleischman[2] and Harry Atwater[2]; [1]Northrop Grumman Aerospace Systems, United States; [2]California Institute of Technology, United States

Nanophotonic design spaces are often highly nonlinear; the large number of parameters (both geometric and material properties) will result in an exceptionally complex and high dimensionality design space that renders an exhaustive parameter sweep computationally insurmountable. Additionally, the design of a full nanophotonic device involves optimization at

multiple levels, including material selection/design, device design, and system level design. In this talk, I will discuss multiple optimization frameworks for different design problems, including device level design for multispectral filters and phase modulation devices and system level design for beamsteering devices and other active metasurfaces. At the device level, we have (1) employed NOMAD (non-linear optimization using mesh adaptive direct search), a hybrid (global +local), derivative free optimization method, and (2) developed a new Bayesian optimization algorithm, MF-MI-Greedy, which uses multiple levels of fidelity, to optimize various nanophotonic structures including dielectric metasurfaces and multispectral filters. At the system level, we have (1) developed a new iterative genetic algorithm and (2) employed neural nets to optimize antenna arrays of active metasurfaces with non-ideal phase and amplitude characteristics. These studies suggest that selection of the correct optimization algorithm at a given design level can significantly reduce computational time for design and improve overall device performance.

5:45 AM *F.NM01.07.04
Manipulating Light and Matter at the Nanoscale for Next Generation Solar Energy Conversion Devices Esther Alarcon-Llado; AMOLF, Netherlands

Introducing thin, light-weight and high efficiency photovoltaics will ensure solar cells to be integrated in urban landscapes, small gadgets or even in space. While thinning down of absorber materials is a good strategy to overcome these restrictions, it comes down to the expense of poor light absorption. By contrast, nano-structuring is an effective approach to tackle flexibility, material and weight reduction without compromising absorption through the exploiting of their strong interactions with light.
In this talk I will describe the power of semiconductor nanostructures to capture and trap sunlight, enabling a wide range of new solar cells designs. First, I will introduce the wave guiding effects in semiconductor nanowires. The absorption cross-section in semiconductor nanowires can reach up to x100 their geometrical footprint, so that nanowire arrays can reach to the same absorption as in bulk films with a small fraction (< 3%) of the material. We have seen experimental evidence for the strong extinction in vertically standing GaAs and InAs nanowires, using 3D confocal fluorescence microscopy. We observe how light is perturbed up to few microns away from the nanowires for a broad range of wavelengths. We demonstrate that by probing ordered arrays with this method, the effective absorption coefficient and cross-section can be obtained without the need of a transparent substrate. Because of the absorption cross-section in nanowires is ruled by the efficient incoupling of light to the waveguide modes, absorption is relatively narrow-band (~50 nm) with the central wavelength depending on the nanowire diameter. The coloured appearance in sparse arrays are actually the perfect framework to generate a new class of semi-transparent photovoltaics, that can be used as windows and other urban spaces. We find that the multi-mode absorption in the arrays, result into higher absorbance as compared to the thin film counterpart with the same average visible transparency. Second, I will show that the diffractive power of nanowire arrays can be modulated by the wavelength-selective 1D wave guiding in the nanowires. Using the tailored structural properties in the array, we show that a nanowire array can serve as both solar cell and light in-coupler to a thin film cell underneath. The dual waveguiding effects in GaAs nanowire-Si thin film tandem architectures give rise to a 4-fold light absorption increase in the Si ultrathin bottom cell. This is a significant light trapping scheme that is obtained “for free” when using a nanostructured top cell. As a final remark, I will touch upon emerging fabrication methods for nanostructured semiconductor and conducting metamaterials. In particular, electrochemical deposition is a convenient growth method that allows for control over the growth conditions through combinations of solvents, additives, and pH, in addition to conventional parameters such as heat and pressure. By combining scalable imprint lithography with electrochemical deposition, we demonstrate large-area plasmonic lattices of In,Ga metals that can be electrochemically transformed to dielectric (In,Ga)As.

Photonic Designs for Laser Driven Propulsion Ho-Ting Tung and Artur Davoyan; University of California, Los Angeles, United States

In this work we examine principles of laser propulsion for spaceflight in the solar system. We discuss regimes of laser operation, system requirements on acceleration distance and sail-craft dimensions and weight. We show that with laser

propulsion small satellites may be injected into various trajectories on a path to other planets. We show that travel times to planets may be as small as one month. We analyze spacecraft trajectory for various laser illumination regimes. Lastly, we discuss sail-craft materials and photonic design. We show that with a proper choice of low-loss materials and photonic engineering highly reflective sails may be crafted to ensure efficient momentum transfer. We further study pathways for radiative heat dissipation to ensure sustainable spacecraft operation and propulsion. We discuss several specific design concepts and demonstrate the feasibility and promise of such laser propulsion with today's technology. Our work shows that laser propulsion may offer an alternative for fast transit time and high velocity missions beyond the reach of conventional chemical rockets and plasma engines.

6:10 AM F.NM01.07.06

Inverse Designed Metagratings for Far-Field Integral Equations Solving Andrea Cordaro[1], Brian Edwards[2], Vahid Nikkhah[2], Andrea Alù[3], Albert Polman[1] and Nader Engheta[2]; [1]AMOLF, Netherlands; [2]University of Pennsylvania, United States; [3]The City University of New York, United States

As we approach the physical speed and power consumption limits of standard microelectronics processors, new strategies for computing are required. Among the different explored routes, analog optical computing has gained significant attention for its capability to process large amounts of data at negligible energy per bit and high speeds. Moreover, recent advances in nanofabrication techniques have enabled unprecedented control over light propagation and manipulation via subwavelength thickness metasurfaces. This, in turn, opens entirely new avenues in the field of optical analog computing.
Here, we propose a metasurface-based platform for analog computing that solves the Fredholm integral equation of the second kind for free-space radiation
$\Phi(x) = I_0(x) + \int_a^b K(x,t)\Phi(t)dt$ (1)
where $\Phi(x)$ is the unknown solution of Eq.(1), K(x,t) is a function of two variables that acts as the kernel of the integral operator, and $I_0(x)$ is an arbitrary input function. When the kernel of such an integral equation does not match that of an integral transform for which we have an inversion formula (e.g. Fourier transform) and is not separable, the last resort to solve Eq. (1) is to exploit the Neumann series. The latter is a successive approximation method: the initial guess $\Phi_0(x) = I_0(x)$ is fed into the integral in Eq. (1) obtaining a second approximation $\Phi_1(x)$. By repeating this procedure iteratively, our guess $\Phi_n(x)$ approaches the solution $\Phi(x)$ as $n\rightarrow\infty$.
Following the same reasoning, it is possible to physically implement this method in an analog fashion by means of a metasurface coupled to a feedback system. In fact, Eq. (1) can be discretized by sampling its terms over *N* points in the interval [a, b] thus being equivalent to an NxN matrix equation. Next, it is possible to think of the *N* sampling points as *N* physical modes addressing the system and to consider the integral operator as a scattering matrix which performs matrix multiplication between sets of these modes. In our proposed scheme, the modes are the discrete diffraction channels characterizing a 2D metagrating, determined by its periodicity, while the discretized integral operator is given by the metasurface scattering matrix **S**. An arbitrary discretized input $I_0(\mathbf{x})$ (where **x** is a vector of length *N*) is multiplied by the metasurface S-matrix upon reflection and it is fed back by a semi-transparent mirror for the next iteration. Intuitively, this system performs an analog Neumann series.
The core requirement of this procedure is the possibility of designing a metasurface that has a prescribed S-matrix. To this end, we optimize the metagrating unit cell by means of the adjoint method. In order to prove the generality of this method, we choose a random passive and reciprocal S-matrix with N=3 as our objective. The resulting optimized unit cell consists of a complex silicon nanostructure on a sapphire substrate. The unit cell is embedded in a SiO_2 superstrate capped on top by a silver semi-transparent mirror. The design wavelength is =710 nm while the unit cell is 825 nm wide and 415 nm deep. These dimensions are chosen such that only 3 diffraction order exists in the superstrate (where the Neumann series is performed) while 3 plus 4 extra "dump" channels diffraction order are present in the substrate to act as energy dumps in the case of a non-unitary kernel. The optimized metagrating can approximate rather well the desired S-matrix achieving a figure of merit $FOM = \sum_{i,j} |S_{ij} - S_{opt,ij}|^2$, where $S_{opt,ij}$ is the simulated optimized S-matrix and S_{ij} is the prescribed one.
Next, we compared the simulated response of the entire structure (including the mirror) to the ideal solution of Eq. (1) showing a nice agreement. At the conference, we will show our experimental progress and optical measurements.

