Homogeneous Bioluminescent Immunoassays: Cheap, Fast, and Sensitive Alternatives for ELISA in Point of Care Diagnostics Maarten Merkx; Eindhoven University of Technology, Netherlands

The widely recognized need for more personalized, patient-centered healthcare requires the development of cheap, easy-to-use, yet reliable biomedical devices that are capable of detecting specific diseases. The current COVID-19 pandemic has made this need abundantly clear and has shown that we are ill-prepared for this and future viral pandemics. Immunoassays form the cornerstone of today`s clinical biomolecular diagnosis. Their success is rooted in their modularity and the possibility to generate specific and high-affinity antibodies for almost any molecular target. However, translation of traditional heterogeneous immunoassays into point-of-care assays has proven challenging, because they require multiple incubation and washing steps, the addition of exogenous reagents, and external calibration. Laminar flow immune assays (LFIAs) have been introduced as cheap and relatively easy-to-use POC immunoassays, but they suffer from limited sensitivity and are primarily used as qualitative tests.
In recent years our group pioneered the development of bioluminescent sensor proteins that allow affinity-based detection of antibodies, proteins, small molecules, and DNA/RNA directly in blood plasma using the camera of a smart phone as the sole piece of equipment. Unlike fluorescence, whose dependence on external illumination gives rise to autofluorescence and scattering, bioluminescence is ideally suited to measure analytes directly in complex media such as blood with minimal sample handling. In my presentation I'll focus on the development of a generic bioluminescent sandwich immunoassay platform that combines the analytical performance of a laboratory-based immunoassay such as ELISA with the speed and ease-of-use of laminar flow immunoassays. RAPPID (Ratiometric Plug-and-Play Immunodiagnostics) combines ratiometric bioluminescent detection with antibody-based target recognition into an easy-to-implement standardized workflow, and

therefore represents an attractive, fast, and low-cost alternative to traditional immunoassays, both in an academic setting and in clinical laboratories for point-of-care applications. The modularity of the RAPPID workflow also enables rapid development of point of diagnostics for newly emerging analytes, as demonstrated here by development of RAPPID assays for SARS-CoV-2 spike proteins and anti-SARS-CoV-2 antibodies. To allow further development for point-of-care diagnostic applications, RAPPID can be integrated in cheap and simple paper- or thread-based analytical devices or integrated into microfluidic cartridges, and dedicated readers could be developed to further increase sensitivity.

8:20 AM *F.GI01.03.01
Skin-Integrated Wireless Biosensors for Symptom Tracking John A. Rogers; Northwestern University, United States

Rigorous and widespread testing remains a critical component of strategies for containing the COVID-19 pandemic. The limited availability of molecular diagnostics, however, creates a gap between requirements for population level testing and the availability of tests, likely to persist for the foreseeable future. These circumstances motivate the development of complementary technologies for diagnosing and monitoring COVID-19 infections. Consumer-grade wearables may have some utility in this context, but intrinsic shortcomings prevent measurements of the key symptoms of the disease: fever (98%), cough (65%) and shortness of breath (55%). This talk describes the custom development of a soft, hybrid electronic device, originally designed to track patients with aphasia and dysphagia, that mounts on the suprasternal notch to track all of these symptoms, continuously and with clinical-grade accuracy. Uses range from detecting early signs of symptoms in high risk populations, to monitoring the progression of patients with the disease in the hospital and in the home. Deployments on more than 250 healthcare workers and COVID-19 patients across the medical complex in Chicago over the last 20 weeks demonstrate the power of this technology, particularly when paired with HIPAA-compliant cloud data services and advanced analytics. Current and future activities will be discussed.

8:40 AM *F.GI01.03.02
High-Quality Factor ("High-Q") Nanophotonics for COVID-19 Diagnostics Jennifer A. Dionne, Jack Hu, Fareeha Safir, Jefferson Dixon, John M. Abendroth, Mark Lawrence, Scott Boyd, Benjamin Pinsky and Stefanie S. Jeffrey; Stanford University, United States

The emergence of COVID-19 has underscored the importance of rapid, frequent, sensitive and specific diagnostics for tracking and containing an infectious disease. Current detection methods including polymerase chain reaction (PCR) and enzyme-linked immunosorbent assays (ELISA) are robust and sensitive, but generally either rapid and qualitative or quantitative and slow; they are also constrained to measuring one analyte, such as a gene sequence or antibody isotype, at a time, and cannot correlate viral load to antibody type and level. Here, we present a new photonic chip-based technology that uses optical characterization to rapidly and quantitatively measure gene sequences and antibodies, and determine the corresponding viral load from the same patient. Our platform relies on high-quality-factor ("high-Q") nanostructured dielectric substrates, known as metasurfaces. These high Q metasurfaces produce a large amplification of the electromagnetic field intensity, increasing the response to minute refractive index changes from targeted binding of a nucleic acid sequence or antibody; simultaneously, the optical signal is beam-steered for multiplexed detection. We will present the design and development of this quantitative optical assay, as well as application to clinical nasal-pharangeal and serological samples from Stanford's Clinical Virology Lab.

Leveraging Nanotechnology for Controlling SARS-CoV-2 Transmission Danmeng Shuai; George Washington University, United States

COVID-19 has raised serious global public health concerns. The causative agent, SARS-CoV-2, has found to be environmentally persistent, and it can be transmitted through droplets or aerosols from an infected person and indirect contact via fomites. Nanotechnology has emerged as a promising tool for fighting against COVID-19, including but not limited to disease diagnosis, drug delivery, vaccine development, and pathogen detection and inactivation. In this talk, we will highlight recent progresses in controlling and inactivating pathogens in different environmental media, including SARS-CoV-2, by harnessing the power of nanotechnology. Specifically, electrospun nanofibrous membranes are developed to capture SARS-CoV-2-laden aerosols and they can be used for HVAC filters and masks/respirators. Photocatalysis that takes the advantage of environmental light can be implemented for effectively inactivating persistent pathogens on contact surfaces at an ambient condition.

11:50 AM *F.GI01.02.02
Harnessing Synthetic Biology to Address the COVID-19 Pandemic James J. Collins; Massachusetts Institute of Technology, United States

Synthetic biology is bringing together engineers, physicists and biologists to model, design and construct biological circuits out of proteins, genes and other bits of DNA, and to use these circuits to rewire and reprogram organisms as well as create novel biomaterials. These biological circuits, living materials and re-engineered organisms are going to change our lives in the coming years, leading to cheaper drugs, rapid diagnostic tests, and synthetic probiotics to treat infections and a range of complex diseases. In this talk, we highlight recent efforts to create synthetic gene networks and programmable cells as new classes of diagnostics, therapeutics and vaccines for fighting pathogens, including SARS-CoV-2.

12:10 PM *F.GI01.02.03
Facial Masks during COVID-19: Imaging, Disinfection, Homemaking, and Future Materials Design Yi Cui[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

Facial masks are among the most important personal protection equipment to fight COVID-19. This talk covers our exciting progress related to facial masks including: 1) We utilized X-ray tomography and deep learning to perform 3D imaging and analysis of facial masks and the particle filtration to provide critical understanding how facial masks work. 2) We developed heating methods (dry and humid) as the most efficiency methods to disinfect N-95 level facial masks while maintaining their high filtration efficiency for over 20 times. 3) We studied a variety of household textiles and identify the most effective ones for homemade masks; 4) We propose that nanofiber filtration technology would afford the next generation high performance facial masks with high filtration efficiency and great breathability.

Microneedles Arrays for Effective and Efficient Mass Vaccinations Burak Ozdoganlar; Carnegie Mellon University, United States

An effective mass vaccination strategy against SARS-CoV-2 and future pandemics requires both an efficacious vaccine and *a reliable delivery method*. To this end, intradermal (ID) delivery offers significant advantages over intramuscular (IM) or subcutaneous (SC) routes for developing rapid, potent, and long-lasting immunity. However, current ID delivery methods are unreliable and inconsistent, particularly for replication-competent and/or live attenuated vaccines. An effective way to address this problem is to use *microneedle arrays* (MNAs) for safe, reliable, efficient, and clinically relevant intradermal delivery of vaccines into the skin. MNAs include hundreds of micro-scale needles in a patch form. Vaccination using MNAs facilitates reproducible delivery of a high concentration of antigen to skin microenvironments for efficient and effective presentation of antigens to the skin's immune cells. In this talk, we will discuss the different type of MNA technologies, associated fabrication approaches for scalable manufacturing of MNAs, and their effectiveness in delivering surrogate vaccines to the human skin ex vivo and animal skin in vivo. One of those technologies include our new approach that uses Hybrid-MNAs, which combines advantages of other MNA technologies while addressing their drawbacks to realize significant advantages in regulation, manufacturing, application, and distribution aspects. Hybrid-MNAs will be inexpensive and patient friendly, will minimize cold-chain requirements and eliminate biohazardous sharps disposal. This would be transformational for global immunization programs.

6:50 PM *F.GI01.01.02
Insight from the Physical Sciences on Coronavirus Host Entry and Therapeutic Interventions Susan Daniel; Cornell University, United States

The coronavirus disease 2019 (COVID-19) pandemic has focused attention on the need to develop effective therapies against the causative agent, SARS-CoV-2, and also against other pathogenic coronaviruses (CoV) that have yet to emerge. Focusing on steps in the CoV replication cycle, in particular the entry steps involving membrane fusion that are vulnerable to inhibition by broad-spectrum or specific antiviral agents, is an astute choice because of the conserved nature of the fusion machinery and mechanism across the CoV family. For coronavirus, entry into a host cell is mediated by a single glycoprotein protruding from its membrane envelope, called spike (S). Within S, the region that directly interacts with the membrane is called the fusion peptide, FP. It is the physico-chemical interactions of the FP with the host membrane that anchors it, thus enabling the necessary deformations of the membrane that lead to delivery of the viral genome into the cell when a fusion pore opens. Understanding of thermodynamics, kinetics, and intermolecular interactions are useful to describe FP interactions with the host membrane at the most fundamental molecular level. This knowledge in turn, can be used to facilitate the development of strategies to limit those interactions to stop the spread of infection. In this talk, I will describe our work on understanding the impact of calcium ions on CoV infection. Using cell infectivity, biophysical assays, and spectroscopic methods, we found that calcium ions serve to stabilize the fusion peptide structure during conformational change that then allows its insertion into the host membrane, resulting in increased lipid ordering in the membrane. This lipid ordering precedes membrane fusion and has been shown to correlate with increased fusion activity and higher levels of infection in the presence of calcium. As such, depletion of calcium ions leads to structure and activity changes in the fusion peptide that correlate well with *in vitro* experiments using calcium-chelating agents to block cell infection. In a final set of experiments, we used calcium channel blockers that are FDA approved for cardiac conditions to test their ability to block virus infection in lung cells. In some cases, these drugs eliminated infection, pointing to the possibility for re-purposing these drugs to treat COVID-19.

7:10 PM *F.GI01.01.03
Membrane Based Affinity Capture to Quantify Antibodies to COVID-19 Merlin Bruening; University of Notre Dame, United States

We are developing porous membranes containing affinity molecules to quantitatively capture antibodies and determine their concentration. Previously, we immobilized peptide mimotopes to bind therapeutic antibodies in serum. Flow through the membrane rapidly brings antibodies to binding sites to enable their capture with high efficiencies. In an effort to apply this to quantitation of COVID-19 antibodies, we are immobilizing COVID-19 proteins and capturing their antibodies. Subsequent binding of a fluorescently labelled secondary antibody provides a signal that we hope will be proportional to the quantity of polyclonal antibody. Moreover, because capture rates are high we will try to use a monoclonal antibody as a standard to estimate the absolute antibody concentration, whereas most analyses give a relative or qualitative value for antibody concentration. The presentation will present preliminary results and explain the method.

5:45 AM F.GI01.01.04
Vent-Lock—A Bioinspired Ventilator Splitter to Enhance the Capacity of Treating Patients with COVID-19 Helen Xun[1], Christopher Shallal[1], Justin Unger[1], Runhan Tao[1], Alberto Torres[1], Michael Vladimirov[1], Jenna Frye[2], Bo Soo Kim[1], Broc Burke[3], Michael Talcott[3], Michael Montana[3], Justin M. Sacks[3], Julie Caffrey[1], Jamie Guest[1] and Sung H. Kang[1]; [1]Johns Hopkins University, United States; [2]Maryland Institute College of Art, United States; [3]Washington University in St. Louis, United States

Due to the COVID-19 outbreak, many critical supplies for patient care and disease prevention are becoming increasingly scarce. One area that is increasingly in demand is ventilators. Ventilators are the mainstay treatment for COVID-19 patients that develop ARDS (Acute Respiratory Distress Syndrome), one of the primary causes of death of COVID-19. There exists an enormous gap between demand and supply. It is predicted that there is a global shortage of 880,000 ventilators. This is especially concerning in developing countries, where ventilators are already in short supply, and the hospitals may not have resources to meet those demands. Ventilator splitters are the most feasible option to increase capacity rapidly but face many challenges in inpatient care. The Society of Critical Care Medicine released a statement listing the challenges of splitting ventilators. Despite these challenges, ventilator splitting has already happened globally, including in New York City, as “the other option is death.” We have worked with anesthesiologists, clinicians, and ICU intensivists at Johns Hopkins Hospital to address pressing needs through materials research.

We will present our approaches to provide safe treatments for each patient by addressing the challenges associated with splitting ventilators. Due to the unstable supply chain, we have prototyped de novo ventilator splitters (“Vent-lock”) with flow restriction valve via 3D printing using biocompatible and easily sterilizable materials. Inspired by the shape and angles of the human bronchi, we designed the splitter to minimize turbulent airflow. We have used the ventilator splitter and flow restriction valve in a circuit containing filters, one-way valves, continuous monitoring, and positive end-expiratory pressure (PEEP) valves to safely allow clinicians to split ventilators for patients. Our 1+n(1) system is compatible with most ventilators and anesthesia machines.

We have tested our breathing circuits using a ventilator for two simulated patients with differing lung compliances, with continuous intrapulmonary data collection. We validated our airtight breathing circuit, and also produced one-way valves integrated into the ventilator splitter and filter drawers with replaceable filters to minimize aerosolization or cross-contamination of viruses. Our device was also validated for splitting anesthesia machines in in-vivo swine studies. Two swine were stably ventilated for five hours by one anesthesia gas machine, as confirmed by arterial blood gases, continuous airflow monitoring, and final lung histopathology. Our device is currently under review by the U.S. Food and Drug Administration for Emergency Use Authorization.

We envision that our study can contribute to increasing ventilator capacity safely to meet urgent ventilator shortages and provide another example that materials scientists and engineers contribute to addressing societal challenges such as COVID-19 by working with stakeholders from healthcare, government, and industry. Due to the multidisciplinary and collaborative nature of the materials research, the materials community is well-positioned to enable advances in medicine and public health.

5:55 AM F.GI01.01.05
Late News: The pH-Varying Conformational States of SARS-CoV-2 Spike Glycoprotein Ziyuan Niu, Miriam H. Rafailovich, Marcia Simon, Yuefan Deng and Peng Zhang; Stony Brook University, United States

Introduction: The coronavirus SARS-CoV-2 is postulated to infect cells by attaching its outer membrane S-protein (spike glycoprotein) [1] to the host cell targets such as ACE2, CD26, Ezrin, and cyclophilins [2]. Structurally altering the S-protein may mitigate or even block the infectivity of coronavirus. One way to alter the S-protein's physicochemical properties including structures and function is to surgically change the protonation and deprotonation state of each ionizable group to control the pH value[3]. The pH values of the aerosol droplets environment are known to change the chemical form, distribution, and reactivity [4-6] of the protein. Performing such study, e.g., immersing the virus and especially the S-protein in a solution of given pH values, is dangerous and nebulous. Our all-atomic molecular dynamics simulations, with their own challenges of long computation, allow us to examine the conformational states of the S-protein at extreme pH values. This is what we report in this work.

Contributions: We have performed our MD simulations of S-protein for five pH values in 3, 4, 5, 7, 11 for longer than the microsecond scales. With the current rate of simulation progress, we expect to reach a record simulated time and obtain the states of the S-protein for the first time. As the first attempt to control the pH values during MD simulation by protonation and deprotonation state of the amino acid sidechain residues in the S-protein, we may corroborate the simulated conformational states with the properties obtained in the lab bench experiments. We examine the detailed conformational states change at different pH values of the entire S-protein as well as the individual residues of interest.

Methodologies: We use the Gromacs program [7] to perform the MD simulation on the IBM Power9-based AiMOS supercomputer. The S-protein structure data is taken from the protein data bank (6VXX.pdb) and the force field for the S-protein and water molecule is from the CHARMM27. The S-protein is $12\times13\times16$ nm^3 in size which is placed in the water box of size $21\times21\times21$ nm^3. Every simulation is controlled at the normal human body temperature of 37°C and a control group at this temperature and the neutral pH7 is run. Our MD simulations away from this neutral pH require the addition of the Na^+ or Cl^- ions in the solvent to balance the charges and ensure the protonation state accuracy [8].

Results: The protein structure changes measured by RMSD for backbone and RMSF for individual residue were performed. Here is a list of brief observations: (1) The states of protein show significant RMSD increases for pH3 and pH11. We expect the protein to denature as we continue the simulation. (2) The conformational states for pH4 and pH5 appear to be quite similar to those of the pH7, at least for the simulated time we reached so far. (3) After 500ns, the protein at pH3 and pH11 showed obvious structural changes in specific residues. For pH3, ARG-466 and ASP-467 in Chain B are extremely active. Moreover, this is on the S1 domain, for binding the host cell [9]. For pH11, in both Chain A and Chain C, ASP-1146 and SER-1147 are more active than others. This part is on the S2 domain, which is for membrane fusion [9].

Conclusion and Future Work: The first studies of the effects of pH on S-protein at the microseconds scales provide us detailed pictures of the structural changes of whole S-protein and its individual residues. We continue the MD simulations to collect more data for various analyses of structures and functions of the S-protein and corroborate them with laboratory results.

Facial Masks during COVID-19: Imaging, Disinfection, Homemaking, and Future Materials Design Yi Cui[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

Facial masks are among the most important personal protection equipment to fight COVID-19. This talk covers our exciting progress related to facial masks including: 1) We utilized X-ray tomography and deep learning to perform 3D imaging and analysis of facial masks and the particle filtration to provide critical understanding how facial masks work. 2) We developed heating methods (dry and humid) as the most efficiency methods to disinfect N-95 level facial masks while maintaining their high filtration efficiency for over 20 times. 3) We studied a variety of household textiles and identify the most effective ones for homemade masks; 4) We propose that nanofiber filtration technology would afford the next generation high performance facial masks with high filtration efficiency and great breathability.

5:45 AM F.GI01.02.04
Facile Post-Process Coating for 3D Printed Nasopharyngeal Collection Swabs for Lubrication and Enhanced Specimen Collection Jason Hoffman-Bice and Randall M. Erb; Northeastern University, United States

The disruption of the COVID-19 global pandemic has caused severe supply-chain disruption within several industries, to include food and medical devices. Due to supply shortages, focusing on medical devices, innovative solutions in additive manufacturing have been expedited through FDA approval, specifically in the arena of nasopharyngeal (NP) swabs, to increase testing rates of suspected COVID-19 patients. Further, there are other innovations, such as touchless door handles, allowing individuals to avoid hand contact with entry points if desired, leading to more hygienic interactions with public spaces. These provide strong examples that 3D printing can provide end-use products beyond prototyping. However, like many such manufacturing processes, additional processing techniques are required to produce the end-use products. The technology leading 3D printed NP swabs are SLA/DLP printers with acrylic based resins. This chemistry exhibits many drawbacks including both poor lubrication that leads to patient discomfort as well as less than desired wettability with specimens of patient sputum. This study investigated and screened biocompatible and hydrophilic coatings that may be applied to NP swabs in post-processing to increase lubrication and improve upon specimen collection quantity. Notably, the study was conducted during COVID lockdown which offers some additional supply chain learnings. To this end, a biocompatible modified poly(vinyl alcohol) (PVA) coating was applied to a 3D printed swab with a current marketed NP swab printing material already in use. The coating results showed an improvement in wettability as demonstrated by a 43.9% lowering of contact angle and a 39.3% improvement of specimen collection using synthetic saliva. This test case study was completed to help provide an additional solution to the manufacturing bottleneck for NP swabs. Additionally some further COVID case studies that are enabled by 3D printing will be briefly highlighted.

5:55 AM F.GI01.02.05
Self-Limiting Electrospray Deposition to Create Bioactive Coatings Lin Lei, Emran Lallow, Catherine Nachtigal, Hao Lin and Jonathan P. Singer; Rutgers University, United States

Electrospray deposition (ESD) is a well-established technique for the creation of thin films from the spray of highly-charged droplets loaded with the materials to be deposited. While a majority of ESD research has focused on droplet evolution in air, the dissipation of charge on arrival at the substrate is critical in determining the macro- and micro-scale morphology of the final spray. Recently, we have categorized various modes of ESD, including self-limiting electrospray deposition (SLED). In SLED, specific manipulation of the electrostatic repulsion, hydrodynamic forces, and evaporation kinetics can be employed to conformally cover 3D architectures with microcoatings. The generated coatings are hierarchical, possessing either

nanoshell or nanoparticle microstructure. The initial demonstrations of SLED employed single glassy polymers as the solutes and simple cm-scale geometries as substrates. Here, I will discuss opportunities to create bioactive conformal coatings on medically-relevant architectures by employing blending, self-assembly, and complex geometries. Specifically, we explore coating transdermal microneedles with blends of DNA vaccines and rapid-dissolving matrices as a high-efficiency, scalable alternative to dip or inkjet coating. We demonstrate that we can deposit up to 70 wt% viable coatings of DNA in a sugar matrix that quickly dissolve upon insertion into the skin and show expression of GFP (pEGFP-N1). This method is compatible with rapid continuous manufacturing and is a route to shelf-stable, low-training vaccination administration for the current and future pandemic crises.

6:05 AM F.GI01.02.07
Late News: Binding Dynamics of SARS-CoV-2 Spike Glycoprotein to Polylactic Acid Karin Hasegawa, Bernard Essuman, Fan Yang, Marcia Simon, Miriam H. Rafailovich, Yuefan Deng and Peng Zhang; Stony Brook University, United States

The personal protective equipment (PPE) may help reduce the risk of infection of the front-line healthcare workers of COVID-19 patients and others but the virus in aerosols, PPE and other materials' surfaces may also cause infections[1,2]. Studying the dynamics of the binding of SARS-CoV-2 spike glycoprotein (S-protein) to various substrates such as polylactic acid (PLA), the common material used in PPE, by *in silico* and *in vitro* experiments is essential. The S-protein, the key receptor for binding and promoting entry to host cells, is the main subject of our study that correlates *in silico* and *in vitro* data for validating the analysis of guidelines for improving PPE and other protection measures.
For *in silico* experiment, GROMACS is used for the MD simulations that are carried out at the reference room temperature (297K). The initial structure of the S-protein is obtained from the Protein Data Bank (PDB: 6VXX). CHARMM22/CMAP is used as the force field to perform MD for 200 ns for the structural relaxation of the S-protein in the NPT ensemble in the water system. PLA substrate is built with repeating optimized unit cells, where each unit cell is made of a set of lactic acid monomer which is generated using AVOGADRO and LigParGen. The structure of the PLA sheet is relaxed in a vacuum box in the NVT ensemble using OPLS-AA. To achieve the desired structure of the sheet, additional relaxation is performed in the NVT ensemble with CHARMM36. The well-relaxed S-protein and the PLA sheet are placed in a water box of size 21×27×21 nm^3 and the initial distance between two species is set to 0.8 nm. CHARMM36 is adapted to this system and Van der Waals radii of the carbon atom are increased to 0.51 nm to prevent the H2O molecules from erroneously slipping into the PLA substrate. The substrate is restrained during the equilibriums. The NPT production run is carried and the RMSD of the S-protein and the system trajectory are monitored to ensure the stability of the system. For *in vitro* experiment, the H1N1 is used as an alternative to the SARS-CoV-2 due to the laboratory restrictions. The viruses are placed on a plate and the plate is left at room temperature (297K) for an arbitrary period.
The relaxed S-protein-PLA system allows us to do an analysis of binding by i) counting the number of the atomic contacts among S-protein and PLA atoms and quantify the binding intensity. ii) calculating the binding force as a function of time to extract the binding dynamics. The analysis of *in vitro* experiment is done by washing the virus adhered to the plate with water every arbitrary period. The number of remaining viruses on the plate is counted accordingly and the results are plotted over time. Finally, both *in silico* and *in vitro* data are correlated with statistical tools and both results are cross-validated.
The data we obtain from our *in silico* and *in vitro* experiments provide a vital understanding of the binding dynamics of the protein and the guidelines for the protection of the contagion. We will expand our research to a matrix of various environmental conditions including temperature, pH values, and salinities on various substrates including inorganic, organic, and living cells, beyond our current studies with only one temperature (297K) and one material (PLA). In addition to understanding the elusive virus-substrate properties for the S-protein, our methodology and the resulting platform can be extended to the study of other viruses and substrates at other conditions.

The project is supported by OVPR&IEDM COVID-19 Grant and SUNY-IBM Consortium Award.

Late News: Towards the Design of a Novel Antimicrobial/Antiviral Filtration System Antwine W. McFarland, Chris Miller, Anusha Elumalai, Ahmed Humayun and David K. Mills; Louisiana Tech University, United States

With the COVID-19 pandemic, we face a global health crisis not seen since the influenza pandemic of 1918. It is believed

that the transmission of COVID-19 is thought to occur through respiratory droplets. As such, current CDC guidelines recommend using N95 masks for healthcare providers managing the care of patients infected with SARS-CoV-2 or persons under investigation (PUI) for COVID-19. The shortage of N95 style masks that could effectively protect health care professionals against harmful pathogens is of critical need in halting the current pandemic's trajectory and containing future outbreaks.

Using modified halloysite nanotubes (HNTs), we manufactured two products that work in conjunction with each other. We applied a simple, novel, and effective electrodeposition method for coating the surfaces of HNTs with metal nanoparticles (copper, silver, and zinc). Each metal is known to possess potent antiviral and antimicrobial properties. Metal-coated HNTs (mHNTs) were then added to polylactic acid and extruded to form a mHNT/PLA 3D printer filament. Furthermore, the halloysite's inner lumen was vacuum loaded with an additional antibacterial agent before the extrusion process.

Our antimicrobial/antiviral mHNT/polymer composite 3D printer filament was used to fabricate an N95-style mask with an interchangeable filter with surfaces that will deactivate a virus and reduce or eliminate adhesion, prevent bacterial growth, and reduce deadly infections. Antibacterial studies were conducted using methods that tested the efficacy of our design in a liquid medium and as a surface. Testing discs were 3D printed using the antimicrobial polymer composite. *E. coli* and *S. aureus* were the bacteria used in our experiments as they represent fast-growing gram-positive and gram-negative bacteria. The samples containing non-doped mHNTs showed a marked inhibition in the growth of both bacteria. However, the samples containing doped mHNTs showed an even greater ability to inhibit bacterial growth.

The filter respirator was made using the same ratio of PLA to mHNTs. Once dissolved in the solvent, the mixture was sprayed onto sterile gauze using a commercially available airbrush. Following the blow spraying of the gauze, the new filter was allowed to dry before another layer of treated gauze was added to the filter to make a three-layer sandwich consisting of gauze, blow spun antimicrobial fibers, and gauze. Simultaneously, the mask can be sanitized by alcohol or hydrogen peroxide solution, or UV light radiation and reused. The *National Institute for Occupational Safety and Health (NIOSH) guidelines require that a mask must be able to protect people with different facial features. Our mask can be form-fitted to an individual's unique facial features due to our mask's unique design.* Merely placing the mask in warm water will momentarily make the mask moldable. Once cooled, the shape is preserved for a custom fit. Additionally, masks were manufactured in smaller sizes that could accommodate children and young adults.

The technology developed for the respirator has additional uses. Utilizing the airbrushing method to cover a filter material, air-conditioning filters can be coated with the antimicrobial coating. Using preexisting air conditioning filters as a building platform, this technology can be used to keep areas such as hospitals, clean rooms, and quarantine areas free of contaminants. Moreover, the air can be filtered on its way out using a different filtration system to keep harmful pathogens from exiting those closed-off areas.

Future studies will include antiviral studies. We are confident in our mask and filter system's ability to perform as designed and eliminate the viruses promptly. Fit testing to become NIOSH certified will also be conducted. A qualitative study will rate the degree of discomfort the wearer experiences while wearing the mask for long periods, ranging between 4, 8, and 10 hours.

Late News: Artificial Intelligence Accelerated Design of Antimicrobial/Antiviral Surfaces—A Promising Route to Mitigate SARS-COV-2 Fomite Transmission Heesoo Park[1], El Tayeb Bentria[1], Abdelilah Arredouani[2], Halima Bensmail[3] and Fadwa El Mellouhi[1]; [1]Qatar Environment and Energy Research Institute, Hamad Bin Khalifa University, Qatar; [2]Qatar Biomedical Research Institute, Qatar; [3]Qatar Computing Research Institute, Qatar

Coronavirus disease 19 (Covid-19), caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection, is the worst global pandemic of the 21st century to date, and continues to infect and kill many individuals worldwide. SARS-CoV-2 remains intact and contagious in small droplets (<5μm) and can be suspended in the air for up to three hours. Therefore, airborne isolation, room ventilation, and appropriate application of disinfectant might restrict aerosolspread of the virus. However, the virus-laden droplets that are too heavy to remain in the air would rather fall on nearby floors or surfaces, creating fomites (or contaminated surfaces). Recent studies have evaluated the stability of SARS-CoV-2 on different surfaces, and it was found that the virus could survive from 24h on cardboard to 2 days on stainless steel and wood and even to 7 days on outside of surgical masks. This indicates that the fomites can represent a considerable mode of transmission mainly in closed areas.

Nowadays, most experiments to synthesize and test antimicrobial/antiviral materials are based on trial and error, and often it is not known how the inhibitors act on the microorganism. In this work we will showcase how artificial intelligence andmachine learning methods could be used to speed the design and optimization of antimicrobial/antiviral surfaces. Using computational methods, namely electronic structure calculations combined with data analytics and machine learning algorithms, we build a model able to estimate the activity of pathogen inhibitors. We focus our attention on photocatalytic systems that can be tailored to give a balanced production of Reactive Oxygen Species (ROS) upon illumination while taking into consideration the cost associated with a large-scale deployment of this solution. We built an artificial intelligence model that is able to predict the rates of ROS production while varying the composition and properties of the photocatalyticsystem. The proposed candidate materials, predicted from the computational modeling, may find application for high touch surfaces to avoid fomite viral and bacterial transmission, and also as coating for air conditioning and air cleaning filters to mitigate the viral transmission via aerosol.

Late News: Thermal Analysis of the SARS-CoV-2 Spike Glycoprotein by *In Silico* and *In Vitro* Experiments Meichen Song, Fan Yang, Miriam H. Rafailovich, Marcia Simon, Yuefan Deng and Peng Zhang; Stony Brook University, The State University of New York, United States

Objectives: The SARS-CoV-2 engulfs the world from tropical countries like India [1] at 51°C to cold supply chains [2, 3]at 3-4°C.Our molecular dynamics (MD) analysis of the temperature-dependent structural changes of the virus' spike glycoprotein (S-protein) [4-6] help bridge the data gaps from *in vitro* experiments to viral transmission assessment. Our thermolability studies of the protein immersing in H2O, differing from most protein binding simulations as the percentage of drug bound or unbound fraction [7, 8], complement the sparse and inconsistent *in vitro* experiments with high-infectious virus cultivation [9-12]. Correlating the *in vitro* and *in silico* experiments allows us to establish a deep nueral network model for relating the virus's survival time or metamorphosis to the ambient temperatures.
Methods and Materials: Our *in silico* experiments of S-protein (PDB file 6VXX) involve immersing it in a H2O box of $21\times21\times21$ nm^3 using the CHARMM27 force field under NVT ensemble. We calculate the S-protein's thermal inabilities based on RMSD of backbone, at eventful or purposeful temperatures: 3°C, 20°C, 37°C, 60°C, 80°C, 95°C, and 300°C. The *in vitro* experiments, where the infectivity is determined by a TCID50 assay, is reported [12, 13]. The curve of RMSD vs. temperatures of the *in silico* data is corroborated with that of the inactivation time vs. temperature of the *in vitro*. The *in vitro* and *in silico* data are applied to cluster the distributions of RMSD of both experiments to generate a rough grouping of the protein's survival duration from weeks to milliseconds.
Results: The *in vitro* experiments and the *in silica* results can complement and verify each other:
Stable at low temperature: The average of RMSD at 3°C is 38% lower than it at 20°C with the small variance, agreeing with *in vitro* experiments that salmon-attached coronavirus at 4°C remain infectious for more than a week [3] and there was only around a 0.7 log-unit reduction of infectious titer on day 14 at 4°C[13].
Sensitive at 60°C~80°C: the distribution of RMSD at 20°C is similar to it at 37°C but different with it at 60°C. Two peaks in distribution at 60°C indicate the structure inability is shifting from a lower to higher level. The average of RMSD increases 30% with temperature from 60°C and 80°C, serving as a signal for the presence of a critical heat denaturation in that range. Those *in silico* results perfect agree with *in vitro* results that the inactivation time at 37°C, 56°C and 70°C change from 24h, 30min to 5min [12, 13].
3) The *in vitro* survival time vs. temperature [12] agrees with the curve of RMSD vs. temperatures *in silico* experiments, showing a zone of substantial structural variation, suggesting existence of a critical temperature.
4) Correlate with *in vitro* data [12, 13], the clustering distributions of RMSD roughly group the virus' survival time at temperature ranges: 60°C-70°C, 80°C-95°C, and 300°C groups to week-, day-, hour-, minute- and microsecond-scales, respectively.
Discussions: Our millisecond-scale MD simulations help reveal the thermal properties of the S-protein. These *in silico* experiments corroborate well with the *in vitro* ones and, conversely, guide additional *in vitro* experiments, showing the benefits of "amalgamating" these two experiments. The 10-ms runs are expected to enhance the correlation and prediction accuracy. Our continued simulations at higher temperatures will likely capture the denaturation. This vital ground truth, coupled with *in vitro* experiments, will allow us to develop machine learning algorithms to predict the virus' survival duration at a given temperature and make quicker and wider discovery of properties of the coronavirus and, potentially, other materials.
Acknowledgment: The project is supported by OVPR&IEDM COVID-19 Grant and SUNY-IBM Consortium Award.

Skin-Integrated Wireless Biosensors for Symptom Tracking John A. Rogers; Northwestern University, United States

Rigorous and widespread testing remains a critical component of strategies for containing the COVID-19 pandemic. The limited availability of molecular diagnostics, however, creates a gap between requirements for population level testing and the availability of tests, likely to persist for the foreseeable future. These circumstances motivate the development of complementary technologies for diagnosing and monitoring COVID-19 infections. Consumer-grade wearables may have some utility in this context, but intrinsic shortcomings prevent measurements of the key symptoms of the disease: fever (98%), cough (65%) and shortness of breath (55%). This talk describes the custom development of a soft, hybrid electronic device, originally designed to track patients with aphasia and dysphagia, that mounts on the suprasternal notch to track all of these symptoms, continuously and with clinical-grade accuracy. Uses range from detecting early signs of symptoms in high risk populations, to monitoring the progression of patients with the disease in the hospital and in the home. Deployments on more than 250 healthcare workers and COVID-19 patients across the medical complex in Chicago over the last 20 weeks demonstrate the power of this technology, particularly when paired with HIPAA-compliant cloud data services and advanced analytics. Current and future activities will be discussed.

High-Quality Factor ("High-Q") Nanophotonics for COVID-19 Diagnostics Jennifer A. Dionne, Jack Hu, Fareeha Safir, Jefferson Dixon, John M. Abendroth, Mark Lawrence, Scott Boyd, Benjamin Pinsky and Stefanie S. Jeffrey; Stanford University, United States

The emergence of COVID-19 has underscored the importance of rapid, frequent, sensitive and specific diagnostics for tracking and containing an infectious disease. Current detection methods including polymerase chain reaction (PCR) and enzyme-linked immunosorbent assays (ELISA) are robust and sensitive, but generally either rapid and qualitative or quantitative and slow; they are also constrained to measuring one analyte, such as a gene sequence or antibody isotype, at a time, and cannot correlate viral load to antibody type and level. Here, we present a new photonic chip-based technology that uses optical characterization to rapidly and quantitatively measure gene sequences and antibodies, and determine the corresponding viral load from the same patient. Our platform relies on high-quality-factor ("high-Q") nanostructured dielectric substrates, known as metasurfaces. These high Q metasurfaces produce a large amplification of the electromagnetic field intensity, increasing the response to minute refractive index changes from targeted binding of a nucleic acid sequence or antibody; simultaneously, the optical signal is beam-steered for multiplexed detection. We will present the design and development of this quantitative optical assay, as well as application to clinical nasal-pharangeal and serological samples from Stanford's Clinical Virology Lab.

Homogeneous Bioluminescent Immunoassays: Cheap, Fast, and Sensitive Alternatives for ELISA in Point of Care Diagnostics Maarten Merkx; Eindhoven University of Technology, Netherlands

The widely recognized need for more personalized, patient-centered healthcare requires the development of cheap, easy-to-use, yet reliable biomedical devices that are capable of detecting specific diseases. The current COVID-19 pandemic has made this need abundantly clear and has shown that we are ill-prepared for this and future viral pandemics. Immunoassays form the cornerstone of today`s clinical biomolecular diagnosis. Their success is rooted in their modularity and the possibility to generate specific and high-affinity antibodies for almost any molecular target. However, translation of traditional heterogeneous immunoassays into point-of-care assays has proven challenging, because they require multiple incubation and washing steps, the addition of exogenous reagents, and external calibration. Laminar flow immune assays (LFIAs) have been introduced as cheap and relatively easy-to-use POC immunoassays, but they suffer from limited sensitivity and are primarily used as qualitative tests.
In recent years our group pioneered the development of bioluminescent sensor proteins that allow affinity-based detection of antibodies, proteins, small molecules, and DNA/RNA directly in blood plasma using the camera of a smart phone as the sole piece of equipment. Unlike fluorescence, whose dependence on external illumination gives rise to autofluorescence and scattering, bioluminescence is ideally suited to measure analytes directly in complex media such as blood with minimal sample handling. In my presentation I'll focus on the development of a generic bioluminescent sandwich immunoassay

platform that combines the analytical performance of a laboratory-based immunoassay such as ELISA with the speed and ease-of-use of laminar flow immunoassays. RAPPID (Ratiometric Plug-and-Play Immunodiagnostics) combines ratiometric bioluminescent detection with antibody-based target recognition into an easy-to-implement standardized workflow, and therefore represents an attractive, fast, and low-cost alternative to traditional immunoassays, both in an academic setting and in clinical laboratories for point-of-care applications. The modularity of the RAPPID workflow also enables rapid development of point of diagnostics for newly emerging analytes, as demonstrated here by development of RAPPID assays for SARS-CoV-2 spike proteins and anti-SARS-CoV-2 antibodies. To allow further development for point-of-care diagnostic applications, RAPPID can be integrated in cheap and simple paper- or thread-based analytical devices or integrated into microfluidic cartridges, and dedicated readers could be developed to further increase sensitivity.

5:45 AM F.GI01.03.04
Low Cost Paper-Based Immunoassays for COVID-19 Diagnostics Kimberly Hamad-Schifferli; University of Massachusetts Boston, United States

The COVID-19 pandemic has suffered from a lack of rapid diagnostic tests, where the need far exceeds current supplies. Tests are required both for diagnosing infections as well those that can test for the presence of antibodies, which will aid in determining immunity. To meet what is expected to be an extreme demand for mass testing, there needs to be point of care tests that can be run by non-experts and go from sample to answer within minutes. Also, because the supply chain for reagents has been unable to meet the needs for testing, a diversified portfolio of biological reagents tests is also needed.

Paper based immunoassays are attractive for use as rapid diagnostics for COVID-19 and many other infectious diseases because they are low cost and can be administered at point of care and in field settings. Readout by eye is made possible by the gold nanoparticle-antibody conjugates, which have a strong absorption due to the nanoparticle surface plasmon resonance, thus providing sample-to-answer times of minutes. We describe the development of gold nanoparticle-antibody conjugates for use in COVID-19 tests, and how the physical properties of the nanoparticle can impact test performance and sensitivity.

In addition, preparation for the next emerging outbreak requires the ability to develop tests in a nimble manner. We describe a route for repurposing stockpiled antibodies to make immunoassays for new diseases for which antibodies have not yet been developed. We leverage cross reactive antibodies and the size- and material- dependent properties of gold nanoparticles, demonstrating it for
for multiplexed diagnostics for yellow fever, dengue, and zika viruses. By adapting immunoassays for selective sensing as opposed to specific sensing and using machine learning of the color test lines, we are able to construct an assay for yellow fever non structural protein 1(NS1) using cross-reactive antibodies raised for dengue and zika.