6:20 AM F.NM01.07.08

Guided-Mode Resonator Devices for Quantitative Phase-Contrast Imaging Anqi Ji[1], Jung-Hwan Song[1], Qitong Li[1], Pieter Kik[2], David A. Miller[1] and Mark L. Brongersma[1]; [1]Stanford University, United States; [2]University of Central Florida, United States

Phase-contrast imaging is an optical method invented by Nobel Laureate Frits Zernike to visualize unstained living cells. As cells are highly transparent, their structural information is hidden in the phase profile of the transmitted light field, where different micro-organisms inside the cell induce different amounts of phase delay. The underlying key principle of the phase-

contrast technique is to interfere the light scattered by a specimen with reduced, $\pi/2$ phase-retarded unscattered light (DC component). As a result, the original phase undulation of the electric field is transformed into an enhanced amplitude modulation and thus the contrast in the image is maximized. Conventionally, phase-contrast imaging is achieved with a set of bulky Fourier optics components for filtering and selective phase retarding elements, limiting its use in certain applications. Due to the physical diffraction by these elements, conventional phase-contrast suffers from a limited range of enhancement and various artifacts, including halos and shade-off.

Here, we propose to replace the bulky optics in conventional phase contrast imaging by nanopatterned cover slip that can conveniently be inserted into any bright field microscope to achieve phase-contrast imaging. The cover slip is patterned with a 1 mm-by-1 mm area of a visually transparent guided-mode resonance structure. More specifically, we fabricated a 90-nm-thick, 210-nm-wide Si_3N_4 gratings on top of 136-nm-thick Si_3N_4 slab waveguide with a lattice constant of 390 nm. The structure can be used to perform phase-contrast microscopy by interfacing the normally-incident planewave to the guided-mode resonance at a 630 nm illumination wavelength. The DC incident light incurs a 98% amplitude reduction and a $\pi/2$ phase pickup while the scattered, non-DC Fourier components of the scattered light from a specimen pass through with near-unity transmission. We deposit the Si_3N_4 waveguide on an amorphous quartz substrate by plasma-enhanced chemical vapor deposition (PECVD) and pattern the grating with electron beam lithography and reactive ion etching (RIE). We characterize the optical dispersion properties of the fabricated samples and verify the phase contrast imaging capability with various phase objects such as cells, nanofabricated samples and 2D material flakes. We observe a 10 fold contrast enhancement for a wide range of objects with reduced artifacts as compared to Zernike's method. We expect this opens a promising avenue for compact, quantitative, and high-accuracy phase-contrast microscopy.

6:30 AM F.NM01.07.09
Meta-Sails for Stable Beam-Riding—Local Manipulation of Optical Forces Mohammad Mahdi Salary and Hossein Mosallaei; Northeastern University, United States

Light can exert an optical force upon its interaction with an object due to the momentum exchange between massless photons and the object. The optical force has been harnessed for a variety of applications including trapping, accelerating and binding microscopic particles as well as pressurizing thin-films and two-dimensional materials. It has also been envisioned as a propulsion mechanism for space applications, leading to the advent of light sailing technology. Light sails gain momentum from the radiation pressure due to illumination from a light source - the Sun or laser beams - to provide the thrust for driving satellites in an obit or driving spacecrafts in certain trajectories without reliance on reaction mass thus allowing for continuous acceleration and greater longevity. In this talk, we will demonstrate how photonic metasurfaces can be used as light sails offering an unprecedented control over motion degrees of freedom via local manipulation of optical forces and torques through anomalous reflection and refraction. We will present a comprehensive modeling of motion dynamics of large-area meta-sails consisting of graded pattern nanostructured metasurfaces by linking the macroscopic optical response evaluated via a ray tracing approach based on the generalized Snell's law to the mechanical response governed by Newton-Euler equations, through Maxwell's stress tensor method. We will discuss the required conditions for the stability of a meta-sail riding on a high-power laser beam toward achieving relativistic velocities for deep space exploration and interstellar voyage, in terms of phase gradient and center of mass location. We will show an all-dielectric metasurface design featuring ultralow areal density while offering a high reflectivity and wide phase agility in a broad bandwidth which enables efficient acceleration with sustainable beam-riding stability for target relativistic velocities up to 20% speed of light despite relativistic Doppler broadening. In particular, we will disuss how the chromatic dispersion of the metasurface affects the stability and acceleration due to the relativistic Doppler shift in the frame of the accelerating meta-sail. We will present the estimated motion trajectories of the meta-sail driven by a 100 GW laser beam reaching to 20% speed of light in less than 12 minutes and illustrate that the Doppler-induced effects can be used for damping the amplitude of bounded oscillations through an engineered chromatic dispersion to yield a radiative loss in the reflection channel, toward minimizing the residual motion of the meta-sail and achieving a high-precision trajectory en route to a far destination.

6:40 AM F.NM01.07.10
Nanowire Devices Add Another Dimension to Terahertz Spectroscopy and Imaging Kun Peng[1], Dimitars Jevtics[2], Fanlu Zhang[3], Sabrina Sterzl[1], Djamshid A. Damry[1], Mathias U. Rothmann[1], Benoit Guilhabert[2], Michael Strain[2], H. Hoe Tan[3,3], Laura Herz[1], Lan Fu[3,3], Martin Dawson[2], Antonio Hurtado[2], Chennupati Jagadish[3,3] and Michael Johnston[1]; [1]University of Oxford, United Kingdom; [2]University of Strathclyde, United Kingdom; [3]The Australian National University, Australia

The terahertz (THz) band of the electromagnetic spectrum falls in the region between microwaves and infrared, spanning from 0.1 to 30 THz. This is an information-rich frequency regime, where many molecular vibration/rotation modes and collective excitations occur in materials, providing THz "fingerprints". Hence, THz spectroscopy and imaging are considered

powerful tools for materials characterization and identification [1], being particularly beneficial to the biomedical field (e.g. diagnostics) and defense (e.g. security screening) due to their ionization-free nature and transparency to non-conducting materials. Furthermore, pulsed THz spectroscopy and imaging are particularly powerful for studying dynamic processes in materials with femtosecond time resolution. To date, the vast majority of THz pulsed systems are based on generation of single-cycle linearly polarized THz pulses, with a detection technique that can only measure one polarization component over one real-time scan. This is problematic when exploring complex material systems (e.g. birefringent materials) with anisotropic properties that could be affected by surface topography, crystal structure, stress and magnetic fields.
In this work, we have designed, fabricated and characterized polarization-sensitive THz detectors based on orthogonally-crossed semiconductor nanowire networks [2], and realized a single monolithic device that allows simultaneous measurements of the orthogonal components of the electric field of THz pulses without crosstalk. This device architecture is inspired by our pervious findings [3] that both single semiconductor nanowires and bow-tie THz antenna exhibit extremely high polarization selectivity to THz radiation. Single-crystal indium phosphide nanowires were used as the active material, grown by selective area epitaxy in a metalorganic chemical vapor deposition system, and were fabricated with a double-bowtie electrode (antenna) geometry design. A nanoscale 'Transfer Print' technique was developed [4], enabling rapid and accurate integration of nanowires onto the devices with well-defined location and orientation. The fabricated nanowire devices were incorporated into a THz time-domain spectroscopy system for performance tests. Moreover, the capabilities of the detector in metamaterials and birefringent materials analysis were demonstrated. Our nanowire detectors are derived from photoconductive antennas, and thus share the same operating mechanism and data analysis technique, which are the most popular detector type employed in many custom-made and commercial THz pulsed systems, suggesting an ease of direct implementation in both scientific and industrial settings. This detector type can be miniaturized down to the nanoscale size for on-chip THz spectroscopic and imaging applications.

Mid-Infrared Molecular Sensing Using Mie Antennas on a Mirror Kan Yao, Jie Fang and Yuebing Zheng; University of Texas at Austin, United States

Mid-infrared (MIR) spectroscopy is a powerful technique for sensing through identifying the vibrational fingerprints of the analyte molecules. However, due to the large mismatch between the nanometric sizes of the molecules and the wavelengths of MIR light, a sufficient amount of samples is a necessity to produce long enough optical paths so that signals from the intrinsically weak light-molecule interactions can accumulate to the sensitivity threshold of the detectors. Conventional characterization techniques, such as Fourier-transform infrared (FTIR) spectrometers, require either samples with a thickness of at least some hundreds of nanometers or complex apparatus, such as attenuated total reflection (ATR) accessories. As a consequence, high-sensitivity identification of molecules with minute samples is still a challenge in MIR spectroscopy. Nanophotonic resonators offer unprecedented opportunities to boost the optical fields at the subwavelength scale. Coupling the analyte molecules with resonant building blocks has been proven an effective approach to enhance light-molecule interactions. However, as the wavelength extends to the MIR region, plasmonic resonances gradually fade out and become less intense compared with in the visible region, making them not ideal candidates for sensing purposes. Here, taking advantage of the high-quality silicon microspheres as lossless Mie resonators, we exploit the possibility of using high-index dielectric antennas for enhanced molecular sensing.
High-index dielectric particles are well-known for their capability to support Mie resonances. For example, spheres sized a few hundreds of nanometers can scatter visible light in a highly directional manner due to the interference between electric and magnetic dipole modes. By using FTIR microspectroscopy, we manage to characterize infrared optical properties of single silicon microspheres and identify the first 14 modes, from magnetic dipole up to the electric 128-pole, with the help of Mie theory. Then, to get the optima conditions for the sensing purpose, we study the evolution of the resonance modes when the particles are placed on a mirror, i.e., at different locations of a standing wave. It is found that at MIR wavelengths, the fundamental magnetic and electric dipole modes, which spectrally overlap the molecular vibrations, can be selectively enhanced by altering the design of the substrate. We demonstrate ultra-sensitive measurements of sub-10 nm Poly(methyl methacrylate) (PMMA) under different conditions, evidenced by the pronounced spectral feature corresponding to the C=O bond vibration near 1722 cm^{-1}. In comparison, measurements in the absence of the Si antennas or an optimized spacer do not record any meaningful sensing signals. Our results provide a possible solution to high-sensitivity MIR molecular sensing based on a miniaturized photonic platform with minute analytes.

Late News: Mie Resonances in High-Index Nanoparticle Arrays for Control of Coherent Light States Vahid Karimi and Viktoriia Babicheva; The University of New Mexico, United States

The ultra-thin optical structures of high-refractive-index materials, such as semiconductors and III-V compounds, can be used for control of light at the subwavelength scale [1]. We envision that metasurfaces with Mie resonances have a high potential in being utilized for control of coherent light states. The integration of light-emitting devices, such as VCSELs and VeCSELs, and dielectric metasurfaces has been shown as a viable technique to solve the issues of an arbitrary beam-shaping light-emitting device with programmable controllability as well as laser profiles and self-collimation [2]. The monolithic approach based on direct sculpturing of emitting surfaces into metasurfaces provides an authentic new degree of freedom of beam-shaping VCSELs without compromising the device performance.
Nanopillar metasurface at the back-side surface of a bare VCSEL is used as polarization insensitive meta-atoms, and each nanopillar works as an independent nanoscale resonator with a low-quality factor. The larger the effective refractive index, the more drastic change in the transmitted phase delay can be induced. Simultaneously, the bigger diameter of nanopillars, the better the transverse confinement of light is achieved. The integrated III-V compound metasurface operates as a passive element shaping the laser beam at the emission surface rather than adjusting the laser cavity. Programmable laser emission is controlled by the metasurface properties with the employment of arbitrary beam profiles.
We examine the scattering properties as well as reflection, transmission, and absorption of various high-index nanopillar supporting Mie resonances. We also analyze the effect of the thickness of the intermediate layer between the nanopillars and oxide substrate. We report on the scattering features of the metasurface illuminated normally from either substrate or superstrate side. We demonstrate that adding the high-index intermediate layer can shift desired resonances along the spectrum.

Progress on Topological Light Sources and Sensors Boubacar Kante[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Topology plays a fundamental role in contemporary physics and enables new information processing schemes and wave device physics with built-in robustness. Recently, significant efforts have been devoted to transposing topological principles to bosonic systems. In the first part of this talk, I will discuss our invention of the first topological laser, a non-reciprocal light source capable of coupling stimulated emission to selected waveguide output in a controllable manner. I will also discuss unique optical devices based on this platform. In the second part of the talk, I will discuss our recently proposed scheme to systematically implement singularities known as exceptional points in passive plasmonics. I will discuss the new scheme and how we overcame current immuno-assay nano sensing record with plasmons by more than two orders of magnitude.

Holography, Quantum Correlations and Extreme Near Fields in Optical Metasurfaces Albert Polman; AMOLF, Netherlands

We use cathodoluminescence imaging spectroscopy (CL) as a powerful tool to characterize optical metasurfaces at deep-subwavelength spatial resolution.[1] In CL, a 5-30 keV electron beam is raster-scanned over the surface while the emitted radiation in the optical and near-infrared spectral range is detected. In the coherent excitation mode the electron beam passing through the metasurface creates a femtosecond electric field oscillation that couples strongly to polarizable electrons in the material, providing a spectrally broadband nanoscale probe of the local optical density of states.

We use CL to image localized modes of resonant plasmonic and dielectric nanostructures and reconstruct their scattering wavefronts using CL holography. We determine the phase and amplitude of wavefronts scattered by single-crystalline Au nanocubes and nanoholes, and derive from that the dominant scattering dipoles.[2] We discuss how the electron wavepacket may collapse as it generates a coherent superposition of surface plasmon polaritons and plasmonic transition dipole radiation that interfere in the far field.

We correlate CL data with photon-induced near-field electron microscopy (PINEM) of plasmonic nanotips in Au nanostars. As shown before,[3] strong plasmonic near fields can dress the high-energy electron energy spectrum into a ladder of coherent harmonics, shaping the electron quantum wavepacket. We will show that this enables probing of the plasmon charge distribution and the corresponding near-field intensity of plasmonic nanotips at the true nanoscale. We introduce how specially tailored optical metasurfaces enable entirely new ways to shape electron wavepackets in space and time.

Plasmonic, Photonic and Excitonic States Interfaces—Time-Modulated Flat Optics and Time-Resolved Measurements Harry Atwater; California Institute of Technology, United States

Plasmonic, photonic and excitonic states at interfaces govern the optical response of tunable nanophotonic structures such as active metasurfaces, photodetectors and photocatalysts. I will discuss how we can harness plasmonic and excitonic states at interfaces to enable power-efficient phase modulation of active metasurfaces and discuss implications for time-modulated flat optics. Specifically, I will discuss avenues for increasing the power density and power efficiency of plasmonic conducting oxide metasurfaces for temporal phase and amplitude modulation and requirements for time-modulated photonic applications, such as multi-frequency generation and realization of non-reciprocal metasurfaces. I will also report on how time-resolved measurements of plasmonic and excitonic states at interfaces can yield insights about fundamental light-matter interactions in these systems. Specifically, I will discuss i) how electron-hole correlations affect the dynamics of hot carrier relaxation in plasmonic Au/GaN photodetectors and photocatalysts and ii) how time-resolved measurements of excitons generation inform our understanding of carrier dynamics and transport in transition metal dichalcogenides such as WS_2 and MoS_2.

5:45 AM *F.NM01.08.04
Plasmonics in Topological Insulator Thin Films and Multilayers Stephanie Law; University of Delaware, United States

Topological insulators (TIs) are materials with a bulk bandgap crossed by surface states that exhibit linear dispersion and spin-momentum locking. Electrons occupying these surface states have low mass and large Fermi velocity, while the spin-momentum locking leads to a reduction in scattering, since a change in momentum requires a spin flip. Among other interesting properties, two-dimensional Dirac plasmons can be excited from these surface electrons. These plasmons are expected to exhibit resonances in the terahertz (THz), a frequency range of interest for chemical identification, imaging, and communication. The TI plasmons should inherit the unusual properties of their constituent electrons: the excitations should be two-dimensional and massless, similar to those found in graphene. Unlike graphene, TI plasmons should also exhibit spin-momentum locking, leading to a reduction in scattering and an increased plasmon lifetime.
In this talk, I will describe our efforts to excite localized plasmon polaritons in TI nanoribbons, propagating plasmon polaritons in TI thin films, and complex plasmon phonon polariton modes in TI multilayer stacks. In thin films, a plasmon can be excited on the top and bottom of the film simultaneously. These plasmons couple to each other, resulting in an acoustic and optical mode. When the film is etched into stripes, we can excite localized plasmon polaritons. By changing the stripe width and film thickness, we can map out the dispersion of these modes, demonstrating extraordinarily high mode indices and long plasmon lifetimes. We can also apply a metallic grating to an unpatterned TI thin film and couple into propagating plasmon polariton modes. I will discuss our efforts to map the propagating plasmon polariton dispersion by changing the grating parameters. Finally, using molecular beam epitaxy, we can grow stacks comprising alternating layers of TI material and trivially-insulating band insulator material. These stacks house multiple topological surface states, and the plasmons residing in these states can couple to one another and to the phonons in the system. The multilayers thus contain complex coupled plasmon phonon polariton modes. We can understand the properties of these modes by changing the

various structural parameters in these films. By growing a stack comprising many alternating TI/trivial insulator layers, we can move toward creating a THz Dirac metamaterial.

6:00 AM *F.NM01.08.05
Investigating and Controlling the Opto-Electronic/Valleytronic/Spintronic Properties of van der Waals Nanomaterials/Heterostructures/Metastructures Nai-Chang Yeh, Wei-Hsiang Lin, Chen-Chih Hsu, Duxing Hao, Deepan Kishore Kumar and Chia-Shuo Li; California Institute of Technology, United States

Thin layers of van der Waals (vdW) materials, ranging from insulators to semiconductors, semi-metals and superconductors, exhibit novel optical, electronic, orbital, magnetic, topological and superconducting properties. Varying the interfacial stacking order of vdW homo/heterostructures further yields Moiré bands and new physical phenomena. Nanoscale strain-engineering of vdW materials (*e.g.*, graphene, transition-metal dichalcogenides, TMDs) can induce novel quantum/topological phenomena, such as giant pseudo-magnetic fields (PMF) and flat bands associated with quantized Landau levels in monolayer graphene, and strain-dependent energy gaps and exciton lifetimes for monolayer 2H-phase TMDs. Quantum confinement due to reduced spatial dimensions and broken symmetry is known to induce new quantum states that are non-existent in the bulk. Spin-orbit coupling of light by optical vortices (*a.k.a.* twisted light, Laguerre-Gaussian beam) and plasmonic vortices produces photons with nontrivial spin/orbital-angular-momentum, which can impart integer and fractional *topological charges* onto condensed matter and atomic/molecular systems through light-matter interactions. Therefore, investigating and controlling the light-matter interactions in vdW nanomaterials/heterostructures/metastructures represents a pathway to explore new quantum phenomena and to advance opto-electronic/valleytronic/spintronic applications.