Screening and Management of COVID-19 with Paper-Based Nanoparticle Tests Roberto de la Rica[1,2], Antonio Clemente[1], Cristina Adrover-Jaume[1,2], Alejandra Alba-Patiño[1,2], Andreu Vaquer[1] and Giulia Santopolo[1,2]; [1]IdISBa (Health Research Institute of the Balearic Islands), Spain; [2]University of the Balearic Islands, Spain

The global COVID-19 pandemic strains healthcare systems with a sharp increase in critical care demand coupled with a decrease in available staff as healthcare workers are more likely to fall ill as well. To prevent these strains from leading to collapse, it is essential to find new ways to quickly detect new infections and closely monitor disease progression. Quick detection would greatly assist in the process of contact tracing. As for monitoring, one critical point in the healthcare chain is to identify patients who are developing severe COVID-19 and to provide treatment before critical care becomes necessary in order to avoid oversaturation of ICUs (1). There is a common consensus that a hyper-inflammatory syndrome or a “cytokine storm” is responsible for poor outcomes in COVID-19. Thus, it is crucial to develop rapid point-of-care tests for cytokine detection so that patients with a poor prognosis can be detected early and eschew the need for critical care. At the same time, healthcare workers must be tested regularly to limit contagions. While this is currently done with RT-PCR, it would be desirable to find alternative ways to screen for new infections for hospital staff.

In this presentation I introduce a diagnostic platform for monitoring disease severity and new SARS-CoV-2 infections. It is based on modifying conventional filter paper with polymers so that it can store antibody-decorated gold nanoparticles (2). The polymer treatment also ensures a highly efficient transfer to other substrates such as cellulose or polypropylene, which is the basis for the diverse family of diagnostic tests presented here. For example, we have developed tests for detecting IL-6 at the point of care using cellulose as the substrate. IL-6 is a key player in the COVID-19 cytokine storm as well as a therapeutic target for immunomodulating drugs. Our tests can detect alarming levels of this biomarker in the blood of

COVID-19 patients in less than 20 min. They can also detect IL-6 in respiratory samples (bronchial aspirate, sputum) of COVID-19 patients rapidly thanks to our method for sample liquefaction. This approach could greatly improve the evidence base for the coronavirus management by revealing fluctuations in local inflammatory biomarkers. We have also developed diagnostic tests based on the detection of viral proteins attached to a medical face mask. In this approach, biomarkers adsorbed to the propylene fibers inside the filter of the mask are detected by pressing our paper-based tests against them. This transfers antibody-decorated nanoparticles to the mask, which then generate a colored spot on it if the target proteins are present. This approach could be an inexpensive alternative to RT-PCR for COVID-19 screening. All our analytical platforms benefit from smartphone-based detection approaches developed in our lab, which makes them highly portable and easy to implement at the bedside. Because the assays are paper-based, they can be easily disposed of by incineration, therefore circumventing biosafety issues. These features, along with the versatile design for detecting antigens in different sample types, make our diagnostic tests excellent candidates for managing and screening COVID-19 at the point of care.

Late News: Molecular Imprinted Biosensor for SARS-CoV-2 Detection Won-Il Lee[1], Robert Wong[1], Steffen Mueller[2], Chang-Yong Nam[3], Michelle Chang[4], Nishanth Chinnadurai[5], Jolene Huey[6], James Kim[7], Udithi Kothapalli[8], Hugo Onghai[9], Jeannie She[10] and Miriam H. Rafailovich[1]; [1]Stony Brook University, The State University of New York, United States; [2]Codagenix Inc, United States; [3]Center for Functional Nanomaterials, Brookhaven National Laboratory, United States; [4]Seoul International School, Korea (the Republic of); [5]East Meadow High School, United States; [6]Arcadia High School, United States; [7]Great Neck South High School, United States; [8]Saint Anthony's High School, United States; [9]Earl L. Vandermeulen High School, United States; [10]Walt Whitman High School, United States

The proliferation of cases during the COVID-19 pandemic has increased the urgency for point-of-care (POC) diagnostic tests. A rapid, accurate, affordable, and accessible diagnostic system in the field is necessary to extensively monitor an affected population to suppress the spread of the epidemics effectively. In this study, an electrochemical diagnostic sensor was developed to be capable of detecting entire virions or virion-associated proteins, which can be applied for rapid POC detection of SARS-CoV-2. The molecular imprinting (MI) technique was utilized on the surface of a gold substrate with virions and hydroxyl-terminated alkanethiol chains to form a self-assembled-monolayer (SAM) crystallized to the specific shape of targeted analytes. The crystalline SAM behaved as a footprint by forming cavities on the surface, and it allows specificity can be attributed to the cavities formed in the thiol layer based upon the size, orientation, and hydrophilicity of the analytes. Real-time detection of the target virus was possible by measuring the potential difference through the re-adsorbing of the analyte with the imprinted pattern to generate a surface charge on the chip. The technique was previously shown to be comparable to Elisa in accuracy of CEA cancer marker detection in humans but with 1/100 of the test volume [1]. In a recent publication, we also demonstrated that the technique could detect ZIKV in saliva at sub infectious concentrations of less than 10 PFU/mL and accurately discriminate against DENV [2]. Here we show that the sensor could selectively detect the influenza A viruses H1N1 and H3N2, which are morphologically similar to SARS-CoV-2, as well as the four capsid SARS-COV-2 proteins, in phosphate-buffered saline and human saliva without any sample manipulation. Heat inactivated H1N1 and H3N2 will also be tested and compared to results from heat inactivated SARS-COV-2 virus. These results demonstrate that the molecular imprinting technique has the potential to become a POC detection system for rapid and accurate screening of SARS-CoV-2.
This work was performed in part at the Center for Functional Nanomaterials (CFN) of Brookhaven National Laboratory (BNL).

Late News: Point-of-Care Biosensor for Rapid SARS-CoV-2 S1 Spike Protein Detection Using Aerosol Jet Printed Organic Electrochemical Transistor Jiaxin Fan, Sheldon Parr, Seongdae Kang and Manisha Gupta; University of Alberta, Canada

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has spread across the world and led to more than 924,000 deaths to date according to John Hopkins Coronavirus Resource Centre (September 14, 2020). Researchers and scientists around the world are actively working on developing therapeutics and vaccines for coronavirus disease 2019 (COVID-19).

The rapid transmission from asymptomatic infected people has made COVID-19 such a widespread and deadly pandemic compared to SARS or MERS. Relying on “social-distancing” measures comes at enormous economic and social cost; this type of compliance is not a sustainable long-term solution. Rapid large population screening to determine the confirmed cases and contact tracing are vital for controlling the spread. The current essential technology for confirmation of SARS-CoV-2 infection is nucleic acid amplification. Nucleic acid amplification-based diagnostics are reliable and highly sensitive, however, the time required for sample transportation, preparation, and completion of the assay does not provide the high throughput capacity for quick and mass population screening. Hence, developing a rapid and accurate sensing platform for SARS-CoV-2 detection is still an urgent need.
In this work, we have developed a prototype point-of-care device for rapid SARS-CoV-2 subunit 1 (S1) spike protein detection using organic electrochemical transistor (OECT) based biosensors. These sensors are being developed to work with saliva samples. The OECTs were fabricated using Optomec Aerosol Jet 5X 3D printer on flexible polyimide substrate, with Au nanoparticle ink for source, drain and gate electrodes, PEDOT:PSS channel, and UV-curable PDMS as the insulator. The printed in-plane Au gate electrode was chemically modified and immobilized with a specific antibody against the SARS-CoV-2 S1 spike protein. A distinctive shift in the transfer characteristics of OECT before and after the chemical modification and the antibody immobilization. Spike test was performed with biasing the OECT at constant voltages and adding SARS-CoV-2 S1 spike protein with different concentrations. The biosensors being developed are single use disposable chips. In addition, a small measurement kit has been developed which will provide the readout result from the chip indicating a positive or negative test result. As the proposed biosensors are printed using aerosol jet 3D printer and they can economically be scaled while maintaining their quality. The sensor can be deployed quickly at workplaces, schools, hospitals, airports, etc. for immediate test results.

Substrate-Free PEDOT:PSS Fibre Arrays as Breath Sensor Wenyu Wang and Yan Yan Shery Huang; University of Cambridge, United Kingdom

The development of a portable, rapid and efficient breath detector could potentially benefit the study of human respiration. This is of particular interest under the background of a global pandemic which could be spread through the respiratory system. Herein, we report an integrated, low-cost breath analyser that is composed of multi-layered, suspended PEDOT:PSS microfibre arrays, fabricated by original inflight fluidic fibre printing technique. Based on that the resistance of PEDOT:PSS is sensitive to the moisture change, this breath analyser offers a direct signal read-out. Thanks to the small diameter and large surface-to-volume ratio, the microfibres are much more responsive to the dynamics of moisture flow in air compared with planer or film based moisture sensor. Moreover, the ultrathin diameter and substrate-free feature enable the entire fibre array to be transparent and air permissive; thus, this sensor could be directly mounted in front of a camera, allowing visualisation at the same time. We demonstrate that this human breath analyser could be able to detect and distinguish the human breath level, when talking, breathing and coughing. In addition, we show that the breath sensor is also able to distinguish the human breath level change when wearing various face masks.

F.GI01.04.02
Combat COVID-19—Sterilize and Recharge Masks Simultaneously for Safe Reuse Sriram Sundar Shankara Narayanan, Xudong Wang, Zijian Weng, Vladislav Paley, Libin Ye and Ying Zhong; University of South Florida, United States

To rapidly respond to the COVID-19 pandemic and address the extreme shortage of proper sterilization methods for Personal Protective Equipment (PPE) and surfaces, we have urgently advanced safe, sustainable and high-efficiency corona discharge (CD) based sterilization technology. Filtering facepiece respirators (FFRs) like N95 masks and surgical masks are essential for reducing the spread of the virus. FFRs are primarily made of hydrophobic melt blown polypropylene layers. In addition to small pore sizes (<1μm), the filtration efficiency of N95 masks are also attributed to the electrostatic charges embedded in the fibers. These charges result in electrostatic attraction of small droplets carrying micro-organisms, effectively trapping them between the fibers. There are several attempts to decontaminate and reuse masks using existing sterilization techniques like heat, UV, etc. Although, these methods are effective in killing the virus, they negatively affect the filtration efficiency over

time.
In this study, we use CD to effectively sterilize masks and renew their filtration efficiency to make masks reusable. A high voltage is applied to a sharp electrode leading to dielectric breakdown of air. Electron and ion pairs are generated due to the avalanche effect. The combination of high electric field, ion bombardment and reactive species leads to effective sterilization of FFRs. The ions also renew the electrostatic charges on the surface of the fibers, thus recovering the filtration efficiency of the masks. Sterilization effect and mechanisms are being tested against E. coli, spores and SARS-CoV-2 virus. The sterility assurance level (SAL) has reached 10^{-3} with single spot electrode discharge, which is the requirement for safe mask reuse. Masks are also successfully recharged after CD treatment within seconds, sterilizing them simultaneously, making them safe to reuse. We are also developing portable devices for sterilization of FFRs and other kinds of surfaces.

Late News: Investigation of the COVID-19 Spike Glycoprotein at Varied Salt Concentrations—Correlating *In Silico* Modelling with *In Vitro* Droplet Drying Experiments Kaitlyn Swayze[1], Jacob Myers[2], Fan Yang[1], Miriam H. Rafailovich[1], Marcia Simon[1], Robert Elder[3], Yuefan Deng[1] and Peng Zhang[1,1]; [1]Stony Brook University, The State University of New York, United States; [2]University of Scranton, United States; [3]U.S. Food and Drug Administration, United States

SARS-CoV-2 is transmitted by respiratory droplets containing protein surfactants and NaCl, which relates to virus transmission when surfactants are in negligible amounts. These droplets land on surfaces and evaporate depending on environmental factors such as relative humidity, temperature, and contact surface causing NaCl concentration to increase as the droplet dries. We aim to examine the effect of electrostatic interactions on the conformation of the spike glycoprotein (S-protein), as has been done in vitro with other respiratory viruses, showing a decrease in viability [2] throughout evaporation. This is a leading investigation correlating the results of in silico modelling and in vitro droplet drying dynamic experiments to analyze the transmission of SARS-CoV-2.
Saline droplets of 1-2µl are pipetted onto paper, PLA, glass, and aluminum and left to evaporate at 297K, 1 atm, and 48% relative humidity. Concentration is extrapolated from droplet mass using a microbalance. The S-protein structure was retrieved from the Protein Data Bank (PDB: 6VXX), cleaned, and placed into a system using the AMBERsb14 force field with Joung and Cheatham ion parameters [1], placed 2.0nm from the box edge in 0M, 0.5M, 1M and 4.0nm from the box edge in 1.5M. The system was solvated with TIP3P water and ions were added by replacing water molecules. Equilibration steps were carried out with a timestep of 2.0fs. Energy minimization was performed for 50,000 steps followed by NVT equilibration for 100ps to heat the system to the temperature of in vitro experiments. NPT equilibration was employed for 100ps and the system was brought to 1 atm. The equilibrated structure is input to the production run using an NPT ensemble and Parrinello-Rahman pressure coupling. Density is monitored to ensure no system collapse or changes in concentration. Raw trajectories from the run are processed by re-centering the protein in the box and realigning with the first frame as the reference structure.
Benchtop experiments indicate that a 2µl droplet of saline reaches 1M in 45 minutes and fully desiccates over several hours with concentrations between 0.15M and 6M. The evaporation rate of saline on different surfaces is constant regardless of NaCl concentration. On non-metal substrates, the evaporation rate is negatively correlated to the water contact angle of the substrate and on metal substrates the evaporation rate remains lowest of all the substrates, although it has a higher water contact angle than glass. The in silico model is analyzed by calculating the RMSD of atomic positions for the S-protein backbone yielding that the 1.5M increases more rapidly.
Simulation of the S-protein in varied NaCl concentrations is consistent with droplet drying experiments and depicts how Na+ and Cl- ions interact with S-protein structure. We aim to correlate the volume and concentration from in vitro droplet drying experiments with the structural analysis from in silico experiments and to eventually utilize machine learning to predict the relationship between NaCl concentration and S-protein conformation over longer time, and to conduct further structural analysis on the S-protein. Simulation at higher salt concentrations (above 1.5M) has yet to be validated due to the need for a large number of monovalent ions, currently crashing our simulations. Future benchtop work will include plaque assays with the BSL-2 coronavirus OC-43 in drying saline droplets.

The project is supported by OVPR&IEDM COVID-19 Grant and SUNY-IBM Consortium Award.

Late News: Characterizing Viral Lifetimes from Droplet-Surface Interactions Junsang Yoon[1], Jacob Myers[2], Anand Srinivasan[3], Fan Yang[4] and Miriam H. Rafailovich[4]; [1]Cupertino High School, United States; [2]The University of Scranton, United States; [3]The Westminster Schools, United States; [4]Stony Brook University, The State University of New York, United States

SARS-CoV-2 (CoV) has sickened millions and killed hundreds of thousands since emerging less than a year ago. Aerosol transmission of CoV in respiratory droplets is well-established, but its capacity for fomite transmission is not well defined [1,2]. Fomite transmission of viruses are generally impacted by two factors: surface materials and droplet composition. However, both mechanisms are not well defined. For example, viral lifetimes may be affected by different surface-droplet interactions which influence the amount of water retained in a dried droplet residue, or through distribution patterns that create the localization of dried droplet solutes. Thus, this study aims to better characterize the expected lifetime of CoV by simulating various surface-droplet interactions frequent in real life.
Droplets of distilled water, saline, DMEM+10%FBS, lung fluid, and human saliva, with volumes ranging from 0.25 - 2.0 uL, were deposited onto paper, glass, polylactic acid (PLA), and aluminum. All samples were analyzed using contact angle goniometry and microbalance data; the changes in droplet volume over time were recorded, from which the evaporation rate and concentration of solutes were determined. Images of the drying pattern of each surface-droplet interaction were generated using confocal laser scanning. Plaque assays are now being performed at 10-minute time intervals to determine virus lifetimes.
Results indicate that the surface material greatly affects the drying rate. Significantly different evaporation rates were obtained when placing distilled water on aluminum, glass, and PLA. More importantly, fluids relevant to virus transmission, such as saliva and lung fluid, evaporated significantly slower on paper and faster on glass than they did on PLA and aluminum, with rabbit lung fluid evaporating at 0.164ul/min on glass and 0.051 ul/min on paper. Droplet composition also impacted the drying rates. Based on the contents of the droplets, two different drying mechanisms have been observed. Distilled water and human saliva dried at a linear rate, but in saline, DMEM+10%FBS and lung fluid, an initial linear decrease in volume followed by a slower asymptotic approach to the volume of the solutes was observed. Droplets with the asymptotic mechanism could keep viruses hydrated for a much longer time than previously predicted. Saline droplets retained 3.75% of their starting mass and porcine lung fluid retained 12.08% after 50 minutes, compared to 0.08% for water droplets after only 39 minutes. This contrast suggests increased hydration, and potentially lengthened virus lifetimes, for droplets that dry by the asymptotic mechanism. Images taken using confocal laser scanning show that both the surface and the composition of the liquid droplet affect the distribution of droplet solutes. On aluminum, glass, and PLA, droplets of saline and rabbit lung fluid showed a pinned contact line, leading to the buildup of solutes near the edge of the droplet, while saliva droplets created a buildup of solutes in the center of the droplet. The localization of solutes in saline, rabbit lung, and saliva droplets may also indicate an ability to hold water for a longer period of time.
Continued experiments using plaque assays of droplets and droplet residues containing H1N1 and the coronavirus OC43 deposited on different surfaces will reveal more directly the lifetime of CoV on different surfaces over time.

Late News: SARS-CoV-2 Biosensor Development—Exhaled Particle Measurements Using OPC, QMS, QCM and Potential for Hydrophilic LiNbO3 Biosensor Substrate Finn O'Hara, Bart Checinski, Guenevere O'Hara and Jozef Ociepa; OCI Vacuum Microengineering Inc., Canada

In light of the global need for COVID-19 testing there is a need for much faster testing device and the exhaled breath present significant potential to be used for this purpose. SARS-CoV-2 19 attacks the upper respiratory tract (nose and throat) and progresses down to the lower respiratory tract (lungs). SARS-CoV-2 causes lung inflammation increasing the number of particles in an individual's exhale. Pathogens present in respiratory fluid can be carried in aerosol particles. It is uncertain if SARS-CoV-2 stays viable in droplet nuclei particles; some studies that claim that droplet nuclei particles remain viable, presenting the threat of airborne transmission [1, 2]. Air samples tested positive in a Wuhan hospital confirming aerosol transmission [3]. SARS-CoV-2 microdroplets exhaled from infectious patients can be detected by specially developed breath analyzer. This analyzer is based on the biosensor to detect viral SARS-CoV-2 microdroplets from exhaled breath.
The aim of the present work is examining the characteristic of exhaled air samples from healthy individuals and finding

suitable substrate that can be used for further development of SARS-CoV-2 biosensor. We are using three techniques to measure the quantity and composition of exhaled air samples such as Optical Particle Counter (OPC), Quartz Crystal Microbalance (QCM) and Quadrupole Mass Spectrometer (QMS). The LiNbO3 crystal was selected to the biosensor substrate and characterized with Low Energy Electron Diffraction (LEED) and Auger Electron Spectroscopy (AES) for the capturing of the microdroples from exhaled breath. In order to work as SARS-CoV-2 biosensor the LiNbO3 substrate has to be developed further to be functionalized with ACE2 receptor.
OPC tests confirm the possibility of significant exhale particle generation -356% of inhaled air. High concentration of background particles induce a greater difference in exhale to inhale than low particle concentration background. Low relative humidity (RH) influences the amount of particles added by the breath to be lower. This indicates that that the amount of exhaled particles produced increases when worse air quality is inhaled. QMS data confirm that less gaseous water is in exhale than in inhaled air suggesting exhaled microdroplets agglomeration. QCM data shows difficulties in adsorption and holding the microdroplets on the crystal sensor. A LiNbO3 crystal was selected for the biosensor suitable substrate because it is strongly hydrophilic and has a very stable surface crystalline structure even after exposure to ambient air, water, and alcohol as was confirmed with LEED and AES study.

Late News: Molecular Dynamics Prediction of SARS-CoV-2 Spike Glycoproteins at Varying Temperature Using Machine Learning Models David Liang[1], Meichen Song[2], Ziyuan Niu[2], Peng Zhang[2], Miriam H. Rafailovich[2] and Yuefan Deng[2]; [1]Ward Melville High School, United States; [2]Stony Brook University, The State University of New York, United States

As the SARS-CoV-2 pandemic continues to spread, the effects of environmental factors on the molecular level remain unclear. While molecular dynamics (MD) simulations are a widely-used technique in modeling complex nanoscale interactions, its high computation requirements limit capabilities in long-term modeling.
This work explores a machine learning (ML) solution to predicting long-term properties of SARS-CoV-2 spike glycoproteins through the analysis of nanosecond S-protein backbone RMSD (root-mean-square deviation) MD simulation data at varying temperatures. The changes in the spike glycoprotein structure as time progresses are key to understanding the behavior and functionality of the virus under specific conditions.
Our data consists of 5000 RMSD values from 750ns to 1250ns. The data processing is characterized primarily with the denoising of the data with fast Fourier transforms (FFT) through filtering the Fourier terms or frequencies from the power spectrum. In addition to the data denoising, various statistical models, such as the autoregressive integrated moving average (ARIMA) and neural network models incorporating LSTM (Long short-term memory), GRU (Gated Recurrent Unit), and CNN (Convolutional neural network), were evaluated in performance on recursive forecasts. This work experiments with specific models including CNN-LSTM and CNN-GRU hybrid models and evaluates the incorporation of multi-step prediction features. Certain models were also trained on sliding window distributions of the data, where each window was characterized by a mean and standard deviation (SD) value, thus reducing the effect of variability in simulations. The performance of these distribution models was measured as overlap coefficients between actual and predicted windowed distributions. In predicting both the RMSD values and distributions, the hybrid CNN-LSTM and CNN-GRU, along with their multi-step counterparts, were more suitable for capturing and retaining the trends. The Multi-step CNN-LSTM model was able to achieve RMSE (root mean square error) scores of 0.0077 on actual value forecasts of 1230 points (123 ns), along wih overlap coefficients of around 0.15 on 1105 distribution value forecasts, showing promise in predicting long-term RMSD values. This work essentially demonstrated the feasibility of using ML to predict long-term properties of SARS-CoV-2 spike glycoproteins from MD simulation data.

Late News: Monte Carlo Simulation Studies of SARS-CoV-2 Spike Glycoproteins Clarise Han[1], Karin Hasegawa[2], Peng Zhang[2] and Miriam H. Rafailovich[2]; [1]Mission San Jose High School, United States; [2]Stony Brook University, The State

University of New York, United States

Given the severity of the COVID-19 pandemic caused by the novel SARS-CoV-2 coronavirus, it is essential to develop effective approaches for treatment and prevention. The improvement of personal protective equipment (PPE) for front-line healthcare workers also relies on comprehensive binding analysis of surface stability and binding intensity of the virus on certain substrates1. As the SARS-CoV-2 spike glycoprotein (S protein) is the key receptor for promoting entry to host cells and binding, we investigate its conformational transitions during binding using computer simulations to inform development and improvement of drugs and PPE to treat and prevent infection.
Our plan is to use Monte Carlo methods for our simulations. Two main methods for such computer simulations are molecular dynamics (MD) and MC. MD simulations are based on trajectories determined by Newton's equations of motion and use small time steps typically on the order of femtoseconds. This makes the simulations computationally expensive. MC simulations generate random movements based on probability distributions at each step. This has often been found to be more computationally efficient. As such, we are motivated to employ MC methods to greatly increase the efficiency of the S protein simulations. Our first step is to simulate the S protein in an aerosol environment. Our next steps include simulating the binding of the S protein-aerosol system onto various substrates such as polylactic acid (PLA), the common material used in PPE. We plan to correlate the in silico results with in vitro experiments to better inform and improve PPE guidelines.
Our current step is simulating the closed state 6vxx S protein in its aerosol environment. The Cassandra and GOMC (GPU-optimized MC) softwares were employed. Using Cassandra, data files such as the molecular connectivity file (MCF) needed to be generated. However, due to the complex nature of the S protein creating difficulties in generating the MCF file and the fact that Cassandra is not specifically designed for such large systems, we concluded that Cassandra was not suited for our simulation studies. As such, we decided to employ GOMC. We overcame difficulties with generating the appropriate PDB and PSF files. However, we discovered that there were limitations with GOMC for this type of simulation that prevented us from successfully running the entire simulation, including the fact that it does not support simulations for proteins with multiple residues. We are currently working on adjusting the source code with the help of the GOMC developers to support this type of simulation. We made some progress, and we expect to complete the simulations within the next few months. Ultimately, these simulations of the conformational changes of the S protein during binding will allow scientists to make more informed decisions on developments of drugs and PPE to treat and prevent infection. However, as time is of the essence, the need for efficient simulations using MC methods is vital to studying the S protein binding at a larger scale.

The Biology and Pathology of COVID-19: An Immunology Primer Bryan Bryson; Massachusetts Institute of Technology, United States

The SARS-CoV-2 pandemic has quickly spread throughout the globe in 2020. As such, engineers have applied their knowledge in materials design to approach prevention of infection, testing to diagnose infections, and treatment after an individual has COVID-19. These advancements rely on an understanding of the basic biology of SARS-CoV-2 from virology to immunology. Here, we will focus on a general overview of what is known about SARS-CoV-2 biology, focusing on components that are critical for materials design in prevention, diagnostics, and treatments.

Substrate-Free PEDOT:PSS Fibre Arrays as Breath Sensor Wenyu Wang and Yan Yan Shery Huang; University of Cambridge, United Kingdom

The development of a portable, rapid and efficient breath detector could potentially benefit the study of human respiration. This is of particular interest under the background of a global pandemic which could be spread through the respiratory system. Herein, we report an integrated, low-cost breath analyser that is composed of multi-layered, suspended PEDOT:PSS microfibre arrays, fabricated by original inflight fluidic fibre printing technique. Based on that the resistance of PEDOT:PSS is sensitive to the moisture change, this breath analyser offers a direct signal read-out. Thanks to the small diameter and large surface-to-volume ratio, the microfibres are much more responsive to the dynamics of moisture flow in air compared with planer or film based moisture sensor. Moreover, the ultrathin diameter and substrate-free feature enable the entire fibre array to be transparent and air permissive; thus, this sensor could be directly mounted in front of a camera, allowing visualisation at the same time. We demonstrate that this human breath analyser could be able to detect and distinguish the human breath level, when talking, breathing and coughing. In addition, we show that the breath sensor is also able to distinguish the human breath level change when wearing various face masks.

F.GI01.04.02
Combat COVID-19—Sterilize and Recharge Masks Simultaneously for Safe Reuse Sriram Sundar Shankara Narayanan, Xudong Wang, Zijian Weng, Vladislav Paley, Libin Ye and Ying Zhong; University of South Florida, United States

To rapidly respond to the COVID-19 pandemic and address the extreme shortage of proper sterilization methods for Personal Protective Equipment (PPE) and surfaces, we have urgently advanced safe, sustainable and high-efficiency corona discharge (CD) based sterilization technology. Filtering facepiece respirators (FFRs) like N95 masks and surgical masks are essential for reducing the spread of the virus. FFRs are primarily made of hydrophobic melt blown polypropylene layers. In addition to small pore sizes (<1μm), the filtration efficiency of N95 masks are also attributed to the electrostatic charges embedded in the fibers. These charges result in electrostatic attraction of small droplets carrying micro-organisms, effectively trapping them between the fibers. There are several attempts to decontaminate and reuse masks using existing sterilization techniques like heat, UV, etc. Although, these methods are effective in killing the virus, they negatively affect the filtration efficiency over time.
In this study, we use CD to effectively sterilize masks and renew their filtration efficiency to make masks reusable. A high voltage is applied to a sharp electrode leading to dielectric breakdown of air. Electron and ion pairs are generated due to the avalanche effect. The combination of high electric field, ion bombardment and reactive species leads to effective sterilization of FFRs. The ions also renew the electrostatic charges on the surface of the fibers, thus recovering the filtration efficiency of the masks. Sterilization effect and mechanisms are being tested against E. coli, spores and SARS-CoV-2 virus. The sterility assurance level (SAL) has reached 10^{-3} with single spot electrode discharge, which is the requirement for safe mask reuse. Masks are also successfully recharged after CD treatment within seconds, sterilizing them simultaneously, making them safe to reuse. We are also developing portable devices for sterilization of FFRs and other kinds of surfaces.

Air samples tested positive in a Wuhan hospital confirming aerosol transmission [3]. SARS-CoV-2 microdroplets exhaled from infectious patients can be detected by specially developed breath analyzer. This analyzer is based on the biosensor to detect viral SARS-CoV-2 microdroplets from exhaled breath.
The aim of the present work is examining the characteristic of exhaled air samples from healthy individuals and finding suitable substrate that can be used for further development of SARS-CoV-2 biosensor. We are using three techniques to measure the quantity and composition of exhaled air samples such as Optical Particle Counter (OPC), Quartz Crystal Microbalance (QCM) and Quadrupole Mass Spectrometer (QMS). The LiNbO3 crystal was selected to the biosensor substrate and characterized with Low Energy Electron Diffraction (LEED) and Auger Electron Spectroscopy (AES) for the capturing of the microdroples from exhaled breath. In order to work as SARS-CoV-2 biosensor the LiNbO3 substrate has to be developed further to be functionalized with ACE2 receptor.
OPC tests confirm the possibility of significant exhale particle generation -356% of inhaled air. High concentration of background particles induce a greater difference in exhale to inhale than low particle concentration background. Low relative humidity (RH) influences the amount of particles added by the breath to be lower. This indicates that that the amount of exhaled particles produced increases when worse air quality is inhaled. QMS data confirm that less gaseous water is in exhale than in inhaled air suggesting exhaled microdroplets agglomeration. QCM data shows difficulties in adsorption and holding the microdroplets on the crystal sensor. A LiNbO3 crystal was selected for the biosensor suitable substrate because it is strongly hydrophilic and has a very stable surface crystalline structure even after exposure to ambient air, water, and alcohol as was confirmed with LEED and AES study.

Late News: Molecular Dynamics Prediction of SARS-CoV-2 Spike Glycoproteins at Varying Temperature Using Machine Learning Models David Liang[1], Meichen Song[2], Ziyuan Niu[2], Peng Zhang[2], Miriam H. Rafailovich[2] and Yuefan Deng[2]; [1]Ward Melville High School, United States; [2]Stony Brook University, The State University of New York, United States

As the SARS-CoV-2 pandemic continues to spread, the effects of environmental factors on the molecular level remain unclear. While molecular dynamics (MD) simulations are a widely-used technique in modeling complex nanoscale interactions, its high computation requirements limit capabilities in long-term modeling.
This work explores a machine learning (ML) solution to predicting long-term properties of SARS-CoV-2 spike glycoproteins through the analysis of nanosecond S-protein backbone RMSD (root-mean-square deviation) MD simulation data at varying temperatures. The changes in the spike glycoprotein structure as time progresses are key to understanding the behavior and functionality of the virus under specific conditions.
Our data consists of 5000 RMSD values from 750ns to 1250ns. The data processing is characterized primarily with the denoising of the data with fast Fourier transforms (FFT) through filtering the Fourier terms or frequencies from the power spectrum. In addition to the data denoising, various statistical models, such as the autoregressive integrated moving average (ARIMA) and neural network models incorporating LSTM (Long short-term memory), GRU (Gated Recurrent Unit), and CNN (Convolutional neural network), were evaluated in performance on recursive forecasts. This work experiments with specific models including CNN-LSTM and CNN-GRU hybrid models and evaluates the incorporation of multi-step prediction features. Certain models were also trained on sliding window distributions of the data, where each window was characterized by a mean and standard deviation (SD) value, thus reducing the effect of variability in simulations. The performance of these distribution models was measured as overlap coefficients between actual and predicted windowed distributions. In predicting both the RMSD values and distributions, the hybrid CNN-LSTM and CNN-GRU, along with their multi-step counterparts, were more suitable for capturing and retaining the trends. The Multi-step CNN-LSTM model was able to achieve RMSE (root mean square error) scores of 0.0077 on actual value forecasts of 1230 points (123 ns), along wih overlap coefficients of around 0.15 on 1105 distribution value forecasts, showing promise in predicting long-term RMSD values. This work essentially demonstrated the feasibility of using ML to predict long-term properties of SARS-CoV-2 spike glycoproteins from MD simulation data.

We gratefully acknowledge support from the Louis Morin Charitable Trust

F.GI01.04.08

Late News: Monte Carlo Simulation Studies of SARS-CoV-2 Spike Glycoproteins Clarise Han[1], Karin Hasegawa[2], Peng Zhang[2] and Miriam H. Rafailovich[2]; [1]Mission San Jose High School, United States; [2]Stony Brook University, The State University of New York, United States

Given the severity of the COVID-19 pandemic caused by the novel SARS-CoV-2 coronavirus, it is essential to develop effective approaches for treatment and prevention. The improvement of personal protective equipment (PPE) for front-line healthcare workers also relies on comprehensive binding analysis of surface stability and binding intensity of the virus on certain substrates1. As the SARS-CoV-2 spike glycoprotein (S protein) is the key receptor for promoting entry to host cells and binding, we investigate its conformational transitions during binding using computer simulations to inform development and improvement of drugs and PPE to treat and prevent infection.
Our plan is to use Monte Carlo methods for our simulations. Two main methods for such computer simulations are molecular dynamics (MD) and MC. MD simulations are based on trajectories determined by Newton's equations of motion and use small time steps typically on the order of femtoseconds. This makes the simulations computationally expensive. MC simulations generate random movements based on probability distributions at each step. This has often been found to be more computationally efficient. As such, we are motivated to employ MC methods to greatly increase the efficiency of the S protein simulations. Our first step is to simulate the S protein in an aerosol environment. Our next steps include simulating the binding of the S protein-aerosol system onto various substrates such as polylactic acid (PLA), the common material used in PPE. We plan to correlate the in silico results with in vitro experiments to better inform and improve PPE guidelines.
Our current step is simulating the closed state 6vxx S protein in its aerosol environment. The Cassandra and GOMC (GPU-optimized MC) softwares were employed. Using Cassandra, data files such as the molecular connectivity file (MCF) needed to be generated. However, due to the complex nature of the S protein creating difficulties in generating the MCF file and the

fact that Cassandra is not specifically designed for such large systems, we concluded that Cassandra was not suited for our simulation studies. As such, we decided to employ GOMC. We overcame difficulties with generating the appropriate PDB and PSF files. However, we discovered that there were limitations with GOMC for this type of simulation that prevented us from successfully running the entire simulation, including the fact that it does not support simulations for proteins with multiple residues. We are currently working on adjusting the source code with the help of the GOMC developers to support this type of simulation. We made some progress, and we expect to complete the simulations within the next few months. Ultimately, these simulations of the conformational changes of the S protein during binding will allow scientists to make more informed decisions on developments of drugs and PPE to treat and prevent infection. However, as time is of the essence, the need for efficient simulations using MC methods is vital to studying the S protein binding at a larger scale.

F-BI01

5:00 AM *F.BI01.01.01
Publishing Insights from Materials Today Stewart R. Bland; Elsevier | Materials Today, United Kingdom

In this session we will discuss the information flow in materials science and the broader publishing landscape, including the varied roles of Authors, Editors, Referees, and Publishers in connecting communities, providing perspectives on best practices for publication in journals such as those in the *Materials Today* family. We'll try to elucidate the most significant trends in the information landscape, including open access, article transfer, novel article formats, data sharing, and wider dissemination to society and decision makers.

Dr Stewart Bland is a former Editor-in-Chief and currently Executive Publisher in Elsevier's *Materials Today* family, responsible for journals including high impact titles such as *Materials Today*, *Applied Materials Today*, and *Progress in Materials Science.*

5:15 AM F.BI01.01.02
Publishing with MRS Journals—Engaging with Our Community at Early Career Stage Y. Shirley Meng; University of California, San Diego, United States

Publishing scholarly research articles is one of the most effective ways to enage with our materials research community and dissimnate our work to our peers. MRS is a member-driven organization of approximately 14,000 materials researchers from academia, industry and government. I will present my perspectives as the editor-in-chife for MRS Energy & Sustainability how young researchers can fully leverage with the platforms MRS offer to maximize the impact of one's scholarly work.

5:25 AM *F.BI01.01.03
Inside *Nature Materials* Maria Maragkou; Nature Materials, United Kingdom

Since its launch in 2002, Nature Materials remains a leading journal in the field of materials science across many disciplines, aiming at publishing cutting edge science for the relevant scientific communities as well as disseminating exciting results among the wider readership of materials scientists. This talk will describe how these principles shape the editorial process in *Nature Materials* and other journals within the *Nature* family, amidst a rapidly changing scientific publishing landscape, underlining the key points from submission of original research papers to publication.

5:40 AM *F.BI01.01.04
Publishing in Wiley Materials Science Journals Bo Weng; Wiley, China

A highly competitive research environment with increasingly limited research funding has created a “Publish or Perish” attitude among scientists who are judged on the quantity rather than quality of their research articles. This presentation provides a brief overview of current trends and challenges in scientific publishing, some ethical considerations, how publishers and authors interact and influence each other, and how the publishing arena is being transformed. Tips will be presented on how to select an appropriate journal for your paper, what aspects of preparation and presentation to focus on from an editor’s and referee’s perspective, and hints for increasing the discoverability of your paper after publication.

5:55 AM *F.BI01.01.05
NSF Early Career Opportunities in Materials Research Linda S. Sapochak; National Science Foundation, United States

The National Science Foundation (NSF) is an independent federal agency created by Congress in 1950 "to promote the progress of science; to advance the national health, prosperity, and welfare; to secure the national defense..." NSF is vital because it supports basic research and people from all science and engineering disciplines. The Division of Materials Research (DMR) in the Directorate for Mathematical and Physical Sciences (MPS) has eight topical materials research programs (TMRPs) that participate in the NSF-wide Faculty Early Career Development (CAREER) program. Materials research is also supported in other divisions in MPS and in the Directorate for Engineering. This presentation will provide an overview of NSF programs supporting materials research and the early career opportunities they offer.

6:10 AM F.BI01.01.06
Late News: Finding Funding—A Glimpse into Science Funding in the Philippines Bryan G. Alamani; University of the Philippines Diliman, Philippines

Science funding in the Philippines is guided by roadmaps and advices from the Department of Science and Technology. Early career scientists often apply for this funding call and find themselves working in a system that require broad range of knowledge and experience in project management and legalities that surround government funded calls. The complexity of the funding application process presents challenges to early career scientists who are not familiar navigating through the system. Funding agencies have also preference on proposals that will lead to technologies or innovaitons that can be implemmented to society, and this entails some challenges to principal investigators who aim to answer fundamental scientific questions. Here, I will present some insights on the funding landscape in the Philippines for early career scientists by looking at scientists' roles in academe, support from the administration, and impact of government policy on R&D priorities. I shall also present certain coping mechanisms of early career scientists in obtaining support when their field is not considered top priority for funding.

SESSION F.BI01.02: Getting Ready for Your Future Career—Creating Your Next Research Environment
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-BI01

5:00 AM *F.BI01.02.01
Finding Your Career Pathway in a Foreign Country—A Minority Perspective Monica Jung de Andrade; The University of Texas at Dallas, United States

There is no ‘one path fits all’ as we are all different. With patented technologies and as one of the pioneers on carbon nanotube glass nanocomposites, I will share my ongoing career path. Being in a foreign country as a minority, the challenges are different: support system and cultural background, are just a few. Thus, one shall not just follow the flow, but forge one’s path aligned to their values, background, and passions. This is the ongoing story of a family’s first scientist enriched with different cultural exposures while finding her path. It is an unfinished story of challenges, failures, and learnings to be shared.

5:15 AM *F.BI01.02.02
Should I Stay or Should I Move? Thoughts about Early Career Mobility Eva Hemmer; University of Ottawa, Canada

This presentation will provide a snapshot on the journey of a materials scientist from Germany moving via Japan to Canada. It will not only tell about the geographical, but also about the scientific and academic journey, and how studying materials science and engineering can lead to an academic position in a chemistry department, conducting research on multifunctional lanthanides in molecules and nanomaterials.

In this context, some experience from the time being a PhD student and the period discovering new countries and research areas as a postdoctoral fellow and how these may lead to a position in academia will be shared with the audience. This will include a personal answer to the question many young researchers may ask themselves: "*Should I stay or should I move?*". It will also address some ongoing adventures (aka challenges) of starting an independent research group as assistant professor – because: having landed your first position does not mean to stand still, even when remaining in the same geographical location.

5:30 AM *F.BI01.02.03
Navigating an Academic Career in an Evolving Landscape Susan B. Sinnott; The Pennsylvania State University, United States

This presentation will summarize the ways in which materials science and engineering in academia has evolved over the last decade, including abrupt changes over the last few months in response to the COVID-19 pandemic. It will review the implications of these changes for the field and provide some projections for the future. The objective is to prepare listeners for a career in higher education and to help them navigate the many choices available.

5:45 AM *F.BI01.02.04
Drawing Inspiration from Industrial Problematics in Academia—Examples of Water Retention and Microsensing Remi Dreyfus; CNRS, United States

In the last 10 years, the University of Pennsylvania, the French CNRS and the chemical company Solvay teamed up in a joint laboratory in Philadelphia. The goal of the laboratory was to design sustainable solutions for "real-world" applications. Through two specific examples, I will show how members of the laboratory on the academic side gained inspirations from industrial problematics. The first example revolves around soil treatment, which can modify water retention for agricultural applications; the second example shows how smart formulations can lead to cheap dispersible sensors for monitoring bacterial growth.

6:00 AM *F.BI01.02.05
Useful Skill-Set Outside of the Employment Arena—Best Practices for the Solo Practitioner Joe Sabol; Chemical Consultant, United States

The 2020 business cycle presented employment terms much different from previous times. Even if you are employed and have an enjoyable and challenging career, the global COVID recession of 2020, like what occurred in 2009, shows that the economy turn down quickly. Advice for anyone is to have skills that are marketable, i.e., you can get paid money for in the "1099-gig" economy. You don't need a complicated business plan, extensive intellectual property, or even a physical footprint. Setting up a business does not have to be complicated, but there are some fundamental decisions around the way a business is structured and taxed and regulatory requirements that must be followed. Being aware of the issues will make it easier for you to define your core products and/or services and establish the necessary marketing, resources, and effort required to keep your operation afloat. This presentation holds the speaker's perspective on the technical, business, and regulatory elements that were encountered when opening a start-up and maintaining a 20-year solo business, serving science and engineering-related customers.

6:15 AM *F.BI01.02.06
My Journey from Academia to Industry—Useful Tips and Tricks Kamalika Chatterjee; Intel Corporation, United States

In this talk, I will go over my journey from being a PhD student at University of Illinois at Urbana-Champaign to a postdoctoral researcher at Cornell and finally becoming a process development engineer at Intel. I will discuss in detail the possible options I had or did not have, some struggles as an international student, how and why I decided to move from academia to industry and the process of mental preparation. Then, I will talk about my job application process, the successes and failures, why I decided to choose Intel and some experiences after starting at Intel. There will be useful tips for students preparing for a career in industry.

5:00 AM *F.BI01.03.01
Life as a Program Manager in the U.S. DOE's Office of Science Robin L. Hayes; U.S. Department of Energy—Office of Basic Energy Sciences, United States

Ever wonder what it is like to work as a federal program manager in the U. S. Department of Energy (DOE)? Join Dr. Robin Hayes as she shares her journey from a graduate student to program manager in the DOE Office of Science via an American Association for the Advancement of Science (AAAS) Science and Technology Policy Fellowship. In addition, learn about fundamental materials research funding opportunities for early career professionals in the DOE Office of Basic Energy Sciences (https://science.osti.gov/bes).

5:15 AM *F.BI01.03.02
Behind the Curtain" at the Army Research Office, and How We Can Help You David M. Stepp; U.S. Army Research Office, United States

Early career decisions can be daunting and often appear to be ill-posed. Concurrently, maneuvering the diverse and complex funding pipelines can often seem a challenge that threatens the very future of innovative materials science research. David Stepp brings more than twenty years of experience at the U.S. Army Research Office to share his career story (including some key failures) and provide insight and perspective on the "why" behind one of the preeminent materials science funding agencies. This talk will also include a discusion of some of the most common misunderstandings held by proposal authors.

5:30 AM *F.BI01.03.03
What to Consider When Switching to Industry Pascaline Hayoun; Saint-Gobain, United States

Doctoral graduates are attractive for an ever-growing number of Research & Development (R&D) and Innovation roles across manifold companies and industries. PhD graduates possess the technical expertise and unique mindset that many companies find critical in order to cultivate innovative thinking and achieve their strategic objectives. Ask yourself: why are recruiters and hiring managers targeting academic candidates? The answer lies within the transferable skill sets that PhD candidates have developed throughout their studies and their early career positions within Academia. There are key aspects within a typical PhD CV that recruiters tease out and use to quickly identify the value add of hiring a PhD candidate and their impact on the job market. Whether PhD student or Post-doc, fully decided or still shaping their Academia or Industry career paths, I will draw on my personal experience at Saint-Gobain to help you decide if Industry is right for you. I have vast experience as an Innovation Manager and strategic & technical leader and will share tips and recommendations on what to expect while considering a job in Industry. Notably, I will discuss drivers that can motivate you to make the transition, as well as discuss the technical and non-technical transferable skills that are applicable to a corporate environment, the importance of building a network both in Academia and Industry and how to find a company that is suited right for you. Finally, I will paint an overview of the range of opportunities for career progression in Industry to pursue a fulfilling professional journey.

5:45 AM *F.BI01.03.04
Navigating the Academic Hiring Process at a Top Research University Steven M. Yalisove; University of Michigan, United States

Getting hired as a faculty member at a top research university is not an easy thing to do. Yes you have to be an excellent researcher and teacher. Yes you need to understand how to fit into the department, university, and worldwide community through service. Yes you have to be a passionate and excellent teacher. But, those are only the first, necessary steps. Sadly, it is far from sufficient to land a top faculty position. This talk will go over the many things that must align for a candidate to get an in person interview and actually land the position. There is no guarantee, nor should their be any regrets when you start a search for a position. The real truth in getting hired as a faculty member is that once you reach the necessary conditions, the rest is really all about fit and the goals of each individual department that is looking for a faculty member to hire. Can a candidate influence this process? Yes. But it is not always possible to influence it enough. This talk will discuss how a candidate should at least consider a few things. In short, they are: why should a department believe that you will be successful in bringing in research funding?, How will your hire help bring in center grant funding? How will your hire have a positive impact on the culture of the department and make it more diverse, inclusive, and equitable? How will your hire help

the department increase its ranking? How will your hire improve the teaching of the entire department? How will your hire lead to “the next big thing?, Why is it that you can convince a department of all of the last few topics and still not get hired?

6:00 AM *F.BI01.03.05
Navigating Towards a Faculty Position in Materials Engineering—Application To Appointment David F. Bahr; Purdue University, United States

The initial stages of approaching a career in academia can be daunting to the candidate (just like any career path choice), and at times may seem opaque. This presentation will address some of the common stages that occur in becoming a faculty member in engineering in general, both when considering a materials engineering program, and the case where a materials researcher is joining a unit which does not offer an MSE (or related) degree. Common points in application materials for faculty positions for a range of departments, schools, and universities will be noted; addressing both a “direct” application route (right after PhD or post-doc) and applying after some time in other sectors (industry, government, or non-profit). In particular the presentation will highlight the need to demonstrate independent thought and ownership of research activities, maturity and dedication to education at the appropriate level of the institution, and articulating a vision of career success that covers both short- and long-term time scales. The presentation will strive to engage discussion points on topics that often arise during phone and in-person interviews, including addressing your vision for student advising, balancing teamwork versus independence within a unit, and identifying audiences in the hiring process. The need to speak directly to the variety of audiences, and to pivot your delivery while maintaining consistency amongst the range of groups you’d be speaking with. Finally, some details of perceived pitfalls in the process will be presented.

6:15 AM *F.BI01.03.06
Black Sheep—The Choice is Yours (Revisited) Suveen N. Mathaudhu; University of California, Riverside, United States

Some may recognize that this title matches a classic 1991 track from the Black Sheep with the lyrics, “You can get with this, or you can get with that.” This rap group name represents the struggles of the members of a group who are often perceived as outliers, and the term often implies waywardness. This specific song presents listeners with concepts of key choices in life. The pathways to success for “black sheep” (may it be race, gender, ethnicity, sexual orientation, educational background, religion, physical ability, nationality and many others) are decidedly different from those who align with majority “preferable” groups across disciplines, and the Materials Science and Engineering community is not immune to these biases. Through the lens of this song and anecdotal stories, this talk will present career choices that can be made to overcome the “black sheep effect” in materials science and engineering industry and academia. Further, strategies on exploiting the factors that make one unique for positive outcomes in your research, teaching, mentoring and service activities will be discussed.

6:30 AM *F.BI01.03.07
From Academia to Startup—Insights to Starting a Technology-Driven Company Max Kory; Battrion AG, Switzerland

Finishing my PhD I asked myself: "What next? Similar to the time years before, when I decided what I was going to study, I was facing once more a deeply personal question, what should should I do with my life? Should I continue with a postdoc, go to industry, or do something completely different?
it was the idea of founding a startup that somehow had sparked my interest already for quite some time.
During my PhD I had developed a novel 2D material with interesting properties, and so I decided to extend the time in my research group to determine whether the material could be applied somewhere in a useful way, hoping it may lead to the foundation of company - It didn't. As time passed, I came to the conclusion that the material was interesting in the context of basic research, but far away from any useful application. Meanwhile a friend of mine who had finished his PhD on lithium-ion batteries was in a different situation, his research had what mine was lacking, a real application in sight. When he asked me in 2015, if I was interested in co-founding a startup, I said yes.
Founding a technology-driven company is very challenging on many different levels. In this talk, I would like to share my personal startup experience, hoping I can help answer some questions relevant to young researchers thinking about starting a company.

F.EL01

8:00 AM *F.EL01.07.02
Molecular Transducers for Spin-Sensitive Optical Sensing Using Nitrogen-Vacancy Centers Petr Cigler; Institute of Organic Chemistry and Biochemistry, Czech Academy of Sciences, Czechia

Non-perturbing sensing techniques applicable to biological systems currently are of central interest in the biosciences. Nanodiamond is a highly biocompatible nanomaterial for construction of nanosensors, which can accommodate various photoluminescent crystal defects. Nitrogen-vacancy (NV) centers show high photostability and unique electronic sensitivity to magnetic field. Their spin properties can be read by optical means, which enables construction of various probes based on quantum mechanical interactions. If embedded in nanodiamond particles, NV centers can be exposed to biological environment and report sensitively on the spin-related processes occurring in a close vicinity of the particle. Molecular transducers designed for NV centers transposing the presence of particular analytes to a selective and unambiguous readout will be presented. Different types of surface architectures will be shown [1, 2]. Optical nanosensors designed for selective measurements of pH, redox potential, and ascorbate under physiological conditions will be discussed.

8:15 AM F.EL01.02.01
Optimization of NV Centers Density in Pink Irradiated-CVD Diamond Lahcene Mehmel[1], Ovidiu Brinza[1], Alexandre Tallaire[1,2], Fabien Bénédic[1], Gabriel Hetet[3], Clément Pellet-Mary[3], Paul Huillery[3], Bernd Abel[4], Robert Staacke[4], Jan Meijer[4] and Jocelyn Achard[1]; [1]LSPM-CNRS, France; [2]IRCP, France; [3]LPENS-CNRS, France; [4]Leipzig University, Germany

NV centers in diamond are point like defects that have attracted a lot of attention as one of the best candidates for quantum technologies particularly for sensing and imaging nanoscale magnetic fields. For this application, the use of an ensemble of NV centers with a high concentration in a high quality diamond layer is of prime interest. In previous works, it has been demonstrated that N_2O doping rather than N_2, allows improving diamond quality by limiting the formation of macroscopic defects and NV's photobleaching [1]. More recently, the growth of N_2O doped samples thicker than 1.5 mm has been achieved with substitutional nitrogen (Ns) concentration as high as a few tens of ppm which is very difficult to obtain by a CVD process using a conventional N_2 precursor. After irradiation by a 10 MeV electron beam, a conversion ratio of 20% has been obtained leading to a CVD grown layer with 4 ppm of NV^-. A decrease of the longitudinal spin relaxation time T_1 observed when the magnetic field is aligned along the [100] direction (i.e. when all NV centers classes are equally degenerate) indicates that NV-NV dipolar coupling becomes a dominant mechanism in such highly doped samples.
In this work, we will more particularly focus on the optimization of N_2O concentration in the gas phase in order to limit NV^--

NV^- interaction while maximizing density and spin properties. In the same time, samples grown in the presence of N_2 + O_2 and N_2 only will be compared in order to investigate the benefit of the use of N_2O. We aim at evaluating the maximum sensitivity achievable in a magnetic quantum sensor using such defect ensembles.

Stabilizing the Charge State of the Tin-Vacancy Center by Defect Engineering Johannes Görlitz[1], Dennis Herrmann[1], Philipp Fuchs[1], Michael Kieschnick[2], Sebastien Pezzagna[2], Jan Meijer[2] and Christoph Becher[1]; [1]Universität des Saarlandes, Germany; [2]University Leipzig, Germany

The recently discovered negatively charged tin-vacancy center (SnV-) in diamond combines high brightness single photon emission [1,2], large Debye-Waller factors and Fourier-limited linewidths [3,4]. Furthermore, the ground state fine structure splitting exceeds 800 GHz which potentially suppresses phonon mediated decoherence of the lowest ground state's spin doublet, which is the predominant decoherence mechanism for other negatively charged group-IV – vacancy centers (Silicon-vacancy center (SiV-) and germanium-vacancy center (GeV-)). Therefore, the SnV- center supposedly combines the advantages of the most established colour centers, namely the long spin coherence time of the nitrogen vacancy center and the large Debye-Waller factor and insensitivity to first order stark shifts of the silicon vacancy center. The exploitation of these very promising features for quantum information processing is up to now limited by the charge instability of the center under resonant optical excitation [4]. This instability results in termination of the fluorescence and therefore inhibits the use of coherent manipulation protocols.
We here present studies on stabilizing the SnV- charge state based on the recently discovered Coulomb-driven single defect engineering by co-implantation of charge donors into diamond [5]. We co-implant oxygen, sulfur and boron together with tin and find a suppression of bleaching (reduction of fluorescence intensity under continuous illumination) and fluorescence termination together with increased photo-luminescence intensity for sulfur co-doping. These results pave the way for application of the SnV center in coherent optical spin control experiments.

Generation of Nitrogen-Vacancy Ensembles in Diamond for Use in Magnetic-Field Sensing Applications Matthew Markham, Andrew Edmonds, Pierre-Olivier Colard and William Hillman; Element Six Ltd, United Kingdom

Ensembles of negatively-charged nitrogen-vacancy (NV^-) centres in diamond constitute a promising platform for magnetometry applications. However, the sensitivity of present NV-ensemble devices and the need for diamond material with reproducible properties have hindered progress toward many envisioned applications. The work presented here addresses these challenges by optimising a chemical vapor deposition (CVD) growth process to produce material at scale with improved NV-ensemble properties.

Through development of the CVD process it is shown that nitrogen incorporation can be increased without an increase in the density of unwanted vacancy-related defects which act as charge acceptors, reducing the $[N_s^0]/[N_S]$ and $[NV^-]/[NV]$ ratios, and limiting the dephasing time, T_2*. The process of irradiation and annealing is optimised and subsequent measurements of the NV concentration, charge ratio and contrast suggest that these grown-in defects have a detrimental impact on the NV-ensemble properties. Strain is also demonstrated to be a critical parameter to control.

This work also investigated the potential to produce material with reproducible NV concentration, NV charge ratio, strain homogeneity, and T2* by characterising a batch of samples containing approx. 4 ppm NV. The measured NV^- and NV^0 concentrations in the batch of samples varied by less than 7% (1 standard deviation) and exhibited well-controlled strain inhomogeneity. The resulting T2* = 1 μs in material enriched with >99.99% 12C was as expected for the concentration of N, establishing that other sources of decoherence have been controlled.
The material reported in this work enables immediate sensitivity improvements for present quantum-sensing devices and the correlations observed between material properties at different stages of processing provide efficient metrics for future work

targeting other NV densities or sample geometries such as micron-scale, NV-rich layers for magnetic imaging.

Enhanced Emission from Silicon-Vacancy Centers in Ag-Diamond Core-Shell Nanostructures Shuo Li[1,2], Nicholas Melosh[3] and Robert Hamers[2]; [1]SLAC National Accelerator Laboratory, United States; [2]University of Wisconsin-Madison, United States; [3]Stanford University, United States

Color centers in diamond are promising candidates for emerging quantum sensing and quantum information processing applications due to their exceptional properties. Coupling diamond color centers with metal plasmonic nanostructures is reported to enhance the optical properties of color centers effectively, but the plasmonic metal structures of previous studies are vulnerable to the environment, making the diamond-metal system unstable. Here, we demonstrate a novel and highly-tunable structure of Ag nanospheres coated with a layer of diamond containing SiV centers. The Ag was grown by thermal vapor deposition and then plasma treated to form uniform nanospheres, which were protected by the stable diamond shell grown by plasma-enhanced chemical vapor deposition (PECVD) method. This enhances the emission rate and brightness of SiV in diamond drastically. The structure also shows great stability to extreme corrosive and high-temperature conditions. Our finding is promising for developing ultrabright quantum sensing, high-efficiency imaging, and surface plasmon-quantum emitter waveguide.

How the Surface Orientation of Diamond Crystals Influences its Interaction with Biological Matter Romana Schirhagl[1], Viraj Damle[1], Kaiqi Wu[1], Oreste De Luca[1], Natalia Orti Casan[1], Neda Norouzi[1], Aryan Morita[1], Joop de Vries[1], Hans Kaper[1], Inge Zuhorn[1], Ulrich Eisel[1] and Danny Vanpouke[2]; [1]Groningen University, Netherlands; [2]Hasselt University, Belgium

Here we show how the diamond crystal orientation influences the interaction with biological systems[1]. More specifically we are investigating the interaction between the <100>, <110> and <111> surfaces of single crystal diamond with biomolecules, cell culture medium, mammalian cells and bacteria. We show that the crystal orientation significantly alters these biological interactions. Most surprising is the two orders of magnitude difference in the number of bacteria adhering on <111> surface compared to <100> surface when both the surfaces were maintained under the same conditions. We also observe differences in how small biomolecules attach to the surfaces. Neurons or HeLa cells on the other hand do not have clear preferences for either of the surfaces. To explain the observed differences, we theoretically estimated the surface charge for these three low index diamond surfaces and followed by the surface composition analysis using x-ray photoelectron spectroscopy (XPS). We conclude that the differences in negative surface charge, atomic composition and functional groups of the different surface orientations lead to significant variations in how the single crystal diamond surface interacts with the studied biological entities.

Identifying the Multiple Classes of Diamond Nanoparticles Using Machine Learning Amanda Barnard[1] and Amanda J. Parker[2]; [1]The Australian National University, Australia; [2]CSIRO, Australia

Diamond nanoparticles are complicated materials, presenting a diverse range of sizes, shapes, speciation and defects that cannot easily be controlled during synthesis. Each of these features contribute to structure/property relationships, but in different ways. Attempts to purify samples to tune the properties often fail due to lack of specificity, and polydispersivity usually persists. An alternative approach is to separate classes of nanodiamonds based on their properties, rather than seeking monodispersed samples based on their structure. To investigate if this approach has merit we have used machine learning to classify nanodiamonds and identify class-dependent properties and characteristics. Using a fully reconstructed data set that spans the experimentally observed size range from 1 nm to 4.5 nm we find that there are multiple classes of particles, based on their similarity in the high dimensional feature space. By using an interpretable classifier, with excellent accuracy, precision and recall, we also identify possible purification pathways based on the important features ranked by the AI.

Surface Functionalized Nanodiamond with Improved Protein Repulsion for Drug Delivery and Sensing Julia Puck, Viktor Merz and Anke Krueger; Wuerzburg University, Germany

For many applications the surface chemistry of nanodiamond (ND) is a key factor for the control of properties such as the wetting behavior, biocompatibility and functionality[1]. By attaching appropriate moieties, the interaction with physiological environments can be controlled.
An important point for biomedical applications is the inhibition of a nonspecific protein corona. This shell of e.g. serum proteins masks the desired functions and renders the physiological properties of the nanoparticle uncontrollable[2].
Here we report on the grafting of zwitterionic moieties enabling the formation of NDs without protein corona [3] that enable the specific grafting of antibodies, targeting peptides and CO releasing drug molecules using visible light. The resulting constructs have been characterized using IR, Raman, x-ray spectroscopies as well as particle analysis, TGA and electron microscopy.
The ND conjugates have been tested in vitro as well as in cell assays and demonstrated their functionality in the cellular environment. Additionally, these NDs have been functionalized with pyrene moieties for fluorescence sensing in solution with strong ion background and demonstrated colloidal stability, sensitivity and specificity for the detection of heavy metal ions against a background of ions present in physiological environments.
This research has received funding from Volkswagenstiftung under Grant Agreement no. 88393.

Scalable Assembly of Fluorescent Nanodiamonds for Quantum Sensing Henry J. Shulevitz, Tzu-Yung Huang, Steven Neuhaus, Lee Bassett and Cherie Kagan; University of Pennsylvania, United States

Milled fluorescent nanodiamonds containing nitrogen-vacancy (NV) centers provide an excellent platform for sensing applications due to their quantum sensitivity to a variety of external fields at nanometer length scales. Currently, the irregularity in crystal morphology and the difficulty of functionalizing the nanodiamond surface impede efforts to realize scalable assemblies of nanodiamonds, or to create heteroassemblies with other materials. Poor control over the nanodiamond composition and surface chemistry also creates significant heterogeneity in their optical and quantum characteristics. We will present scalable strategies to form ordered arrays of nanodiamonds using template-directed capillary assembly. This method enables the precise spatial arrangement of primary nanodiamonds with diameters below 50 nm, and it is compatible with the assembly of other compositions of colloidal nanoparticles. Large-scale arrays facilitate automated, repeatable measurements of the nanodiamonds' optical, structural, and quantum characteristics, enabling improved statistical understanding of these key properties and their heterogeneity. The flexible assembly method will allow for detailed studies of chemical treatments, integration of nanodiamonds within photonic and electronic devices, and the realization of quantum heterostructure devices composed from complementary nanomaterials.

9:50 AM F.EL01.05.05
Surface Contamination Impact on Nanodiamond Seeding of Plasma-Treated Tantalum Films Paulius Pobedinskas[1,2], Wim Dexters[1,2], Jan D'Haen[1,2] and Ken Haenen[1,2]; [1]Hasselt University, Belgium; [2]IMEC vzw, Belgium

The deposition of closed nanocrystalline diamond (NCD) thin films on non-diamond substrates requires diamond nucleation sites. An established technique for creating nucleation sites is a surface treatment with a water-based colloidal solution of ultra-dispersed nanodiamond (ND) particles.[1] In ND seeding the most important factors are the surface charge of the substrate and the zeta-potential of the used colloid. Together, they determine the nucleation density, which can lead to an extreme difference in the observed seeding density.[2–6] However, surface contamination by hydrocarbons, which is an unavoidable and quick process even in a cleanroom environment,[7] is often not taken into consideration. Such contamination can alter the surface wetting properties[8] and surface charge[9], and thus the eventual seeding density. In this work we investigate and model the impact such surface contamination has on the ND seeding efficiency.

Tantalum is a metal well known for its resistivity to corrosion, bioinertness, biocompatibility and excellent osteoconductivity.[10] After sputtering a thin film of Ta on silicon substrates, these stacks were exposed to the ambient atmosphere for different times, allowing to achieve various degrees of surface contamination. Then, the Ta surface wettability was measured, samples were seeded with NDs, and the subsequent seeding density evaluated. As surface coverage by

hydrocarbons increased, the wetting properties gradually turned from hydrophilic to hydrophobic. The ND seeding density first decreased and then increased again. To understand this correlation, we propose an analytical model that describes the dynamics of surface contamination and hydrocarbon contaminant interaction with the surface, and the resulting ND seeding density.

We assume that when a hydrocarbon (HC) molecule lands on the Ta surface it attracts negative surface charge towards it, while creating a positive surface charge around it. Due to said dipole formation, the top part of the HC molecule is charging negatively. Solving differential equations for the dynamics of the normalized surface coverage number density of the HC molecules, **n**, and surface charge density, **σ**, we derive $\boldsymbol{\sigma(n,\eta) = n + (1 - n)^{(1+\eta)}}$, where **η** is a ratio between an area of the depleted charge around the HC molecule and the area of the HC molecule itself. The assumption that the contact angle, **θ**, is linearly proportional to the surface coverage by HC, $\boldsymbol{n = \theta / \theta_{sat}}$, makes wettability measurements a valid method for determining the degree of surface contamination. If the sum of electrostatic double-layer and Van der Waals interaction energies becomes positive, a potential energy barrier for a ND particle approaching a surface exists. ND particles must surmount a positive potential peak for a deposition onto the surface to occur. This occurs with a probability exponentially proportional to the potential barrier. By fitting the experimental data, we find that the ND seeding density is exponentially proportional to the calculated positive surface charge number density, which forms around HC molecules. This constitutes 57% of the HC molecule area, while the created barrier height is estimated to be ~ 0.18 eV.

The Role of Interfaces and Heterogenous Integration in the Thermal Management of Wide Bandgap Semiconductors

Samuel Graham[1], Zhe Cheng[1], Mark Goorsky[2], Fengwen Mu[3], Jim Speck[4] and Tadatomo Suga[3]; [1]Georgia Institute of Technology, United States; [2]University of California, Los Angeles, United States; [3]Meisei University, Japan; [4]University of California, Santa Barbara, United States

Wide bandgap electronics made from GaN and Ga_2O_3 are currently under development due to their potential to create advanced RF and power electronics. However, the performance and reliability of these devices are often controlled by their electrothermal response during device operation. A key feature which limits thermal control of the peak temperature is the thermal resistance that is encountered intrinsically from the material as well as across material interfaces with these devices. One method that has shown promise for mitigating the high thermal resistance of these devices is through their heterogenous integration with other materials which assist in heat dissipation and aid thermal management. For this, thermal transport across interfaces and novel integration methods are necessary.

In this work we will present modeling efforts which guide the impact of heterogenous integration on the thermal performance of UWBG devices. Thermal metrology methods used to measure interfacial thermal conductance will be discussed and new insights into the control of thermal boundary conductance given. Techniques such as surface activated bonding will be presented to demonstrate the integration of GaN and Ga_2O_3 with high thermal conductivity substrates such as SiC and diamond. The use of other high thermal conductivity dielectrics for improved heat dissipation from the top side and bottom

side of the devices will be discussed. Finally, the prospects for the future development of thermal management via heterogenous integration will be presented.

Formation Process of High Thermal-Stability Diamond/Si and Diamond/GaAs Heterointerfaces by Surface Activated Bonding Yutaka Ohno[1], Jianbo Liang[2], Yasuo Shimizu[1], Hideto Yoshida[3] and Naoteru Shigekawa[2]; [1]Tohoku University, Japan; [2]Osaka City University, Japan; [3]Osaka University, Japan

Diamond is a promising candidate for a base material of high power electronic devices, as well as for a superior heat spreading substrate, due to its excellent physical properties such as the highest electrical breakdown field strength, the highest thermal conductivity, and a high RF power capability that is 3 times higher in comparison with SiC. For the practical application toward power devices, we need diamond/semiconductor heterointerfaces with high thermal stability and can withstand the temperature rise of power devices during operating. Recently, Liang has demonstrated that diamond/Si [1] and diamond/GaAs [2] heterointerfaces with high thermal stability can be fabricated by surface activated bonding (SAB) at room temperature (RT). In this work, we have examined the bonding mechanism using cross-sectional scanning transmission electron microscopy (STEM) combined with electron energy loss spectroscopy (EELS) and energy dispersive x-ray spectroscopy (EDX).
In the SAB process, surfaces of diamond and Si (or GaAs) wafers are activated at RT before bonding by creating dangling bonds via the irradiation of high-energy Ar atoms in a high vacuum, and the surfaces are then bonded by the contact most of the time under pressure to form strong chemical bonds even for imperfect surfaces. For diamond/Si heterointerfaces, atomic diffusion at the interfaces, presumably due to the transient enhanced diffusion assisted by the point defects introduced in the surface activation process [3], is confirmed during the bonding process. The crystallinity at the diffusing region is rather low, and it is recovered by 1000 ºC annealing via the formation of SiC layers, that would play a pivotal role in the relaxation process of residual stress due to the misfit of thermal expansion coefficient between diamond and Si [1]. Therefore, the defect-assisted atomic diffusion at the interfaces would be a key concept for the formation of high thermal-stability diamond/Si heterointerfaces. Similar atomic diffusion is also confirmed at diamond/GaAs heterointerfaces during the SAB process.

5:40 PM F.EL01.06.03
The Impact of Polycrystalline Diamond Growth Nucleation on N-Polar GaN Channel Performance Mohamadali Malakoutian[1,2], Chenhao Ren[1,2], Kelly Woo[2], Shubhra Pasayat[3] and Srabanti Chowdhury[2]; [1]University of California, Davis, United States; [2]Stanford University, United States; [3]University of California, Santa Barbara, United States

N-polar gallium nitride (GaN) high electron mobility transistors (HEMTs) have shown superior performances when scaling for W-band frequencies over Ga-polar GaN HEMTs [1]. However, due to the shorter channel and closer gate fingers its ability to dissipate the heat from the channel to the heat-sink is limited. Polycrystalline (PC) diamond due to its very large thermal conductivity (TC) is one of the solutions for self-heating problem in high-power high-frequency devices. PC Diamond can be grown in a closed proximity to high temperature spot in the channel and spread the heat efficiently [2]. The standard Si_3N_4 thickness as a gate dielectric for W-band N-polar HEMTs is 5 nm, which can be used as thermal interface material to reduce thermal boundary resistance (TBR<2 m^2K/GW) between diamond and GaN as well [3]. As diamond growth takes place in a high temperature hydrogen plasma environment using MPCVD, it can decompose both Si_3N_4 and GaN layers by reacting with silicon, nitrogen, and gallium and making volatile gases (SiH_4, NH_3, and GaH, respectively) [4]. Any damage to GaN channel may result in a degradation of device performance after the growth. In this work, we investigated the impact of diamond growth nucleation and main stages on 2-dimentional electron gas (2DEG) properties such as electron mobility, sheet carrier concentration, and sheet resistivity (before growth: μ_n=1200 $cm^2/V.s$, n_s=1.34E13 cm^{-2}, and ρ_s=388 Ω/sq).
The main goal of the growth nucleation stage is to guarantee no damage to the 2DEG by covering the substrate (Si_3N_4/GaN) with thinnest possible nano-crystalline diamond (NCD) in shortest possible time as NCD has a poor TC (<100 W/m.K). The 2DEG has been characterized using Hall mobility measurement, and the thickness of nucleation layer has been measured by high resolution TEM. The nucleation layer can prevent diffusion of hydrogen radicals into the substrate which is highly dependent on the microwave power and gas pressure. To increase the diamond growth rate and decrease substrate etching rate the sample holder was redesigned to provide higher temperature (~700 C) with minimum power (600 W) and pressure

(20 Torr). The CH_4% and time were changed from 3 to 10% and 10 to 15 min, respectively for nucleation stage followed by the same main growth for all samples (2% CH_4, 1600 W, 60 Torr, 45 min). We observed no degradation in 2DEG by using >5% CH_4 and 15 min growth, while by lowering the time to 10 min we started to see about 20-30% reduction in μ_n and 50-150 Ω/sq increase in ρ_s. This degradation varies with different cap layers on top of the channel; no cap layer, 1-2 nm AlN, or 1-2 nm 46% AlGaN.
To study the impact of main growth on 2DEG, we have chosen 5% CH_4 and 15 min for nucleation stage and changed main growth parameters including CH_4% (0.5-2%), power (600-1600 W), pressure (20-90 Torr), and sample holder design. CH_4% showed the highest impact in determination of damage level to 2DEG and pressure had the lowest impact. With the sample holder same as nucleation stage, 1% CH_4 is the minimum required for no damage. For the case with original sample holder, 1.5% CH_4 is the lowest acceptable value for the first 45 min of the growth.
In this work, we were able to achieve a smooth interface between diamond and GaN (including 5 nm Si_3N_4 interfacial layer) without using argon or nitrogen in the gas mixture by redesigning the sample holder and modifying growth parameters for lower etch rate of the substrate. This recipe is compatible with W-band N-polar GaN HEMTs as maintains device performance after the growth.
This work was supported by the Semiconductor Research Corporation (SRC) and DARPA under the JUMP program.

Microfabrication of Sensors and Nanodiamond Structures on Diamond Substrates for Extreme Environments Yogesh K. Vohra; University of Alabama-Birmingham, United States

Maskless lithography has been combined with the microwave plasma chemical vapor deposition (CVD) of diamond to fabricate a variety of micro-sensors that can be deposited on substrates and encapsulated in a protective CVD diamond layer to survive extreme conditions of high-pressure, high- and low-temperatures, corrosive, and high radiation environments. These hardened sensors provide electrical conductivity, magnetic susceptibility, and stress data on a variety of metallic and superconducting materials under extreme conditions of pressures and temperatures in diamond anvil cell devices. In addition, boron-doping of CVD diamond also enables the fabrication of micro-heaters in diamond anvil cell devices. Microfabrication techniques have also been utilized to selectively grow localized nanodiamond structures on single crystalline diamond substrates. Since nanodiamond structures lack the cleavage planes representative of single crystal diamond; ultrahigh pressures of over 500 GPa can be generated in this nanodiamond/single crystal diamond structures. The studies on materials under extreme conditions using these diamond-based sensors and nanodiamond structures are carried out at the Advanced Photon Source, Argonne National Laboratory. Future research directions in vertical integration of multiple sensors, wireless communications, and controlling the sp-3 bonded content in nanodiamond microstructures will be presented.

Diamond Electronics for the Surface of Venus Robert J. Nemanich[1], Mohamadali Malakoutian[2,3], Harshad Surdi[1], Manpuneet Benipal[4], Franz A. Koeck[1], Srabanti Chowdhury[3], Stephen M. Goodnick[1] and James Lyons[1]; [1]Arizona State University, United States; [2]University of California - Davis, United States; [3]Stanford University, United States; [4]Advent Diamond, United States

The surface temperature of Venus is ~460 C, with a corrosive atmosphere including CO_2 and sulfuric acid at a pressure of 92 bar. A number of missions to Venus are being considered or planned that would include surface or atmosphere probes, and high temperature electronics would be required for power control, mechanical system control, and sensor electronics. While it is long been recognized that the wide bandgap of diamond would result in a negligible increase in the intrinsic carrier concentration, at high temperature the devices based on Schottky barriers would show a great reduction in the forward-reverse current rectification ratio. This research presents results of diamond diodes with a thin n-type layer in a Schottky-n-i-p structure, which achieves high current density, high breakdown field and a designed on-off rectification ration. The metal-n-i-p diamond diodes were prepared on single crystal p-type, boron doped (100) or (111) substrates, with undoped intrinsic epitaxial layers and phosphorus doped epitaxial layers prepared by microwave plasma CVD. The electrical results and simulations show regimes with low drift layer resistance where the contact resistance limits the current. The diodes have been confined in a high pressure CO_2 atmosphere for over 100 hrs. After removal, inspection of the surfaces shows dark regions thought to be carbon containing layers, which did not result in evident changes of the current-voltage characteristics. More

extensive Venus atmosphere testing planned at the NASA GEER facility will include active electrical measurements. The results establish that with control of p- and n-type doping optimal device designs can be achieved for diamond electronics at high temperature.
This research supported by NASA through grant NNX17AG45G as part of the HOTTech program.

Electrical and Quantum Application of Diamond—From the Viewpoint of Diamond CVD Growth and Device Fabrication Satoshi Yamasaki[1,2], Toshiharu Makino[1], Hiromitsu Kato[1], Masahiko Ogura[1], Daisuke Takeuchi[1], Yukako Kato[1], Norio Tokuda[2] and Tsubasa Matsumoto[2]; [1]National Institute of Advanced Industrial Science and Technology, Japan; [2]Kanazawa University, Japan

Diamond has many unique physical properties. Due to these unique properties diamond has high potential for applications; electrical devises, quantum devices, etc. Depending on the target application we need to develop the growth and fabrication technique, In this talk, we introduce the electronic applications and the quantum application using nitrogen-vacancy centers from the viewpoint of diamond growth and fabrication technique.

6:40 PM *F.EL01.04.01
Nuclear Battery Applications of Diamond Junction Devices Takehiro Shimaoka[1,2], Hitoshi Umezawa[2,3], Kimiyoshi Ichikawa[1], Julien Pernot[3] and Satoshi Koizumi[1]; [1]National Institute for Materials Science, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan; [3]Université Grenoble Alpes, France

Betavoltaic cells directly convert the energy of beta particles into electricity.[1] The operation principle of a betavoltaic cell is similar to that of a solar cell, except that the energy source is beta-emitting isotopes. In betavoltaic cells, semiconductor junctions play the role of energy conversion. These cells have the advantage of longevity, which is determined by the half-life ($T_{1/2}$) of the beta-emitting radioisotopes. The cells can operate for several years to a decade. Betavoltaic cells are expected to be utilized for battery applications in remote locations such as outer space and underground.

Diamond is advantageous material for betavoltaic cells because the wide bandgap could offer high open circuit voltage due to large built-in potential of the junction, which improves the conversion efficiency of the cells. From theoretical perspective, ultrawidebandgap materials such as diamond and BN have potential to realize extreme conversion efficiency of the cells.[2] Moreover, diamond has durability against radiation and high temperature. Diamond betavoltaic cells could be utilized to application under extreme condition. In this study, we show the highest semiconductor conversion efficiency among the betavoltaic cells reported thus far by utilizing the large built-in potential of a diamond *pn* junction.
We formed pseudo-vertical diamond *pn* diodes. Homoepitaxial p^+, p, n^-, and n^+ diamond layers were grown on a {111} high-pressure high-temperature (HPHT) type-Ib diamond substrate by using microwave plasma-assisted chemical vapor deposition (MPCVD). Each B- (*p*-type) and P- doped (*n*-type) diamond layer were grown with the use of individual MPCVD systems. The thickness of the p^+, p, n^-, and n^+ layers were, respectively, 2, 0.1, 1.8, and <0.1 μm. The impurity concentrations confirmed by secondary ion mass spectrometry (SIMS) were [B]: 3×10^{19} cm^{-3} for the p^+ layer, [B]: 2×10^{18} cm^{-3} for the p layer, [P]: 1×10^{16} cm^{-3} for the n^- layer, and [P]: 1×10^{20} cm^{-3} for the n^+ layer. Highly P- doped diamond was grown using homemade CVD reactor to enhance P incorporation into diamond to reduce series resistance. After the growth, mesa structures were formed by induction coupling plasma etching with oxygen gas. Subsequently, Ohmic contacts were formed by electron beam deposition of Ti/Mo/Au both on the mesa structure of the n^+-layer and on the p^+-layer. The diameters of the mesa and electrodes were, respectively, 240 and 150 μm.

Then we evaluated power – voltage (*P-V)* and current-voltage (*I-V*) characteristics under electron-beam irradiation. For electron-beam irradiation, a scanning electron microscope was used as the electron source. Electron beams at accelerating voltages of 15 kV were irradiated on top of the n^+ layer. The open-circuit voltage (V_{oc}) under the electron-beam irradiation was 4.26 V, which is the highest among the betavoltaic cells reported thus far. The output power at the maximum point (P_{MP}) was 10.7 nW. Fill factor (*FF*) and semiconductor conversion efficiency (η_s) calculated as following eqs (1) and (2)
$FF = P_{MP}/I_{sc}V_{oc}$, …(1)
$\eta_s = VocFF/\varepsilon$, …(2)
where ε is the electron–hole pair creation energy. Here, we substitute ε = 13 eV in eq. (2). The *FF* and the semiconductor conversion efficiency η_s were respectively, 0.85 and 28%. Among the semiconductors, the diamond *pn* junction achieved the highest η_s , which enables to be utilized to energy efficient and long-life cells for remote sensing applications. In the talk, we will also present charge collection efficiency and total conversion efficiency of diamond *pn* diode against different energy of electrons.

Stabilizing Diamond's Surface Conduction with Mixed-Oxide ALD Films and Deuterium Surface Termination Michael Geis[1], Joseph Varghese[1], Yichen Yao[2], Robert J. Nemanich[2], Mark Hollis[1], Charles H. Wuorio[1], Xingyu Zhang[1], George W. Turner[1], Shireen M. Warnock[1], Steven A. Vitale[1], Richard J. Molnar[1], Thomas Osadchy[1] and Beijia Zhang; [1]Massachusetts Institute of Technology, United States; [2]Arizona State University, United States

When the surface of diamond is H-terminated, a p-type surface conductive layer is formed. Atmospheric impurities, NO_2, O_3, fluoropolymer, transition metal oxides and Al_2O_3 adhere to the diamond surface and activate diamond's surface conductance by generating and trapping negative charges on the diamond surface. These charges increase the positive p-type carrier densities in the diamond surface and reduce its resistance. High drain current field effect transistors (FETs) of 1.2 to 1.3 A mm^{-1}, high frequency f_T of 75 GHz, and high voltage, >2000 V, devices have been demonstrated with these activation surface chemistries. However, these devices degraded in a few days or when stressed with high voltage.
Research to stabilize diamond's surface conductance has met with some success. H-terminated diamonds overcoated using atomic layer deposition (ALD) Al_2O_3 have the best demonstrated stability, but the surface resistance is high (5 to 12 kW sq^{-1}). Diamonds coated with transition metal oxides such as WO_2, MoO_3, and V_2O_5 have lower resistances of 2.5 to 3.5 kW sq^{-1} [1,2]. Their stability has been demonstrated although these oxides are conductive, have several oxidations states, and may electrochemically degrade under the high electric fields associated with FETs. This presentation will discuss the use of a mixed-oxide (Al_2O_3-SiO_2) ALD film to generate resistances between 1.5 and 3.5 kW sq^{-1} with demonstrated stability in excess of half a year.
The low surface resistance obtained with this mixed oxide is a result of a change in the structure of Al_2O_3 when mixed with SiO_2. The electron trap surface density of Al_2O_3 is ~$7x10^{12}$ cm^{-2} while the mixed oxide surface density is $3x10^{13}$ to $8x10^{13}$ cm^{-2} [3,4] with an estimated trap depth of 5.4 eV. This mixed oxide is just one of a group of oxides [5] with deep, > 5 eV, high-density electron traps.
Increased stability of the diamond surface is obtained by terminating the surface with deuterium atoms instead of hydrogen atoms. This additional stability is beneficial during device fabrication. This presentation will discuss diamond's surface conduction with Al_2O_3-SiO_2 combined with deuterium atom termination.