We employ scalable CVD and PECVD fabrication techniques to synthesize a variety of vdW nanomaterials and their heterostructures, including monolayer and bilayer graphene,[1-3] quasi one-dimensional (1D) graphene nanostripes,[1,4] h-BN,[5] and monolayer-to-multilayer TMDs MX_2 and $MX_{2-y}X'_y$ (M = Mo, W; X, X′ = S, Se, Te; $0 \leq y \leq 2$).[6] We investigate their properties by means of spatially resolved and polarization-dependent photoluminescence (PL), time-resolved PL (TRPL), Raman spectroscopy, x-ray photoelectron spectroscopy (XPS), Kelvin-probe force microscopy, conductive atomic force microscopy (c-AFM), scanning tunneling microscopy/spectroscopy (STM/STS).[6,7] We perform nanoscale strain engineering on monolayer graphene to control the strain-dependent PMF and electronic correlation, and to achieve valley/spin polarization;[7] and on TMDs to control the energy gaps and exciton lifetimes. We develop plasmonic vortices on TMDs by metasurfaces together with circularly polarized light to control the light-matter interaction and valley/spin polarization in TMD and the topological charge. Our approach leads to various interesting findings, including: valley splitting, quantum oscillations, spontaneous symmetry breaking and spin polarization, quantum valley-Hall and quantum anomalous-Hall effects in valley Hall transistors based on nanoscale strain-engineered monolayer graphene;[7] exceedingly long and temperature independent optically excited carrier lifetimes (~ 10 ns) as well as broadband (from IR to UV) photoluminescence in quasi-1D graphene nanostripes; much enhanced valley polarization in monolayer WS_2 by combining plasmonic vortices with circularly polarized light; and compositional dependent opto-electronic/valleytronic properties in $WS_{2-y}Te_y$ ($0 < y < 2$). Based on these experimental findings, we discuss potential applications of van der Waals nanomaterials/heterostructures/metastructures to opto-electronic/valleytronic/spintronic devices.

Dipole-Coupled Defect Pairs as Deterministic Entangled Photon Pair Sources Derek Wang, Tomas Neuman and Prineha Narang; Harvard University, United States

Non-classical states of light are important resources for scalable quantum technologies, such as quantum information processing, networking, and metrology. Entangled photon pairs, in particular, have applications in solid-state quantum repeaters, a crucial component of long-distance quantum networking that overcomes transmission loss by leveraging the effects of entanglement swapping and quantum teleportation. Despite the diverse applications for such non-classical states of

light, methods for generating them deterministically remain limited. Here, we propose a scheme to deterministically generate entangled photon pairs from dipole-coupled pairs of defects in solid-state materials [1], which already have wide applicability in quantum technologies as quantum memories because they combine the favorable coherence and nonclassical emission properties of isolated atoms with the scalability and stability of solid-state technologies. Based on this scheme, we predict spectroscopic signatures and quantify the entanglement with physically realizable system parameters. We find that the entanglement measures of the emitted photons are robust to relative differences in frequency between the intermediate states. Importantly, the Bell state fidelity can be optimized by e.g. tuning the defect transition dipole moments. A defect-based entangled photon pair source would offer numerous advantages including flexible on-chip photonic integration and tunable emission properties via external fields, electromagnetic environments, and defect selection.

6:25 AM F.NM01.08.08
Electrons Generate Broadband Vortex Light Beams Using Chiral Plasmonic Metasurfaces Nika van Nielen[1], Mario Hentschel[2], Nick Schilder[1], Harald Giessen[2], Albert Polman[1] and Nahid Talebi[3]; [1]Center for Nanophotonics, AMOLF, Netherlands; [2]4th Physics Institute and Research Center SCoPE, University of Stuttgart, Germany; [3]Institute of Experimental and Applied Physics, Christian Albrechts University, Germany

Vortex beams of light have recently attracted great attention because of their ability to sensitively probe symmetries and topologies of materials. At the same time, electron beams are known to excite special states of light, for example by the generation of transition radiation (TR) or surface plasmon polaritons (SPPs). Here we bring together these two worlds, and present a plasmonic optical metasurface which under excitation with 30 keV electrons generates a collimated light beam with well-defined orbital angular momentum in the visible-near-infrared spectral range.
We fabricate spiral-shaped geometries composed of arrays of holes in a 40-nm Au film on a Si_3N_4 membrane by Au^{++} focused ion beam milling. We excite the spiral geometries with 30 keV electrons almost at the center and collect the coherent cathodoluminescence and observe clear light vortex beams in the far field. We fabricate spiral arrays with left-and right-handed geometries and different winding numbers and find that the angular momentum of the generated TE- and TM-polarized Laguerre-Gauss-like light beams matches the number of spiral arms in our structure. Finite-difference-time-domain (FDTD) simulations are used to determine the evolution of electric and magnetic field components over time and space, and provide detailed insights in the interference effects that lead to the build of the vortex beams over time.
We describe the observation of the vortex CL beams with well-defined topological charge by a model in which 30 keV electrons create: (1) TR at the point of impact and (2) SPPs that travel over the metal surface and scatter out by generating magnetic dipoles in the plasmonic holes. Interference of these two scattering contributions in the far field then leads to the vortex beams. Propagation of SPPs along the spiral shaped hole arrays contributes strongly to the creation of the vortex beam. In our geometries, the diameter of the holes was varied from 50-200 nm along the spirals, which enabled the creation of vortex beams over a broad spectral range from 380-900 nm.
The generation of electron-beam induced light beams with tailored topology, spectrum, and temporal profile enables femtosecond pump-probe spectroscopy in which material excitations are created by electron excitation and probed with tailored light pulses that arrive at well-defined times.

6:35 AM F.NM01.08.09
Highly Directional Light Emission from Perovskite Nanocrystals by Dielectric Nanolenses Julia van der Burgt and Erik C. Garnett; Amolf institute, Netherlands

On macroscopic scale, solar cell efficiency can be increased with concentrating lenses, that focus the sunlight on the cell. An equivalent effect can be achieved with nanostructures that make the light emitted by the solar cell directive towards the sun, while eliminating some of the drawbacks of macroscopic concentration. We have developed an evolutionary algorithm to design dielectric nanostructures for directional emission, leading to structures with a directivity as high as 306. In our previous work[1] the experimentally achieved value was significantly lower than the modeled directivity, due to several limiting factors. In this work we overcome these limitations, by using a newly build measurement setup and a specially designed material system. By combining a Fourier microscope with an integrating sphere, we are able to measure emission into the full 4π solid angle, which allows us to measure full directivity. The predicted directivity is calculated for a point source at the center of the nanolens. In the experiment the point source is resembled by small clusters of emitting particles, which are placed in an ordered array to facilitate the proper alignment. This is achieved with a recently developed technique of direct patterning of $CsPbBr_3$ perovskite nanocrystals by e-beam lithography, by which the ligands of the nanocrystals are directly crosslinked upon exposure. Subsequently the dielectric nanolenses are fabricated on top of the clusters by 2-photon lithography.

Confinement of Light in Monolayers of Oxide Perovskites Dominik M. Juraschek and Prineha Narang; Harvard University, United States

The confinement of electromagnetic radiation in hybrid modes of light and collective excitations in solids (polaritons) promises to open new ways of dynamical control of matter, such as manipulation of radiative electronic transitions and of redistribution of vibrational energy. Two-dimensional (2D) materials have become the primary platform for polaritonic applications, where hexagonal boron nitride is the gold standard for exhibiting 2D phonon polaritons that confine light to volumes several orders of magnitude smaller than in free space [1,2].

Here, we show that phonon polaritons in the recently synthesized monolayers of oxide perovskites [3] can keep up with the benchmarks set by hexagonal boron nitride and confine electromagnetic radiation to extremely small volumes in the technologically important low mid-infrared and terahertz spectral regions. Specifically, we use a combination of first-principles calculations and microscopic phenomenological modeling to compute polaritonic figures of merit, such as the confinement and propagation quality factors of monolayers of $SrTiO_3$, $KTaO_3$, and $LiNbO_3$. Our results combined with the extraordinary tunability of oxides suggest that monolayers of oxide perovskites will become an emergent platform for 2D phonon polaritonics in the near future.