Investigation of Li Doping and SnO Termination on the Diamond (100) Surface for Thermionic Emission Application Sami Ullah, Liam Cullingford, Tongfie Zhang, Jing Ren Wong, Gary Wan, Mattia Cattelan and Neil Fox; University of Bristol, United Kingdom

Diamond electrodes terminated with surface layers can impart significant changes to the electronic properties of a diamond

interface and we have previously reported on studies of the tunability of surface work function by substituting hydrogen with oxygen under controlled conditions [1]. Engineering a functionalised diamond surface that is stable and reproducible is of technological importance to future diamond electronic devices such as Schottky junctions and electron-emitting electrodes for field emission, thermionic energy converters, secondary electron multipliers.
O'Donnell and his group have demonstrated the formation of a stable Li-O termination of diamond by physical vapour deposition of a monolayer of Li on the diamond surface which develops and exhibits Negative electron affinity (NEA) and hence lowers the work function, even at an elevated temperature of 800 °C [2]. In this work we are seeking an alternative method, a novel and easy chemical means of introducing and coordinating lithium with oxygen on the diamond surface to realize a more controlled approach of creating a stable –O-Li dipole. with uniformity over the diamond surface which also serves as a means to study and visualize for the first time the effect of temperature on the concentration of Li atoms in the diamond surface and on the Li-O species on the surface of diamond sample.
Also, Tin monoxide has been considered as potential material for battery anodes, coating, gas sensing, catalysis, etc. The application area of SnO extends over photovoltaics, displays, information storage, etc. as it has a large optical bandgap of 4.12 eV, high transparency (~90%) non-toxic and abundant [3]. SnO has been found to form a layered structure in a crystallographic direction of [001] with a monolayer thickness of 0.48 nm. Sn 5s form a lone pair of electrons which point towards the interlayer spacing and result in dipole-dipole interaction leading to a Van der Waals gap of 2.52 A between the layers. Various groups have demonstrated the growth of SnO mono and multiple layers by various methods but many of these result in an upper SnO_2 layer that forms as soon as the sample is taken into the oxygen environment as SnO is metastable and hence rapidly converts into SnO_2.
We are doping oxygen terminated Boron doped Polycrystalline diamond and Nitrogen doped HPHT diamond (111) with Li atoms using microwave plasma technique. The oxygen termination was induced by acid washing. We analyze the sample with X- Ray Photoemission Spectroscopy (XPS) and Raman spectroscopy. The main aim of this study is to analyze the change in concentration of Li atoms in the bulk and on the surface of diamond with annealing temperature. We have produced sub ML SnO on conductive, p-type single crystal diamond under ultra-high vacuum (UHV) conditions by e-beam evaporation. The samples will be characterised in-situ by Spot Profile Analysis Low-Energy electron diffraction (SPA-LEED) and Energy Filtered Photo Emission Electron Microscopy (EF-PEEM) and X-ray Photoemission Spectroscopy (XPS). We quantify the change in work function between mono and few layer SnO and its effect upon the barrier height of a p-type diamond Schottky junction.

F-EL01

5:00 AM F.EL01.01.01
A Study on Photoconductive Properties of Boron Doped Diamond Kelly Woo[1], Mohamadali Malakoutian[1,2], Diego R. Yankelevich[2] and Srabanti Chowdhury[1]; [1]Stanford University, United States; [2]University of California, Davis, United States

In photoconductive semiconductor switches (PCSS), the conductance, measured between the two electrodes placed on the semiconductor, is modulated by the absorption of optical radiation in the gap between them. This switching device can be applied to pulsed power technology for high speed and jitter free switching. These may include radar, particle acceleration, and pulsed high-power lasers. However, typical materials studied for photoconductive switching, such as Si and GaAs suffer from thermal runaway effects at high power [1]. Since diamond is an ideal material for high power electronics due to its large bandgap (5.47 eV), high breakdown electric field (10 MV/cm), high carrier mobility, high thermal conductivity (10-20 W/cm.K), and low coefficient of thermal expansion (~1.1μm/mK) [2], we chose to study its photoconductive properties and

potential as a high power optoelectronic switch. Past studies have shown photoconductivity in intrinsic diamond by UV-band excimers in high electric fields up to 2 MV/cm [3].

In this work, however, we utilized boron-doped diamond substrates to excite carriers by sub-bandgap photon energies while maintaining the desirable properties of diamond that would facilitate higher breakdown field and better thermal management. Boron is the only known p-type dopant occupying substitutional sites and has an activation energy of 0.3-0.37eV above the valence band [4].
In designing extrinsic PCSS, on/off current ratios should be maximized for high performance switching. In the off state, the material conductance primarily depends on the number of ionized dopants, which decreases with lower doping levels or compensation. In the on state, the conduction is increased due to the photogeneration of free carriers through dopants and traps, which increases with doping concentration. However, on conductance is also limited by the number of excitable carriers based on the surface area of the substrate and absorption depth at the excitation wavelength. Thus, by analyzing the conduction as a function of doping concentration between the on and off state, a doping level of 10^{18} cm^{-3} was chosen in efforts to maximize the on/off current ratio in fabricated devices.

In this work, we have fabricated lateral electrodes on the surface of boron doped single crystalline diamond substrates and analyzed the photoresponse. The 1µm doped epilayer was grown by MPCVD on a diamond HPHT seed. Then, electron-beam evaporation was used to deposit ohmic Ti/Pt/Au contacts on its surface to form planar devices. Testing of the extrinsic diamond substrate was performed by exciting with a frequency doubled (532nm) Nd:YAG pulsed laser with an output energy of 20mJ and ~10ns duration. Our experiments with these devices have shown a pulsed photoresponse with a full width half maximum of 11.5 ns. Furthermore, sharper rise times and slower fall times were observed, which could be explained by the presence of traps. Aided by residual heating from the source, its captured carriers could still be thermally excited leading to a current tail. Through this work, photoconductivity was successfully shown in extrinsic homoepitaxial diamond using a lower energy, below bandgap Vis-NIR excitation source.

This work was supported by Precourt Institute, Stanford under the Bits and Watts initiative. Fabrication was done in the Stanford Nanofabrication Facility.

Raman Spectroscopy of Boron-Doped Diamond Vincent Mortet, Ivan Gregora, Andrew Taylor, Nicolas Lambert, Petr Ashcheulov, Marina Davydova, Zuzana Gedeonova and Pavel Hubik; Fyzikální ústav AV ČR, Czechia

Although a Raman spectroscopy presents a basis for an effective assessment of the atomic boron concentration in the boron-doped diamond, determination of further physical properties of diamond using non-destructive Raman approach requires advancement in the Raman analysis. In this work, we analyze Raman spectra of heavily boron-doped epitaxial (113) diamond layers measured at temperatures up to 600 °C based on the interaction between phonon and electronic Raman scattering effects. Raman spectra are modelled using a combination of multiple decoupled Fano-functions and the established “dirty-metal” electronic Raman scattering cross section model. The presented analysis demonstrates the imperative contribution of the electronic Raman scattering to the Raman spectrum and opens a new practical route towards determination of electronic transport properties in boron-doped diamond.

Investigating Diamond Defect Formation with Quantitative Birefringence Benjamin M. Farris[1,2], Matthias Muehle[2] and Elias Garratt[1,2]; [1]Michigan State University, United States; [2]Fraunhofer USA, United States

Lab-grown diamonds are candidate materials for several emerging technologies, including next-generation high-power electronics. These diamonds can be grown using high-pressure high-temperature (HPHT) synthesis or chemical vapor deposition (CVD). However, these methods produce defects in the diamond crystal structure, impairing the diamond’s performance. To better understand defect formation in diamonds, the Fraunhofer USA Center for Coatings and Diamond Technologies (CCD) is developing a quantitative birefringence setup capable of imaging these defects. Because a defect-free diamond has an isotropic crystal structure, it transmits all polarizations of light identically. However, when defects are present, the resulting strain produces birefringence, in which the polarization of transmitted light is distorted. Diamond

samples are measured in an imaging polarimeter. By analyzing the raw data with Mueller calculus, the amount and orientation of birefringence are mapped across the diamond, revealing crystal defects.
Not only can defects, such as threading edge dislocations, be visualized, the relative strain produced by defects can be quantified. Furthermore, statistical analysis on defect type and strength within the diamond can be performed, enabling distributions, concentrations, and types of defects to be identified and analyzed relative to reactor conditions. This analysis is part of a larger effort to develop data pipelines for diamond research. These pipelines will be integrated into an overall diamond database to enable cross-correlative analysis across different measurement techniques such as x-ray rocking curve or Raman mapping on diamond samples grown using specific processes. Cross-comparisons using statistical analysis (data science) on these data sets are predicted to yield deeper insights into process-structure relationships of diamond growth.

5:30 AM F.EL01.01.04
Relaxation of Compressive Stress in Diamond Nanomembranes Paulius Pobedinskas[1,2] and Ken Haenen[1,2]; [1]Institute for Materials Research (IMO), Hasselt University, Belgium; [2]IMOMEC, IMEC vzw, Belgium

Nanomembranes (NMs) are very thin (≤ 500 nm) and have very high aspect ratios of thickness to lateral dimension (≥ 10^4). This makes them extremely flexible due to the linear decrease of bending strain with thickness. At the extreme thinness, materials fold much easier [1]. When nanocrystalline diamond (NCD) thin films are grown on substrates, which have a higher thermal expansion coefficient than diamond, unavoidably, compressive stress is generated. When a NCD NM is released from such substrate a pattern of wrinkles and wrinklons evolves. The out-of-plane deformation is associated with the onset of an elastic instability, where the total energy is best minimized by the film bending rather than straining in-plane. These deformations strongly affect the electrical properties of B-doped NCD NMs [2]. Therefore, one cannot disregard the influence of wrinkles when dealing with any type of device that is based on NMs.

In this work, we present finite element simulations of compressive stress relaxation under gravity in a diamond NM as it is released from a supporting substrate. As NCD consists of hard diamond grains and soft grain boundaries, the Young's modulus and Poisson's ratio are not expected to be the same as in bulk diamond [3]. To study the impact of elastic constants on wrinkling, the calculations were made with different Young's moduli (E = 300, 600, 900, and 1200 GPa) and Poisson's ratios (v = 0, 0.07, 0.14, and 0.21). The initial compressive stress of the NM was varied in the range from 0 Pa up to −6 GPa. NCD thin film, which is 150 nm thick and has a compressive stress of up to -10^4 Pa, relaxes without forming wrinkles when is released from the substrate as the NCD membrane. Symmetrical wrinkles form when the membrane relaxes from -10^5 Pa and higher compression. At absolute stresses larger than −1 GPa the asymmetric wrinkling is dominant. Young's modulus and Poisson's ratio does not have notable impact on the relaxed membrane shape as stress does. However, the Young's modulus has higher impact on the relaxed membrane area and out-of-plane deformation range than Poisson's ratio. The higher the Young's modulus (or Poisson's ratio) the smaller the area (and out-of-plane deformation range) of the NM is obtain after the compressive stress relaxation. Finally, the obtained results on wrinkling phenomena are explain through the system's energy minimization when streching, bending and twisting events are competing.

SESSION F.EL01.02: Color Centers in Diamond
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-EL01

5:00 AM F.EL01.02.01
Optimization of NV Centers Density in Pink Irradiated-CVD Diamond Lahcene Mehmel[1], Ovidiu Brinza[1], Alexandre Tallaire[1,2], Fabien Bénédic[1], Gabriel Hetet[3], Clément Pellet-Mary[3], Paul Huillery[3], Bernd Abel[4], Robert Staacke[4], Jan Meijer[4] and Jocelyn Achard[1]; [1]LSPM-CNRS, France; [2]IRCP, France; [3]LPENS-CNRS, France; [4]Leipzig University, Germany

NV centers in diamond are point like defects that have attracted a lot of attention as one of the best candidates for quantum technologies particularly for sensing and imaging nanoscale magnetic fields. For this application, the use of an ensemble of NV centers with a high concentration in a high quality diamond layer is of prime interest. In previous works, it has been

demonstrated that N_2O doping rather than N_2, allows improving diamond quality by limiting the formation of macroscopic defects and NV's photobleaching [1]. More recently, the growth of N_2O doped samples thicker than 1.5 mm has been achieved with substitutional nitrogen (Ns) concentration as high as a few tens of ppm which is very difficult to obtain by a CVD process using a conventional N_2 precursor. After irradiation by a 10 MeV electron beam, a conversion ratio of 20% has been obtained leading to a CVD grown layer with 4 ppm of NV^-. A decrease of the longitudinal spin relaxation time T_1 observed when the magnetic field is aligned along the [100] direction (i.e. when all NV centers classes are equally degenerate) indicates that NV-NV dipolar coupling becomes a dominant mechanism in such highly doped samples.
In this work, we will more particularly focus on the optimization of N_2O concentration in the gas phase in order to limit NV^--NV^- interaction while maximizing density and spin properties. In the same time, samples grown in the presence of N_2 + O_2 and N_2 only will be compared in order to investigate the benefit of the use of N_2O. We aim at evaluating the maximum sensitivity achievable in a magnetic quantum sensor using such defect ensembles.

5:10 AM F.EL01.02.02
Stabilizing the Charge State of the Tin-Vacancy Center by Defect Engineering Johannes Görlitz[1], Dennis Herrmann[1], Philipp Fuchs[1], Michael Kieschnick[2], Sebastien Pezzagna[2], Jan Meijer[2] and Christoph Becher[1]; [1]Universität des Saarlandes, Germany; [2]University Leipzig, Germany

The recently discovered negatively charged tin-vacancy center (SnV-) in diamond combines high brightness single photon emission [1,2], large Debye-Waller factors and Fourier-limited linewidths [3,4]. Furthermore, the ground state fine structure splitting exceeds 800 GHz which potentially suppresses phonon mediated decoherence of the lowest ground state's spin doublet, which is the predominant decoherence mechanism for other negatively charged group-IV – vacancy centers (Silicon-vacancy center (SiV-) and germanium-vacancy center (GeV-)). Therefore, the SnV- center supposedly combines the advantages of the most established colour centers, namely the long spin coherence time of the nitrogen vacancy center and the large Debye-Waller factor and insensitivity to first order stark shifts of the silicon vacancy center. The exploitation of these very promising features for quantum information processing is up to now limited by the charge instability of the center under resonant optical excitation [4]. This instability results in termination of the fluorescence and therefore inhibits the use of coherent manipulation protocols.
We here present studies on stabilizing the SnV- charge state based on the recently discovered Coulomb-driven single defect engineering by co-implantation of charge donors into diamond [5]. We co-implant oxygen, sulfur and boron together with tin and find a suppression of bleaching (reduction of fluorescence intensity under continuous illumination) and fluorescence termination together with increased photo-luminescence intensity for sulfur co-doping. These results pave the way for application of the SnV center in coherent optical spin control experiments.

5:20 AM F.EL01.02.03
Generation of Nitrogen-Vacancy Ensembles in Diamond for Use in Magnetic-Field Sensing Applications Matthew Markham, Andrew Edmonds, Pierre-Olivier Colard and William Hillman; Element Six Ltd, United Kingdom

Ensembles of negatively-charged nitrogen-vacancy (NV^-) centres in diamond constitute a promising platform for magnetometry applications. However, the sensitivity of present NV-ensemble devices and the need for diamond material with reproducible properties have hindered progress toward many envisioned applications. The work presented here addresses these challenges by optimising a chemical vapor deposition (CVD) growth process to produce material at scale with improved NV-ensemble properties.

Through development of the CVD process it is shown that nitrogen incorporation can be increased without an increase in the density of unwanted vacancy-related defects which act as charge acceptors, reducing the $[N_s^0]/[N_S]$ and $[NV^-]/[NV]$ ratios, and limiting the dephasing time, T_2^*. The process of irradiation and annealing is optimised and subsequent measurements of the NV concentration, charge ratio and contrast suggest that these grown-in defects have a detrimental impact on the NV-ensemble properties. Strain is also demonstrated to be a critical parameter to control.

This work also investigated the potential to produce material with reproducible NV concentration, NV charge ratio, strain homogeneity, and T2* by characterising a batch of samples containing approx. 4 ppm NV. The measured NV^- and NV^0 concentrations in the batch of samples varied by less than 7% (1 standard deviation) and exhibited well-controlled strain inhomogeneity. The resulting T2* = 1 μs in material enriched with >99.99% 12C was as expected for the concentration of N, establishing that other sources of decoherence have been controlled.
The material reported in this work enables immediate sensitivity improvements for present quantum-sensing devices and the correlations observed between material properties at different stages of processing provide efficient metrics for future work targeting other NV densities or sample geometries such as micron-scale, NV-rich layers for magnetic imaging.

5:30 AM F.EL01.02.04
Enhanced Emission from Silicon-Vacancy Centers in Ag-Diamond Core-Shell Nanostructures Shuo Li[1,2], Nicholas Melosh[3] and Robert Hamers[2]; [1]SLAC National Accelerator Laboratory, United States; [2]University of Wisconsin-Madison, United States; [3]Stanford University, United States

Color centers in diamond are promising candidates for emerging quantum sensing and quantum information processing applications due to their exceptional properties. Coupling diamond color centers with metal plasmonic nanostructures is reported to enhance the optical properties of color centers effectively, but the plasmonic metal structures of previous studies are vulnerable to the environment, making the diamond-metal system unstable. Here, we demonstrate a novel and highly-tunable structure of Ag nanospheres coated with a layer of diamond containing SiV centers. The Ag was grown by thermal vapor deposition and then plasma treated to form uniform nanospheres, which were protected by the stable diamond shell grown by plasma-enhanced chemical vapor deposition (PECVD) method. This enhances the emission rate and brightness of SiV in diamond drastically. The structure also shows great stability to extreme corrosive and high-temperature conditions. Our finding is promising for developing ultrabright quantum sensing, high-efficiency imaging, and surface plasmon-quantum emitter waveguide.

5:40 AM F.EL01.02.05
Late News: The Spin-Flip Bethe-Salpeter Equation Approach, and Applications to Defects in Diamond Bradford A. Barker and David A. Strubbe; University of California, Merced, United States

The NV^- center in diamond is a notable example of a system that has open-shell electronic structure. The challenge in describing open-shell systems for computational methods is that the wavefunctions for the ground-state and excited-states are composed of two or more electronic configurations. Wavefunction-based techniques to describe these multi-configurational systems, then, will necessarily be sums of multiple Slater determinants, called “multi-reference wavefunctions.” Their calculation is quite expensive for all but the smallest molecular systems. The Spin-Flip ansatz, however, allows for electronic structure methods based on an initial single-reference calculation that can capture contributions from the multiple configurations for open-shell systems. This method was originally applied to the Configuration Interaction and Equation-of-Motion Coupled-Cluster approaches, and then later applied to density-functional techniques, called Spin-Flip Time Dependent Density Functional Theory (or SF-TDDFT). In this work, we consider the Spin-Flip method being adapted for electronic structure calculations from the framework of the *GW*/BSE approach, which gives the Spin-Flip Bethe-Salpeter Equation, a method with lower scaling than Coupled Cluster Singles-Doubles and other similar wavefunction-based methods. SF-BSE is also *ab initio* and is accurate in solids. The SF-BSE Hamiltonian resembles that of SF-TDDFT but with an *ab initio* kernel. We present results for the open-shell test systems of ethylene under torsion and the NV^- center defect in diamond. The excitation energies calculated for the NV^- center in diamond compare reasonably well with both experiment and Configuration Interaction-based theoretical methods.

This work was supported by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, CTC and CPIMS Programs, under Award DE-SC0019053.

Microfabrication of Sensors and Nanodiamond Structures on Diamond Substrates for Extreme Environments Yogesh K. Vohra; University of Alabama-Birmingham, United States

Maskless lithography has been combined with the microwave plasma chemical vapor deposition (CVD) of diamond to fabricate a variety of micro-sensors that can be deposited on substrates and encapsulated in a protective CVD diamond layer to survive extreme conditions of high-pressure, high- and low-temperatures, corrosive, and high radiation environments. These hardened sensors provide electrical conductivity, magnetic susceptibility, and stress data on a variety of metallic and superconducting materials under extreme conditions of pressures and temperatures in diamond anvil cell devices. In addition, boron-doping of CVD diamond also enables the fabrication of micro-heaters in diamond anvil cell devices. Microfabrication techniques have also been utilized to selectively grow localized nanodiamond structures on single crystalline diamond substrates. Since nanodiamond structures lack the cleavage planes representative of single crystal diamond; ultrahigh pressures of over 500 GPa can be generated in this nanodiamond/single crystal diamond structures. The studies on materials under extreme conditions using these diamond-based sensors and nanodiamond structures are carried out at the Advanced Photon Source, Argonne National Laboratory. Future research directions in vertical integration of multiple sensors, wireless communications, and controlling the sp-3 bonded content in nanodiamond microstructures will be presented.

5:15 AM F.EL01.03.02
The Use of Diamond in the Detection of High Energy Neutrons Hank M. Thurston and Elias Garratt; Michigan State University, United States

Current state of the art scintillating neutron detectors are typically of large form factor, or detection node, on the order of cubic metres to achieve efficiencies of ~70%. This results in spatial resolutions of cm^2, which relatively low for detecting certain particle species. However, detectors with a lower form factor (mm^2) built into an array are expected to provide an order of magnitude increase in spatial resolution. Moreover, placing such detectors in series will enable higher resolution in for energy spectrum as well as tracking of scattered particles. Diamond is a highly favorable material for sensing radiation in very harsh environments, such as the beamlines of high energy particle colliders and space environments. This is primarily due to the strong covalent carbon-carbon bonding in the sp^3 hybridized orbital structure of diamond. Arranged in a periodic lattice this molecular structure also give rise to high electron mobilities and thermal transport properties which have the net effect of simplifying radiation sensor device design while maintaining a fast response rate and low dark current. A design consisting of a high cross-section neutron activation layer sandwiched by layers intrinsic CVD diamond and Boron doped semi-conducting diamond has been proposed.
The “sandwich” design takes advantage of the molecular density of diamond, allowing for detection in either the intrinsic or semiconducting layers. The activation layer material can be chosen to optimize detection at a desired energy. This device will be built and commissioned for use with the Facility for Rare Isotope Beams. To facilitate nuclear experiments at the FRIB’s capacity of 400MeV per nucleon, we plan to provide high efficiency detection of neutrons up to 250 MeV, in a form factor allowing for modular addition of neutron detection to experiments which otherwise would not have the capability. Due to the radiation hardness of diamond, the device could also effectively be employed as a permanent beamline monitoring or veto detector. The development of the device requires several stages of work, beginning with design optimization through computer modeling.
The current stage of work develops Monte Carlo simulations of atomic and nuclear processes inside of diamond crystal using several simulation frameworks. We simulate irradiation of diamond of neutrons and a variety of heavy ions. Using the GEANT 4 framework we are able to model the crystal lattice structure and monitor structure damage through the simulation. Through judicious selection of GEANT 4 physics lists we are able to model non-ionizing energy loss, both elastic and inelastic scattering, and nuclear interactions during irradiation. Secondary and tertiary effects and interactions can also be monitored. This allows us to identify points of lattice damage; creation of vacancies and interstitial ions. Throughout development, simulations were benchmarked against SRIM 2013. These benchmarks, discrepancies, and improvements are discussed.

Electrochemiluminescence at Hybrid Boron Doped Diamond Electrodes Samuel Stewart, Emmanuel Scorsone and Matthieu Hamel; CEA-LIST, France

Electrochemiluminescence (ECL) is a phenomenon in which photons are emitted during electrochemical reactions. It already proved to be a very promising analytical tool for sensing applications where both high sensitivity and selectivity are needed. Indeed, it merges the advantages of chemiluminescent analysis with the absence of background optical signal, with wide possibilities for reaction control using diverse electrochemical protocols. ECL can be observed in organic solvents where both oxidized and reduced forms of luminescent species are produced, e.g. by sweeping electrode potential between anodic

and cathodic. Excitation energy is then obtained from recombination of oxidized and/or reduced species. As an example, superoxide ions may be involved through electrochemical reduction of dissolved oxygen. In aqueous environments, simultaneous oxidation and reduction of luminescent species is difficult to achieve due to electrochemical splitting of water, implying the use of a co-reactant. In this case luminescent species are oxidized at the electrode together with the co-reactant, which gives a strong reducing agent after some chemical transformations. In this context, Boron Doped Diamond electrodes offer numerous advantages that have been little explored for ECL analytical applications. They display high electrochemical stability together with resilience to fouling, and good optical transparency. Furthermore, in aqueous media electro-generated hydroxyl radicals play important roles in ECL, implying that a co-reactant family can be expanded by taking advantage of the strong oxidation ability of electrogenerated hydroxyl radicals at boron doped diamond electrodes. The potential of diamond electrodes for ECL analytical applications will be discussed and illustrated through a comparative study using different electrode materials, including both highly textured electrodes and BDD electrodes functionalized with transition metal nanoparticles.

Boron-Doped Diamond/Pd-SnO_2 Heterojunction Gas Sensor for Enhanced Room-Temperature NO_2 Detection Marina Davydova[1], Alexandra Palla Papavlu[2], Alexandr Laposa[3], Andrew Taylor[1], Ladislav Klimša[1], Jiri Kroutil[3], Petr Ashcheulov[1] and Thomas Lippert[4,5]; [1]FZU-Institute of Physics of the Czech Academy of Sciences, Czechia; [2]National Institute for Lasers, Plasma, and Radiation Physics, Romania; [3]Czech Technical University in Prague, Czechia; [4]Paul Scherrer Institut, Switzerland; [5]ETH Zürich, Switzerland

In recent years, wide band gap semiconductors have been recognized as very promising sensitive materials for detection of toxic pollutants and hazardous gases. A majority of research work has been carried out on metal oxide (MO) semiconductors by simple change of resistance measurements. However, the main issues for MO chemiresistor sensors are high operating temperature (above 300°C) and cross-sensitivity/selectivity. These drawbacks can be partially solved by utilizing the combination of two or more types of semiconductor materials (p-n heterostructures). The use of the combination of *n*-type and *p*-type semiconductor materials is a relatively recent field of research within chemiresistors. Such bilayer structures offer a variety of advantageous characteristics, including a large surface area, improved crystallinity, defect-free interface, and enhanced electrical properties.
In this work we report on the development of heterostructures based on n-type Pd-doped SnO_2 and p-type boron doped diamond (BDD) for room-temperature NO_2 detection. Here, three different gas sensor devices were developed based on (i) BDD, (ii) Pd-SnO_2, and (iii) Pd-SnO_2/BDD heterjunction structures using a combination of ink-jet printing, microwave linear antenna plasma enhanced chemical vapour deposition, and reactive laser induced forward transfer (rLIFT) techniques.
The gas sensing properties of fabricated sensor devices were tested in oxidizing/reducing gases (NO_2, CO, NH_3) at various analyte concentrations (5-20 ppm) in the dark and under UV light illumination. It was found that all sensor structures measured under UV light illumination demonstrate significant enhancement of gas sensor response in comparison to the measurements performed in dark. Moreover, the sensors demonstrate high sensitivity to NO_2 gas and showed dependence on the intensity of UV light, fast response, and reversible character. The Pd-SnO_2/BDD heterojunction structure exhibited a remarkable NO_2 gas sensor response in comparison to Pd-SnO_2 based structure (i.e., 280% for Pd-SnO_2/BDD and 12% for Pd-SnO_2). Finally, the Pd-SnO_2/BDD structures possess the highest response to 10 ppm NO_2, complete reversibility, and reproducible character under UV light illumination.

5:45 AM F.EL01.03.06

Boron-Doped Diamond Electrodes—The Role of Doping Level, Surface Treatment and Porosity in the Electrooxidation of Cresol Environmental Contaminants Andrew Taylor[1], Vincent Mortet[1], Ladislav Klimša[1], Jaromír Kopeček[1], Silvia Sedláková[1], Simona Baluchová[2], Michal Nedvěd[2], Jana Vosáhlová[2] and Karolina Schwarzová-Pecková[2]; [1]FZU - Institute of Physics of the Czech Academy of Sciences, Czechia; [2]Charles University, Faculty of Science, Czechia

Due to its excellent properties in comparison with other carbon-based materials, boron doped diamond (BDD) has become a popular electrode material especially for electrooxidation. These include low background current, wide potential window in the region of positive potentials, mechanical robustness and low proclivity to electrode passivation. Cresols are classified by the US Environmental Protection Agency as a toxic and persistent chemical, exhibiting chronic effects at 12 $mg.L^{-1}$, however they are commonly used for wood impregnation, production of polymers, disinfection and herbicides. Wastewater from these industries along with coal conversion contains a high concentration of cresols and is therefore a problematic environmental contaminant, which requires monitoring.

In this work, the influence of, 1- boron-doping levels (B/C ratio in the gas phase (ppm): 500, 1000, 2000, 4000, and 8000), 2- surface termination (H- vs. O-) and 3- *ex-situ* polishing with alumina, of planar BDD on its electrochemical properties and voltammetric behaviour of cresols was thoroughly investigated. In addition, we compare planar BDD with porous BDD samples for changes in their electrochemical properties. We show that all examined factors have a significant impact on cresol electrooxidation, and therefore should be carefully considered when designing BDD electrodes for electrochemical sensing of these environmental contaminants.

BDD deposition methods will be described together with BDD structural and composition characterisation, and the electrochemical methods used.

Nuclear Battery Applications of Diamond Junction Devices Takehiro Shimaoka[1,2], Hitoshi Umezawa[2,3], Kimiyoshi Ichikawa[1], Julien Pernot[3] and Satoshi Koizumi[1]; [1]National Institute for Materials Science, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan; [3]Université Grenoble Alpes, France

Betavoltaic cells directly convert the energy of beta particles into electricity.[1] The operation principle of a betavoltaic cell is similar to that of a solar cell, except that the energy source is beta-emitting isotopes. In betavoltaic cells, semiconductor junctions play the role of energy conversion. These cells have the advantage of longevity, which is determined by the half-life ($T_{1/2}$) of the beta-emitting radioisotopes. The cells can operate for several years to a decade. Betavoltaic cells are expected to be utilized for battery applications in remote locations such as outer space and underground.

Diamond is advantageous material for betavoltaic cells because the wide bandgap could offer high open circuit voltage due to large built-in potential of the junction, which improves the conversion efficiency of the cells. From theoretical perspective, ultrawidebandgap materials such as diamond and BN have potential to realize extreme conversion efficiency of the cells.[2] Moreover, diamond has durability against radiation and high temperature. Diamond betavoltaic cells could be utilized to application under extreme condition. In this study, we show the highest semiconductor conversion efficiency among the betavoltaic cells reported thus far by utilizing the large built-in potential of a diamond *pn* junction.
We formed pseudo-vertical diamond *pn* diodes. Homoepitaxial p^+, p, n^-, and n^+ diamond layers were grown on a {111} high-pressure high-temperature (HPHT) type-Ib diamond substrate by using microwave plasma-assisted chemical vapor deposition (MPCVD). Each B- (*p*-type) and P- doped (*n*-type) diamond layer were grown with the use of individual MPCVD systems. The thickness of the p^+, p, n^-, and n^+ layers were, respectively, 2, 0.1, 1.8, and <0.1 μm. The impurity concentrations confirmed by secondary ion mass spectrometry (SIMS) were [B]: 3×10^{19} cm^{-3} for the p^+ layer, [B]: 2×10^{18} cm^{-3} for the p layer, [P]: 1×10^{16} cm^{-3} for the n^- layer, and [P]: 1×10^{20} cm^{-3} for the n^+ layer. Highly P- doped diamond was grown using homemade CVD reactor to enhance P incorporation into diamond to reduce series resistance. After the growth, mesa structures were formed by induction coupling plasma etching with oxygen gas. Subsequently, Ohmic contacts were formed by electron beam deposition of Ti/Mo/Au both on the mesa structure of the n^+-layer and on the p^+-layer. The diameters of the mesa and electrodes were, respectively, 240 and 150 μm.

Then we evaluated power – voltage (*P-V)* and current-voltage (*I-V*) characteristics under electron-beam irradiation. For electron-beam irradiation, a scanning electron microscope was used as the electron source. Electron beams at accelerating voltages of 15 kV were irradiated on top of the n^+ layer. The open-circuit voltage (V_{oc}) under the electron-beam irradiation was 4.26 V, which is the highest among the betavoltaic cells reported thus far. The output power at the maximum point (P_{MP}) was 10.7 nW. Fill factor (*FF*) and semiconductor conversion efficiency (η_s) calculated as following eqs (1) and (2)
$FF = P_{MP}/I_{sc}V_{oc}$, …(1)
$\eta_s = VocFF/\varepsilon$, …(2)
where ε is the electron–hole pair creation energy. Here, we substitute ε = 13 eV in eq. (2). The *FF* and the semiconductor conversion efficiency η_s were respectively, 0.85 and 28%. Among the semiconductors, the diamond *pn* junction achieved the highest η_s , which enables to be utilized to energy efficient and long-life cells for remote sensing applications. In the talk, we will also present charge collection efficiency and total conversion efficiency of diamond *pn* diode against different energy of

electrons.

A Simulation Study of Vertical Diamond FinFETs for Power Switching and RF Electronics John P. Niroula[1], Heyi Li[1], Qingyun Xie[1], Garrett Schlenvogt[2], Thomas Jokinen[2] and Tomas Palacios[1]; [1]Massachusetts Institute of Technology, United States; [2]Silvaco, United States

The introduction of wide-bandgap semiconductors such as GaN and SiC have revolutionized the semiconductor electronics industry, especially in the areas of power switching and high frequency RF power amplifiers. While these materials have provided orders of magnitude improvements relative to silicon devices, today we are beginning to see the limitations of these wide-bandgap materials.
Consequently, electronic devices based on diamond, an ultra-wide-bandgap semiconductor, are increasingly explored due to diamonds' extraordinary material properties. A number of promising lateral [1],[2] and vertical diamond transistors [3] have been demonstrated; however, so far all diamond devices rely solely on surface conduction, either through a hydrogen terminated surface or a surface accumulation layer. The use of these transistors for power and RF applications may result in a number of issues, such as current collapse induced by surface trapping and poor reliability caused by non-uniform heat generation. A fin-based vertical transistor based in part on bulk conduction would allow us to take advantage of the superior material properties of diamond while mitigating these issues.
In this work, we use TCAD simulations in Silvaco to explore the potential of vertical diamond FinFETs [4] and compare it to an equivalent vertical GaN FinFET device. In our TCAD framework we incorporate several effects unique to diamond, including incomplete ionization, the metal-insulator transition of boron in diamond [5], and variable range hopping conduction [6].
For power applications, a vertical diamond FinFET of fin width 0.2 µm, fin pitch 0.9 µm, and fin height 0.8 µm was simulated along with an optimized GaN structure. Assuming a critical electric field of 10 MV/cm for diamond and 3.3MV/cm for GaN, we find that to achieve a breakdown voltage of 1200 V, a drift region thicknesses of 1.4 µm and 4.7 µm are needed for diamond and GaN devices, respectively. For such relatively large drift regions, the incomplete ionization of boron in diamond in the on-state leads to a higher specific on-resistance for diamond (1.21 $m\Omega cm^{-2}$) than GaN (0.35 $m\Omega cm^{-2}$). We note, however, that if the dopants were completely ionized for diamond, the specific on-resistance would drop to 0.063 $m\Omega cm^{-2}$, approximately 5x lower than GaN. This could potentially be done by raising the device nominal temperature, by optical activation of boron acceptors, or by high electric fields.
In addition, 200 V breakdown (60 V DC bias operation) devices for high frequency RF applications were simulated with dimensions of fin width 0.1 µm, fin pitch 0.6 µm, and fin height 0.2 µm. In this case, the optimized drift region thicknesses were 0.25 µm and 0.85 µm for diamond and GaN, respectively. Compared with the GaN device, the diamond device exhibited a higher J_{maz} (640 vs. 240 kA/cm^2), lower V_{knee} (25 vs. 30 V), and higher f_T (53 vs. 42 GHz). As a result, the calculated linear power density of diamond was 7.36MW/cm^2 (44.2 W/mm per fin), which is about 2.7x higher than the GaN calculated linear power density at 2.7 MW/cm^2 (16.2W/mm per fin). In the case of the RF diamond device, as the drift region was relatively thin, the large number of holes injected from the channel lead to a significant carrier density in the drift region, which made up for the lack of carriers from unionized acceptors.
In summary, we have simulated a novel vertical fin transistor in diamond along with a reference GaN device, one set for power switching applications and one set for high power RF applications. We identify key priorities and initial results show great promise for vertical diamond FinFETs

Diamond Based High Temperature and High Power Electronics Yuelin Wu[1], Cristian J. Herrera-Rodriguez[1], Aaron Hardy[2], Matthias Muehle[2], Tom Zimmermann[1] and Timothy Grotjohn[1,2]; [1]Michigan State University, United States; [2]Fraunhofer USA Center for Coatings and Diamond Technologies (CCD), United States

Diamond is a promising semiconductor material for high temperature and high power electronics due to its following properties: ultra-wide bandgap (5.45 eV), high electric breakdown field, and high thermal conductivity. Additionally, doped semiconducting diamond has a unique inverse temperature versus resistance correlation. Unlike many other semiconductors, the resistivity of diamond decreases with rising temperature until 150ºC and remains low through 400ºC . As a result, diamond device has lower theoretical "ON-resistance" and power loss than similar SiC and GaN device at temperatures higher than 150ºC.

Diamond field effect transistors (FETs) can operate through surface or bulk conduction. Surface conduction is achieved via a two-dimensional hole gas (2DHG) formed on hydrogen-terminated diamond surface. Bulk conduction is typically achieved via holes generated in p-type boron-doped diamond. Surface conduction diamond FETs, also referred to as hydrogen-terminated diamond FETs, have attracted the most interest due to its current capability being close to commercial SiC and GaN MOSFETs of similar size. However, maintaining stability of the 2DHG at elevated temperatures can be challenging. Generally, hydrogen-terminated diamond FETs are not recommended to operate at temperatures higher than 400ºC even with surface passivation.

In this study, our primary interest is to design and optimize bulk conduction diamond FETs with superior thermal stability and competitive power electronics capability. Three types of boron-doped conduction FETs were fabricated: lateral metal-semiconductor FET (MESFET), lateral metal-oxide-semiconductor FET (MOSFET), and vertical junction FET (JFET). The performance of the MESFET was demonstrated at elevated temperatures up to 430ºC. It operated as a normally-on device at 0 V gate voltage, V_{GS} and became pinched-off at V_{GS} = 6V. The drain current density, I_{DS} increased rapidly with the increasing temperature until ~150ºC. An I_{DS} value had approximately a 100-time increase from room temperature to 150ºC and is attributed to the increase in the activated boron concentration because the boron acceptor level is deep at a value of 0.36 eV. The I_{DS} value peaked at 150ºC and remained high until 430ºC. Despite the high thermal stability, the metal-semiconductor junction limits the applicable gate forward bias to its Schottky turn-on voltage, which is around -1 V. This also limits the maximum drain current at a given drain voltage. To improve the current capability, a similar MOSFET structure was fabricated. With the introduction of an insulating Al_2O_3 layer between the gate metal and diamond, a higher gate forward bias could be applied and a higher maximum drain current could be obtained. For instance, at 150ºC, the maximum drain current of the MOSFET at -10 $V_{D,}$ achieved at -14 V_{GS}, was more than two times of that obtained from the MESFET. However, the thermal stability of Al_2O_3 deteriorated with rising temperature. Its electric breakdown field decreased from above 5 MV/cm at room temperature to 1 MV/cm at 250ºC. The lateral transistors had breakdown voltages demonstrated to above 500 V.

Both lateral MESFET and MOSFET exhibited relatively low current capability due to high channel resistance. To significantly reduce the channel resistance while maintain the high thermal stability and high breakdown voltage, a vertical JFET structure without oxide was designed. A TCAD simulation estimated the "ON-resistance" to be less than 1 $m\Omega*cm^2$ with a targeted 1200 V breakdown voltage. A key fabrication step, selective n-type phosphor doped layer of diamond, was successfully conducted through diamond etching and subsequent re-growth. Preliminary results for the vertical JFET will be presented.

Increasing the Phase Purity of the Cubic Boron Nitride and Boron Doped Polycrystalline Diamond Heterojunction for Device Applications Jesse Brown and Robert J. Nemanich; Arizona State University, United States

The properties of cubic boron nitride (c-BN) and diamond make them ideal materials for applications in a variety of extreme conditions, such as thermal or corrosive protection, ionizing radiation detection, and high-power high frequency electronics. One of the persistent challenges preventing many electronic applications of epitaxial c-BN on diamond is an interfacial hexagonal boron nitride (h-BN). While local epitaxy has been observed previously, a uniform interface for electronic grade applications has not been realized. Understanding the nucleation and subsequent growth of c-BN films on an atomic level at the growth interface and the properties across that interface is fundamentally critical to fully realize the materials' electronic properties.

Research at Arizona State University has studied the effects of hydrogen concentration during the growth of c-BN on diamond via electron cyclotron resonance plasma enhance chemical vapor deposition, and have found that, by forcing the hydrogen to be the limiting reactant in the growth environment, the reaction favors c-BN while suppressing the formation of h-BN impurities. In-Situ X-ray Photoelectron Spectroscopy (XPS) was used to characterize the interface, and Ultraviolet Photoelectron Spectroscopy (UPS) was used to determine the valence band offset of the pure interface. In this presentation we show that minimizing the hydrogen concentration during the deposition maximizes the cubic boron nitride phase purity at

the diamond interface.

Diamond Electronics for the Surface of Venus Robert J. Nemanich[1], Mohamadali Malakoutian[2,3], Harshad Surdi[1], Manpuneet Benipal[4], Franz A. Koeck[1], Srabanti Chowdhury[3], Stephen M. Goodnick[1] and James Lyons[1]; [1]Arizona State University, United States; [2]University of California - Davis, United States; [3]Stanford University, United States; [4]Advent Diamond, United States

The surface temperature of Venus is ~460 C, with a corrosive atmosphere including CO_2 and sulfuric acid at a pressure of 92 bar. A number of missions to Venus are being considered or planned that would include surface or atmosphere probes, and high temperature electronics would be required for power control, mechanical system control, and sensor electronics. While it is long been recognized that the wide bandgap of diamond would result in a negligible increase in the intrinsic carrier concentration, at high temperature the devices based on Schottky barriers would show a great reduction in the forward-reverse current rectification ratio. This research presents results of diamond diodes with a thin n-type layer in a Schottky-n-i-p structure, which achieves high current density, high breakdown field and a designed on-off rectification ration. The metal-n-i-p diamond diodes were prepared on single crystal p-type, boron doped (100) or (111) substrates, with undoped intrinsic epitaxial layers and phosphorus doped epitaxial layers prepared by microwave plasma CVD. The electrical results and simulations show regimes with low drift layer resistance where the contact resistance limits the current. The diodes have been confined in a high pressure CO_2 atmosphere for over 100 hrs. After removal, inspection of the surfaces shows dark regions thought to be carbon containing layers, which did not result in evident changes of the current-voltage characteristics. More extensive Venus atmosphere testing planned at the NASA GEER facility will include active electrical measurements. The results establish that with control of p- and n-type doping optimal device designs can be achieved for diamond electronics at high temperature.

Boundary Condition Effects on Epitaxial Lateral Outgrowth of Single Crystal Diamond Shengyuan Bai[1], Yun Hsiung[2], Karli Deutscher[1], Ramón D. Díaz[1] and Elias Garratt[1,2]; [1]Michigan State University, United States; [2]Fraunhofer USA Center for Coatings and Diamond, United States

For decades, diamond has shown superior properties that make it desirable for novel electronic materials. However, fabricating large size high quality single crystal diamond wafers faces multiple challenges. Single crystal diamond (SCD) is a promising wide bandgap semiconductor material. Epitaxial lateral outgrowth (ELO) using microwave plasma assisted chemical vapor deposition (MPACVD) has shown its advantages in synthesizing large size high quality SCD. This research details experiments focused on the impact of physical boundary conditions on the epitaxial lateral growth of SCD using MPACVD. Growth dynamics, such as lateral growth rates, and as grown diamond crystal structural properties, such as X-ray rocking curves (XRC), relative to pocket holder boundaries is discussed. The boundary conditions of ELO are established relative to growth rate, and internal structure (planar alignment and mosaicity of the lattice) of outgrown areas are discussed. Results indicate the time varying effects of holder boundaries on growth rate can be parameterized into an exponential decay function based on the kinetics of phase change to predict the total lateral outgrowth possible for a given holder design. As expected, these results, in turn, will enable the design next generation reactors to accommodate continuous larger area single crystal diamond growth. Additionally, the structural characteristics of the internal lattice are discussed relative to reactor conditions of holder geometry, temperature, and gas pressure.
Among diamond growth methods, MPACVD has distinct advantages compared to high pressure high temperature (HPHT) growth, but primarily its ability to synthesize diamond at relatively low pressure and temperature makes it attractive as a scale-up method for diamond growth. While a plethora of literature on the chemical and macroscale mechanisms of diamond growth exists, synthesizing large size high quality SCD remains a significant challenge due to the emergence of

heterogeneous structure and morphology from uncontrolled nucleation based on reactor design. This research reveals how the pocket holder and the boundary conditions it creates influence the morphology that a CVD diamond (type IIa) growth on HPHT substrate (type Ib) assume. Crystal structure characteristics reflected from XRC mapping on both peak position and FWHM for both (400) diamond crystal planes shows the importance of the geometry of the sample holder. Further growth results of SCD using multiple types sample holders and their crystal structural measurement and analysis will be shown at the conference. This will give feedbacks on growth processing and lay the foundation for the real large size high quality SCD growth in the near future.

5:10 AM F.EL01.05.02
Diamondization of Multilayer Graphene/Graphitic Structures through a Shear Assisted Phase Transformation Shiddartha Paul[1], Kasra Momeni[1,2] and Valery I. Levitas[3]; [1]Louisiana Tech University, United States; [2]The University of Alabama, United States; [3]Iowa State University, United States

Atomically thin diamond has various industrial applications because of their extreme hardness and excellent thermal conductivity. In this study, we have investigated the possibility of a novel synthesis technique for diamane and diamond thin films from multilayer graphene at pressures far below the graphite → diamond transformation pressure using the atomistic modeling approach. We have used the Molecular Dynamics technique with reactive force fields to study the formation mechanism of diamane. Our results demonstrate a drastic reduction (by a factor of two) in the graphite → diamond transformation stress upon using a combined shear and axial compression. The shear deformation in the multilayer graphene lowers the phase transformation energy barrier and plays the role of thermal fluctuations, which itself promotes the formation of diamond. We revealed weak temperature dependence of the transformation strain and stresses. The transformation stress vs. strain curve for the bulk graphite drops exponentially for finite temperatures. Therefore, our results support the proposition that shear strain plays a vital role in graphite → diamond phase transformation.

5:20 AM *F.EL01.05.03
Electrical and Quantum Application of Diamond—From the Viewpoint of Diamond CVD Growth and Device Fabrication Satoshi Yamasaki[1,2], Toshiharu Makino[1], Hiromitsu Kato[1], Masahiko Ogura[1], Daisuke Takeuchi[1], Yukako Kato[1], Norio Tokuda[2] and Tsubasa Matsumoto[2]; [1]National Institute of Advanced Industrial Science and Technology, Japan; [2]Kanazawa University, Japan

Diamond has many unique physical properties. Due to these unique properties diamond has high potential for applications; electrical devises, quantum devices, etc. Depending on the target application we need to develop the growth and fabrication technique, In this talk, we introduce the electronic applications and the quantum application using nitrogen-vacancy centers from the viewpoint of diamond growth and fabrication technique.

5:35 AM F.EL01.05.04
Exploring the Role of Etching During CVD Diamond Growth Using Kinetic Monte Carlo Modelling Max D. Williams[1,2], Neil L. Allan[1,1] and Paul May[1,2]; [1]University of Bristol, United Kingdom; [2]University of Warwick, United Kingdom

Using a simplified kinetic Monte Carlo (KMC) model of CVD diamond growth, the diamond and computational chemistry groups at the University of Bristol have previously reported simulating many atomic layers of diamond growth at relatively low computational cost. These simulations have been found to reproduce many of the growth features seen experimentally, including growth rates, while keeping the computational time required on the order of hours.[1] However, one limitation of such a simplified model is the use of a cubic representation of the diamond atomic lattice. Although this allows low calculation times and simplified methods, the geometries of specific adsorbates or surface defects thought to be important in the diamond growth mechanism cannot be correctly modelled.

Transitioning the model from a simple cubic lattice to a true tetrahedral diamond structure allows a more realistic representation for the diamond lattice, allowing implementation and testing of more complicated CVD growth reaction schemes, with application of modern software development strategies to maintain computational efficiency. Visualisation of the diamond surface as CVD growth progresses in true tetrahedral co-ordination is also now possible, allowing robust and powerful analysis of implemented reaction schemes and their effect on surface morphology development as a function of time.
Experimental observations of (100) CVD diamond growth have suggested the presence of species incorporation and etching mechanisms whose interplay results in step-flow growth[2] and aligned dimer row domains,[3] implying the presence of an

anisotropic etching mechanism.[4] Previous theoretical models have included etching mechanisms which facilitate the removal of isolated surface species,[5–7] but there has yet to be theoretical modelling studying each mechanism operates as growth conditions and mechanism energetics are varied.

Using our kMC model for (100) CVD diamond growth, we aim to investigate the various etching mechanisms and their associated energetics reported in the literature within a consistent growth model to assess how experimental growth rates can best be reproduced while observing commonly seen experimental surface features.

Surface Contamination Impact on Nanodiamond Seeding of Plasma-Treated Tantalum Films Paulius Pobedinskas[1,2], Wim Dexters[1,2], Jan D'Haen[1,2] and Ken Haenen[1,2]; [1]Hasselt University, Belgium; [2]IMEC vzw, Belgium

The deposition of closed nanocrystalline diamond (NCD) thin films on non-diamond substrates requires diamond nucleation sites. An established technique for creating nucleation sites is a surface treatment with a water-based colloidal solution of ultra-dispersed nanodiamond (ND) particles.[1] In ND seeding the most important factors are the surface charge of the substrate and the zeta-potential of the used colloid. Together, they determine the nucleation density, which can lead to an extreme difference in the observed seeding density.[2–6] However, surface contamination by hydrocarbons, which is an unavoidable and quick process even in a cleanroom environment,[7] is often not taken into consideration. Such contamination can alter the surface wetting properties[8] and surface charge[9], and thus the eventual seeding density. In this work we investigate and model the impact such surface contamination has on the ND seeding efficiency.

Tantalum is a metal well known for its resistivity to corrosion, bioinertness, biocompatibility and excellent osteoconductivity.[10] After sputtering a thin film of Ta on silicon substrates, these stacks were exposed to the ambient atmosphere for different times, allowing to achieve various degrees of surface contamination. Then, the Ta surface wettability was measured, samples were seeded with NDs, and the subsequent seeding density evaluated. As surface coverage by hydrocarbons increased, the wetting properties gradually turned from hydrophilic to hydrophobic. The ND seeding density first decreased and then increased again. To understand this correlation, we propose an analytical model that describes the dynamics of surface contamination and hydrocarbon contaminant interaction with the surface, and the resulting ND seeding density.

We assume that when a hydrocarbon (HC) molecule lands on the Ta surface it attracts negative surface charge towards it, while creating a positive surface charge around it. Due to said dipole formation, the top part of the HC molecule is charging negatively. Solving differential equations for the dynamics of the normalized surface coverage number density of the HC molecules, $\mathbf{n}$, and surface charge density, $\boldsymbol{\sigma}$, we derive $\boldsymbol{\sigma(n,\eta) = n + (1 - n)^{(1+\eta)}}$, where $\boldsymbol{\eta}$ is a ratio between an area of the depleted charge around the HC molecule and the area of the HC molecule itself. The assumption that the contact angle, $\boldsymbol{\theta}$, is linearly proportional to the surface coverage by HC, $\boldsymbol{n = \theta / \theta_{sat}}$, makes wettability measurements a valid method for determining the degree of surface contamination. If the sum of electrostatic double-layer and Van der Waals interaction energies becomes positive, a potential energy barrier for a ND particle approaching a surface exists. ND particles must surmount a positive potential peak for a deposition onto the surface to occur. This occurs with a probability exponentially proportional to the potential barrier. By fitting the experimental data, we find that the ND seeding density is exponentially proportional to the calculated positive surface charge number density, which forms around HC molecules. This constitutes

57% of the HC molecule area, while the created barrier height is estimated to be ~ 0.18 eV.

SESSION F.EL01.06: Diamond Integration
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-EL01

5:00 AM *F.EL01.06.01
The Role of Interfaces and Heterogenous Integration in the Thermal Management of Wide Bandgap Semiconductors Samuel Graham[1], Zhe Cheng[1], Mark Goorsky[2], Fengwen Mu[3], Jim Speck[4] and Tadatomo Suga[3]; [1]Georgia Institute of Technology, United States; [2]University of California, Los Angeles, United States; [3]Meisei University, Japan; [4]University of California, Santa Barbara, United States

Wide bandgap electronics made from GaN and Ga_2O_3 are currently under development due to their potential to create advanced RF and power electronics. However, the performance and reliability of these devices are often controlled by their electrothermal response during device operation. A key feature which limits thermal control of the peak temperature is the thermal resistance that is encountered intrinsically from the material as well as across material interfaces with these devices. One method that has shown promise for mitigating the high thermal resistance of these devices is through their heterogenous integration with other materials which assist in heat dissipation and aid thermal management. For this, thermal transport across interfaces and novel integration methods are necessary.

In this work we will present modeling efforts which guide the impact of heterogenous integration on the thermal performance of UWBG devices. Thermal metrology methods used to measure interfacial thermal conductance will be discussed and new insights into the control of thermal boundary conductance given. Techniques such as surface activated bonding will be presented to demonstrate the integration of GaN and Ga_2O_3 with high thermal conductivity substrates such as SiC and diamond. The use of other high thermal conductivity dielectrics for improved heat dissipation from the top side and bottom side of the devices will be discussed. Finally, the prospects for the future development of thermal management via heterogenous integration will be presented.

5:15 AM F.EL01.06.02
Formation Process of High Thermal-Stability Diamond/Si and Diamond/GaAs Heterointerfaces by Surface Activated Bonding Yutaka Ohno[1], Jianbo Liang[2], Yasuo Shimizu[1], Hideto Yoshida[3] and Naoteru Shigekawa[2]; [1]Tohoku University, Japan; [2]Osaka City University, Japan; [3]Osaka University, Japan

Diamond is a promising candidate for a base material of high power electronic devices, as well as for a superior heat spreading substrate, due to its excellent physical properties such as the highest electrical breakdown field strength, the highest thermal conductivity, and a high RF power capability that is 3 times higher in comparison with SiC. For the practical application toward power devices, we need diamond/semiconductor heterointerfaces with high thermal stability and can withstand the temperature rise of power devices during operating. Recently, Liang has demonstrated that diamond/Si [1] and diamond/GaAs [2] heterointerfaces with high thermal stability can be fabricated by surface activated bonding (SAB) at room temperature (RT). In this work, we have examined the bonding mechanism using cross-sectional scanning transmission electron microscopy (STEM) combined with electron energy loss spectroscopy (EELS) and energy dispersive x-ray spectroscopy (EDX).

In the SAB process, surfaces of diamond and Si (or GaAs) wafers are activated at RT before bonding by creating dangling bonds via the irradiation of high-energy Ar atoms in a high vacuum, and the surfaces are then bonded by the contact most of the time under pressure to form strong chemical bonds even for imperfect surfaces. For diamond/Si heterointerfaces, atomic diffusion at the interfaces, presumably due to the transient enhanced diffusion assisted by the point defects introduced in the surface activation process [3], is confirmed during the bonding process. The crystallinity at the diffusing region is rather low, and it is recovered by 1000 °C annealing via the formation of SiC layers, that would play a pivotal role in the relaxation process of residual stress due to the misfit of thermal expansion coefficient between diamond and Si [1]. Therefore, the defect-assisted atomic diffusion at the interfaces would be a key concept for the formation of high thermal-stability diamond/Si heterointerfaces. Similar atomic diffusion is also confirmed at diamond/GaAs heterointerfaces during the SAB process.

5:25 AM F.EL01.06.03

The Impact of Polycrystalline Diamond Growth Nucleation on N-Polar GaN Channel Performance Mohamadali Malakoutian[1,2], Chenhao Ren[1,2], Kelly Woo[2], Shubhra Pasayat[3] and Srabanti Chowdhury[2]; [1]University of California, Davis, United States; [2]Stanford University, United States; [3]University of California, Santa Barbara, United States

N-polar gallium nitride (GaN) high electron mobility transistors (HEMTs) have shown superior performances when scaling for W-band frequencies over Ga-polar GaN HEMTs [1]. However, due to the shorter channel and closer gate fingers its ability to dissipate the heat from the channel to the heat-sink is limited. Polycrystalline (PC) diamond due to its very large thermal conductivity (TC) is one of the solutions for self-heating problem in high-power high-frequency devices. PC Diamond can be grown in a closed proximity to high temperature spot in the channel and spread the heat efficiently [2]. The standard Si_3N_4 thickness as a gate dielectric for W-band N-polar HEMTs is 5 nm, which can be used as thermal interface material to reduce thermal boundary resistance (TBR<2 m^2K/GW) between diamond and GaN as well [3]. As diamond growth takes place in a high temperature hydrogen plasma environment using MPCVD, it can decompose both Si_3N_4 and GaN layers by reacting with silicon, nitrogen, and gallium and making volatile gases (SiH_4, NH_3, and GaH, respectively) [4]. Any damage to GaN channel may result in a degradation of device performance after the growth. In this work, we investigated the impact of diamond growth nucleation and main stages on 2-dimentional electron gas (2DEG) properties such as electron mobility, sheet carrier concentration, and sheet resistivity (before growth: μ_n=1200 $cm^2/V.s$, n_s=1.34E13 cm^{-2}, and ρ_s=388 Ω/sq).

The main goal of the growth nucleation stage is to guarantee no damage to the 2DEG by covering the substrate (Si_3N_4/GaN) with thinnest possible nano-crystalline diamond (NCD) in shortest possible time as NCD has a poor TC (<100 W/m.K). The 2DEG has been characterized using Hall mobility measurement, and the thickness of nucleation layer has been measured by high resolution TEM. The nucleation layer can prevent diffusion of hydrogen radicals into the substrate which is highly dependent on the microwave power and gas pressure. To increase the diamond growth rate and decrease substrate etching rate the sample holder was redesigned to provide higher temperature (~700 C) with minimum power (600 W) and pressure (20 Torr). The CH_4% and time were changed from 3 to 10% and 10 to 15 min, respectively for nucleation stage followed by the same main growth for all samples (2% CH_4, 1600 W, 60 Torr, 45 min). We observed no degradation in 2DEG by using >5% CH_4 and 15 min growth, while by lowering the time to 10 min we started to see about 20-30% reduction in μ_n and 50-150 Ω/sq increase in ρ_s. This degradation varies with different cap layers on top of the channel; no cap layer, 1-2 nm AlN, or 1-2 nm 46% AlGaN.

To study the impact of main growth on 2DEG, we have chosen 5% CH_4 and 15 min for nucleation stage and changed main growth parameters including CH_4% (0.5-2%), power (600-1600 W), pressure (20-90 Torr), and sample holder design. CH_4% showed the highest impact in determination of damage level to 2DEG and pressure had the lowest impact. With the sample holder same as nucleation stage, 1% CH_4 is the minimum required for no damage. For the case with original sample holder, 1.5% CH_4 is the lowest acceptable value for the first 45 min of the growth.

In this work, we were able to achieve a smooth interface between diamond and GaN (including 5 nm Si_3N_4 interfacial layer) without using argon or nitrogen in the gas mixture by redesigning the sample holder and modifying growth parameters for lower etch rate of the substrate. This recipe is compatible with W-band N-polar GaN HEMTs as maintains device performance after the growth.

This work was supported by the Semiconductor Research Corporation (SRC) and DARPA under the JUMP program.

5:35 AM F.EL01.06.04
Correlation Between Linear Antenna Microwave Plasma CVD Reactor Parameters and the Diamond-on-GaN Films Awadesh K. Mallik[1,2], Paulius Pobedinskas[1,2], Jan D'Haen[1,2] and Ken Haenen[1,2]; [1]Hasselt University, Belgium; [2]imec vzw, Belgium

Compared to classical resonant cavity CVD, linear antenna microwave plasma enhanced CVD (LA MW CVD) is a relatively new route of depositing diamond films onto different vulnerable substrates [1]. It has been reported earlier that GaN surfaces are prone to etching under conventional CVD diamond deposition parameters. So, it was envisaged that due to the low pressure and low temperature regimes of LA MW CVD, it might be possible to deposit diamond onto otherwise reactive GaN surfaces. Although it is a regular practice to put an intermediate SiN buffer layer for successful deposition of diamond films on GaN [2], there are only few reports of such deposition onto bare GaN substrates [3], and not by a LA MW CVD reactor. which could potentially solve the problem associated with an additional SiN barrier layer, i.e. an extra thermal barrier. In the present work, the effect of different LA MW CVD processing parameters on the optimal deposition of the diamond films has been systematically studied. First of all, the distances between the quartz tube and the samples were varied, which has direct impact on the substrate temperature. Thereafter, the microwave input power was altered to attain varied substrate temperatures. There is an upper limit of the substrate temperature beyond which the microwave plasma alone is insufficient to increase the temperature further. Hence, an additional heater was used under the stage for attaining various substrate temperatures. Moreover, the microwave power input was also used in pulsed mode for further optimization of the film properties. The microstructure of the deposited films was observed in the scanning electron microscope (SEM) and the elemental analysis of the film surfaces was done by electron diffraction spectroscopy (EDX). Moreover the diamond film quality and crystallinity was evaluated by Raman spectroscopy. It will be shown that the said parameters have a significant impact on the grown films, both in terms of their quality and microstructure. It was found that the optimum film quality without GaN surface etching was obtained under the pulsed microwave power regime.

5:45 AM F.EL01.06.05
Nitrogen and Phosphorous Doping of Diamond Films on GaN Substrates Awadesh K. Mallik[1,2], Rozita Rouzbahani[1,2], Giridharan Krishnamurthy[1,2], Paulius Pobedinskas[1,2], Wen-Ching Shih[1,3] and Ken Haenen[1,2]; [1]Hasselt University, Belgium; [2]imec vzw, Belgium; [3]Tatung University, Taiwan

In the present work, doped diamond films have been grown on GaN substrates. The CVD diamond processing is not straight forward, as GaN is susceptible to H_2 plasma etching, with formation of elemental Ga in the resulting diamond film, which can thereby enhance the electron emission properties of the stack. However, the electrical resistivity across the CVD grown film surface was found to become very high (~MΩ) after depositing diamond on GaN substrates. So, in order to induce electrical conduction on the top surface film, the diamond films were doped with nitrogen inside a 2.45 GHz resonant cavity reactor [1], and with phosphorous [2] inside a linear antenna CVD chamber [3]. 1%, 3% and 5% N_2 gas was added to the conventional H_2/CH_4 gas mixture. On the other hand, 0.1% PH_3 gas diluted in H_2 was used as precursor gas for phosphorous doping. Different types of microstructures were produced while doping with two different dopants. Nitrogen gas changes the diamond film microstructure from faceted to spherical grains with signs of GaN substrate etching, whereas, the phosphorous doping produced much smaller nanocrystalline grains with strong Ga peaks in their EDX spectra. Nitrogen incorporation in the diamond lattice can happen easily at lower substrate temperatures of 500-600°C, as found from their photoluminescence data, but phosphorus doping was only possible at a high substrate temperature of 900°C, as evidenced from its XPS signal at 132 eV. The porous nanocrystalline grains in the doped diamond could possibly enhance the field emission characteristics in comparison to the bare GaN substrate. The electrical conductivities of the coated and uncoated GaN substrates will also be presented.

F-EL01

5:00 AM *F.EL01.07.01
Identifying the Multiple Classes of Diamond Nanoparticles Using Machine Learning Amanda Barnard[1] and Amanda J. Parker[2]; [1]The Australian National University, Australia; [2]CSIRO, Australia

Diamond nanoparticles are complicated materials, presenting a diverse range of sizes, shapes, speciation and defects that cannot easily be controlled during synthesis. Each of these features contribute to structure/property relationships, but in different ways. Attempts to purify samples to tune the properties often fail due to lack of specificity, and polydispersivity usually persists. An alternative approach is to separate classes of nanodiamonds based on their properties, rather than seeking monodispersed samples based on their structure. To investigate if this approach has merit we have used machine learning to classify nanodiamonds and identify class-dependent properties and characteristics. Using a fully reconstructed data set that spans the experimentally observed size range from 1 nm to 4.5 nm we find that there are multiple classes of particles, based on their similarity in the high dimensional feature space. By using an interpretable classifier, with excellent accuracy, precision and recall, we also identify possible purification pathways based on the important features ranked by the AI.

5:15 AM *F.EL01.07.02
Molecular Transducers for Spin-Sensitive Optical Sensing Using Nitrogen-Vacancy Centers Petr Cigler; Institute of Organic Chemistry and Biochemistry, Czech Academy of Sciences, Czechia

Non-perturbing sensing techniques applicable to biological systems currently are of central interest in the biosciences. Nanodiamond is a highly biocompatible nanomaterial for construction of nanosensors, which can accommodate various photoluminescent crystal defects. Nitrogen-vacancy (NV) centers show high photostability and unique electronic sensitivity to magnetic field. Their spin properties can be read by optical means, which enables construction of various probes based on quantum mechanical interactions. If embedded in nanodiamond particles, NV centers can be exposed to biological environment and report sensitively on the spin-related processes occurring in a close vicinity of the particle. Molecular transducers designed for NV centers transposing the presence of particular analytes to a selective and unambiguous readout will be presented. Different types of surface architectures will be shown [1, 2]. Optical nanosensors designed for selective measurements of pH, redox potential, and ascorbate under physiological conditions will be discussed.

5:30 AM F.EL01.07.03
Scalable Assembly of Fluorescent Nanodiamonds for Quantum Sensing Henry J. Shulevitz, Tzu-Yung Huang, Steven Neuhaus, Lee Bassett and Cherie Kagan; University of Pennsylvania, United States

Milled fluorescent nanodiamonds containing nitrogen-vacancy (NV) centers provide an excellent platform for sensing applications due to their quantum sensitivity to a variety of external fields at nanometer length scales. Currently, the irregularity in crystal morphology and the difficulty of functionalizing the nanodiamond surface impede efforts to realize scalable assemblies of nanodiamonds, or to create heteroassemblies with other materials. Poor control over the nanodiamond

composition and surface chemistry also creates significant heterogeneity in their optical and quantum characteristics. We will present scalable strategies to form ordered arrays of nanodiamonds using template-directed capillary assembly. This method enables the precise spatial arrangement of primary nanodiamonds with diameters below 50 nm, and it is compatible with the assembly of other compositions of colloidal nanoparticles. Large-scale arrays facilitate automated, repeatable measurements of the nanodiamonds' optical, structural, and quantum characteristics, enabling improved statistical understanding of these key properties and their heterogeneity. The flexible assembly method will allow for detailed studies of chemical treatments, integration of nanodiamonds within photonic and electronic devices, and the realization of quantum heterostructure devices composed from complementary nanomaterials.

5:40 AM F.EL01.07.04
Surface Functionalized Nanodiamond with Improved Protein Repulsion for Drug Delivery and Sensing Julia Puck, Viktor Merz and Anke Krueger; Wuerzburg University, Germany

For many applications the surface chemistry of nanodiamond (ND) is a key factor for the control of properties such as the wetting behavior, biocompatibility and functionality[1]. By attaching appropriate moieties, the interaction with physiological environments can be controlled.
An important point for biomedical applications is the inhibition of a nonspecific protein corona. This shell of e.g. serum proteins masks the desired functions and renders the physiological properties of the nanoparticle uncontrollable[2].
Here we report on the grafting of zwitterionic moieties enabling the formation of NDs without protein corona [3] that enable the specific grafting of antibodies, targeting peptides and CO releasing drug molecules using visible light. The resulting constructs have been characterized using IR, Raman, x-ray spectroscopies as well as particle analysis, TGA and electron microscopy.
The ND conjugates have been tested in vitro as well as in cell assays and demonstrated their functionality in the cellular environment. Additionally, these NDs have been functionalized with pyrene moieties for fluorescence sensing in solution with strong ion background and demonstrated colloidal stability, sensitivity and specificity for the detection of heavy metal ions against a background of ions present in physiological environments.
This research has received funding from Volkswagenstiftung under Grant Agreement no. 88393.

5:50 AM *F.EL01.07.05
How the Surface Orientation of Diamond Crystals Influences its Interaction with Biological Matter Romana Schirhagl[1], Viraj Damle[1], Kaiqi Wu[1], Oreste De Luca[1], Natalia Orti Casan[1], Neda Norouzi[1], Aryan Morita[1], Joop de Vries[1], Hans Kaper[1], Inge Zuhorn[1], Ulrich Eisel[1] and Danny Vanpouke[2]; [1]Groningen University, Netherlands; [2]Hasselt University, Belgium

Here we show how the diamond crystal orientation influences the interaction with biological systems[1]. More specifically we are investigating the interaction between the <100>, <110> and <111> surfaces of single crystal diamond with biomolecules, cell culture medium, mammalian cells and bacteria. We show that the crystal orientation significantly alters these biological interactions. Most surprising is the two orders of magnitude difference in the number of bacteria adhering on <111> surface compared to <100> surface when both the surfaces were maintained under the same conditions. We also observe differences in how small biomolecules attach to the surfaces. Neurons or HeLa cells on the other hand do not have clear preferences for either of the surfaces. To explain the observed differences, we theoretically estimated the surface charge for these three low index diamond surfaces and followed by the surface composition analysis using x-ray photoelectron spectroscopy (XPS). We conclude that the differences in negative surface charge, atomic composition and functional groups of the different surface orientations lead to significant variations in how the single crystal diamond surface interacts with the studied biological entities.

Investigation of Li Doping and SnO Termination on the Diamond (100) Surface for Thermionic Emission Application Sami Ullah, Liam Cullingford, Tongfie Zhang, Jing Ren Wong, Gary Wan, Mattia Cattelan and Neil Fox; University of Bristol, United Kingdom

Diamond electrodes terminated with surface layers can impart significant changes to the electronic properties of a diamond interface and we have previously reported on studies of the tunability of surface work function by substituting hydrogen with oxygen under controlled conditions [1]. Engineering a functionalised diamond surface that is stable and reproducible is of technological importance to future diamond electronic devices such as Schottky junctions and electron-emitting electrodes for field emission, thermionic energy converters, secondary electron multipliers.
O'Donnell and his group have demonstrated the formation of a stable Li-O termination of diamond by physical vapour deposition of a monolayer of Li on the diamond surface which develops and exhibits Negative electron affinity (NEA) and hence lowers the work function, even at an elevated temperature of 800 °C [2]. In this work we are seeking an alternative method, a novel and easy chemical means of introducing and coordinating lithium with oxygen on the diamond surface to realize a more controlled approach of creating a stable –O-Li dipole. with uniformity over the diamond surface which also serves as a means to study and visualize for the first time the effect of temperature on the concentration of Li atoms in the diamond surface and on the Li-O species on the surface of diamond sample.
Also, Tin monoxide has been considered as potential material for battery anodes, coating, gas sensing, catalysis, etc. The application area of SnO extends over photovoltaics, displays, information storage, etc. as it has a large optical bandgap of 4.12 eV, high transparency (~90%) non-toxic and abundant [3]. SnO has been found to form a layered structure in a crystallographic direction of [001] with a monolayer thickness of 0.48 nm. Sn 5s form a lone pair of electrons which point towards the interlayer spacing and result in dipole-dipole interaction leading to a Van der Waals gap of 2.52 A between the layers. Various groups have demonstrated the growth of SnO mono and multiple layers by various methods but many of these result in an upper SnO_2 layer that forms as soon as the sample is taken into the oxygen environment as SnO is metastable and hence rapidly converts into SnO_2.
We are doping oxygen terminated Boron doped Polycrystalline diamond and Nitrogen doped HPHT diamond (111) with Li atoms using microwave plasma technique. The oxygen termination was induced by acid washing. We analyze the sample with X- Ray Photoemission Spectroscopy (XPS) and Raman spectroscopy. The main aim of this study is to analyze the change in concentration of Li atoms in the bulk and on the surface of diamond with annealing temperature. We have produced sub ML SnO on conductive, p-type single crystal diamond under ultra-high vacuum (UHV) conditions by e-beam evaporation. The samples will be characterised in-situ by Spot Profile Analysis Low-Energy electron diffraction (SPA-LEED) and Energy Filtered Photo Emission Electron Microscopy (EF-PEEM) and X-ray Photoemission Spectroscopy (XPS). We quantify the change in work function between mono and few layer SnO and its effect upon the barrier height of a p-type diamond Schottky junction.

Stabilizing Diamond's Surface Conduction with Mixed-Oxide ALD Films and Deuterium Surface Termination Michael Geis[1], Joseph Varghese[1], Yichen Yao[2], Robert J. Nemanich[2], Mark Hollis[1], Charles H. Wuorio[1], Xingyu Zhang[1], George W. Turner[1], Shireen M. Warnock[1], Steven A. Vitale[1], Richard J. Molnar[1], Thomas Osadchy[1] and Beijia Zhang; [1]Massachusetts Institute of Technology, United States; [2]Arizona State University, United States

When the surface of diamond is H-terminated, a p-type surface conductive layer is formed. Atmospheric impurities, NO_2, O_3,

fluoropolymer, transition metal oxides and Al_2O_3 adhere to the diamond surface and activate diamond's surface conductance by generating and trapping negative charges on the diamond surface. These charges increase the positive p-type carrier densities in the diamond surface and reduce its resistance. High drain current field effect transistors (FETs) of 1.2 to 1.3 A mm^{-1}, high frequency f_T of 75 GHz, and high voltage, >2000 V, devices have been demonstrated with these activation surface chemistries. However, these devices degraded in a few days or when stressed with high voltage.

Research to stabilize diamond's surface conductance has met with some success. H-terminated diamonds overcoated using atomic layer deposition (ALD) Al_2O_3 have the best demonstrated stability, but the surface resistance is high (5 to 12 kW sq^{-1}). Diamonds coated with transition metal oxides such as WO_2, MoO_3, and V_2O_5 have lower resistances of 2.5 to 3.5 kW sq^{-1} [1,2]. Their stability has been demonstrated although these oxides are conductive, have several oxidations states, and may electrochemically degrade under the high electric fields associated with FETs. This presentation will discuss the use of a mixed-oxide (Al_2O_3-SiO_2) ALD film to generate resistances between 1.5 and 3.5 kW sq^{-1} with demonstrated stability in excess of half a year.

The low surface resistance obtained with this mixed oxide is a result of a change in the structure of Al_2O_3 when mixed with SiO_2. The electron trap surface density of Al_2O_3 is ~$7x10^{12}$ cm^{-2} while the mixed oxide surface density is $3x10^{13}$ to $8x10^{13}$ cm^{-2} [3,4] with an estimated trap depth of 5.4 eV. This mixed oxide is just one of a group of oxides [5] with deep, > 5 eV, high-density electron traps.

Increased stability of the diamond surface is obtained by terminating the surface with deuterium atoms instead of hydrogen atoms. This additional stability is beneficial during device fabrication. This presentation will discuss diamond's surface conduction with Al_2O_3-SiO_2 combined with deuterium atom termination.

Diamond and Silicon Carbide as Passivation Layers for Packageless SAW Sensors Lucie Drbohlavová[1,2], Abdelkrim Talbi[3], Yuxin Liu[3], Cecile Ghouila-Houri[3], Olivier Bou Matar[3], Andrew Taylor[1] and Vincent Mortet[1,2]; [1]FZU - Institute of Physics of the Czech Academy of Sciences, Czechia; [2]Czech Technical University, Faculty of Biomedical Engineering, Czechia; [3]University Lille, CNRS, France

Surface acoustic waves (SAWs) and bulk acoustic waves are two of MEMS technologies of industrial relevance and can be found in a myriad of devices. Acoustic RF filters, for instance, are integral parts of wireless communication systems. SAW devices have been adapted as sensors which can be configured to operate both passively and wirelessly. For example, SAWs find applications in life sciences, in structural health monitoring, etc. In particular, SAW devices can also be operated in extremely confined environments such as implantable sensors to monitor or to provide real-time treatment. In this case, it

would make sense to protect the sensor surface and leave only the functionalized area visible for detection. This is true for implantable sensors where space is a major constraint and therefore requires the development of an intrinsically protected design. Also, this is true for biosensors where the surface is continuously exposed to the analysed biofluid.

In this work, we propose the use of a shear surface wave guided between the semi-infinite substrate and high acoustic velocity thin film materials. The upper high acoustic velocity layer works as an acoustically isolating layer, protecting the guided surface shear wave from undesired mechanical damping and eliminate the need for packaging. With very high acoustic velocities, diamond and silicon carbide (SiC) are excellent candidates for packageless SAW sensors applications. In previous studies, we have already demonstrated the possibility of diamond coating of SAW devices using Microwave Plasma Enhanced Chemical Vapor Deposition with Linear Antennas (MW-LA-PECVD) at low temperature [1, 2].

Here we investigate, theoretically and experimentally, the use of diamond and SiC as a passivation layer for SAW devices. Theoretical calculations were carried out using COMSOL Multiphysics FEM simulation software. Two different piezoelectric materials were investigated, ST-cut quartz and 36°YX $LiTaO_3$ as well as two common guiding layer materials – zinc oxide (ZnO) and silicone oxide (SiO_2). Theoretical calculations show, that 2 μm thick diamond or SiC layers are sufficient to confine the acoustic wave in the guiding layer at a wavelength close to 10 μm. From the displacement curve we could see, that for 36°YX $LiTaO_3$ substrates the acoustic wave is very well confined for both guiding layer materials. On the contrary, shear wave disperses within the ST-cut quartz bulk with the addition of a passivation layer.

Based on theoretical results, SAW devices were fabricated on 36°YX $LiTaO_3$ substrates with 10 nm/190 nm Ti/Au electrodes patterned by RF sputtering, photolithography and chemical wet etching techniques. The SiO_2 layer was deposited using low temperature plasma enhanced chemical vapor deposition with a resulting normalized thickness equal to $h_{SiO2}/\lambda = 0.2$. Depositions of nano-crystalline diamond (NCD) and SiC layers were carried out by MW-LA-PECVD with resulting normalized thicknesses of $h/\lambda = 0.2$. All depositions were carried out at a temperature below 500 °C to preserve the piezoelectric properties of substrates.

Our results are promising for waveguide protection applications as well as opening other directions, such as the introduction of the local sensitive zone in the diamond layer, which can be interesting for bio or electrochemical sensing applications.

F.EL01.09.02
Enhancing the Sensitivity of SAW Sensors Using the Diamond Surface Phononic Metamaterials Lucie Drbohlavová[1,2], Yuxin Liu[3], Abdelkrim Talbi[3], Cecile Ghouila-Houri[3], Olivier Bou Matar[3], Andrew Taylor[1] and Vincent Mortet[1,2]; [1]FZU - Institute of Physics of the Czech Academy of Sciences, Czechia; [2]Czech Technical University, Faculty of Biomedical Engineering, Czechia; [3]University Lille, CNRS, France

Phononic metamaterials (PnMs), analogue to photonic and plasmonic in optics, have attracted a great deal of attention in the last two decades. Based on phononic band-gap and local resonance mechanisms, these artificial materials enabled advanced control of elastic waves in solid condensed matter including wave-guiding, trapping, multiplexing, demultiplexing, etc. They offer the possibility to confine and focus an acoustic wave in an ultra-small region of sub-wavelength dimensions and to extend mechanical resonance lifetimes (high quality factor (Q)). For biosensing applications, Shear surface wave (Sh-SAW) and Antisymmetric Lamb waves are the most interesting, as they are compatible with liquid environments. Diamond is an attractive material for biosensing applications thanks to its chemical inertness, biocompatibility and prolonged stability of covalently attached biomolecules. Therefore, combining diamond PnMs and shear surface waveguides is of great interest to enhance the performance of biosensor.

In this work, we investigated the properties of Sh-SAW sensors with diamond pillar PnMs. Band structures and sensitivity were calculated with the finite element method (FEM, COMSOL Multiphysics). The sensitivity of studied structures was

investigated by adding 200 nm thick polymethyl methacrylate layer on top of the structure. The studied structure consists of 60 µm high and 10 µm wide block of 90ST-cut quartz substrate, which supports shear wave propagation. For comparison of sensitivity either a 2 µm thick continuous SiO_2 guiding layer or the diamond pillars with radius = 1 µm and height = 1 or 2 µm were introduced on top of the quartz substrate. For the diamond PnMs, the slowest shear wave mode is completely localized in the pillar for both heights. The sensitivity is significantly increased for diamond pillar phononic crystals (4.4 % for 2 µm height pillar) in comparison with plain ST-cut quartz (0.9 %) and also ST-cut quartz + 2 µm SiO_2 guiding layer (2.5 %). These results are very promising for the fabrication of highly sensitive LW-SAW sensor for biosensing applications.

This work has been supported by the Grant Agency of the Czech Republic (GACR) contract 19-09784Y, Czech Science Foundation (project 20-03187S) and by the Czech Technical University in Prague project SGS20/084/OHK4/1T/17.

Spice Model Parameter Extraction for Diamond Schottky P-I-N Diodes Mohammad Faizan Ahmad, Harshad Surdi, Vishal Jha, Franz A. Koeck, Robert J. Nemanich, Stephen M. Goodnick and Trevor Thornton; Arizona State University, United States

To develop practical applications for diamond-based electronics it will be important to have calibrated device models for use in circuit simulators such as LTSpice and Cadence. These Spice models consist of lumped-element components with values extracted by DC and RF measurements for bias conditions that represent typical operating conditions. Of particular importance for PN junction diodes are the on-resistance, R_{on}, and off-state capacitance, C_{off}. The product $R_{on}C_{off}$ is a useful figure of merit that is minimized by careful optimization of the device design. While C_{off} is controlled largely by the thickness of the intrinsic region of the diode, there are several factors that contribute to the on-resistance, including the contact resistance present at the interfaces between the metal contacts and the doped semiconductor. To minimize the contact resistance, high doping concentration is required in the *n*- and *p*-type diamond regions. To further minimize on-resistance, smaller i-layer thickness is required. We have fabricated vertical diamond P-I-N diodes by plasma enhanced chemical vapor deposition of intrinsic and heavily phosphorus doped diamond films on boron doped diamond <111> substrates. Secondary ion mass spectroscopy (SIMS) confirms that the boron doping in the substrate exceeds 10^{20} cm^{-3}, the unintentional *p*-type doping in the *i*-layer is ~10^{16} cm^{-3}, while the peak concentration at the surface of the *n*-layer is ~ 10^{19} cm^{-3}. The thickness of the intrinsic layer was 300 nm and that of the heavily doped *n*-layer was 50 nm. Despite the heavy doping of the *n*-layer it is thin enough to be fully depleted by the metal contact resulting in a Schottky PIN diode.

The diodes were fabricated with ground-signal-ground (GSG) contacts on the top surface allowing for DC and RF probing. To electrically isolate the devices a partial mesa etch was performed using O_2/SF_6 reactive ion-etching to define the diode area and top anode contact. A second RIE step etched through the *i*-layer to expose the p-type substrate on the top surface. Electron-beam evaporation of Ti/Ni/Au (50 nm/50 nm/300 nm) metals form the top cathode and anode contacts to the n and p-layer diamond respectively.