6:55 AM F.NM01.08.13
On-Demand Directivity Modulations of the Excitation and Emission of Nanoemitters Using a Subwavelength Mie Antenna Jie Fang, Mingsong Wang, Kan Yao and Yuebing Zheng; The University of Texas at Austin, United States

Effective control over the emission properties is of great importance to nanoemitters in order to realize optimized functionalities and to reduce undesired losses. However, challenges exist in both efficiency and integration when extra optical components are coupled at the nanometer scale. High-index dielectric nanoantennas hold particular promise to tackle these challenges, owing to their multipolar Mie resonances and low material loss. Uniquely, the mutual interference of the size-dependent magnetic and electric modes can lead to effective directivity modulation of the far-field radiation pattern. Since coupling with nanoantennas can significantly modify the emission properties of emitters via Purcell effect and sophisticated interference, positioning such dielectric resonators in the near field of a nanoemitter is also a potential route for directional emission. Moreover, a combination of the directivity modulations of both excitation and emission can provide more degrees of freedom to tune the emission properties in total.
Here, we propose a universal platform for dipole nanoemitters, based on single lossless hydrogenated amorphous Si nanospheres (a-SiNS:H), to modulate the directivity of both the excitation and emission at visible wavelengths. Thanks to its truly subwavelength nature, a-SiNS:H can strongly modify the emission of coupled emitters and make the radiation pattern highly directional. As a zero-dimensional (0D) structure, it also provides high spatial resolution so that multiple functions can be realized under an ultra-compact design, which fits well with the compactness of nanoemitters. Specifically, rigorous analytical theory for dipole-sphere hybrids is derived, along with numerical simulations, to predict the performance under a variety of conditions. Controllable forward-to-backward intensity (F/B) ratios as predicted by theory are experimentally proved with 125 samples of 532 nm laser excitation and 635 nm exciton emission from a monolayer WS_2. Moreover, flexible emission property engineering is demonstrated for different nanoemitters (e.g. WS_2 and MoS_2) and excitation wavelengths, thanks to the facile sphere size control.
In the derivation, we consider an a-SiNS:H coupled with an electric dipole emitter, which is oriented tangential to the surface of a-SiNS:H and positioned out of it by a small distance, mimicking the exciton emission from the monolayer of transition-metal dichalcogenides (TMDs). Following a similar procedure as in the standard Lorenz-Mie theory, we expand the incident field, i.e., the exciton emission, and the scattered field, by vector spherical harmonics. The derived analytical solution in the form of expanded spherical harmonics then allows fast computation of the far-field optical properties for information to guide the directivity modulation. Also, it helps to understand the role of each resonance in constituting the total scattering and determining the directivity.

To demonstrate the controllable F/B ratios experimentally, we modify our microscope system to effectively separate the directivity modulations of the excitation and emission. A CVD-grown monolayer WS_2 is used as the nanoemitter. The comparison of the modulated emission (excitation) in the forward and backward directions is always made with fixed excitation (emission) conditions. The F/B ratio can be up to 2.5 and down to 0.5.
Finally, the proposed a-SiNS:H-based platform enables us to achieve the desired emission properties, such as enhanced/suppressed emission in the forward/backward direction. More importantly, the same a-SiNS:H-nanoemitter hybrid can perform different functions by tuning the excitation wavelengths with rational designs. This gives us two degrees of freedom, i.e., the a-SiNS:H size and excitation wavelength, to fit the wanted performances for any nanoemitters, leading to potential applications in ultra-compact and multiplexed integrated photonics.

7:05 AM F.NM01.08.14
Late News: Liquid Crystal Cavities as a Platform for Engineering of Spin-Orbit Optical Interaction Katarzyna Rechcinska[1], Mateusz Król[1], Rafal Mazur[2], Przemyslaw Morawiak[2], Karolina Lempicka[1], Rafal Mirek[1], Przemyslaw Kula[2], Wiktor Piecek[2], Michal Matuszewski[3], Witold Bardyszewski[1], Pavlos G. Lagoudakis[4], Barbara Pietka[1] and Jacek Szczytko[1]; [1]University of Warsaw, Poland; [2]Military University of Technology, Poland; [3]Polish Academy of Sciences, Poland; [4]University of Southampton, United Kingdom

Spin-orbit optical interactions in photonic systems exploit the analogy between the quantum mechanical description of electronic spin-orbit system and synthetic Hamiltonians derived for propagation of electromagnetic waves in dedicated spatial structures. In the presented work a two-dimensional system – a thin optical cavity filled with liquid crystal – was created, in which trapped photons have unusual properties. It was found that during the modification of the properties of the cavity by external voltage, they behaved like quasiparticles endowed with a magnetic moment, that is "spin", under the influence of an artificial magnetic field. We show that for the liquid crystal cavity different regimes can be obtained. First this unique system allows for tunability of TE-TM splitting and shows giant values of this splitting. One of the most interesting phenomena directly dependent on the TE-TM splitting in a cavity is the optical spin Hall effect. We show that thanks to the novel design and the unique possibility to tune the splitting even for zero incidence angle, we are able to observe typical for normal cavities quadrupole spin textures as well as never reported before patterns resembling: dipole, spin doughnuts and whirls [1]. Secondly, we investigate an artificial Rashba-Dresselhaus spin-orbit interaction (SOI) and synthetic magnetic field (Zeeman-like term) [2]. With the ability to manipulate the effective refractive indices for different polarizations of light it is possible to tune the energy splitting between cavity modes. When two linearly polarized modes of different parity are brought into resonance theoretical analysis of birefringent electromagnetic waveguide results in SOI effects of light, in the form of $H_{RD}=-2\alpha\sigma_z k_y$, where σ_z is the Pauli matrix describing polarization (spin) of light and k_y is light's direction of propagation. The new photonic system perfectly imitates electronic properties and leads to many surprising physical effects. It allows to control the spin state of photon making a new building block for the novel optoelectronic devices e.g., optical neural networks and performing neuromorphic calculations. It can be integrated with light emitters (like various dopants: quantum dots, dyes, thin layers of transition metal dichalcogenides) for room-temperature strong light-matter coupling and lasing. While, engineering of spin-orbit synthetic Hamiltonians in cavities opens the way to photonic emulators of quantum Hamiltonians with internal degrees of freedom.

5:00 AM *F.NM01.09.01
Dynamically Switchable Photonics Based on Alloyed Metal Hydrides Jeremy N. Munday; University of California, Davis, United States

The ability to control the optical properties of photonic materials on demand is essential for the operation of a variety of devices ranging from active color filters and routers to switchable mirrors and sensors. Here we will present our latest work

on actively controllable photonic devices using alloyed metal hydrides. Using our recently developed apparatus for *in situ* measurements of optical and mechanical response upon hydrogenation, we first show how pure metal hydrides containing Pd, Mg, Zr, Ti, and V can be used as tunable photonic elements throughout the visible and near-infrared [1]. A number of devices will be shown including structures that have five orders of magnitude change in reflectivity, as well as planar systems for physical encryption and counterfeit detection. Second, we will show how alloying can not only improve cyclability, but also lead to higher hydrogen fractions than previously obtained as a result of film stresses and microstructuring [2]. These results have led to new insights in the dynamic behavior of metal-hydrides and will help in the design of next-generation hydrogen sensors and tunable photonic devices.

5:15 AM *F.NM01.09.02
Approaches for Tuning of Chalcogenide Glass Dielectric Metasurfaces Jesse Frantz[1], Jason D. Myers[1], Robel Y. Bekele[2], Anthony Clabeau[2], Vinh Nguyen[1], Jiannan Gao[3], Mikhail Shalaev[3], Natalia Litchinitser[3] and Jas Sanghera[1]; [1]U.S. Naval Research Laboratory, United States; [2]University Research Foundation, United States; [3]Duke University, United States

Chalcogenide glasses have recently received attention for their potential use in dielectric metasurfaces for several reasons: They typically possess high linear refractive indexes, enabling high index contrast devices; some compositions exhibit exceptionally high optical nonlinearity (n_2>1000× that of silica) making them good candidates for nonlinear devices; they have wide transmission windows spanning from the visible through the longwave infrared; and some compositions undergo a structural phase transition, enabling devices with switching based on phase-change. We discuss a variety of approaches to achieve tunability in chalcogenide glass metasurfaces from our work and that of others. We review recent progress on the use of the Kerr nonlinearity in As_2S_3 films to achieve power-dependent behavior and the application of this effect for the manipulation of orbital angular momentum. We discuss the design and realization of chalcogenide-based photonic quasicrystals enabling simultaneous phase matching of an arbitrary number of nonlinear optical processes in a single engineered nanostructure. We discuss recent observations that a permanent index change can be induced in As_2Se_3 via thermal tuning and the use of this effect to achieve permanent one-way tuning of the optical resonance of a metasurface. We discuss work being done by a variety of groups on phase-change chalcogenide materials such as germanium-antimony-telluride and gallium-lanthanum-sulfide in order to realize switchable metasurfaces. Finally, we discuss future prospects for the use of chalcogenide glass metasurfaces for applications that require tuning of the optical response.