A combination of DC, and S-parameter measurements were used to extract the small-signal parameters for a diode Spice model. At a forward bias of 15 V the diode supports a current density in excess of 36 kA/cm^2, with an on-resistance of $9x10^{-5}$ Ohm-cm^2. The S-parameter measurements were converted to Z-parameters from which the diode off-capacitance was found to be 17.5 nF/cm^2. The FOM is 1.6 ps corresponding to a frequency of 101 GHz. The full diode model provides excellent agreement with the measured current-voltage characteristics up to a forward bias of 15 V/3 A. It also reproduces the one-port s-parameter, S11, up to 25 GHz over all DC bias conditions.

Late News: Crystal Orientation Dependence of Local Electrical Characteristics on CVD-Grown Poly-Crystalline Diamond: Combined SPM and EBSD Study Daichi Yoshii, Mami Fujii and Yukiharu Uraoka; Nara Institute of Science and Technology, Japan

Hydrogen-terminated surfaces of diamond are known to exhibit p-type conductivity, and power devices are being considered as an application that will take advantage of this property. Recently, poly-crystalline diamond devices have been attracting attention because it was reported that high breakdown voltage (>1 kV) MOSFETs can be fabricated[1] despite its lower cost compared to single-crystalline diamond. This property originates from non-doped hydrogen-terminated poly-crystalline diamond. However, the electrical characteristics variability depends on the crystal orientation. In this study, the correlation between the local electrical characteristics obtained by scanning probe microscopy (SPM) and the crystal orientation obtained

by electron backscattering diffraction (EBSD) was evaluated in order to clarify the electrical defect state of each crystal orientation.
Poly-crystalline diamond substrates (size: 3 mm × 3 mm, thickness: 0.33 mm) manufactured by Diamond Materials GmbH were used in this experiment. After cleaning the substrate in the order of aqua regia (80 °C, 5 min.), piranha solution (120 °C, 10 min.) and HNO_3 and H_2SO_4 mixed acid (240 °C, 30 min.), the substrate was subjected to microwave plasma CVD with 199.5 sccm of CH_4 and 0.5 sccm of H_2 to grow diamond films. The hydrogen termination was processed by the same CVD equipment. Afterwards, the substrate surfaces were measured by current-AFM (c-AFM), and the same area was measured by EBSD. We used SPM-9600 (Shimadzu Corp.) for c-AFM measurement, using PtIr-coated conductive cantilever to measure surface morphology and c-AFM current images at bias of -0.05 V.
As a result of the measurements using c-AFM, it was confirmed that there were spots with different current flow patterns. These current spots were concentrated at the grain boundaries, and they were also confirmed in some parts of the grain. In addition, variation in the current spots density was confirmed. Next, we measured the same area as the c-AFM site with SEM/EBSD to investigate the correlation between the current spots in the grains and the crystal orientation. The surface morphology images and current images obtained from c-AFM measurements were compared with the inverse pole figure (IPF) map obtained from SEM/EBSD measurements. These results suggest that there is a correlation between the current spot density distribution and crystal orientation, ex, (111) oriented crystal shows lower current spots density, and (101) oriented crystal shows high current spots density. The results suggest that this is caused by the difference in the etching and/or growing condition of each crystal orientation. This study can reveal the suitable crystal orientation for electrical device fabrication that requires low electrical defect density.

Late News: Development of Nanodiamond-Based Multifunctional Biosensors Yoobeen Lee; Hanyang University, Korea (the Republic of)

Nanodiamonds (NDs) have excited a lot of interest in the field of biomedical application as they can be used as spin probes for optical magnetic sensing and biological environments. Due to their optical and biological properties, NDs are expected to be employed as multitasking markers for the accurate visualization of biophysical parameters such as and magnetic fields and temperature. However, the engineered NDs to intracellular structures of interest within a complicated biological environment remains a challenge.
In this work, we investigated each property of the 4 types of nanodiamonds like SEM, PL spectra and then the NDs were transfected into human skin cells (WS1) using silicon nanopillar. For the development of nanodiamonds as multifunctional biosensor, researchers are still engaged in the in-depth study of NDs and their effect on life interfaces.

Late News: Development of Nanodiamond-Based Multifunctional Biosensors Yoobeen Lee; Hanyang University, Korea (the Republic of)

Nanodiamonds (NDs) have excited a lot of interest in the field of biomedical application as they can be used as spin probes for optical magnetic sensing and biological environments. Due to their optical and biological properties, NDs are expected to be employed as multitasking markers for the accurate visualization of biophysical parameters such as and magnetic fields and temperature. However, the engineered NDs to intracellular structures of interest within a complicated biological environment remains a challenge.
In this work, we investigated each property of the 4 types of nanodiamonds like SEM, PL spectra and then the NDs were transfected into human skin cells (WS1) using silicon nanopillar. For the development of nanodiamonds as multifunctional biosensor, researchers are still engaged in the in-depth study of NDs and their effect on life interfaces.

Triple-Wavelength Emission from Mn^{2+}/Yb^{3+} Codoped $CsPbCl_3$ Perovskite Nanocrystals and Luminescent Solar Concentrator Applications Tong Cai, Junyu Wang and Ou Chen; Brown University, United States

Doping metal ions into lead halide perovskite nanocrystals (NCs) has attracted great attention over the past few years due to the emergence of novel properties relevant to optoelectronic applications. Current studies focus mostly on doping a single type of metal ions into the host perovskite NCs, while few research efforts have been made on simultaneous doping more than one type of metal ions into the same perovskite hosts and to study their synergic effects with intra-particle energy transfer processes. Here, a facile synthesis of Mn^{2+}/Yb^{3+} codoped $CsPbCl_3$ NCs through a hot-injection technique is firstly reported. Owing to the completely separated energy relaxation channels among the intrinsic bandgap (BG), Mn^{2+} and Yb^{3+} dopant emissions, the obtained Mn^{2+}/Yb^{3+} codoped $CsPbCl_3$ perovskite NCs exhibit a unique triple-wavelength emission profile simultaneously covering UV/blue (BG-PL), visible (Mn-PL) and NIR (Yb-PL) spectral regions. By optimizing the dopant concentrations, the total photoluminescence quantum yield (PL QY) of the codoped NCs can reach up to ~125.3% due to quantum cutting effects. Mechanism studies reveal different natures of emission mechanisms can be involved in a single batch of Mn^{2+}/Yb^{3+} codoped perovskite NCs: (i) electronic inter-band transition (BG-PL); (ii) electronic transition of ion centers within local molecular complexes (Mn-PL); and (iii) defect-induced energy transfer and subsequent

quantum cutting scheme (Yb-PL). Owing to the high PL QYs and minimal reabsorption loss, the codoped perovskite NCs are demonstrated to be used as efficient emitters in luminescent solar concentrators, with greatly enhanced external optical efficiency compared to that of using solely Mn^{2+} doped $CsPbCl_3$ NCs. Therefore, co-doping both Mn^{2+} and Yb^{3+} ions into perovskite NCs can serve as a unique model system for studies of host-to-dopant and inter-dopant energy transfer mechanisms, as well as associated radiative and non-radiative decay pathways at each step. Most importantly, such codoped NCs with multiple emission channels hold a high potential to be applied in a wide range of applications, including multiplexed biological labelling and sensing, multi-channel photodetectors, stimuli-responsive inks for coding, encryption and decryption, and photon management devices in the future.

Control of Excitonic Spin States via Magnetic Interactions with Transition-Metal Dopants in Ruddlesden-Popper Hybrid Perovskites Jonathan Zerhoch, Timo Neumann, Martin S. Brandt, Jonathan Finley, Andreas Stier and Felix Deschler; Walter Schottky Institut and Physik-Department, Technische Universität München, Germany

Combining the advantageous electrical and optical properties of semiconductors with magnetic characteristics gives access to extraordinary phenomena and applications. Fully inorganic dilute magnetic semiconductors (DMS) have been known for decades, which show diverse functionalities like control of magnetism by electrical fields. The material class of DMS is obtained by introducing a substantial number of magnetic ions to an otherwise non-magnetic host semiconductor.
Due to their outstanding optoelectronic properties and high defect tolerance, organo-metal halide perovskites form an ideal system for efficient magnetic doping. We produced a selection of magnetic perovskites using simple solution processing techniques by doping of the host material, Ruddlesden-Popper hybrid perovskite ($(PEA)_2PbX_4$ with X = Cl, Br, I), with different magnetic ions like Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+} and Eu^{2+}. We investigated the influence of both halides and magnetic impurities on the long-range magnetic ordering of the materials with respect to the structural and optical properties. We investigate how localized excitons couple with the magnetic moments of the introduced impurities by detecting a dependence of the emitted lights polarization on the magnetization. We perform structural, magnetic, optical and magneto-optical temperature-dependent measurements to verify a successful magnetic doping of the perovskite and to show how photoluminescence and magnetization properties relate.

Illuminating the Structural and Optical Changes Behind Photo-Induced Degradation in Mixed-Halide Perovskites Gabriel C. Halford, Annie Gomez, Jill Mankoff and Rebecca Belisle; Wellesley College, United States

While mixed-halide perovskites are ideal for use in tandem solar cells due to their tunable band gap, they are limited by reversible photo-induced degradation. While the impacts of photo-induced segregation on optical properties have been well documented, the underlying impacts on perovskite structure remain less clear. Structural changes that result in optical changes may come from halide migration and subsequent segregation in the perovskite. Utilizing grazing-incidence wide angle x-ray scattering (GIWAXS), we have observed in situ reversible structural changes that occur over time scales of 30 minutes to an hour in mixed-halide methylammonium perovskite thin films as a result of light soaking at approximately 1 sun intensity. Looking at a range of different compositions with varying ratios of bromine to iodine, we are able to observe the kinetics of photo-induced unmixing of mixed-halide perovskites and the formation of multiple distinct crystalline phases.. Data taken in the dark after illumination demonstrates the reversibility of this process, as the crystal structures relax back to approximately their original structure. Analyzing the x-ray diffraction data, we see multiple distinct phases we quantify as bromine-dominated and iodine-dominated crystal structures. Correlating our x-ray diffraction results with in situ photoluminescence, we are able to present a timeline of photo-induced halide segregation that captures changes in local structure with observed optoelectronic performance. Photoluminescence shifts occur during photo-induced halide segregation such that majority iodine films shift toward lower intensity, lower energy peaks and majority bromine films shift toward higher intensity, lower energy peaks. While optical changes appear to occur before structural changes are visible in the GIWAXS data, both optical and structural changes saturate at time scales approaching one hour. Looking forward we may be able to demonstrate whether this is a surface or a bulk phenomenon. Understanding the origins of the structural changes behind photo-induced degradation could help find strategies to mitigate the optical changes it causes to produce more stable mixed-halide perovskite solar cells. Overall, this work demonstrates more fully the correlation between structural and optical changes related to light-induced halide migration and gives the possibility of finding targeted solutions to minimizing degradation.

High Affinity Polysalt Ligands Promote Long Term Stability While Enhancing the Quantum Yields of $CsPbBr_3$ Nanocrystals Sisi Wang, Liang Du and Hedi M. Mattoussi; Florida State University, United States

Recently, cesium lead halide perovskite quantum dots (PQDs) have generated tremendous interests, due to the great promise they offer for use in optoelectronic applications. However, their poor colloidal stability, which can be traced to the ionic nature of the crystal cores and the high desorption rates of the native ligands, has impeded progress in fundamental research and slowed integration of such materials in devices. Developing novel surface ligands with strong coordination to both passivate surface traps and enhance fluorescence performance, while improving colloidal stability is urgently needed. Here, we detail the synthesis of a new family of multifunctional polymer ligands and their use for surface engineering of the $CsPbBr_3$ nanocrystals. The ligand synthesis relies on the ring opening reaction between distinct nucleophiles and poly(isobutylene-alt-maleic anhydride), PIMA. The modular ligand stoichiometrically displays multiple ammonium and/or imidazolium anchors for coordination onto PQD surfaces, along with several alky chains with different length to promote affinity to various organic solvents. The results show that the PQDs coated with those polysalts exhibit great colloidal stability and significantly enhanced photoluminescence. The coating also allows the resulting colloids to be dispersed a wide range of solvent conditions, including ethanol and methanol, while maintaining strong fluorescence and preserving the nanocrystal integrity after ligand substitution.

Polar Solvent Mediated Shape Control of $CsPbBr_3$ Perovskite Nanocrystals for Applications in LEDs Arkajyoti Chakrabarty, Parvez Akhtar, Samridhi Satija, Upanshu Gangwar, Jitendra Kumar, Madhusudan Singh and Sameer Sapra; IIT Delhi, India

Nanocrystals (NCs) with different shapes, are of tremendous interest to material chemists, and precise control of their shapes and sizes through colloidal synthetic routes, with further solution-processability of the NCs, provides us with a great opportunity to tune their optoelectronic behaviour for advanced applications.[1] Interestingly, polar solvents are known to play crucial roles in determining the shapes of $CsPbBr_3$ perovskite NCs owing to the prevailing anisotropic growth conditions. However, to induce polar environment in the perovskite synthesis, a suitable precursor soluble in the desired polar solvent, is primarily required. In this work, we describe an efficient, MeOH-soluble steroidal Cs-precursor: cesium cholate and the different shapes of $CsPbBr_3$ NCs (nanorods, nanocubes and nanoplatelets) obtained from it, utilizing miniscule amount of polar solvents (methanol and methanol-water) in conjunction with commonly used 1-octadecene solvent and varying the reaction temperatures (90 °C and 180 °C). The resulting NCs exhibit very high photoluminescence (PL) quantum yields (94% for nanoplatelets and 96% for nanocubes), due to mitigation of Br vacancies by large cholate molecules, slowing down the complex nucleation and lattice construction processes in the synthetic pathway.[2] To study the application of these luminophores for application in perovskite light emitting diodes (PeLEDs), powdered $CsPbBr_3$ nanocubes were dispersed in toluene at different concentrations to prepare inks. Inks were spin-coated at different speeds (500, 1000 and 1500 rpm) and film quality was optimized to produce uniform and pinhole free films on an ITO substrate. Thin films produced at optimal deposition conditions and ink compositions were characterized using thin film photoluminescence measurements at 325 nm. A sharp and highly intense peak at 514 nm was observed. Initial device fabrication employing a spin-coated hole transport layer (poly (9-vinylcarbazole), and an electron transport layer (2,2′,2"-(1,3,5-Benzinetriyl)-tris(1-phenyl-1-*H*-benzimidazole)) produced promising initial results. These initial results with perovskite nanocubes based thin films invite more studies of complete devices, possibly with other nanomaterial geometries (nanorods and nanoplatelets).

Chemically-Casted MoO_3 Hole Transport Active Layer for Perovskite Solar Cells Taliya Gunawansa, Messaoud Bahoura and Sangram K. Pradhan; Norfolk State University, United States

Perovskite solar cells (PSCs) are promising contenders in the solar cell technology market having achieved photo-conversion efficiencies greater than 25%. The role of the hole transport layer in perovskite solar cells is essential for incredible

enhancement of their significant photo-conversion efficiency. Iron oxide is one of the interesting hole transport materials that can potentially improve the performance; however, the frequently used chemical synthesis technique of the micaceous iron oxide (MiO) precursors is very toxic, harmful and time-consuming. Molybdenum dioxide (MoO_3) is a commonly studied hole transport layer utilized in perovskite solar cell; This study analyzes a chemically casted process preferably hot-casting technique to prepare a non-toxic molybdenum dioxide precursor that would fabricate a highly effective and densely packed MoO_3 films. Various temperatures below 100 ^oC results in intermittent deposition of the MoO_3 films. When the hot-casting temperature is increased, the MoO_3 thin film are uniformed and resulted in greater charge extraction and insignificant light soaking. Photoluminescence spectroscopy (PL), ultraviolent-visible spectroscopy (UV-VIS), and scanning electron microscopy (SEM) are the characterization techniques utilized to observe the opto-electronic properties of the MoO_3 films. The capacitance, frequency dispersion, and leakage current measurements display stable performance of the MoO_3 perovskite solar cells.

Material Development And Emission Spectroscopy of Mn Doped CsPbCl3 Bulk Crystals and Nanoparticles for Light Source Applications Uwe Hommerich[1], Jihaad Barnett[1], Kesete Ghebreyessus[1], Al Amin Kabir[1], Khalid Hampton[1], Samuel Uba[1], Ikemefuna Uba[1], Demetris Geddis[1], Clayton S. Yang[2], Sudhir Trivedi[2], Seth Fraden[3] and S. Ali Aghvami[3]; [1]Hampton University, United States; [2]Brimrose Technology Corporation, United States; [3]Brandeis University, United States

Manganese doped inorganic halide perovskites continue to be of current interest for applications in light emitting devices and down-converters in solar cells. In this work we prepared Mn doped $CsPbCl_3$ (Mn: CPC) bulk crystals and nano-particles (NPs) and compared their emission properties. Bulk crystals were grown from the melt by vertical Bridgman technique and NPs were synthesized using a microwave assisted method. Under ultra-violet excitation at 350 nm, bulk crystal and NPs of Mn: CPC exhibited a broad orange emission centered at ~605 nm at room temperature. The broadband emission was assigned to the intra-3d transition $^4T_1 \rightarrow {}^6A_1$ of Mn^{2+} ions incorporated in the CPC host lattice. The Mn^{2+} emission lifetimes were nearly exponential with values of 1.07 ms for NPs and 0.73 ms for the bulk crystal. Mn: CPC NPs also showed exciton emission peaking at ~402 nm, whereas the bulk crystal exhibited no significant emission near the band edge. Instead, the bulk material of Mn: CPC revealed a weak below-gap emission in the 450-550 nm region suggesting the existence of defect states. The excitation spectra for the orange Mn^{2+} emission from Mn: CPC NPs and bulk crystals were significantly different indicating distinct excitation pathways. The excitation spectrum of the orange Mn^{2+} emission for Mn: CPC NPs showed excitonic structure similar to the absorption spectrum suggesting energy transfer from excitons to Mn^{2+} ions. In contrast, UV excitation was less efficient for the bulk Mn: CPC crystal and the excitation was dominated by well defined below-gap excitation bands centered at ~425 and ~530 nm. More details of the material preparation emission spectroscopy, and initial hybrid LED experiments will be discussed at the conference.

F.EL02.13.09

Red Light Emitting Ytterbium Activated $Sr_3Al_2O_6$ Nanophosphor for LED Applications Chitra Mallela; Tumkur University, India

Present study analyses the salient features of the newly synthesized phosphor powders of 1, 3, 5, 7, 9 and 11 molar concentrations of Ytterrbium activated Strontium Aluminate by solution Combustion method using Urea. The prepared phosphors were calcined at 950degree celcius for 4 hours. The Powder X-ray diffraction (PXRD) profiles of nanophosphors showed crystalline face centered cubic phase. The average crystallite sizes of the phosphors were in the range 34 to 48 nm. The samples showed pores and voids on their surface that formed by the escaping gases during the combustion method. The morphology showed the inherent nature of combustion process. The Scanning electron microscope (SEM) images showed non-uniform and irregular shapes of the particles. The Particle sizes were further confirmed by Transmission electron microscope (TEM). Energy dispersive analysis of X-ray techniques were used to study the structural characteristics of calcined phosphors. Fourier infrared spectral studies were carried out to evaluate the stretching and vibrational bonds in the product. They showed an absorption peak at 1456 cm^{-1} that indicates the formation of crystallized Strontium Aluminate and a sharp peak at 3670 cm^{-1} due to the presence of AlO_4 group in the powders. Energy dispersive X-ray analysis (EDAX) with SEM image, revealed the uniform distribution of Yb^{3+} ions. The energy band gaps of the prepared phosphors from Kubelka-Munk plots of the Diffused reflectance Studies (DRS) were found to be in the range 5.31 eV to 5.78 eV. The Photoluminescence studies showed an emission peak at 708 nm when phosphors were excited with 355 nm. All the phosphors were found to emit red light as their Commission Internationale de L'Eclairage (CIE) co-ordinates have fallen in red region of chromaticity diagram. The average correlated color temperature of the phosphors was found to be 3950 degree Kelvin.

Support for the Self-Trapped-Exciton Hypothesis in Multi-Layered (n > 1) Two-Dimensional Lead Iodide Perovskites Watcharaphol Paritmongkol, Eric Powers, Nabeel Dahod and William Tisdale; Massachusetts Institute of Technology, United States

Two-dimensional (2D) lead halide perovskites have been shown to exhibit broadband or white-light emission under certain conditions. Broadband emission in lead iodide 2D perovskites has been alternately attributed to self-trapped excitons (STEs) or permanent structural defects and/or impurities. Here, we investigate the photophysical characteristics of broadband emission in six different multi-layered (n > 1) 2D lead iodide perovskites as a function of sample temperature from 5 K to 300 K. We distinguish shallow defect-associated emission from a broad near-infrared (NIR) spectral feature, which we assign to the STE. Sub-gap photoexcitation experiments and NIR transient absorption spectroscopy rule out permanent structural defects as the origin of this feature. When we varied the thickness (n = 2, 3, 4), A-site cation (methylammonium vs. formamidinium), and organic cation spacer (butylammonium vs. hexylammonium vs. phenylethylammonium), we found that the temperature dependence of broad NIR emission was strongly correlated with both the strength of electron-phonon coupling and the extent of structural deformation of the ground state lattice, strongly supporting the assignment of this spectral feature to a STE.

F.EL02.13.12

Thermal Impact on InAs Quantum Dots Covered by Different Capping Layers in GaAs/AlGaAs Structures Georgiy Polupan[1], Ricardo Cisneros Tamayo[2], Tetyana V. Torchynska[1], Íngrid. J. Íngrid. J. Guerrero Moreno1[1] and Arturo Escobosa Echavarria[3]; [1]Instituto Politecnico Nacional, Mexico; [2]Universidad Politécnica del Valle de México,, Mexico; [3]CINVESTAV-IPN, Mexico

InAs quantum dots (QDs) embedded in MBE grown GaAs/$Al_{0.30}Ga_{0.70}As$/AlGaInAs heterostructures have been investigated in as grown state and after thermal annealing at 640ºC or 710ºC for two hours. Two types of QD structures with the different compositions of AlGaInAs capping layers (GaAs (#1) or $Al_{0.10}Ga_{0.75}In_{0.15}As$ (#2)) and the same composition of buffer layers ($In_{015}Ga_{0.85}As$) are compared and studied by means of photoluminescence (PL), X-ray diffraction (XRD) and high resolution HR-XRD methods. XRD and HR-XRD techniques are applied with the aim to control the crystal structures, the material compositions and elastic strains in quantum well (QW) layers.

The highest PL intensity, smaller PL band half width and lower energy of ground state (GS) emission are detected in the structure with the $Al_{0.10}Ga_{0.75}In_{0.15}As$ capping layer. Thermal annealing leads to the shift of PL spectra into higher energy range and the value of this shift is more essential in the structure with the $Al_{0.10}Ga_{0.75}In_{0.15}As$ capping layer as well.

The variation of GS emission peak versus temperature has been monitored within the range of 10-450K for as grown and annealed states and it compared with temperature shrinkage of band gap in the InAs and GaAs bulk crystals. It permits to reveal the QD composition that in #2 was closer to InAs than in #1. Finally, the reasons of PL spectrum transformation at annealing, the mechanism of PL thermal decay, and the advantages of the QD structure with strain reduced $Al_{0.10}Ga_{0.75}In_{0.15}As$ capping layer have been analyzed and discussed. The composition variation of QDs and QWs at annealing has been modeled using the simulation of HR-XRD results with Xpert Expitaxy software.

F.EL02.13.14

Superparamagnetic Properties of Metal-Free Nitrogen Doped Graphene Quantum Dots Synthesized by Pulsed Laser Ablation Muhammad Shehzad Sultan[1], Vladimir I. Makarov[1], Muhammad Sajjad[2], Wojciech Jadwisienczak[3], Brad R. Weiner[1] and Gerardo Morell[1]; [1]University of Puerto Rico - Río Piedras, United States; [2]Indiana University Northwest, United States; [3]Ohio University, United States

In this study, we developed a novel approach to synthesize high-quality metal-free Nitrogen-doped graphene quantum dots (N-GQDs) with high quantum yield, via irradiation of s-triazene in a solution with benzene by using pulsed laser. The TEM, HRTEM, XPS, XRD, Raman spectroscopy and FTIR were carried out to observe the morphology, size distribution, crystalline structure and to prove successful doping of GQDs with nitrogen atoms. Furthermore, for the first time, to our knowledge, their magnetic properties were investigated. The results indicate that N-GQDs exhibit superparamagnetic behavior. The specific size, shape and zigzag edge structure of N-GQDs were considered to explain the origin of the observed magnetism. The magnetization dependence led to estimating the N-GQD material magnetic permeability for different ambient temperatures. From the zero-field-cooled (ZFC) and field-cooled (FC) magnetization measurements, carried out at 50 Oe magnetic field strength, we estimated the blocking temperature T_B to be around 300 K. Based on the experimental data analysis, the magnetic permeability, number of correlated spins per single N-GQD, and number density of superparamagnetic N-GQD per gram of material were estimated. The excellent superparamagnetic properties together with optical properties

manifested by N-GQDs have the potential to lead to high performance biomedical applications.

F.EL02.13.15

Highly Stable Luminescent Encapsulation Material Using Quantum Dot/Siloxane Hybrid for Reliable and Wide Color Gamut Light-Emitting Diode Junho Jang, Da-Eun Yoon, Doh C. Lee and Byeong-Soo Bae; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Semiconducting nanocrystals, also known as quantum dots (QDs), are a promising color converting materials for next-generation display application due to their unique photophysical properties such as size-dependent color tunability, narrow spectral bandwidth, and high photoluminescence (PL) quantum yield (QY). However, the vulnerability of QDs to oxygen and moisture is a huge obstacle to practical applications. The commercialized QD for display has been a form of color converting QD films in liquid crystal display (LCD) backlight unit (BLU) using blue light-emitting diode (LED) (*i.e.*, On-Surface type), where QDs were physically blended in polymer matrixes sandwiched between two barrier layers. It is more desirable for LCD BLU using LEDs encapsulated the QDs directly into the packaging (*i.e.*, On-Chip type) in terms of performance, amount of QDs, and cost. Nevertheless, LEDs that are directly encapsulated by QDs have not been used in display applications due to their fatal instability. Therefore, reliable LEDs using highly stable luminescent encapsulation material that contains uniformly dispersed QDs in optical resin should be developed without additional protecting layers (such as SiO_2 or Al_2O_3) and ligand-exchange processes.
Herein, we developed luminescent LED encapsulation material (TSE-QD) using CdSe/CdZnS core/shell QDs (passivated by oleic acid) dispersed in a thermally resistant sol-gel derived siloxane matrix with high refractive index (> 1.57) [1,2]. The TSE-QD was fabricated via hydrosilylation of QD dispersed siloxane resin that was synthesized via *in situ* sol-gel reactions of silane precursors in the presence of QDs. The QDs were uniformly distributed in a linear-structured siloxane matrix in which functional groups of siloxane matrix is chemically cross-linked with ligands of the surface on QDs, and retained their initial optical properties during the fabrication processes [3]. Notably, we achieved dramatically enhanced thermal (at 120 °C in ambient air) and chemical stability (in acid or base solutions and alcohol) without additional barrier films and ligand-exchange process. We demonstrated a natural-white emitting LED using a blue LED chip directly encapsulated (*i.e.*, On-Chip type) by yellow-emitting TSE-QD that consist of red and green QDs in a siloxane matrix. Fabricated white LED exhibited wide color gamut (116% of NTSC 1931), excellent reliability (under 85 °C & 85% relative humidity), and high photostability (under continuous blue light irradiation).

F.EL02.13.16

$Cs_4Cd_{1-x}Mn_xBi_2Cl_{12}$—A Vacancy Ordered Halide Perovskite Phosphor with High Efficiency Orange-Red Emission Noah P. Holzapfel[1], Jackson Majher[1], T. Amanda Strom[2], Curtis Moore[1] and Patrick Woodward[1]; [1]The Ohio State University, United States; [2]University of California Santa Barbara, United States

The structural, optical, and magnetic properties of the vacancy-ordered quadruple perovskites $Cs_4CdBi_2Cl_{12}$ and $Cs_4MnBi_2Cl_{12}$ and their solid solution have been investigated. Both compounds are found to crystallize with *R*-3*m* space group symmetry that arises from ordering of Bi^{3+}, Mn^{2+}/Cd^{2+}, and cation vacancies into layers that run perpendicular to the <111> direction of the cubic perovskite structure. Magnetic measurements reveal that $Cs_4MnBi_2Cl_{12}$ is paramagnetic down to 2 K with a Weiss constant of −2.88(3) K and an effective moment of 5.840(1) μ_B. This compound exhibits weak orange-red luminescence, which involves Bi^{3+} ions absorbing near UV photons followed by energy transfer to Mn^{2+} ions and finally radiative decay that is attributed to a spin-forbidden $^4T_1(G)$ to $^6A_1(S)$ d–d transition. The emission peak is centered near 605 nm and has a full-width-half-maximum of ~90 nm and a photoluminescent quantum yield (PLQY) of ~ 4%. The isostructural $Cs_4CdBi_2Cl_{12}$ is neither magnetic nor does it show detectable photoluminescence at room temperature. Replacing Mn^{2+} with Cd^{2+} to form $Cs_4Cd_{1-x}Mn_xBi_2Cl_{12}$ leads to a zero-dimensional electronic structure that inhibits energy migration to defect sites where non-radiative decay can occur, increasing the room temperature PLQY to 57% in the x = 0.27 sample. $Cs_4Cd_{1-x}Mn_xBi_2Cl_{12}$ phosphors are easily synthesized from solution, free of rare-earth ions, and possess emission spectra that compare favorably to narrow-band red emitting phosphors based on Eu^{2+} ions.

F.EL02.13.17

Fluorene-Based Organic Phosphorescent Materials for LECs C KY, Maxime Remond, Donghwan Kim and Eunkyoung Kim; Yonsei University, Korea (the Republic of)

Fluorene-based organic phosphorescent materials (OPMs) were explored for organic light-emitting electrochemical cells

(LECs) taking advantages of their tunability in color and film processibility. TO tackle the problem of the apparent low emission efficiency of OPMS, compared to inorganic or organometallic materials, fluorene unit was designed as a π-bridge between halogen and n-π transition groups. These OPMs provided a long-lived phosphorences at film state, possibly due to enhanced intersystem crossing (ISC) to the triplet state in the optimized structure. Thus OPMs were applied to light-emitting cells (LECs) along with a host and electrolyte, to show the highest luminescence among the organic phosphorescent LECs up to date. Synthesis of OPMs, mechanism of enhanced emission, and fabrication details on LECs will be presented.

F.EL02.13.18

Synthesis of Efficient Blue Emitting $CsPb(Br/Cl)_3$ Nanoparticles via Post-Treatment with Short Organic Ligands and LED Fabrication Jang Kyung Yeon, Jinwoo Park and Tae-Woo Lee; Seoul National University, Korea (the Republic of)

Perovskite nanoparticles (PeNPs) are promising emitters owing to their high color purity, low-cost synthesis, and facile wavelength control with halide composition control. However, chloride-based blue-emitting colloidal PeNPs have suffered from low photoluminescence quantum efficiency (PLQE) due to chloride-induced defect states. Their low PLQE hinders their use of blue-emitting devices.
In this work, we propose a method to improve the efficiency of blue PeNPs. At first, blue-emitting perovskite was synthesized by the hot injection method. Near Unity PLQE of as-synthesized PeNPs was obtained. For the efficient perovskite light-emitting diodes (PeLEDs), additional washing steps are required to remove excess ligands on the surface. But after washing steps, the PLQE rapidly decreased to ~50% because of surface defects.
A simple post-treatment process using short organic ligands solution was done after washing steps. PLQE increased again because the halide anions passivate defect sites. Moreover, those short organic ligands do not impede charge injection. By these methods, highly efficient blue-emitting PeNPs with PLQE > 92 % and high device efficiency of 2% was obtained.

F.EL02.13.19

Water Passivation of Perovskite Nanocrystals Enables Air-Stable Intrinsically-Stretchable Color-Conversion Layers for Stretchable Displays Huanyu Zhou[1], Jinwoo Park[1], Yeongjun Lee[1], Jae-Man Park[1], Jin-Hoon Kim[2], Joo Sung Kim[1], Hyeon-Dong Lee[1], Seung Hyeon Jo[1], Xue Cai[1], Lizhu Li[3], Xing Sheng[3], Hyung Joong Yun[4], Jin-Woo Park[2], Jeong-Yun Sun[1] and Tae-Woo Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of); [3]Tsinghua University, China; [4]Korea Basic Science Institute, Korea (the Republic of)

Despite organic light-emitting diode (OLED) technology has already left an indelible mark on the display industry, conventional OLEDs are still susceptible to degradation when exposed to air. A greater hurdle is to achieve the stretchable OLED as protecting devices from the penetration of moisture and oxygen is even more difficult under stretching. Here, we propose an air-stable intrinsically stretchable display without using any encapsulations by integrating a stretchable light-emitting device (SLED) with a stretchable color conversion layer that contains perovskites nanocrystals (PeNCs). PeNCs normally decay when exposed to air; counterintuitively, the moisture-assisted surface passivation of PeNCs is first observed. This work is believed to stimulate considerable research on fundamental aspects of PeNCs and furthermore into the practical applications both in academia and industries. The above-mentioned SLED can also open new ways toward intrinsically stretchable OLEDs.

F.EL02.13.20

***In Situ* Fabrication of Highly Luminescent Halide Perovskite Thin Films Incorporating Organic Dispersing Agent** Eojin Yoon and Tae-Woo Lee; Seoul National University, Korea (the Republic of)

Recently, lead halide perovskite nanoparticles became promising candidates for light emitters due to narrow full-width at half maximum (FWHM), solution processability, easily tunable bandgap.[1] Excitons are well confined with the aids of long passivating ligands promoting radiative recombination, thus, lead halide perovskite nanoparticles exhibit high photoluminescence quantum yield (PLQY). [2] However, the synthesis of perovskite nanoparticles is complicated requiring several centrifugations and production yield is low because only the small amount of precipitate is utilized by reprecipitation method.
So, we took *in-situ* strategy for synthesizing perovskite nanoparticles by incorporating bulky ligand, phenyl ethyl ammonium bromide (PEABr).[3] To achieve stable in situ fabricated perovskite nanoparticles, dispersion of PEABr is essential because PEABr aggregates form local quasi-2D structure.[4] Here, we successfully synthesized perovskite nanoparticles by exploiting crown additive of 1,4,7,10,13,16-Hexaoxacyclooctadecane (18-crown-6) as a dispersing agent. From UV-vis spectroscopy, it was confirmed that low n phases (~440 nm) considerably decreased with 18-crown-6 and the average lifetime also enhanced due to reduced defect sites. Moreover, temperature-dependent PL represented increased exciton binding energy from 24.6 to

63.9 (meV) owing to the fine dispersion of PEABr and dielectric confinement effect. Finally, with optimized concentration, highly bright perovskite films with maximum PLQY of 93.036 % could be achieved, which is 47 times higher than pristine films.

Core-Shell Structure Perovskite Nanoparticles with Atomic Surface Passivation for Highly-Efficient Pure-Red Emitting Perovskite Light-Emitting Diodes Jinwoo Park, Sinil Choi, Sungjin Kim, Joo Sung Kim and Tae-Woo Lee; Seoul National University, Korea (the Republic of)

Perovskite nanoparticles (PeNPs) is attractive next-generation sources for light-emitting diodes (LEDs) due to their efficient luminescent, solution processability, tunable bandgap and extremely high color purity which is superior to conventional light emitters (e.g. organic emitters, traditional quantum dots). However, due to halide segregation, emmision wavelength shift while LED operation and precise control of emission wavelength is limited. Here, we develop facile atomic surface defect passivation method exploited post-synthesis treatment using high bandgap perovskite precursor. With this strategy, we synthesized color-stable and pure-red-emitting $CsPbI_3$ PeNPs with 630 nm of peak emission wavelength with core-shell structure. Highly efficient PeNP LEDs without electroluminescence wavelength shift was also demonstrated.

Late News: Maximizing the Photoluminescence Intensity in Quasi 2D Perovskites Through Surface Passivation of Defect States - Yukta and Soumitra Satapathi; Indian Institute of Technology Roorkee, India

Quasi two-dimensional (2D) perovskites are currently considered as materials of choice for light emitting diodes (LEDs) due to their unique optoelectronic properties such as strong exciton binding energy, multiple quantum well structure, and reasonable ambient stability for practical applications. Tremendous progress has been achieved in 2D perovskites LEDs in terms of external quantum efficiency (EQE) (~17%), luminescence (6785 cd/m^2) and stability through compositional and device engineering. However, the excessive surface defect states generated due to the reduced crystal size, the presence of un-coordinated Pb^{+2} ions or shallow vacancy defects generated by MA or halide ions at the surface and grain boundaries, limits the radiative recombination and in turn the electro-luminescence (EL) efficiency of the LEDs. It has been realized that surface passivation with suitable organic/inorganic moieties can play a vital role in overcoming the adverse effect of defect states through their interaction with uncoordinated ions and can improve the stability.
In the present work, we have chosen n=4 composition quasi-2D perovskite $(BA)_2(MA)_3Pb_4Br_{13}$ films as emissive layer by optimal phase engineering and have shown the order of magnitude enhancement of radiative emission after passivating them with two different molecules namely- triphenyl phosphine oxide (TPPO) and an insulating polymer polymethyl methacrylate (PMMA). Both the steady state and time resolved study confirm up to 400% enhancement in fluorescence intensity and improved average lifetime (=19.4 ns) after surface passivation. Additionally, the effect of passivating agents on film morphology and radiative emission efficiency is studied in details. Also, the interaction mechanism between layered perovskite and passivating agents has been probed with FTIR spectroscopy, XPS and KPFM study. Our systematic investigation with detailed mechanistic study will pave the way for further development of the highly efficient LEDs.

Late News: Quantum Confinement in Type I Heterostructure of Hybrid Lead Halide Perovskite Embedded in Organic Matrix Amrita Dey[1,2], Shivam Singh[2] and Dinesh Kabra[2]; [1]Ludwig-Maximilians-Universität, Germany; [2]Indian Institute of Technology Bombay, India

The type I heterostructure forms between Organic semiconductor molecule (4,4'-bis[9-dicarbazolyl]-2,2'-biphenyl [CBP] and bathocuproine [BCP]) and methylammonium lead halide ($MAPbX_3$), assists easy growth of perovskite nanocrystals (PNCs) in an organic matrix. Herein, we present the modulation of electronic states of $MAPbX_3$ PNCs (MA = $CH3NH3^+$ and X= Br^- and I^-) as a function of crystallite size. This results in the growth of $MAPbX_3$ PNCs of tunable sizes from ~110 nm to ~10 nm in the organic semiconductor matrix. A blue shift is observed in the photoluminescence peak (PL_{max}) energy over a range of ~200 meV for $MAPbI_3$ PNCs embedded in the BCP matrix. However, PL_{max} energy tunes over ~32 meV only with a similar volumetric concentration in the case of $MAPbBr_3$ PNCs in the same BCP matrix. Moreover, the PL blue shift is even lower in the case of the CBP matrix in comparison with the BCP matrix for both the perovskites. This discrepancy could be resolved by determining the resultant crystallite size using X-ray diffraction studies and the Debye–Scherrer formula. Results about the blue shift in the PL peak can be explained using the classic particle-in-a-box versus excitonic Bohr radius model under a weak confinement regime.

Two-Dimensional Layered Germanium Monochalcogenides as Anode in Metal-Ion Batteries Shakir Bin Mujib, Maren Ellis, Sophie Justus, Porter Herold and Gurpreet Singh; Kansas State University, United States

In this work, we investigate two-dimensional (2D) sheets of germanium sulfide (GeS) and germanium telluride (GeTe) as promising high-capacity and stable materials for energy storage. GeS and GeTe with layered structures are prepared via a simple liquid-phase exfoliation approach. As-synthesized 2D nanosheets can effectively increase the electrolyte-electrode interface area and facilitate metal ion transport. As a result, GeS and GeTe nanosheets deliver a high areal capacity of 1.76 mAh cm^{-2} and 1.05 mAh cm^{-2}, respectively as anodes in lithium-ion batteries (LIBs). Further analysis of GeS and GeTe in sodium-ion batteries (SIBs) and potassium-ion batteries (KIBs) suggest that layered germanium monochalcogenides can be potential anodes in other metal-ion batteries.

Two-Dimensional Nanosheet Inks Using Zwitterion Dispersants for Biocompatible and Scalable Inkjet Printing Hyeokjung Lee, Seung Won Lee, Chanho Park, Kyuho Lee and Cheolmin Park; Yonsei University, Korea (the Republic of)

Inkjet printing of two-dimensional (2D) transition metal dichalcogenide (TMD) nanosheets fabricated by liquid-phase exfoliation (LPE) allows simple, low-cost, and mass-producible photo-electronic devices. Many LPE processes involving toxic and environmentally hazardous solvents; however, dispersants have restricted the extent of applications of 2D-TMD inks. Herein, various 2D-TMD nanosheets, including MoS_2, $MoSe_2$, WS_2, and WSe_2, in addition to few-layered graphene, are inkjet-printed using a LPE process based on zwitterionic dispersants in water. Zwitterions with cationic and anionic species are water-soluble, while alkyl chain moieties associated with two ionic species adhere universally on the surface of TMD nanosheets, resulting in high throughput liquid exfoliation of the nanosheets. The zwitterion-assisted TMD nanosheets in water are successfully employed as an ink without the need for additives to adjust the viscosity and surface tension of the ink for use in an office inkjet printer; this gives rise to A4 scale, large-area inkjet-printed images on diverse substrates, such as metals, oxides, and polymer substrates patchable onto human skin. The development of mechanically flexible, biocompatible-printed arrays of photodetectors with pixelated $MoSe_2$ channels and conductive graphene electrodes on a paper exhibits a photocurrent ON/OFF ratio of approximately $10^{3.8}$ and photocurrent switching of 500 ms.