5:30 AM *F.NM01.09.03
Designing Tunable Phase-Change Material Based Metasurfaces Using Multiphysics Simulations Dmitry N. Chigrin[1,2]; [1]DWI–Leibniz Institute for Interactive Materials, Germany; [2]RWTH Aachen University, Germany

Tunable metasurfaces allow to control the phase, amplitude and propagation direction of electromagnetic waves. Integrating phase-change materials into metasurface design provide an opportunity to control metamaterial properties at the meta-atom length scale. This could enable full reprogrammability and post-fabrication adjustments of adaptive metasurfaces. A state of phase change material near a meta-atom can be switched by a local deposition of heat using optical, electrical pulses or hot scanning probes. Resulting phase transition process is intrinsically non-stationary and inhomogeneous. The phase transition from crystalline to amorphous state is accompanied by the drastic change of the material properties leading to time-varying and position-dependent refractive index, conductivity, absorption rate and heat conduction. In order to describe local phase transition in metamaterials, a self-consistent numerical treatment of electromagnetic, carrier transport, heat transfer and phase transition processes becomes of primarily importance. Understanding the phase transition process at the meta-atom length scale is essential for a purposeful design of programmable adaptive metasurfaces. Here, we report on a self-consistent multiphysics description of a local phase transition in metasurfaces. The developed model is applied to analyse local phase transition in different metasurfaces under the application of different mechanism of the local heat deposition.

Nonlinear Metasurfaces—New Frontiers in Nonlinear Optics Igal Brener; Sandia National Laboratories and Center for Integrated Nanotechnologies, United States

While metasurfaces are on the path to revolutionize the way we realize passive optical components, they have the same potential to affect the field of nonlinear optics. The interplay between relaxation of phase matching, control over microscopic

optical fields and ability to manipulate far-fields make nonlinear metasurfaces a new paradigm for this field. Metasurfaces can become nonlinear in different ways: they can be made from nonlinear optical materials or can be fabricated on top of such materials. In this tutorial I will cover the evolution of nonlinear metasurfaces starting from all metallic, metallic on different nonlinear materials, to dielectric and then using engineered nonlinearities using heterostructures of different materials.

5:55 AM *F.NM01.09.05
Light with a Phase Transition for Tunable Nanophotonics Guru V. Naik; Rice University, United States

Among many emerging technologies, energy and display are two essential technologies that can revolutionize our current society. Tunable nanophotonics holds the key to both these emerging technologies. While tunable meta-devices enable 3D displays and such other display applications, tunable thermal emitters enable efficient energy conversion. Phase transition phenomena that arise from the collective behavior of materials enables both these classes of nanophotonic devices. While an electronic phase transition leads to a huge optical tunability, an optical one results in highly selective thermal emitters necessary for efficient energy conversion. Here, we demonstrate tunable nanophotonic devices based on strong correlations in 1T-TaS_2 and frequency-selective thermal emitters based on non-Hermitian nanophotonics.

Optical systems with losses such as thermal emitters require non-Hermitian physics to describe them. Such a non-Hermitian description of thermal emitters allows new powerful design tools such as phase, symmetry, topology. Here, we demonstrate an optical phase transition in a hybrid plasmonic-photonic system exhibiting passive parity-time symmetry. We employ localized dielectric resonances in an array of silicon disks forming a quasi-bound state in-continuum for dielectric resonance. A tungsten bottom plane serves as a plasmonic resonator. The electric dipolar resonance in the silicon resonator is coupled to its image in the tungsten and exhibits passive parity-time symmetry. The thickness of the MgF_2 spacer controls the coupling between the two resonators. Using this hybrid plasmonic-photonic system, we show that the best of both plasmonic and dielectric resonances, i.e., high spectral selectivity and near-unity emissivity can be achieved. Further, we elicit the role of symmetry and topology on the spatial and spectral selectivity of the thermal radiation in this system.

Another type of phase transition arising from the collective behavior of electrons in solids results in a large optical tunability. In general, the speed and magnitude of optical tunability trade-off with each other. For example, MEMS devices are slow but highly tunable, while nonlinear materials are ultrafast but possess tiny tunability. However, a large tunability and a moderately fast response are simultaneously possible in strongly correlated materials exhibiting phase transition due to their collective behavior. 1T-TaS_2 is one such strongly correlated material that exhibits an electronic phase transition above room temperature. Previous studies have shown that many stimuli can tune the electrical properties of 1T-TaS_2. However, optical properties remained less explored. Here, we demonstrate that a unity-order index tunability at room temperature is possible in 1T-TaS_2 shows just by shining low-intensity incoherent white light. Upon incoherent illumination of intensity less than 1000 mW/cm^2, the c-axis permittivity of this material was observed to change by unity order. We show that the tunability arises from the change in stacking order of charge density wave-domains across layers of this material. The observed tunability has a sub-microsecond response time allowing a few MHz speed. Thus, 1T-TaS_2 is promising for tunable nanophotonic devices. We demonstrate an optically tunable meta-grating device that could potentially revolutionize the emerging display and imaging technologies.

6:10 AM F.NM01.09.06
A Comprehensive Active Photonic Platform Driven by Liquids Qitong Li, Jorik Van de Groep, Adam White, Jung-Hwan Song, Scott Longwell, Polly Fordyce, Stephen Quake and Mark L. Brongersma; Stanford University, United States

Starting from the 1970s, great efforts have been made to miniaturize bulky optical devices. The progress accelerated significantly over the last decade due to the emerging field of metasurfaces. These planar nanophotonic devices, made from judiciously-engineered, subwavelength-thick optical nano-resonators, are capable of controlling the amplitude, phase, and spectral properties of light waves with subwavelength resolution. Some progress has also been made to create active metasurfaces, but it remains challenging to create large-scale devices that offer repeatable and fast dynamic manipulation of the light field. Dynamic tuning is challenging, as the semiconductors and noble metals used in metasurfaces generally display weak electrorefractive and electroabsorptive effects. On the other hand, materials which show larger tunability often only support low-quality optical resonances and/or are not chemically stable.

Here, we demonstrate a comprehensive active photonic platform that affords facile tuning of silicon (Si) nano-resonators by altering their isotropic dielectric environment with microfluidics. We show this platform enables broadband amplitude

control, full-color spectral control, and precise manipulation of geometric phase elements. The tunability, speed and robustness meet the requirements of various display and phased array applications. Specifically, we show that the integration of a nanophotonic device with a microfluidic cavity can provide on-demand control over the refractive index (n=1-1.7) of the environment of the nanoresonators in a metasurface by flowing different liquids in real time.

The observed, broad tunability of our metasurfaces results from the strong dispersion of the resonances with the refractive-index of the surrounding medium. This dispersion allows us to manipulate the interference of the scattered light from the Si nano-resonators. By summing up the scattering contribution from all the excited multipoles with the same symmetry, the optical response of a Si nano-resonator array can be modeled as two effective optical planar cavities with symmetric and anti-symmetric radiation profiles. Because of the different electric field distribution inside the nanoresonators, the two cavities show different dispersion with the refractive index of surrounding medium. An intuitive temporal coupled mode theory is applied to calculate the reflection and polarization conversion (diffraction) efficiency spectra and they agree well with full-field simulations.

To show of our platform and design concept, we experimentally demonstrate both a broadband (~100 nm) large amplitude modulation and full-color spectral tuning (from blue to red, reflection peak shifts from 480 nm to 580 nm) for individual pixels. We stress that these numbers are measured under un-polarized white light illumination. A digital number display controlled by microfluidic circuitry is also fabricated and characterized to verify the possible use of these elements for display applications. We also demonstrate that a geometric phase metasurface can be turned “on” and “off” actively, leading to new applications such as temporal beam tapping. What’s more, multiplexing different resonator arrays enables the opportunity to switch the function of a metasurface phased array. For example, an achromatic active lens that can select which color of light be focused is demonstrated. We show that the dielectric environment can be programmed up to 20 Hz, satisfying a number of vision-related applications.

Altogether, these results demonstrate an unprecedented comprehensive active photonic platform driven by liquids. They can lead to many practical applications, ranging from temporal beam focusing, steering, to real-time holography. The successful integration of nanophotonics with mature microfluidic cavity technologies further paves the way towards actively controlled nanophotonic displays and phased arrays.

6:20 AM F.NM01.09.07
Optical Nanomanipulation and Reconfigurable Assembly of Colloidal Nanostructures Jingang Li and Yuebing Zheng; The University of Texas at Austin, United States

Subwavelength nanostructures with tunable compositions and geometries show favorable optical functionalities for the implementation of nanophotonic devices. Diverse colloidal particles are appealing building blocks to construct these functional nanostructures. So far, many optical techniques have been developed to manipulate, assemble, and print colloidal particles from aqueous solutions into desired configurations on solid substrates. However, these techniques operated in liquid environments usually suffer from pattern collapses, Brownian motion of nanoparticles, and challenges on reconfigurable assembly.

Here, we present an all-optical technique, termed optothermally-gated photon nudging (OPN), for the versatile manipulation and dynamic patterning of a variety of colloidal particles on a solid substrate at nanoscale accuracy. OPN takes advantage of a thin surfactant layer to optothermally modulate the particle-substrate interaction, which enables the manipulation of colloidal particles on substrates with optical scattering forces. Along with in situ optical spectroscopy, this non-invasive and contactless nanomanipulation technique provides a powerful platform to design active optical devices and study the coupling between colloidal structures. We further demonstrated the assembly of active dielectric chiral nanostructures on a solid surface, where the chiroptical responses are tailored on-demand via manipulating the silicon nanoparticle. The optical chirality originates from the coupling between the optical resonances of the silicon nanoparticle and the silicon nanowire, which is supported by both numerical simulations and coupled mode theory analysis. Our technique not only provides insights into designing functional nanomaterials but also kindles new strategies to develop adaptive devices for photonic and electronic applications.