Effect of Bilayer Growth on the Thermoelectric Properties of Sb_2Te_3 / $Bi_{0.4}Sb_{1.6}Te_3$ Thin Film Andrew W. Howe, Mamadou T. Mbaye, Sangram K. Pradhan and Messaoud Bahoura; Norfolk State University, United States

Thermoelectric devices based on Sb_2Te_3 and related alloys are of great interest to academia, industry, and government due to their efficiency in low-temperature applications such as micro-heating and small-scale refrigeration. The search for high performing thermoelectric devices is dominated by manipulating the electronic structure to boost the power factor through an increase in the density of states and/or reduction of the lattice thermal conductivity to maintain a large enough temperature

gradient. Superlattice structures are long heralded as potential candidates to increase the thermoelectric power factor as well as significantly reduce the lattice thermal conductivity. In this report, we compare the thermoelectric properties of bilayer p-type Sb_2Te_3 / $Bi_{0.4}Sb_{1.6}Te_3$ film and single layer p-type $Bi_{0.4}Sb_{1.6}Te_3$ film of the same thickness. Preliminary Hall effect measurements showed that the carrier concentration of our bilayer and $Bi_{0.4}Sb_{1.6}Te_3$ samples fall within the desired values common to heavily doped semiconductors. Carrier mobility and electrical conductivity are higher for our bilayer than the single-layer film. We noted a significant increase in the Seebeck coefficient values of our bilayer, 202 μV/K compared to 130 μV/K for our single-layer film. NanoTR thermoreflectance measurements revealed a significant reduction in the overall thermal conductivity of our bilayer system compared to our single-layer film. The low thermal conductivity reduction can be associated with, not only species intermixing -which allows phonon scattering events- interfacial boundary scatterings. When these observations are combined into a device, we would expect to see a great jump in the overall efficiency while maintaining the ease of fabrication allowing for quick scaling of production.

Dimensionality Effects on Drift Resistivity of Nanoscale Phase-Change Memory (PCM) Cells in Reset State Kazimierz J. Plucinski; Military University of Technology, Poland

Although the device physics related to the operation of PCM (Phase change Memory) have been widely studied since its discovery in the 1960s, questions relating to the nature of the physical principle responsible for the resistivity drift is still controversial [1, 4].
These problems are deepening at the transition to the nanoscale in the construction of PCM memory [2, 3].
Drift resistivity of the PCM in reset state in terms of subthreshold conductivity is analyzed.
This subthreshold conductivity is analyzed with respect to nanoscaling effects, especially:
the contribution of tunneling and trapping to electrical transport;
contribution of ballistic transport and diffusive transport;
analysis of the scattering in relation to dimension and mean free path in amorphous GST;
limitation of Poole-Frankel approach.

The results are verified on the base of present models of the subthreshold conduction and drift resistivity in reset state of the PCM memory [e.g. 4, 5].

Vacancy Defects Induced Changes in the Electronic and Optical Properties of NiO Studied by Spectroscopic Ellipsometry and First-Principles Calculations Kingsley O. Egbo[1], Chao Ping Liu[2], Chinedu E. Ekuma[3] and Kin Man Yu[1]; [1]City University of Hong Kong, Hong Kong; [2]Shantou University, China; [3]Lehigh University, United States

Native defects in semiconductors are known to play an important role in determining their optoelectronic properties. Nickel oxide (NiO) is one of the few wide gap oxide semiconductors broadly applied as the hole transport layer in many optoelectronic devices. NiO exhibits *p*-type conductivity and its conductivity is believed to be controlled by Ni vacancy acceptors. Herein, we present a systematic study comparing the optical and electronic properties of *p*-type oxygen-rich NiO with Ni vacancies (NiO:V_{Ni}) and insulating Ni-rich NiO with O vacancies (NiO:V_O) and stoichiometric NiO. The optical properties were obtained by spectroscopic ellipsometry while valence band spectra were probed by high-resolution X-ray photoelectron spectroscopy. The experimental results are directly compared to first-principles DFT + *U* calculations. The absorption spectra for the NiO:V_{Ni} sample show significant defect-induced features below 3.0 eV compared to NiO, and NiO:V_O samples. The increase in sub-gap absorptions in the NiO:V_{Ni} can be attributed to gap states observed in the electronic

density of states. Computational results confirm that gap states in NiO:*V*o are predominantly Ni 3*d* states while those of NiO:V_{Ni} is composed of both the Ni 3*d* and O 2*p* states. This work reveals the relations between native vacancy defects and optical properties of NiO and provides insights that would aid in designing optoelectronic devices utilizing NiO with native defects.

Solvent Toolkit for Electrochemical Characterization of Hybrid Perovskite Films Jason D. Slinker[1], Alexander Zakhidov[2] and Sauraj Jha[1]; [1]The University of Texas at Dallas, United States; [2]Texas State University San Marcos, United States

Organohalide lead (hybrid) perovskites have emerged as competitive semiconducting materials for photovoltaic devices due to their high performance and low cost. To further the understanding and optimization of these materials, solution-based methods for interrogating and modifying perovskite thin films are needed. In this work, we report a hydrofluoroether (HFE) solvent-based electrolyte for electrochemical processing and characterization of organic–inorganic trihalide lead perovskite thin films. Organic perovskite films are soluble in most of the polar organic solvents, and thus until now, they were not considered suitable for electrochemical processing. We have enabled electrochemical characterization and demonstrated a processing toolset for these materials utilizing highly fluorinated electrolytes based on a HFE solvent. Our results show that chemically orthogonal electrolytes based on HFE solvents do not dissolve organic perovskite films and thus allow electrochemical characterization of the electronic structure, investigation of charge transport properties, and potential electrochemical doping of the films with in situ diagnostic capabilities

F.EL06.08.04

Structural, Optical and Electrical Properties of NiO_x Thin Films Obtained by Various Techniques Jhonathan R. Castillo[1,2], Nicola R. Nedev[1], Benjamín Valdez[1] and Maria Bernechea[2,3,4]; [1]Institute of Engineering, Autonomous University of Baja California, Blvd. Benito Juárez s/n, Mexico; [2]Institute of Nanoscience of Aragon (INA), University of Zaragoza, Spain; [3]Instituto de Ciencia de Materiales de Aragón (ICMA-CISC), Spain; [4]ARAID, Spain

NiO_x is a transparent conductive oxide (TCO) that has attracted a lot of attention because of its electrical and optical properties. Most of the available TCOs are n-type semiconductors, while the development of efficient p-type TCOs remains a challenge. NiO_x is one of the promising p-type candidates, because of its superior chemical stability and optical transparency. Some potential optoelectronic applications of NiO_x are as a p-type channel in transparent thin film transistors (TFTs) and as a hole transport layer in perovskite solar cells. In this work thin NiO_x films were obtained by Pulsed Laser Deposition (PLD), d.c. sputtering, e-beam evaporation and sol-gel techniques.
All films were deposited on glass substrates with a size of 2×2 cm. The PLD films were deposited from a NiO target at room temperature. D.C sputtering and e-beam evaporation were used to deposit pure Ni films, which were then oxidized in air at various temperatures. The sol-gel NiO_x was obtained by depositing chemical precursors and subsequent thermal treatment. Various parameters were varied in the experiments and it was found that the structural, optical and electrical properties of the PLD films depend strongly on the oxygen pressure. The most important parameter for the other three types of oxides was the annealing temperature.
All samples were characterized by UV-Vis spectroscopy, X-ray diffraction, X-ray photoelectron spectroscopy, scanning electron microscopy and atomic force microscopy. Results for the properties of NiO_x films deposited by the above techniques will be presented and a discussion for their possible application in TFTs and solar cells will be given.

The Role of Post Synthetic Treatment and Ligand Population on Optoelectronic Properties of PbS Quantum Dot Films and Devices Fiaz Ahmed, Adam Roberge and Andrew B. Greytak; University of South Carolina, United States

Colloidal quantum dots (CQDs) are promising semiconducting materials to engineer photovoltaic and optoelectronic devices due to tunable size-dependent absorption and emission properties. Great efforts have been made to find suitable surface ligand to reduce spacing between the adjacent quantum dots to ease charge transport but there has been negligible attention given to purification strategies and systematic efforts to find the ideal ligand populations to optimize device performance. Charge transport could be hindered in the presence of excess free ligands forming interparticle barriers; on the contrary, an under-passivated QD can have high density of trap states and could also undermine the nanocrystal's stability toward coalescence. Precipitation and redissolution (PR) methods are widely used purification techniques that must typically be repeated to get clean CQDs with appropriate populations of surface-bound molecules (ligands). PR often results in loss of native ligands bound to the surface which induces more surface traps and/or compromise the chemical stability of these nanocrystals.

Gel permeation chromatography (GPC) has been proven to be an effective technique to remove the byproducts and impurities from CQDs without damaging the QDs surface. In this study, we demonstrate the effectiveness of GPC in removing byproducts and unbound ligands from pre and post ligand exchanged PbS CQDs.
NMR and UV-Vis-NIR spectroscopy of oleate-capped PbS quantum dots shows that despite removal of unbound surfactants, PbS QDs remain stable in solution following GPC. These purified nanocrystals were used to made CQDs photodetectors and photovoltaic devices.
We show that films fabricated using GPC purified PbS QD solutions exhibit higher charge transport, and low contact resistance, as investigated through in-plane conductivity and photoresponse. The charge carrier mobility was extracted from the mobility lifetime product and recombination lifetime determined by the spatial profiles of the photocurrent obtained through scanning photocurrent microscopy (SPCM), and transient photocurrent measurements, respectively. Furthermore, our findings show that post synthetic purification and optimum ligand population can significantly improve physical characteristics including reduced surface roughness, suggesting that impurities and optimum ligand coverage play an important role in film morphology and device performance.

F.EL06.08.07
Revisiting *c*-type Screw Dislocations in GaN by First Principles—Implications on Nanopipes Formation Liverios Lymperakis, Su-Hyun Yoo and Jorg Neugebauer; Max-Planck-Institut für Eisenforschung GmbH, Germany

Dislocations in III-Nitrides constitute a long standing controversial topic. The lattice and thermal mismatch associated with the heteroepitaxy of GaN results in high dislocation densities in the order of 10^8 to 10^{10} cm^{-2}. Although III-Nitride optoelectronic devices can operate even at these high dislocation densities, recent investigations indicate that *c*-type screw dislocations may have a detrimental effect on the properties and reliability of high-power electronic as well as of optoelectronic devices: For example, the observed high reverse (forward) leakage current in electronic (optolectronic) devices is attributed to screw type dislocations [1]. Recently, it has been proposed that these defects are associated with open core structures, thus forming nanopipes with diameters of a few nms [2]. However, imaging screw dislocations at atomic resolution by electron microscopy to validate this model is not trivial. Moreover, first principles calculations that can accurately describe the energetics and atomic and electronic structure of these defects, have been restricted to MBE growth and/or did not explicitly consider the highly strained core region of these defects [3].

In the present study we combine density functional theory (DFT) with large scale empirical potential calculations within an Implicit Boundaries Mutliscale Scheme calculations [4] to investigate the energetics, atomic structure and electronic properties of *c*-type screw dislocations in GaN. We explicitly consider both closed and open core screw dislocations as well as more than 100 different core reconstructions. Based on these calculations we construct a *c*-type screw dislocation phase diagram which describes the energetically most favorable core structures as function of the Ga, N and H chemical potentials. Our calculations indicate, in agreement with previous DFT studies, that growth under typical MBE growth conditions, i.e. metal rich growth, that these defects stabilize a Ga filled core. Moreover, under N rich conditions the core is stoichiometric, though a column of Ga-N dimers is removed form the core. However, the energy of the free *m*-plane surfaces under MBE conditions cannot be compensated by the core and strain energy and hence nanopipe formation is highly unfavorable. In contrast, under typical MOCVD or MOVPE growth conditions the Ga and N dangling bonds at the open core inner surfaces are passivated by NH_x molecules and H atoms, respectively. This reduces considerably the surface energy under these conditions enabling the formation of nanopipes with hexagonal cross section and diameters ranging for ≈1 to ≈2 nm. Our calculations show that these nanopipes obey electron counting rule and hence are semiconducting. Nevertheless, they have important implications on the efficient diffusion and/or incorporation of impurities and/or dopants at the side facets and at the neighborhood of the open core, which will be discussed in detail. We will also discuss in detail the energetics and structure of superscrew dislocations and their implications on the diameter of the nanopipes as well as the potential implications of the nanopipes on the properties and the efficiency of the electronic devices.

F.EL06.08.08

The Role of Third Cation Doping on Phase Stability, Carrier Transport and Carrier Suppression in Amorphous Oxide Semiconductors Xingyu Wang[1], Austin Reed[2], Han Wook Song[3] and Sunghwan Lee[1]; [1]Purdue University, United States; [2]Baylor University, United States; [3]KRISS, Korea (the Republic of)

Transparent electronics and optoelectronics have been garnering increasing attention for use in high performance devices such as next generation displays, photovoltaics, electrochromic devices and sensors. Metal oxides are considered to be necessary components in these applications due to their excellent optical transparency ranging from visible to near infrared regime as well as pseudo-metallic electrical conductivity[1, 2]. These metal oxides have been implemented in devices, depending on their electrical conductivity, as transparent electrodes by degenerately-doped oxides such as InSnO and doped ZnO; semiconducting active layers based on indium oxides, ZnO or SnO_2; and insulators (e.g., SiO_2, Al_2O_3, HfO_2) for dielectrics or encapsulations.

Thin film transistors (TFTs) are one of the key elements in displays as a pixel driving switch of which the required properties include high carrier mobility, low thermal budget processing, structural phase stability and reliable device performance in the presence of thermal and bias stress conditions. In recent years, amorphous oxide semiconductors based on indium oxides have been considerably investigated due to their promising carrier mobility, >5-25 cm^2/Vs, compared to conventional amorphous Si (<1 cm^2/Vs); low temperature processing; mechanical flexibility compared to the crystalline counterparts; and large area process-ability. Indium oxide-based binary and ternary cation material systems have shown tremendous promises for next generation displays since these materials meet the property and process needs that are described above. A binary cation material of indium zinc oxides (IZO) has been considered since the addition of Zn into In_2O_3 stabilizes the amorphous phase of In_2O_3 while the amorphous phase of undoped In_2O_3 is rapidly crystallized at very low homologous temperatures (T/T_m<0.19) at 150 °C [3, 4]. The reported carrier mobility of IZO is as high as 20-50 cm^2/Vs for both Hall and TFT field effect mobilities. A ternary cation system of InGaZnO (IGZO) [5, 6] has been more popular than binary systems since the addition of Ga in IGZO suppresses the channel carrier density in TFT application, which is preferred for TFT devices to obtain low device off-state current. Other third cation species such as Hf, Si and Zr were implemented. However, the carrier mobility of those ternary cation systems is significantly lower, 3-10 cm^2/Vs, which is 3-10 fold lower than that of In_2O_3 or IZO.

Therefore, securing strategies to develop a material system that maintains high carrier mobility (>20 cm^2/Vs) and suppresses carrier generation for TFT channel application is of significant importance, which is expected to expedite the realization of next-generation transparent displays exhibiting reliable performance, fast switching speed and, consequently ultra high definition resolution.

Here, we report on a ternary cation material system of InAlZnO (IAZO) where the optimized carrier mobility is as high as 25-45 cm^2/Vs. Further, the IAZO demonstrates an enhanced capability of stabilizing the amorphous phase during thermal stresses compared to InZnO. The effect of Al incorporation on the structural, electrical, optoelectronic and chemical properties of IAZO is systemically investigated and compared to those of IZO. The carrier transport behaviors (ionized impurity scattering; neutral scattering; charge screening) as well as the dominant mechanisms for carrier density and resistivity are discussed. The high mobility and greater phase stability may lead to high performance and sustainable device applications in next generation electronic and optoelectronic devices such as transparent displays.

Investigation of Optical Bleaching Effect in InN-Based Films Junjun Jia[1], Takashi Yagi[2], Taiki Ito[1] and Toshiki Makimoto[1]; [1]Waseda University, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan

Indium nitride (InN) was reported to have a large optical bleaching effect [1], which provides potential application as high-speed and high-frequency optical switches in the optical communications. Due to its narrow direct bandgap (~0.7 eV), the bandgap engineering with GaN allows the ternary InGaN system to cover a range of bandgap energies from the infrared of InN to the ultraviolent of GaN. Such wide bandgap tuning provides spectral flexibility for InGaN as optical switches. In order

to materialize the potential of InGaN for optical device applications, we investigated the optical bleaching behavior and ultrafast carrier dynamics in epitaxial InN and InGaN films, and proposed a phenomenological model to explain the carrier relaxation behavior.

InN and InGaN films with the thickness of 300 nm were deposited on *c*-sapphire substrates by molecular beam epitaxy. The optical bleaching effect and ultrafast carrier dynamics in InN-based epitaxial films was investigated by using femtosecond time-resolved pump-probe transmittance/reflectance measurements with a photon energy of 1.50 eV, which is based on open-aperture Z-scan technique.

Both epitaxial InN and InGaN films show large optical bleaching effect from Z-scan measurements, where a nearly 3 times increase in transmittance was observed at 800 nm without the dependence of the film composition. The time-resolved pump-probe transmittance results indicate that hot carriers are relaxed within a time scale of subpicosecond. The carrier lifetime was found to be independent of the film composition and the fabrication condition. The maximum value in the transient transmittance shows a nonlinear increase with increasing the pump-beam power, which may be associated to a change in the nonlinear refractive index. The detailed mechanism on the carrier relaxation behavior will be given in the conference.

Atomistic Insight in The Band Tailing of Kesterite Solar Absorbers Wei Chen, Gian-Marco Rignanese and Geoffroy Hautier; Université catholique de Louvain, Belgium

The low open-circuit voltage V_{OC} of the earth-abundant kesterite $Cu_2ZnSnS(Se)_4$ (CZTSSe) solar absorbers is often associated with the large band tails, the origin of which has been tentatively assigned to the Cu-Zn disorder. Such an assignment has recently been questioned by some experiments. Here, by using the cluster expansion method and first-principles calculations, we investigate the role of cation disorder in the band tailing of CZTS. Our results show that the formation of local Cu-Cu-Cu-Sn tetrahedral motif as a result of the disorder is responsible for the band-gap narrowing, leading to a redshift of optical absorption onset by up to 0.2 eV. The Urbach energy, however, is hardly modified by the cation disorder, thereby excluding Cu-Zn disorder as a main source of the large band tails observed in stoichiometric CZTS. On the other hand, we find that extensive Cu-Zn disorder could stabilize the formation of point defects to a large extent. In particular, the defect concentration of Sn_{Cu} can be as high as 10^{12} cm^{-3} under typical Cu-poor growth conditions. The defect level is found at 0.2 eV above the VBM, suggesting that Sn_{Cu} could be a hole trap. Sn_{Zn} remains the predominant deep donor with defect levels near the midgap and hence is responsible for nonradiative recombination. We show that Sn antisites could be the main culprit of the low V_{OC} and the persistence of the two donors in the presence of cation disorder presents a major challenge towards a high-efficiency CZTS absorber.

Interface Engineering for Perovskite Solar Cells Based on Tin (IV) Oxide Nanostructures Zhuldyz Yelzhanova[1], Zhiwei Ren[1], Damir Aidarkhanov[1], Gaukhar Nigmetova[1], Bakhytzhan Baptayev[1], Mannix Balanay[1], Patrick W. K. Fong[2], Aleksandra Djurisic[3] and Annie Ng[1]; [1]Nazarbayev University, Kazakhstan; [2]Hong Kong Polytechnic University, Kazakhstan; [3]The University of Hong Kong, China

Tin(IV) oxide (SnO_2) is an n-type wide bandgap semiconductor, which is widely used as an electron transport layer (ETL) in organometal perovskite solar cells (PSCs) due to its promising properties such as high transmittance, high electron mobility, good photostability, good energy alignment and easy processing. In this work, SnO_2 nanostructures were synthesized by a solvothermal technique. The impacts of each growth parameter for the SnO_2 nanostructures were demonstrated. By investigating the relations among different growth conditions, optimized recipes were developed for SnO_2 nanostructured ETLs employing in PSCs. Furthermore, the interfaces between the FTO/ETL and ETL/perovskite are optimized in order to enhance the charge extraction efficiency of the devices. Detailed characterizations such as scanning electron microscopy, electrochemical impedance spectroscopy, atomic force microscopy spectroscopy, X-ray diffraction, *I-V* characteristics etc. have been performed on the SnO_2 ETL alone, material interfaces and the SnO_2 nanostructures-based PSCs. The obtained results provide a valuable insight into the community for preparing desired PSCs with nanostructured ETL.

F.EL06.08.12
Dual-Period Guided-Mode Resonance Filters for SWIR Multi-Spectral Image Sensors Md Ataul Mamun, Rezwan

Mohammad Sayeed, Ümit Özgür and Vitaliy Avrutin; Virginia Commonwealth University, United States

Since their introduction in the early 1990s, subwavelength grating guided-mode resonance (GMR) filters have attracted considerable attention due to their simple and compact structures and versatile spectral characteristics. These outstanding features allow miniaturization of filters to pixel scale and high-density of integration for visible and short-wave infrared (SWIR) image sensors where a mosaic of transmission filters of different resonances can produce selective spectral signals to individual pixels of focal plane arrays. However, the conventional GMR-based transmission filter design, essentially unchanged for more than two decades, remains as a limiting factor for practical implementation of such an array of filters on the same substrate. The conventional design based on a single-period grating necessarily involves a homogeneous layer (of subwavelength thickness) underneath a subwavelength grating of a dielectric material to achieve a narrow transmission peak and a wide stop-band. Maintaining the other spectral characteristics, the transmission peak can then be tuned to the desired wavelength by scaling all the dimensions including the grating and homogeneous layer heights. However, to integrate different filters into a compact mosaic, this conventional design requires either different substrates of corresponding thicknesses or a very complicated non-planar fabrication process to use a single wafer leading to low throughput. In this work, we demonstrate a dual-period design to eliminate this issue by fetching additional design flexibilities. First, the dual-period filters possess two fill-fractions and thus unlike their single-period counterparts allow more degrees of freedom to vary the lateral profile parameters (e.g., fill-fractions and periods) for producing desired resonances at different wavelengths as well as to tune a resonance while keeping the grating height constant. Second, to produce a narrow passband with a wide stopband, these filters, unlike the single-period counterparts, do not require a homogeneous layer, allowing a planar fabrication process for integration of different filters on the same substrate. Moreover, dual-period filters show less sensitivity to the fabrication deviations such as sidewall roughness and to those related to grating and/or homogeneous layer heights where the latter, especially, remains as another limiting problem for the conventional narrow passband single-period based filters. For example, a small variation in grating and/or homogeneous layer thickness (while other parameters remain constant) causes the resonance peaks to disappear or be suppressed significantly and thus the fabrication requires very high precision. In this work, we report dual-period GMR filters of dimensions smaller than on silicon-on-quartz (SOQ) wafers using conventional electron beam lithography (EBL) and reactive ion etching (RIE). The filters demonstrate efficiencies as high as 80% at the peak transmission wavelength, e.g. 1550 nm. The passbands are as small as 15 nm with over 350-nm-wide stopband. The spectra of the fabricated filters are in a good agreement with the results of simulations using the finite element method (FEM) in COMSOL Multiphysics® software. Tunability of narrow passband resonances has also been achieved by only varying the fill-factors and/or period while keeping the substrate thickness constant. An array of four filters (all based on dual-period) have been demonstrated on same substrate to generate well-separated passbands in the SWIR region (1.2-1.6 μm) to work as a pixel. While smaller filter size would allow integration into compact chips, filters should be sufficiently spaced to eliminate the potential cross-talk. In order to produce an optimum pixel size to work in the concerned SWIR region, any potential cross-talk along with filter size effects are also analyzed theoretically and experimentally.

High Power Generation of Double-Junction III-V Solar Cells by Strategically Designed Luminescent Waveguides Shin Hyung Lee, Mun-Jong Kim and Sung-Min Lee; Kookmin University, Korea (the Republic of)

III-V compound solar cells have been considered as the leading photovoltaic devices due to their superior properties including the high carrier mobility, direct bandgap, and controllable bandgap against the solar spectrum. The extremely high solar-to-electric power conversion efficiency can be achieved with III-V solar cells by forming monolithic multi-junction structures through series processes of the epitaxial growth. Nevertheless, their prohibitively high materials and process (i.e. epitaxial growth) cost has limited the application to terrestrial photovoltaic systems. To reduce the cost per watts of III-V solar cells, several approaches have been suggested, such as transfer-printing-assisted assembly for re-using the expensive III-V substrate and solar light concentrator for boosting the power generation in a given cell area. A format of III-V solar cell arrays transfer-printed within the luminescent solar concentrator (LSC) has been particularly of interest due to the potential to mitigate the materials cost and simultaneously to augment the power generation. In spite of the successful demonstration with single-junction (e.g. GaAs) solar cells, the effect of power generation improvement by the LSC system cannot be simply achieved with multi-junction solar cells, because the balanced enhancement of photon absorption at each subcell is required for increasing overall photocurrent of series-connected multi-junction cells. In this regard, here we present a facile route to integrate the transfer-printed multi-junction III-V solar cells with the LSC medium for significantly raising their power generation. Monolithically grown indium gallium phosphide (InGaP)/gallium arsenide (GaAs) double-junction solar cells are completed implanted into a LSC printing medium by the transfer-printing-based fabrication assembly, where luminescent quantum dots (QDs) with the 610 nm emission wavelength are non-uniformly distributed in the LSC. Since the short-circuit current of InGaP/GaAs double-junction cells is limited by a level of photocurrent produced at the InGaP subcell, the LSC is designed for the emitted 610 nm photons of QDs to be preferentially guided into the InGaP subcell. At the optimal LSC

configuration, the power generation of 26%-efficient InGaP/GaAs solar cells can be considerably improved by ~50% compared to the identical cells but without add of the LSC.

F.EL06.08.14
Selective Contacts Using Dipole Amino Acid Layers Eloi Ros Costals, Gerard Masmitjà, Estefania Almache, Benjamin Pusay, Gema Lopez, Kunai Tiwari, Edgardo Saucedo, Pablo Ortega, Isidro Martin, Cristobal Voz and Joaquim Puigdollers; Universitat Politècnica de Catalunya, Spain

There has been a recent trend to use molecular dipole layers as a part of a novel strategy to fabricate selective contacts. Conceptually, a thin film of oriented molecular dipoles mimics a 2D capacitor, and the build-in voltage within the layer affects the final contact equilibrium state. When the dipoles are oriented in a certain direction one achieves larger accumulation of either holes or electrons by modifying the workfunction of the metal. Amongst many of the dipols used amino acids have particularly interesiting properties, for instance easy deposition by PVD methods such as spincoating and thermal evaporation and strong molecular dipole moment due to the presence within the molecule of a negatively charged carboxylic group and a positively charged amino group.
We tested the effect on the contact resistance of a Silicon/dipole/Aluminium stack using Transfer Length Method and testing different amino acids as the dipole layers (e.g. Cysteine, Glycine, Histidine...).
Preliminary results show an enhanced contact resistivity of orders of magnitude when dipoles are used on both p and n type silicon wafers, circumventing the problematic Fermi level pinning in Silicon aluminium as deposited contacts.
Finally, experiments on Histidine using different passivating layers show a clear difference in contact resistance with the change of the substrate dopant. Probably indicating that macroscopic orientation of the dipole layer can be promoted when using proper seed layers.

F.EL06.08.15
Nucleation Site Tailoring at the 2D/3D Interface Using He-Ion Beam Patterning Vera A. Zarubin, Kate Reidy, Joachim D. Thomsen, Julian Klein and Frances M. Ross; Massachusetts Institute of Technology, United States

For many of their applications, 2D materials must be connected to the macroscale world, implying interfaces between the 2D atomic layer and a 3D bulk material. The structure and defects at the interface between a 2D material and a 3D thin film influence (opto-)electronic properties of nanoscale devices such as contact resistance, photo-response and high frequency performance [1]. If the interface is between a 2D material and a 3D nanostructure, the ability to control the nanostructure geometry and lateral positioning is important in enabling nano-optoelectronic applications such as plasmonic arrays or arrays of wires or lines in individual circuits interfaced with 2D materials. When 3D nanoislands are grown on conventional, bulk substrates, “directed self-assembly” is a useful approach where growth takes place spontaneously but is favored at particular nucleation sites. The control of nucleation sites involves control of surface topography, geometry and local interactions [2]. Here we focus on extending this approach to the case of 3D nanoislands on 2D surfaces. We create specific defect locations on 2D materials (graphene, MoS2, WSe2) that act as heterogeneous nucleation sites for 3D metals (Au, Ti), and we tune the 3D metal deposition conditions to produce specific island shapes by self-assembly.

Since directed self-assembly requires avoidance of extraneous nucleation, as well as reliable nucleation at the patterned sites, we first discuss the control of metal island nucleation on unpatterned 2D materials. In particular, the nucleation density is expected to depend on the adatom diffusion distance on the 2D material surface. On 2D materials in the form of suspended layers, we use post-growth imaging by transmission electron microscopy (TEM) to measure the shape and distance between metal islands deposited in an ultra-high vacuum (UHV) evaporation system. We find that nucleation density and island shape depend on factors such as the substrate temperature, topography, background pressure, time, and partial pressure of the deposited material. We achieve the largest island diffusion distance (>2 μm) by removing polymeric residues in the 2D material transfer process, suspending the 2D material samples on TEM grids, using medium (100-200 ºC) temperature deposition, and minimising defect sites such as wrinkles. We next induce locally reduced adatom diffusion distances using He-Ion beam patterning to create periodic defects in the 2D material. The He-Ion dose rates are calibrated and resulting defects characterised using high resolution scanning transmission electron microscopy. We show that these defects act as heterogeneous sites and we discuss the extent to which they can be exploited to produce patterned, periodic Au nanoisland

arrays. We develop automated image analysis techniques and perform statistical analysis of the nucleation site density and location. We believe that this templating and nucleation control opens routes towards self-assembled and tailored interface design. In particular, we discuss the possibilities of interface structures built from self-assembled 3D nanostructures for development of plasmonic nanoarrays with tunable and well-defined resonance frequencies.

Late News: Correlation of Nano-Morphology with Structural and Spectroscopic Studies in Organic Solar Cells Urvashi Bothra[1,2], Chris McNeill[2] and Dinesh Kabra[1]; [1]IIT Bombay, India; [2]Monash University, Australia

The nano-morphology of bulk heterojunction (BHJ) blends based on poly[[4,8-bis[(2-ethylhexyl)oxy]benzo[1,2-b:4,5-b']dithiophene-2,6-diyl][3-fluoro-2-[(2-ethylhexyl)carbonyl]thieno[3,4-b]thiophenediyl]] (PTB7) blended with [6,6]-phenyl-C_{71}-butyric acid methyl ester ($PC_{71}BM$) is systematically varied by changing the volume fraction of the solvent additive 1,8-diiodooctane (DIO) from 0 vol% to 20 vol% in the casting solution to prepare organic solar cells (OSCs). With increasing addition of DIO, the photoluminescence (PL) from the blend is reduced; however, a relative increase in PL from 750 nm onwards is observed for blends with 20 vol% DIO. As quenching of the blend PL is related to the donor/acceptor (D/A) interface, structural characterizations in real-space (microscopy) and *k*-space (scattering) are performed to unravel the morphology of blend systems to correlate nano-morphology with photophysical and charge transport processes. Blends prepared with 0 vol% DIO form large phase separated domains of $PC_{71}BM$, hundreds of nanometer in diameter. With the addition of 3 vol% DIO the size of $PC_{71}BM$ domains is supressed resulting in a more mixed morphology due to the selective dissolution of DIO in $PC_{71}BM$. On the addition of up to 20 vol% of DIO, the film becomes rougher with a finer interconnected morphology due to polymer aggregation, which contrasts with previous reports. Electron-transport length scales measured by scanning photocurrent microscopy (SPM) are found to increase with the addition of up to 3 vol% DIO associated with the break-up of the large $PC_{71}BM$ aggregates, while the hole-transport length is found to increase on adding DIO up to 20 vol% due to aggregation of polymer chains. Finite-difference time-domain (FDTD) simulations are performed to take into account for optical beam spread due to associated roughness of BHJ blend films which further strengthen the experimental findings to take into account for waveguiding/scattering components of excitation beam.The structural results are found to be in good agreement with the PL quenching and the effective transport lengths. Hence, this work represents a complete set of results systematically examining the effect of nanomorphology on structural and opto-electronic properties of BHJ blends, which can have a direct implication on better understanding of the emerging high efficiency OSC blend systems.

Late News: Low Interfacial Thermal Resistance for BeO-on-Diamond Kiumars Aryana[1], Yoonseo Jang[2], David Olson[1], John Gaskins[1], Dohwan Jung[2], Jung H. Yum[3], Eric S. Larsen[4], Christopher W. Bielawski[3,4,5], Sean King[6], Jungwoo Oh[2] and Patrick Hopkins[1,1,1]; [1]University of Virginia, United States; [2]Yonsei University, Korea (the Republic of); [3]Institute for Basic Science (IBS), Korea (the Republic of); [4]Ulsan National Institute of Science and Technology, Korea (the Republic of); [5]Ulsan National Institute of Science and Technology (UNIST), Korea (the Republic of); [6]Intel Corporation, United States

Diamond, by far, is the most thermally conductive material at room temperature and a great candidate for thermal management applications in microelectronic devices. Yet, its application has been discouragingly hindered due to its large thermal barrier at the interface when paired with other CMOS materials. Beryllium oxide (BeO) is a potential material candidate to bridge this thermal barrier between diamond and other wide bandgap semiconductors such as gallium nitride (GaN) and Silicon carbide (SiC) owing to its large bandgap, high thermal conductivity, and large spectral phonon overlap with diamond. In this study, using time-domain thermoreflectance we report the thermal conductivity and interfacial thermal resistance at BeO/diamond and Beo/Si interface across various temperatures. We measure the thermal conductivity of amorphous BeO for thicknesses below 30 nm to be ~10 +- 0.7 W/mK, which is significantly lower than its bulk crystalline value. Our results suggest that the interfacial thermal resistance at BeO/diamond interface is significantly lower than that of GaN/diamond and BeO/Si. This observation paves the way towards more thermally efficient integrated circuits.

F.EL06.08.18
Late News: The High Near-Infrared Transparency of Silver Nanowire Transparent Electrodes Jon Atkinson and Irene Goldthorpe; University of Waterloo, Canada

Transparent electrodes are a necessary component of many optoelectronic devices. Networks of silver nanowires have emerged as a promising alternative to commonly-used metal oxides such as indium tin oxide (ITO). Their transparency and conductivity values are as high as ITO, while being mechanically flexible, less expensive and can be fabricated using high-throughput roll-to-roll methods. In this talk I will outline an additional advantage that has thus far received less attention: the high transparency of silver nanowire networks in the near-infrared region (NIR). This property is highly desirable for some applications such as window coatings and solar cells. I will show that for electrodes that are 96% transparent in the visible, ones made from ITO are only 35% transparent at a wavelength of 2500 nm, whereas those made from silver nanowires maintain a transparency as a high as 94%. I will present results that show that the nanowires in the network should be sparse and larger in diameter to maximize NIR transparency. Modelling of the nanowire networks will also be shown and help demonstrate the physical reasons this is the case.
At the end of my talk I will present my results on passivating silver nanowire electrodes for capacitive-type devices such as smart windows and displays. To fully realize the advantages of silver nanowire electrodes, candidate passivation materials must be optically transparent (including in the NIR range), inexpensive, mechanically flexible and simple to deposit using high-throughput methods. I will present our findings of the passivation effectiveness of polyurethane, PMMA, a commercial optical adhesive and cyclotene passivation layers on silver nanowire networks.

F.EL06.08.19
Late News: Reduced Non-Radiative Losses via Charge Selectivity Enhancement by Using a Fullerenic Anodic Interlayer in Organic Photovoltaics Donato Spoltore[1], Manasi Pranav Ram[1], Johannes Benduhn[1], Mathias Nyman[2], Jonas Kublitski[1] and Karl Leo[1]; [1]TU Dresden, Germany; [2]Abo Akademi, Finland

Charge transport layers play a fundamental role for efficient charge carrier injection and extraction in opto-electronic devices. Using interfacial layers, the open circuit voltage (V_{OC}) and fill factor (FF) of organic solar cells can improve significantly. Here we show experimentally that the extent of contact between a Molybdenum Oxide (MoO_3) hole extraction layer and the donor molecules in the photoactive layer of organic solar cells causes a proportional increase in non-radiative recombination losses. We quantify this effect by using several planar and bulk heterojunction solar cells device architectures, assigning it to surface recombination. We demonstrate that such losses can be suppressed by inserting a thin fullerenic anodic interlayer. This interfacial layer enhances the built-in potential and reduces the presence of minority charge carriers at the electrodes: a new perspective on the principle of selective charge extraction layers. The improvement to device efficiency is limited by a critical interlayer thickness, which depends on the donor material in bilayer devices. These findings are relevant to different branches of organic electronics, given the popularity of MoO_3 as an efficient hole extraction and injection layer, providing insights for future device design.

8:00 AM *
Understanding Photophysics on Light-Emitting Properties at Different Length and Time Scales in Organic-Inorganic Hybrid Halide Perovskites Bin Hu; University of Tennessee, United States

This tutorial lecture will focus on the photophysics to discuss controlling light-emitting and lasing properties in hybrid halide perovskites by considering orbit-orbit interaction between excited states in spontaneous and coherent regimes. Hybrid halide perovskites are defined as multifunctional semiconducting materials with strong orbital momentum, known as strong orbital materials. Orbit-orbit interaction can occur through long-range polarization and short-range magnetic dipole between excited states during developing light-emitting and lasing actions. Essentially, the long-range and short-range orbit-orbit interactions can determine the dynamics of light-emitting states through energy, polarization, and spin parameters. This tutorial lecture will present the fundamental analysis and experimental studies on photophysics involved in light-emitting and lasing actions in hybrid perovskites based on energy, polarization, and spin processes.

9:30 AM BREAK

9:45 AM *
Perovskite Nanocrystals as Quantum Light Sources Gabriele Raino; ETH Zurich, Switzerland

Besides conventional optoelectronic devices (LEDs and laser), colloidal quantum dots (QDs) are pursued as non-classical light sources (i.e. single photon emitters) that play a pivotal role in future quantum technologies, such as quantum cryptography and quantum sensing.

Due to strongly reduced charge trapping on surface states and their defect-tolerant character, perovskite QDs become attractive as alternative quantum light sources. Indeed, very stable, blinking-free emission has been observed at cryogenic temperatures with ultrafast radiative lifetime and very long coherence time. In addition, when organized in highly-ordered three-dimensional superlattices, perovskite NCs exhibit superfluorescence (SF), a cooperative emission of individual emitters that arises due to a coherent collective coupling to a common light field. Single NC spectroscopy has also revealed peculiar optical properties of perovskite compounds offering detailed information of the band-edge exciton fine structure and multi-excitons dynamics.

The tutorial lecture will review the main experimental methods used to perform single NC optical spectroscopy, with special focus on the recent achievements obtained at cryogenic and room temperature. Future prospects for the generation of complex quantum light sources will be also delineated.

Alloying and Slicing Halide Double Perovskites Adam Slavney[1], Bridget Connor[1], Kurt P. Lindquist[1], Linn Leppert[2], Jeffrey Neaton[3] and Hemamala Karunadasa[1,4]; [1]Stanford University, United States; [2]University of Twente, Netherlands; [3]Lawrence Berkeley National Laboratory, United States; [4]SLAC National Accelerator Laboratory, United States

Halide double perovskites provide a flexible platform for manipulating electronic structure through synthetic design. I will present some recent studies from our group, where we have attempted to increase the compositional and structural complexity of halide perovskites through chemical substitution. In our quest to understand the electronic structure of double perovskites, we developed a simple model that allows us to predict the bandgap symmetry based on chemical composition.

Our work constructs an intuitive picture of how the molecular orbitals of metal-hexahalide coordination complexes give rise to electronic bands in the extended perovskite lattice and describes how these molecular orbitals vary across the bands to give rise to the overall band structure. Although the effects of quantum confinement of Pb and Sn perovskites have been well studied, 2D analogs of 3D double perovskites are notably lacking. I will present a series of 2D double perovskites and discuss the optical and electronic consequences of dimensional reduction of the 3D double perovskite lattice to 2D derivatives.

11:50 AM *F.EL02.12/F.EL08.12.02
Hot Carriers in Halide Perovskites Tze Chien Sum; Nanyang Technological University, Singapore

Halide Perovskites exhibit outstanding light-harvesting and emissive properties. Presently, record power conversion efficiencies (PCE) >25% in solar cells and external quantum efficiencies (EQE) >20% in light-emitting devices have been demonstrated. The perovskite field has since expanded well beyond photovoltaics and LEDs into other optoelectronic domains of lasers, x-ray detectors, memristors etc. Emerging frontier areas include multiphoton, multi-exciton generation and hot carrier applications. In this talk, I will focus on the hot carrier phenomena in halide perovskites and our recent work in this area.