6:30 AM F.NM01.09.08
Modulation of Ultrafast Electron Transport Through Photoswitchable Ligands on Quantum Dots Christopher Eckdahl, Suyog Padgaonkar, Jakub Sowa, Dana Westmoreland, Tamar Seideman, Mark Hersam, Julia Kalow and Emily Weiss; Northwestern University, United States

Surface functionalization with photoswitches, organic molecules that reversibly change their conformations in response to light, introduces photoresponsivity to otherwise static nanomaterials. A promising class of nanomaterials for optoelectronics is mixed-dimensional heterojunctions (MDHJs) between quantum dots (QDs) and monolayered semiconductors such as molybdenum disulfide (MoS_2). I have developed ligands that can be used to introduce photoresponsivity to such materials through surface functionalization. The class of photoswitches I will discuss, fulgides, switch between twisted, non-conjugated states and planar, conjugated states on picosecond time scales. I designed and synthesized a fulgide QD ligand that can extract electrons from photoexcited QDs in one state but not the other (Figure 1). This photoswitchable charge extraction enables reversible control of QD photoluminescence, with possible applications in all-optical memory. I synthesized derivatives of these photoswitchable ligands that can functionalize MoS_2 monolayers and thereby serve as bridging ligands in MoS_2-QD MDHJs. In this role, the photoswitches could be used to modulate charge transfer in mixed-dimensional heterojunctions and thus enable reconfigurable optoelectronic devices.

6:40 AM F.NM01.09.09
Late News: Nanoscale Topological Corner States of Light for Nonlinear Optics Sergey Kruk[1,2], Wenlong Gao[1], Duk-Yong Choi[2], Thomas Zentgraf[1], Shuang Zhang[3] and Yuri Kivshar[2]; [1]Universität Paderborn, Germany; [2]Australian National University, Australia; [3]University of Birmingham, United Kingdom

Topological states of light have attracted a lot of attention recently due to the existence of counter-intuitive nontrivial boundary effects arising from bulk properties of optical systems. The corresponding edge states, having their origin in topological properties of a bulk, are protected from perturbations and defects, and therefore they are promising for a wide range of applications in photonic circuitries. Conventionally, the bulk-boundary correspondence relates an n-dimensional bulk to a (n-1)-dimensional boundary state [1]. Recently the bulk-boundary correspondence was generalized to describe higher-order effects such that an n-dimensional bulk defines its (n-m)-dimensional imbedded boundary states. Prominent examples are 0D topological corner states of light in 2D structures [2-4] realized so far at the micrometre scales. Such corner states, due to their tight confinement in all directions, provide a novel route towards facilitating light-matter interactions in novel type of topological cavities. However, the current systems supporting the corner states employ building blocks that are an order of magnitude larger compared to the wavelength of light, which cannot be used for applications in nanophotonics. Here we bring topological corner states of light to the nanoscale and employ them for enhancing nonlinear optical processes. Specifically, we design topologically nontrivial 2D dielectric metasurfaces with C6-symmetric honeycomb lattices supporting both 1D edge states and 0D corner states. We observe topology-driven nonlinear light generation from the nanoscopic corner states and compare topological and trivial localisation of light.

In the past, judiciously designed high-index dielectric nanostructures supporting both electric and magnetic Mie resonances have been successfully employed for conventional forms of bulk-boundary correspondence, such as 1D states in 2D structures [5] and 0D states in 1D structures [6]. Here we observe 0D corner states in a 2D nanophotonic topological insulator. In our system, nontrivial topology arises from topological insulator geometry of periodic photonic structures, and the corner states emerge in a cascaded process in which first a bandgap is opened in a spectrum of 2D bulk modes which is bridged by 1D topological edge modes; second, a mini bandgap is opened in 1D modes hosting 0D corner states. We realize this concept experimentally using resonant dielectric metasurfaces on a metal substrate. The metasurfaces consist of two arrays of silicon nanopillars hexamers —expanded and shrunken hexamers, characterized by distinct topological invariants. We fabricate our sample with standard EBL and employ a nonlinear imaging to excite a broad sample area with a short pulse, high peak power tuneable laser and detect nonlinear third-harmonic signal generated by Si hexamers. We observe experimentally 2D bulk modes, 1D edge states, and 0D corner states at different wavelengths. We study several types of topologically nontrivial corner states and compare them to trivial light localisations. Miniaturization of topological corner states to the nanoscale paves the way towards their on-chip applications in compact classical and quantum nanophotonic cavities.

Late News: Size-Controlled Synthesis of Second Harmonic Active Lithium Niobate Nanocrystals Through Solution-

Phase Methods Rana Faryad Ali and Byron Gates; Simon Fraser University, Canada

We advanced the development of solution-phase approaches for the preparation of lithium niobate ($LiNbO_3$) nanoparticles with an average, tunable size from 7 to 100 nm. This solution-phase process results in the formation of crystalline, uniform nanoparticles of $LiNbO_3$ at a reaction temperature of 220 °C with an optimal reaction time of as short as 30 h. Advantages of these methods include the preparation of single-crystalline $LiNbO_3$ nanoparticles without the need for further heat treatment or without the need for using an inert reaction atmosphere. The growth of these nanoparticles began with a controlled agglomeration of nuclei formed during a solvolysis step. The reactions subsequently underwent the processes of condensation, aggregation, and Ostwald ripening, which remained the dominant process during further growth of the nanoparticles. These processes did produce single-crystalline nanoparticles of $LiNbO_3$, suggesting an oriented attachment process. Average dimensions of the nanoparticles were tuned from 7 to ~100 nm by either increasing the reaction time or changing the concentration of the lithium salts used in the solvothermal process. The nanoparticles were also confirmed to be optically active for second harmonic generation (SHG). These particles could enable further development of SHG based microscopy techniques.

SESSION F.NM01.10: Poster Session: Nanophotonics—Emerging Hybrid Platforms, Materials and Functions

F.NM01.10.01
A General Phase Function of Micro/Nanoparticle Composites Junxin Wang, Annica Nilsson and Gunnar Niklasson; Uppsala University, Sweden

Light scattering from particles show unique angular scattering patterns, which are strongly dependent on the particle size to incident wavelength ratio and the refractive index contrast between host medium and the particles. Multiple scattering becomes important when the particle concentration increases, which complicates the angular scattering distributions. In many cases, empirical phase functions have to be applied. A novel empirical phase function was introduced to describe the angle-dependent distribution of scattered light from a collection of micro/nanoparticles inside a thin layer. Angular dependence of light scattering from a polymer host containing sub-micron dielectric and metallic particles was measured. The method gives an excellent approximation to the angular effects of multiple scattering arising from aggregation, non-spherical shape and surface roughness. In addition, it is also a good approximation in the single scattering regime, since it closely reproduces scattering phase functions of particles in the Rayleigh, Mie and geometrical optics regimes. The feasibility of our approach was demonstrated by its ability to fit experimental data on the forward and backward scattering profiles of plasmonic and dielectric submicron particle composite layers. The robust and wide applicability of our method is expected to attract a board interest from researchers in physics and materials science.

F.NM01.10.02
Arylazopyrazole-Fused PDMS Composites as Solid-State Photo-Switchable Materials Ikemefuna Uba, Demetris Geddis, Kesete Ghebreyessus and Uwe Hommerich; Hampton University, United States

Arylazopyrazoles (AAP) show significant potential as a new family of molecular photoswitches owing to their efficient reversible trans-to-cis photoisomerization behavior and the high thermal stability of their metastable cis-isomer. Herein, we report on the design and synthesis of new arylazopyrazole based molecular switches with different spacer length and functional (OH, COOH) groups. The new AAPs were used for the fabrication of solid-state photoswitchable polydimethylsiloxane (PDMS) based composite films. The thin films were prepared by using PDMS as a polymer matrix and different concentrations of AAPs as chromophores at room temperature *via* spin-coating. The photoswitching behavior of the PDMS-AAP blend films and the neat AAP samples induced by irradiation with specific wavelength of light were investigated. We found that the as prepared PDMS-AAP blend films showed rapid and near-quantitative reversible trans-to-cis isomerization rates upon alternating irradiation with UV (l = 365 nm) and green (l = 525 nm) light which is comparable to the isomerization behavior of the neat AAP chromophores in solution. This indicates that the excellent photoswitching properties of AAPs are preserved in the PDMS-AAP composite films. Additionally, the as prepared PDMS-AAP films in the cis-form possess outstanding thermal stability and long-term optical stability. The results also show that the optical properties of the PDMS-AAP composite films can be tuned by using different ratios of the AAP chromophores and exposure to UV

irradiation. This methodology provides a new approach for exploring the fabrication of polymers with solid-state photoswitching functionality. The effect of concentration of the AAPs on the reversible *trans*-to-*cis* isomerization processes of the PDMS-AAP composite films will be discussed in this presentation.

F.NM01.10.09
Late News: Fabrication of a Fine-Pattern Flexible Nanowire Photodetector by Shadow Mask Mustafa A. Yildirim and Kasif Teker; Marmara University, Turkey

Recently, ultraviolet photodetectors (UVPDs) have been used on large scale applications such as environmental monitoring, flame detection, space communication, biomedical applications, pharmaceutical, and chemical analysis. Besides, advances in internet technologies such as the internet of things (IoT) endorse the integration of sensors more rapidly in every aspect of our lives. This trend demands the fabrication of smaller, lighter, less complicated, and low power devices. Therefore, designing low cost, self-powered, highly sensitive, flexible UVPD nanodevices are becoming a hot research area for near future optoelectronics. Silicon carbide (SiC), a wide bandgap semiconductor, is an excellent contender to fulfill those expectations. In addition to having characteristics of one-dimensional nanostructure such as high surface to volume ratio, high crystalline quality, SiC nanowires also possess superior material attributes like high breakdown voltage, high thermal conductivity, high drift velocity, excellent chemical and physical stability. In this study, we propose a very cost-effective, flexible, self-powered single SiC nanowire ultraviolet photodetector (SiCNW-UVPD) fabricated on a polyvinylchloride (PVC) substrate.
The self-powered flexible SiCNW-UVPD was fabricated via a commercially available transmission electron microscopy (TEM) grid (physical mask) and a sputter coater system. Gold (Au) electrodes of 110 µm x 110 µm and a gap of 4 µm were successfully achieved without the use of complicated and expensive methods like photolithography. Two-probe photocurrent-time (I-t) and I-V measurements were performed to reveal photoresponse characteristics such as the photo-to-dark current ratio (PDCR), sensitivity, and responsivity under 254 nm wavelength UV light at 0 V bias. A shallow dark current around 0.087 pA and a good PDCR value of 18 are obtained. Moreover, sensitivity and responsivity values are calculated as 1756 and 170 mA/W, respectively. In addition, the specific detectivity calculations, the effect of bias, and vigorous bending test results are discussed as well. Our work provides the following unique advantages: (i) to the best of our knowledge, the first demonstration of a single SiC nanowire PD on a flexible substrate with great performance, (ii) a very cost-effective fabrication method and readily applicable to any substrate, (iii) exhibiting high sensitivity and responsivity values under UV light at 0 V bias. Therefore, our SiCNW-UVPD device presents an opportunity for low-cost, easy to fabricate, self-powered photodetectors for upcoming future technologies such as wearable sensors, electronic skins, and the internet of things.

F.NM01.10.10
Late News: Combined, Localized Plasmonic Heating and Temperature Measurement in Nanocomposite Hydrogels Wei Yu, Olivier Deschaume, Stijn Jooken, Pengfei Zhang, Jolan Wellens, Fanglei Guo, Christ Glorieux and Carmen Bartic; KU Leuven, Belgium

As scaffold materials for tissue engineering applications, hydrogels can mimic many important functions of extracellular matrices found in living tissues. Local temperature gradients can greatly impact the bioactivity of the matrix and cellular processes such as adhesion, migration and differentiation [1,2], while the knowledge of local temperature is essential understanding and modulating the cell properties and their responses. Various methods have been developed and applied for thermal measurements at the nano- and micro-scales, relevant to living tissues, such as infrared thermography [3], micro-thermocouples [4], AFM with thermocouple [5] and fluorescence-based thermography [6]. However, only a limited number of successful applications have been reported regarding three-dimensional localized temperature measurements as the first three methods can only be applied in two-dimensional cases [3-5]. In this contribution, we report a versatile platform to realize localized, simultaneous heating and temperature readout in both two and three dimensions. Localized heating was implemented in hydrogels by functionalizing them with gold nanorods (GNR) with high absorption around 785 nm, while the local temperature is reported by the incorporated Rhodamine B (RhB)-loaded silica particles or quantum dots. For these thermal nano-probe, the fluorescence intensity decreases when temperature increases. In combination with the nanomaterials, a versatile optical stimulation and readout platform was developed. We demonstrate that plasmonic NIR heating could lead to localized, up to 10 degrees temperature changes in hydrogel-based cellular matrices that can be monitored in situ by fluorescent nanoprobes, both in 2D and 3D.

Funding: This research was funded by the KU Leuven C1 projects, grant numbers C14/16/063 OPTIPROBE, C14/18/061 and the FWO research grant, grant number G0947.17N.

Creating Metasurfaces and Metadevices with Mie Resonators Mark L. Brongersma; Stanford University, United States

Semiconductor nanostructures are at the heart of electronic devices and systems. When properly sized and shaped, they can also support optical, Mie-type resonances that are capable of boosting light-matter interaction over bulk materials. By combining their desirable electronic and optical properties, it is possible to create new optoelectronic functionalities. In this tutorial talk, I will start with a discussion of the basic properties of Mie resonators and show how they have been harnessed to create a large variety of passive metasurfaces. One of the key application areas for passive metasurfaces is the realization of flat optical components that can replace more bulky traditional counterparts (e.g. lenses and gratings). One of the next frontiers is to realize active flat optics capable of dynamically shaping optical wavefronts to e.g. tune the focal length of a lens or to actively steer laser beams. I will illustrate different approaches to achieve such active functions. Another area of interest that I will highlight is the development of Mie-resonant antennas and metasurfaces that enable real-time measurement of the wavelength, polarization state, angle of incidence and angular momentum of light.

Electrically Tunable Metasurfaces for Control of Absorption, Emission and Scattering Harry Atwater; California Institute of Technology, United States

Progress in understanding resonant subwavelength optical structures has fueled a worldwide explosion of interest in both fundamental processes and nanophotonic devices for imaging, sensing, solar energy conversion and thermal radiation control. For most nanophotonic materials, the optical properties are encoded and fixed permanently into the nanoscale structure at the time of fabrication. Achieving electronic tunability of the optical properties is an emerging opportunity to bring metamaterials and metasurfaces to life as dynamic objects composed of tunable nanoscale resonators and antennas. Gated field effect tuning of the carrier density in conducting oxides and twodimensional materials enables the optical dispersion of individual structures to be altered from dielectric to plasmonic, yielding active nano-antenna arrays with electrically tunable absorption, radiative emission and scattering properties.

Optimization and Machine Learning for Metasurface Design Jonathan Fan; Stanford University, United States

Inverse design, in which the design process is performed through iterative optimization, has the potential to push metasurface performance to the physical limits of composite materials engineering. In this tutorial, we will discuss a range of state-of-the-art numerical optimization methods for metasurface design. We will introduce the objective-first and adjoint variables methods, which are gradient-based optimization concepts that can produce high performance freeform geometries. We will also provide an overview of machine learning techniques as applied to electromagnetics problems and show how generative neural networks can be harnessed as an effective global optimizer for photonic devices.

SESSION F.NM02.09: Live Keynote I: Advanced Linear/Nonlinear, Tunable and Quantum Materials for Metasurfaces, Metamaterials and Plasmonics I
Session Chairs: Ho Wai (Howard) Lee and Jingyi Yang
Tuesday Afternoon, December 1, 2020
F.NM02

Plasmonic, Photonic and Excitonic States Interfaces—Time-Modulated Flat Optics and Time-Resolved Measurements Harry Atwater; California Institute of Technology, United States

Plasmonic, photonic and excitonic states at interfaces govern the optical response of tunable nanophotonic structures such as active metasurfaces, photodetectors and photocatalysts. I will discuss how we can harness plasmonic and excitonic states at interfaces to enable power-efficient phase modulation of active metasurfaces and discuss implications for time-modulated flat optics. Specifically, I will discuss avenues for increasing the power density and power efficiency of plasmonic conducting oxide metasurfaces for temporal phase and amplitude modulation and requirements for time-modulated photonic applications, such as multi-frequency generation and realization of non-reciprocal metasurfaces. I will also report on how time-resolved measurements of plasmonic and excitonic states at interfaces can yield insights about fundamental light-matter interactions in these systems. Specifically, I will discuss i) how electron-hole correlations affect the dynamics of hot carrier

relaxation in plasmonic Au/GaN photodetectors and photocatalysts and ii) how time-resolved measurements of excitons generation inform our understanding of carrier dynamics and transport in transition metal dichalcogenides such as WS_2 and MoS_2.

Dynamic 2D Quantum Metasurfaces Mark L. Brongersma; Stanford University, United States

Since the development of diffractive optical elements in the 1970s, major research efforts have focused on replacing bulky optical components by thinner, planar counterparts. The more recent advent of nanophotonic metasurfaces has further accelerated the development of flat optics through the realization that resonant optical antenna elements can be utilized to facilitate local control over the light scattering amplitude and phase. In this presentation, I will highlight recent efforts to realize electrically-tunable metasurfaces employing nanomechanics, electrical gating, microfluidics, and phase change materials. I will pay particular attention to the opportunity of realizing dynamic metasurfaces from atomically-thin semiconductors. Such elements are capable of active wavefront manipulation for optical beam steering and dynamic holography. I will illustrate how the proposed optical elements can be fabricated by scalable fabrication technologies, opening the door to many commercial applications.