12:10 PM *F.EL02.12/F.EL08.12.03
Defects Engineering and Photophysical Processes in 2D Perovskites Annamaria Petrozza; Istituto Italiano di Tecnologia, Italy

Low-dimensional perovskites are rapidly emerging due to their distinctive emission properties. Here, first I will present the fundamental properties of pristine 2D perovskites, such as the nature of the primary photo-excitations, their relaxation through electronic states and their diffusion across thin films. Such properties will be correlated and modulated by the structural characteristics of the 2D perovskites. Then, I will discuss the possibility of perovskite doping by controlled addition of impurity ions which may enable new electronic, magnetic, and optical performances. I will explore new doping strategies based on transition and rare earth metals for tuning of the emission wavelength (from UV to NIR, further extending the typical range covered with perovskites) and luminescent enhancement. The suitability of doping for the realization of 4 level perovskite lasers will be assessed. Doping with heterovalent ions will be tested to selectively increase *p* and *n* type conductivity of the material. The addition of alkaline-earth metals as B-site dopants will be tested to improve the material stability

12:30 PM F.EL02.12/F.EL08.12.04
High-Efficiency Blue Photoluminescence in the $Cs_2NaInCl_6:Sb^{3+}$ Double Perovskite Phosphor Matthew Gray[1], Shruti Hariyani[2], T. Amanda Strom[3], Jackson Majher[1], Jakoah Brgoch[2] and Patrick Woodward[1]; [1]The Ohio State University, United States; [2]University of Houston, United States; [3]University of California, Santa Barbara, United States

In this report, the photoluminescent properties of a lead-free double perovskite $Cs_2NaInCl_6$ doped with Sb^{3+} are explored. The host crystal structure is a cubic double perovskite with Fm-3m symmetry, a = 10.53344(4) Å, and rock salt ordering of Na^+ and In^{3+}. It is a wide bandgap compound (Eg ≈ 5.1 eV), and substitution with Sb^{3+} leads to strong absorption in the UV due to localized $5s^2 \rightarrow 5s^15p^1$ transitions on Sb^{3+} centers. Radiative relaxation back to the $5s^2$ ground state, via a $^3P_1 \rightarrow {}^1S_0$ transition, leads to intense blue luminescence, centered at 445 nm, with a photoluminescent quantum yield of 79%. The Stokes shift of 0.94 eV is roughly 33% smaller than it is in the related vacancy ordered double perovskite Cs_2SnCl_6. The reduction in Stokes shift is likely due to a change in coordination number of Sb^{3+} from 6-coordinate in $Cs_2NaInCl_6$ to 5-coordinate in Cs_2SnCl_6. In addition to the high quantum yield, $Cs_2NaInCl_6:Sb^{3+}$ exhibits excellent air/moisture stability and can be prepared from solution; characteristics make it a promising blue phosphor for applications involving near-UV excitation.

12:45 PM F.EL02.12/F.EL08.12.07
Tuning the Photophysical Behavior of 2D Perovskites by Engineering the Nature of the Organic Component Ferdinand C. Grozema; Delft University of Technology, Netherlands

Two-dimensional (2D) halide perovskites are a class of emitter materials that are enjoying growing attention recently. The materials are related to 3D halide perovskites but either part or all of the small A-site cations are replaced by large organic molecules with an amonium binding moiety, for example butylamonium or phenyl-ethylamonium. This (generally) leads to the formation of a layered structure where a layer of metal-halide octahedra is formed and the large organic cations separate the layers from each other. Mixing of large and small A-site cations can lead to quasi-2D multi-layer materials where multiple layers of metal halide octahedra are separated by the organic molecules, for instance forming Ruddlesden-Popper or

Dion-Jacobson structures. The emissive properties of these materials are intricately linked to the structural dynamics and formation of possible defects in the inorganic layers.

In this work we explore how modifications of the large organic amonium ion can affect the structural dynamics of the inorganic layer, combining molecular dynamics simulations with time-resolved spectroscopy. Using time-resolved fluorescence and ultrafast transient absorption spectroscopy we have studied the photophsyical behavior of 2D perovskites with a range of different organic cations inorder to gain insight in the relation between the structure and the exciyted state dynamics, These measurements indicate marked differences that can not solely be attributed to changes in the average structure of the materials.

To explain these differences we have performed classical molecular dynamics simulations for a variety of structures, for instance aliphatic alkyl chains, amonium ions containing aromatic moieties such as phenyls or perylene, but also di-functional ions containing two binding sites that can connect to an inorganic pervskite layer on both sides. The results indicate that there are marked differences between the different structures in terms of their structural rigidity. Multi-layer Ruddlesden-Popper structures are generally more rigid than single layers, however, the rigidity of the single layer structures can be strongly enhanced by engineering of the interactions between organic cations, for instance by introduction of large conjugated ions. In addition, di-functional ligands resulting in Dion-Jacobson like structures also lead to more rigid structures. Comparison with the experimental results allows us to derive some design rules that indicate how engineering of the organic part of the structure can help in improving the the emissive properties of the materials that is mostly due to the inorganic layer structure.

Near-Infrared-Emitting CIZSe/CIZS/ZnS Colloidal Heteronanonail Structures Xue Bai, Finn Purcell-Milton and Yurii Goun'ko; Trinity College Dublin, Ireland

Quantum dots (QDs) are very important light emitting materials that can be used in various applications (LED, bioimaging, luminescent solar concentrators and so forth)[1]. The photophysical properties of QDs are not only size and composition dependent, but also determined by the shape and morphology of the sample[2]. The investigation on the synthesis of Cd-based binary anisotropic nanorod QDs have been well explored to date, but using of heavy toxic metal (Cd) in the reaction impede the practical application of Cd-based QDs regarding serious environmental concerns and the unavoidable health damage for biomedical applications. Therefore, there is an urgent need for the development of toxic metal free fluorescent Cu-based quantum nanostructures with anisotropic morphology.
In this project, anisotropic fluorescent Cu-based multicomponent core/shell/shell heteronanonails (HNNs) have been prepared by using the CIZSe/CIZS core/shell structure with wurtzite (WZ) crystal structure as the seed to coat the ZnS shell with a seeded growth method under fine control. Aliquots have been taken out from the reaction vessel at certain time intervals for further characterization and the growth mechanism of the particular anisotropic nanorod structure has been proposed based on the characterization results. Then the Au nanoparticles have been deposited on the surface of the preformed HNNs to give the Au-CIZSe/CIZS/ZnS nanocomposites. These nanomaterials are expected to find important applications in energy harvesting, sensing and nanobiotechnology.

Chemically Reversible Isomerization in Inorganic Cluster-Molecules Richard Robinson; Cornell University, United States

The ability to dynamically tune light emission through controlled structural transformations has promise in research and

application areas. Structural transformations are ubiquitous at all length scales in chemistry, spanning from isomerization reactions of small molecules to solid-solid transformations in bulk crystals, which have generally been studied in isolation. Despite attempts to merge understanding of these disparate regimes by reducing domain size in solids to nanocrystalline dimensions, bulk-like solid-solid transformation behavior still predominates at length scales approaching those of molecules. In-between small molecules and nanocrystals, magic-sized clusters (MSCs) provide an advantageous experimental platform to study isomerization in well-defined atomically precise systems. Additionally, MSCs are atomically identical species, with a narrow optical absorption and potential for precise color emission. Here we show here that a reversible transformation between CdS cluster isomers with distinct stable configurations possesses essential characteristics of both solid-solid transformations and molecular isomerization reactions. These isomers, termed α- and β-$(Cd_2S)_x$, interconvert (α-to-β/β-to-α) reversibly, as identified by a 140 meV shift in the species' excitonic energy gap, that is, the absorption edge and peak emission wavelength is precisely tunable and reversible. A characteristic displacive reconfiguration of the inorganic core (solid-solid transformation), as evidenced by our reconstruction of the atomic pair distribution function from x-ray scattering, accompanies the change in electronic structures. The first order kinetics of the transformation—indicative of molecular isomerization—are driven by a distortion of the ligand binding motifs due to the presence of hydroxyl species in the ligand shell. Chemical control over the surface energy boundary conditions *via* adsorbates appears to be the exclusive determinant of "phase" stability in this system. The reversible transformation of MSCs reported here presents the missing bridge between molecular isomerization and solid-solid transformations. Manipulation of MSCs, which serve as seeds and as a monomer reservoir in nanocrystal growth, will provide an additional strategy for control over the structure of colloidal nanocrystals.

Solvent Effect on Structural Elucidation of Photoluminescent Graphitic Carbon Nanodots Almaz Jalilov; King Fahd University of Petroleum and Minerals, Saudi Arabia

Fluorescent carbon nanoparticles are stable materials that offer wide application potential ranging from the health to sustainable catalysis. Various carbon nanodots (CNDs) already reported, mainly synthesized from organic molecular precursors as a carbon source, and variety of amines as a nitrogen dopant. Photoluminescence (PL) emission of CNDs proposed to originate from the polycyclic aromatic carbon-core and in-situ synthesized molecular fluorophores. Higher temperatures and longer times of pyrolysis known to form higher order of polycyclic aromatic carbon-core. This work reports the CNDs and their fluorescence emission parameters in variety of solvents by means of steady state and time-resolved emission spectroscopies. Response of fluorescence emission lifetime and emission quenching rate constants to changes in solvent parameters such as polarity and tumbling lifetime were essentially independent, unlike molecular fluorophores that display solvent-dependent emission parameters. Fluorescence emission quenched in nitromethane additionally indicating to the polycyclic aromatic carbon-core as a predominant structural feature of the CNDs. The quenching of CNDs emission in the presence of benzophenone that has strong triplet component in excited state was observed. Quenching demonstrate the Stern-Volmer behavior and reveals the additional nonradiative decay pathways of CNDs. The main photophysical features of CNDs are discussed in terms of fluorescence emission originated from the excited state of the polycyclic aromatic carbon-core where contribution from the potential molecular fluorophores considered minimal. Contribution of the molecular fluorophores to emission mechanism of CNDs brings extra complexity and has strong impact on further development of CNDs, therefore, considering the importance of their minimal effect in emission parameters is discussed.

5:30 AM F.EL02.01.05
Long-Term Effects of Impurities on the Particle Size and Optical Emission of Carbon Dots. Nasir Javed and Deirdre O'Carroll; Rutgers, The State University of New Jersey, United States

Carbon dots (CDs) are nanoparticles that exhibit strong photoluminescence (PL) emission throughout the visible spectrum. In addition to strong PL emission, they possess several other promising properties, e.g., high water solubility, easy functionalization, excellent biocompatibility, electron donating and accepting capabilities, and low toxicity. Due to these attractive properties, with easy and low-cost synthesis, and abundance of the raw materials, they have been extensively studied as an alternative to conventional semiconductor quantum dots. Different top-down and bottom-up synthesis methods have been utilized to synthesize CDs. Recent studies highlight the presence of fluorescent byproducts in CD dispersions, especially in CDs synthesized by chemical methods.
Here, we synthesize CDs using citric acid and 1,5-diaminonaphthlene by the solvothermal method, and study their optical and structural properties utilizing UV-visible, PL, Raman and Fourier Transform-Infrared (FTIR) spectroscopy techniques. The long-term impact of reaction byproducts on the stability of the physical and optical properties of CDs is also studied. A significant increase in particle size is observed as a function of time after synthesis. Transmission electron microscopy analysis of unpurified CDs shows their average size increases from 23.5 ± 9.7 nm to 63.2 ± 16.5 nm during the 13-month

period after synthesis. UV-visible and FTIR spectra show strong absorption bands associated with C=O bonds. These absorption bands become less intense with time after synthesis, implying that C=O states decrease with time. PL emission from CD dispersions is measured using different excitation wavelengths. CDs that have not been purified show strong blue emission with a quantum yield of 30%, which is attributed to C=O states mostly associated with molecular fluorophores. In addition to blue emission, CDs also show weak green emission which becomes distinctive only at excitation wavelengths longer than 400 nm. With storage time, the blue emission is substantially reduced (quantum yield of 3% after 13 weeks) as C=O states decrease. This reduction in C=O states is accompanied by an increase in the average size of the CDs. From these observations it is concluded that the blue emission is mostly from the molecular fluorophores which slowly decompose and attach to the CDs, and cause an increase in particle size.
When CDs are properly purified, the intensities of absorption bands in UV-visible and FTIR spectra corresponding to C=O states and the blue PL emission decrease considerably. The quantum yield of purified CDs is just 2.6 %. Besides the blue emission, a solvent-dependent yellow emission arises, which is almost negligible when CDs are dispersed in water; however, the intensity of yellow emission increases significantly when CDs are dispersed in ethanol. This emission is attributed to solvent-activated surface states on CDs. Considerable reduction of blue PL emission along with C=O states after purification is accompanied by stable particle size. These observations strengthen our conclusions that the blue emission originates from free floating molecular fluorophores instead of CDs, and particle size increase is caused by deposition of impurities and subsequent deposition on the CD surface.

Low-Order Phases Suppressed Quasi-2D Perovskites for Efficient and Stable Blue Light Emitting Diodes Zhenwei Ren and Wallace C. Choy; The University of Hong Kong, Hong Kong

Quasi-two-dimensional (quasi-2D) perovskite is rising as an efficient luminescent material for blue light emitting diodes (LEDs). However, typically reported quasi-2D perovskites with a wide distribution of small-n phases show low LED efficiency owing to the inefficient internal energy transfer. Meanwhile, the inevitable defects and traps generated during the perovskite crystallization increase non-radiative recombination, which further aggravate the emission efficiency. In this work, we demonstrate a new class of mixed ligand quasi-2D perovskite system of $PEA_{2-x}PA_2(CsPbBr_3)_{n-1}PbBr_4$ (where PEA is phenethylammonium and PA is propylamine) by introducing a 2D perovskite (PEA_2PbBr_4) into $PA_2(CsPbBr_3)_{n-1}PbBr_4$ quasi-2D perovskite solution. The mixed ligand quasi-2D perovskite shows the unique feature of simultaneous suppression of low-order perovskite phase and defect passivation in quasi-2D perovskite for achieving efficient energy transfer and light emission. We theoretically and experimentally unveil the phase transformation mechanism. By fabricating blue perovskite light-emitting diodes (PeLEDs) from the mixed ligand quasi-2D perovskites, a high external quantum efficiency (EQE) of 7.51% with a brightness of 1765 cd m^{-2} and a very low turn-on voltage of 3.07 V is achieved for the blue perovskite light-emitting diodes (PeLEDs). Our most recent result show that by further modifying the mixed ligand quasi-2D perovskites, EQE can reach over 10%. the which is among the highest efficiency of blue PeLEDs. Equally important, the PeLEDs show a very long operational stability of 3961 sec under continuous constant driving current together with very stable EL spectra without any peak shift during the entire stability test [1], which are superior to the reported blue PeLEDs with unstable EL spectra during operation, and thus contribute to the evolution of highly efficient and stable PeLEDs.

Blue-Emitting $CsPbBr_3$ Nanoplates with Great Stability and High Quantum Yield Promoted by a Polysalt-Coating Sisi Wang and Hedi M. Mattoussi; Florida State University, United States

Lead halide perovskite nanocrystals exhibit tunable photoemission properties across the entire visible spectrum, which make them highly promising materials for use in photovoltaic and light-emitting devices. Whereas green-emitting perovskite nanocrystals have achieved near-unity photoluminescence quantum yield (PLQY), their blue-emitting counterparts still lag-behind in terms of both PLQY and colloidal stability. Recently, two-dimensional colloidal perovskite nanoplates (NPLs), with strong 2-D confinement of charge carriers and large exciton binding energy, have attracted attention as an alternative to the mixed-halide core nanocrystals; these tend to experience phase segregation when used as light-emitting materials, for example. However, colloidal NPLs are strongly susceptible to surface defects, resulting in low PLQYs. They also spontaneously undergo morphological transformation manifesting in a shift of their emission to the green region of the spectrum.
Herein, we introduce a surface ligand-engineering strategy that enhances the PLQY, while preserving the shape of perovskite NPLs, using multi-coordinating poly-salts as ligand based on quaternary ammonium or imidazolium anchoring groups. These

ligands are prepared using ring opening reaction starting from polymaleic anhydride copolymers. When complexed with $PbBr_2$ these salt groups strongly interact with the NPL surfaces, which significantly enhances structural stability while increasing the PLQY of these blue-emitting materials up to 70-80%. As such, these nanocrystals can be stored and processed using a wide range of solvents, while maintaining color purity. These finding are highly promising for use in developing blue light emitting devices.

Large Cation Ethylammonium Incorporated Perovskite for Efficient and Spectra Stable Blue Light-Emitting Diodes Jingbi You; Chinese Academy of Sciences, China

Perovskite light-emitting diodes (PeLEDs) have showed significant progresses in recent years, the external quantum efficiency (EQE) of electroluminescence in green and red regions have been beyond 20%, while the efficiency in blue is far lag behind. Here, we propose to add a large cation $CH_3CH_2NH_2^+$ (EA) into the Cs^+ site in $PEA_2(CsPbBr_3)_2PbBr_4$ perovskite with green emission to decrease the Pb-Br orbit coupling and increase the bandgap for blue emission. X-ray diffraction and nuclear magnetic resonance results confirmed that the EA has been successfully incorporated into $CsPbBr_3$ lattice for formation a $PEA_2(Cs_{1-x}EA_xPbBr_3)_2PbBr_4$ perovskite. This method provide a versatile tool to modulate the photoluminescence from green region (508 nm) into blue (466 nm), and over than 70% photoluminescence quantum yield (PLQY) in blue is obtained. In addition, the emission spectra is stable under light and thermal stress. While configuration of PeLEDs with 60% EABr, as high as 12.1% EQE of sky-blue electroluminescence located at 488 nm has been demonstrated. As we know, this is the highest efficiency for PeLEDs in blue region up to now, which will pave the way for the full color display for the PeLEDs.

5:15 AM *F.EL02.02.02
Improving Perovskite Light Emitting Diodes via Doping Effects Mahesh Gangishetty, Shaocong Hou, Samuel Sanders, Qimin Quan and Dan Congreve; Rowland Institute at Harvard, United States

Perovskite Light Emitting Diodes (LEDs) are a rapidly exploding field, driven by their low cost, facile synthesis, and color purity. Indeed, quantum efficiencies over 20% in both red and green emission have been demonstrated. Yet, key weaknesses in both spectral and operational stability hinder the long term application of these materials, and these issues are particularly exacerbated in blue devices, where both efficiencies and stabilities remain quite low. In this talk, we will demonstrate how atomic doping into the perovskite structure allows us to address these challenges, imparting improved efficiency and stability across different emission wavelengths and compositions. Doping is an effective strategy to drive perovskite LEDs towards commercial applications.

5:30 AM *F.EL02.02.03
Optoelectronic Applications and Fundamental Studies of Metal Halide Perovskite Nanostructures Song Jin; University of Wisconsin-Madison, United States

The remarkable solar performance of lead halide perovskites can be attributed to their excellent physical properties that present many mysteries, challenges, as well as opportunities. Better control over the crystal growth of these fascinating materials and better understanding of their complex solid state chemistry would further enhance their applications. Here I will first report new insights on the crystal growth of perovskite materials and the solution growth of single crystal nanowires and nanoplates of various 3D lead halides perovskites ($APbX_3$, A = MA, FA, Cs) *via* a dissolution-recrystallization pathway. These perovskite nanowires have demonstrated high performance room temperature lasing with broad tunability of emission. Moreover, chemical strategies to stabilize the metastable perovskite phases, such as $FAPbI_3$ and $CsPbI_3$, have been developed by using surface ligands to manipulate the delicate thermodynamic and kinetic balance between 3D and 2D layered perovskites. Such stabilization also allows the incorporation of unconventional large A site cations, such as guanidinium (GA) to be incorporated into n 2D Ruddlesden−Popper (RP) perovskites, and their effects on the physical properties of perovskites are studied. The excellent properties of these nanostructures of diverse families of perovskite materials with

different cations, anions, and dimensionality make them ideal for fundamental physical studies of carrier transport and decay mechanisms, and for enabling high performance lasers, LEDs, and other optoelectronic applications.

5:45 AM F.EL02.02.04
Impact of In Content on Optical Characteristics and Deep Defect Evolution in ZnO:In Nanocrystal Films Brahim El Filali[1], Tetyana V. Torchynska[1], Juan A. Jaramillo Gomez[2], Georgiy Polupan[2] and Lyudmyla Shcherbyna[3]; [1]Instituto Politecnico Nacional, Mexico; [2]Instituto Politécnico Nacional, Mexico; [3]V.Lashkaryov Institute of Semiconductor Physics at the National Academy of Sciences of Ukriane, Ukraine

ZnO nanocrystal films grown at ultrasonic spray pyrolysis and doped by In atoms have been investigated. The In impact on optical and structural parameters, and the evolution of O- and In- related defects versus In contents have been studied by means of the scanning electron microscopy, Raman scattering, photoluminescence and X ray photoelectron spectroscopy (XPS) methods.
Raman scattering spectra revealed the first and second order Raman peaks at In doping 0.5-2.5at% In. Raman peaks shift to higher energy, such as: 231, 245, 285, 324, 438, 481 and 481cm^{-1} owing to decreasing the inter-planar distances in crystal lattice in comparison with un-doped ZnO stimulated by elastic strains. Simultaneously, the intensity of near band edge (NBE) bands enlarges. At In contents (1.0-3.0at%) the PL band (3.034eV) appears in PL spectra and its peak shifts to lower energy with increasing In concentrations. At higher In contents (3.0-5.5at%) the intensities of Raman peaks and NBE bands falling down owing to the formation of O- and In-related defects and decreasing the ZnO film crystallinity.
To analysis In – complex defects the high resolution XPS spectra were measured for lines: i) In $3d_{3/2}$ and $In3d_{5/2}$, and ii) $In4d_{3/2}$ and $In4d_{5/2}$. In the XPS spectrum of ZnO:1.0%In NCs the doublets: In $3d_{3/2}$ and $In3d_{5/2}$ with the energies of 451.7eV and 444.2eV, and overlapped $In4d_{3/2}$ and $In4d_{5/2}$ doublet peaks with the energies of 18.48eV and 17.28eV, respectively, have been detected. These peaks are typical for In^{3+} ions in the In_2O_3 crystal lattice. The In3d and In4d doublets shift to lower binding energies versus In contents, approaching the energies of 450.9 and 443.5 eV, as well as 17.58ev and 16.38eV, respectively, in the ZnO:5.5% In NC films. The last peaks are closer to the In^o doublet lines in the metallic In crystal. Thus, this is a trend connected with the In atom coagulation and formation of In complex defects at higher In contents in ZnO:In NCs. Simultaneously, the oxygen vacancies have appeared in the studied films together with film lattice disordering. The optimal In concentration range to fabricate the ZnO films with the high optical parameters has been estimated.

5:55 AM F.EL02.02.05
Colloidal Manganese-Doped Hybrid Perovskite Nanoplatelets with Tunable Dual Color Emission Seung Kyun Ha, Wenbi Shcherbakov-Wu and William Tisdale; Massachusetts Institute of Technology, United States

Two-dimensional (2D) perovskite nanoplatelets have attracted interest for light-emitting applications due to their strong quantum- and dielectric-confinement, directional emission, and tunable color throughout the visible spectrum. In this work, we demonstrate room-temperature synthesis of atomically-thin colloidal organic-inorganic hybrid perovskite nanoplatelets (Chemical formula: $L_2[ABX_3]_{n-1}BX_4$, L: alkylammonium, A: methylammonium or formamidinium, B: lead, X: halide, *n*(=1 or 2): number of $PbBr_6^{4-}$ octahedral layers in out-of-plane direction) incorporating manganese (Mn^{2+}) dopants using the ligand-assisted reprecipitation method. Substitutional doping of manganese for lead enhances the photoluminescence quantum yield (PLQY) and introduces a broad, red-shifted emission feature in bromide nanoplatelets. We find that the choice of organic cation – in addition to the Pb:Mn ratio - strongly affects the final dopant concentration and the overall emission spectrum. We investigate the photophysics of Mn-doped lead bromide nanoplatelets (varying thickness and A-site cation) using time-resolved photoluminescence, excitation intensity-dependent PLQY, and spectral analysis, and we propose a kinetic model describing exciton dynamics between free-exciton and dopant-bound excitonic states. This work demonstrates a materials platform for tunable dual-wavelength emission from a 2D material and provides new understanding of photophysical interactions between localized Mn^{2+} dopants and delocalized band-edge excitons in 2D perovskites.

6:05 AM F.EL02.02.06
Showerhead-Assisted Chemical Vapor Deposition of Organo-Metal-Halide Perovskite Films for Optoelectronic Application Simon Sanders[1], Dominik Stümmler[1], Gintautas Simkus[1,2], Michael Heuken[1,2], Andrei Vescan[1] and Holger Kalisch[1]; [1]RWTH Aachen University, Germany; [2]AIXTRON SE, Germany

Besides photovoltaics, which represents the main application focus of metal halide perovskites in the last decade, lighting has emerged as another appealing field. Perovskite films demonstrate readily tunable emission color, sharp luminescence spectra

and high external quantum efficiencies exceeding 21 % as emissive layers in perovskite LED (PeLED). Limited long-term stability of perovskite layers under electrical stress and the lack of deposition tools with process control on an industrial level remain as the critical obstacles for the commercialization of PeLED. Chemical vapor deposition (CVD) is an attractive highly scalable alternative to established solution-based techniques, enabling thin-film fabrication with high purity and reproducibility on large-area substrates.
Here, we introduce a custom-developed perovskite hot-wall showerhead CVD tool along with an optimized low-vacuum (5 hPa) CVD process to obtain dense perovskite films. We employ the organo-halide CH_3NH_3Br (MABr) and the metal-halide $PbBr_2$ which are simultaneously introduced into the reactor to synthesize $MAPbBr_3$ layers. To achieve this, the individual halide precursors are thermally sublimed (MABr: 175 °C, $PbBr_2$: 410 °C) and transported via separate N_2 carrier gas flows (100 sccm each) to a static mixing unit. Due to a laminar flow regime, forced intermixing is essential to obtain uniformly distributed precursor molecules in the merged gas stream. A high-temperature run-vent system is employed to prevent undesired deposition during heat-up and cool-down phases. The heated showerhead spreads the carrier gas flow, enabling homogeneous deposition on temperature-controlled substrates up to 108 cm^2 in area. The substrates consist of a layer stack of poly(bis(4-phenyl)(2,4,6-trimethylphenyl)amine) (PTAA, 10 nm) / ITO (100 nm) / glass (substrate size 2.5 cm x 2.5 cm). We investigated the influence of the substrate temperature in the range of 60 °C – 110 °C on the morphology, optical and photophysical properties of the deposited films. The 110 °C-sample exhibits a highly porous morphology and a pronounced vertical growth mode, being unsuitable for device integration. Photoluminescence (PL) spectroscopy reveals green light emission at 530 nm, which is characteristic for $MAPbBr_3$. However, the emission is of low intensity, which likely can be attributed to increased non-radiative recombination losses induced by thermal perovskite degradation, e. g. during reactor cool-down. A reduction of substrate temperature provides a lower energy barrier of nucleation, leading to the formation of smaller crystallites and less porous layers at 100 °C. Besides light emission at 530 nm, a second peak at 500 nm is observed in PL measurements. Decreasing the substrate temperature further to 60 °C leads to dense films and light emission exclusively at 500 nm. The blueshift of 30 nm may be attributed to the formation of $MAPbBr_3$-nanoparticles with a size of 7 – 8 nm, emitting higher-energy photons due to the quantum confinement effect. Furthermore, the emission peak of the 60 °C-sample features a 200x enhanced intensity. The lower substrate temperature induces stronger MABr condensation, passivating perovskite grain boundaries. Thus, the high-intensity PL at 500 nm can be explained by suppressed non-radiative recombination due to $MAPbBr_3$-nanoparticles incorporated in an MABr matrix.

Ongoing work will examine the electrical properties of fabricated CVD layers in PeLED structures and will also focus on $CsPbBr_3$ as a thermally more robust perovskite compound.

High-Efficiency Perovskite Light-Emitting Diodes—Emission Mechanisms and Device Design Dawei Di[1,2]; [1]Zhejiang University, China; [2]University of Cambridge, United Kingdom

Perovskite light-emitting diodes have recently exceeded the 20% external quantum efficiency (EQE) milestone. In particular, we have shown in our recent work that with careful device design, it is possible to achieve near-unity internal quantum efficiencies (IQEs) [1], demonstrating the potential of perovskite materials for extremely efficient electroluminescence. In this presentation, we discuss some design considerations behind the high IQEs, and for achieving EQEs that can approach the theoretical limits [1, 2]. We discuss the lessons learned from our recent studies in high-efficiency OLEDs [3. 4], and the important role of charge-transport interfaces in the realization of this goal [5]. Transient spectroscopy experiments are carried out to illustrate how radiative and non-radiative processes play their roles in the high-efficiency devices. Our work on perovskite LEDs may provide useful implications in the design of high-performance perovskite solar cells.

Bright and Color-Tunable Single Layer Perovskite Host-Ionic Guest Light Emitting Electrochemical Cells Jason D. Slinker[1], Aditya Mishra[1], Stephen DiLuzio[2], Masoud Alahbakhshi[1], Anvar Zakhidov[1] and Stefan Bernhard[2]; [1]The University of Texas at Dallas, United States; [2]Carnegie Mellon University, United States

Perovskite light emitting devices have drawn considerable attention for their favorable optoelectronic properties. High carrier mobilities make perovskites excellent candidates as host materials in electroluminescent devices, and iridium complexes serve as highly efficient triplet emitters. To achieve high performance in a simple single layer device, we employed a $CsPbBr_3$ perovskite host and a novel ionic iridium complex guest along with a polyelectrolyte to demonstrate efficient light emitting electrochemical cells (PeLECs). For an optimal guest/host blend, 10600 cd/m^2 luminance at 11.6 cd/A and 9.04 Lm/W were achieved. These devices showed voltage-dependent electroluminescence color proceeding from orange-red to green, facilitated by the reconfigurable ionic materials blend. Optimized devices exhibited enhanced stability under constant current driving. Our rationally-designed ionic guest at an optimal concentration of the host produced efficient (>90%) Förster energy transfer and improved thin film morphologies for high performance PeLEC operation enabled by ionic migration to interfaces.

5:25 AM F.EL02.03.03
The Arrival of Optical Computers with Photonic CMOS—Techniques for Optoelectronic RF Signal Processors, Digital Switching Circuits and Optical Memories James Pan[1,2]; [1]American Enterprise and License Company, United States; [2]Northrop Grumman Electronic Systems, United States

Traditionally, CMOS is not considered a light emitting device. Electronic instruments based on advanced CMOS technology function without lights in closed dark packages. Similar to laser or LED, photonic CMOS is a light emitting device. A laser is fabricated in the MOSFET drain region. A photon sensor or avalanche photo diode (APD) is fabricated in the MOSFET channel / well region. CMOS, laser and photon sensor are manufactured as one integral device. When the MOSFET is off, laser and photon sensor are also off. When the MOSFET is on, light from the laser is absorbed by the photon sensor or avalanche photo diode, triggering a large photonic current flowing back to the MOSFET drain to produce more lights. This process forms a positive feedback loop for conversion of light and electrons, and reduces heats.

Very low series resistance laser diodes, with forward voltage near 0V, are available, and suitable for the photonic CMOS.

In this paper we will discuss techniques to process small RF light signals with photonic CMOS under certain DC biases. In order to process the light signals, optical waveguide or air optical paths need to be created in an RF ASIC or analog ULSI circuit.

Additional features, such as polarization, optical filter, and grating thin films, can be added to the circuit for processing lights.

For digital switching devices in ULSI or ASIC, the design of a CMOS circuit may need to be optimized for optical processing. For traditional ICs, an electronic voltage is applied to the CMOS gate to turn the transistors on. In a optoelectronic IC, in additional to the electronic voltage, an optical voltage can be generated by directing a laser beam to the CMOS gate. Together electronic and photonic voltage may switch the CMOS invertor to "on". This new function not only increases the CMOS speed, but also reduces heat and power consumption.

A traditional SRAM is a 4 or 6 transistor bi-stable circuit, which consists of two back-to-back CMOS invertors. The speed of SRAM depends on how efficiently the pull-up and pull-down transistors operate for transferring electrons. A "pre-charging" step is always necessary prior to memory operations (WRITE / READ / ERASE).

In theory, the speed of an optoelectronic SRAM, which consists of two back-to-back photonic CMOS invertors, may surpass a traditional SRAM, because it takes less time to remove photon-generated electronics. For instance, when a positive voltage is applied to a pull down NMOSFET, holes need to be removed from the pull-up PMOSFET. If part of the holes are generated by laser from a photonic MOSFET, they can be more quickly removed when the laser if off.

To accomplish this much higher speed photonic SRAM, local interconnect must include optical waveguide or air optical paths, in addition to the traditional metal wires.

Finally, we would like to discuss how to expand the functions of photonic signal processors using nonlinear optics.

Nonlinear optical films can be fabricated in a photonic CMOS device in the isolation, buried oxide (in the case of FDSOI or UTSOI), or as optical waveguides connecting the CMOS. The nonlinear optical operation may increase the photon absorption rate of the embedded photon senor or APD in a photonic CMOS, and quantum efficiencies. Promising near IR nonlinear optical materials will be illustrated, and the requirements for efficient second harmonic generation (SHG).

Operationally Stable Perovskite Light Emitting Diodes with High Radiance Karim Elkhouly[1,2], Iakov Goldberg[1,2], Nirav Annavarapu[1,2], Robert Gehlhaar[1], Jan Genoe[1,2], Paul Heremans[1,2] and Weiming Qiu[1,2]; [1]imec, Belgium; [2]KU Leuven, Belgium

Although perovskite light emitting diodes (PeLEDs) have shown fast advances in external quantum efficiency (EQE), their operational stability is still low compared to other light emitting diode (LED) technologies. Here, we show that by engineering the device stack for optimal band alignment and high mobility, the operating voltage of the PeLED is remarkably reduced, i.e. reaching high current density at low voltage. In depth analysis of the device characteristics shows that the low operating voltage of the stack leads to a significant mitigation of Joule heating. This mitigation leads to a better device performance at high current densities where the PeLED shows < 10% EQE roll-off at 800 mA/cm^2. Furthermore, pulsed excitation and low temperature measurements allow us to show that ion-migration is the root cause for device degradation, while Joule heating accelerates this process. Based on this understanding, we resort to a perovskite layer with high ion-migration activation energy. Together with the optimized device stack, this allows us to demonstrate an unprecedented half-life time (T_{50}) of 110 hours at room temperature, when biased at 100 mA/cm^2. At 163 K, it even displays T_{98} = 90 h at 300 mA/cm^2. Our optimal device shows an EQE of 10.5% at 400 mA/cm^2 and a radiance of 351 W Sr^{-1} m^{-2} at 3.15 V, which rivals some of the highest performing stacks. Achieving an operationally stable high-performance PeLED at high current densities is crucial for a potential demonstration of an electrically pumped perovskite laser. To this end, we fabricate scaled PeLEDs down to 20 µm in diameter, and demonstrate reliable electrical pulsing at current densities > 1 kA/cm^2. Pulsed excitation provides important insights about EQE roll-off at current densities relevant for injection lasing. Furthermore, unlike commonly used PeLED stacks, our PeLED shows optimal charge injection at low temperatures down to 163 K, which provides an opportunity to study PeLEDs at intense excitation at low temperatures.

5:45 AM F.EL02.03.05
Highly Efficient and Stable Perovskite Light-Emitting Diodes by Plasmon Effect Using Hydrophobic PVP Capped Gold Nanoparticles Changmin Lee, Dong hyun Kim, Hyung Ju Chae, Jun Su Yang, Gyu Chan Lee, Ui Jun Lee and Seung Yoon Ryu; Korea University, Korea (the Republic of)

Noble metal nanoparticles are well-known for presenting plasmonic coupling with molecular excitons to enhance the performances of opto-electronic devices, especially light emitting diodes and solar cells. The higher momentum associated with metal surface plasmons can alter the lifetime of molecular excitons, thereby increasing the efficiency in the respective devices and enhancing the outcoupling. Solution processed metal nanoparticles are usually capped with selective surfactants which play significant role in their applications. In particular, for perovskite light-emitting diodes (PeLEDs), this kind of application positively contributes to the efficiency and stability and helps overcome the interface and charge transfer problems between hole injection layer (HTL) and emission layer (EML).

Herein, we have investigated the effect of incorporating size dependent gold nanoparticles (AuNPs) for altering the charge balance in PeLEDs. In addition, we studied the far-field interaction of AuNPs plasmons and charge trap by AuNPs through theoretical and experimental tools. To clearly understand the efficiency improvement tactics, we have fabricated PeLED samples with methylammonium lead bromide ($MAPbBr_3$). AuNPs were incorporated in PeLED through the poly(3,4-ethylenedioxythio-phene):poly(styrene sulfonate) (PEDOT:PSS) solution as hole injection layer (HIL). To understand size dependent behaviors, AuNPs with sizes 10, 50, 90, 100 nm were inserted in PEDOT:PSS. Interestingly, even though we used the conventional perovskite ($MAPbBr_3$) material, the obtained results speculated the possibility of enhancement in other perovskite materials such as CsPbBr3 or FAPbBr3. By controlling the size of Au-NPs, we got the highest efficient inflection point at Au-NPs 90 nm.
By monitoring the lifetime of the excitons through time resolved photoluminescence (TRPL), the effect of plasmon over the perovskite photons can be delved. Each sample except the reference (w/o AuNPs) showed improved exciton lifetime, owing to far-field scattering effect by the AuNPs. We analyzed the modifications by AuNPs in the PEDOT:PSS thin film using ultraviolet photoelectron spectroscopy(UPS) and observed that the work function increment with increased AuNP size. It is

beneficial for reducing the hole injection barrier between HTL and the deep HOMO of perovskite. As expected, an increase in efficiency was observed with the increase in size of AuNPs, however the AuNPs with 90nm size was the inflection point. Using LT_{50} measurement, it was cross-evaluated that the efficiency of the device and the AuNPs size are directly proportional. To further investigate this issue, we fabricated hole-only-device (HOD) for the Richardson-schottky equation. It contains variables for carrier trapping or defect, so additional analysis was conducted to confirm the effects of trap and defect through the temperature-dependent I-V curve.
Device lifetime increasement with the addition of AuNP might attributed to the capping layer PVP. We believed that the hydrophobic nature of PVP ligand on top of AuNPs helps to obstruct the indium diffusion from ITO as well as halide ion from $MAPbBr_3$. Even though PVP serves as a capping layer, it exhibits hydrophobic passivation which prevented water penetration into perovskite. By applying PVP-capped AuNPs, we demonstrated the improved device efficiency and stability in perovskite LED in parallel.

5:55 AM F.EL02.03.06
Perovskite Light Emitting Diode Characteristics—The Effects of Electroluminescence Transient and Hysteresis Karim Elkhouly[1,2], Robert Gehlhaar[1], Jan Genoe[1,2], Paul Heremans[1,2] and Weiming Qiu[1,2]; [1]imec, Belgium; [2]KU Leuven, Belgium

The reproducibility of results is one of the corner stones of scientific research. However, often in emerging technologies, the reported results tend to be sensitive to the chosen measurement protocol. This can stem from measurement artifacts or from poorly understood complex underlying phenomena. Since their rise as an exciting material system for optoelectronic devices, metal halide perovskites have shown anomalous hysteresis effects in the current density-voltage (*J-V*) characteristics. In the case of perovskite solar cells, it has been shown that this anomalous hysteresis effect, which is highly dependent on the voltage scan rate, range, direction as well as the device structure, could significantly influence the extracted device metrics and the reported power conversion efficiency value. This has triggered wide discussions about the best practices to report perovskite solar cell performance to achieve consistency between different research groups. On the other hand, less attention is so far given to the anomalous effects that can affect the reporting of the characteristics of perovskite light emitting diodes (PeLEDs). Here, we show that even for PeLEDs with little *J-V* hysteresis, the electroluminescence (EL) intensity changes by an order of magnitude on a timescale ranging from 10 msec to few seconds. This change is directly observed in the measured value of external quantum efficiency (EQE). Such reversible EL transient which is likely caused by ion-migration, can be followed by a roll-off regime dominated by Joule heating, and potentially device degradation when measured at high current densities. Naturally, this transient response leads to significantly different device characteristics depending on the measurement procedures for the same device. We directly explain those implications using the commonly used *J-V-R* scans with different sweep parameters, and show that these scans are not portraying unique device characteristics, but rather a snapshot in which the true device characteristics are entangled with inter-dependent underlying processes of ion-migration, Joule heating and device degradation in a non-linear way. Therefore, we propose a method based on pulsed excitation that allows better reproducibility and interpretation of the measured device characteristics. Furthermore, we also provide suggestions on reporting PeLED characteristics, as input for further discussions in the scientific community.

6:05 AM F.EL02.03.07
Late News: Perovskite LEDs with Nanostructures for Better Light Out-Coupling and Stability Qianpeng Zhang, Daquan Zhang, Yu Fu, Lei Shu, Bryan Cao, Xiaofei Sun and Zhiyong Fan; Hong Kong University of Science and Technology, Hong Kong

In the past six years, perovskite light-emitting diodes (LEDs) have experienced rapid development. Thanks to the superior optoelectronic properties, perovskite material has made itself as a competitive candidate for next-generation displays and lighting. With the great efforts of researchers in this field, the external quantum efficiencies (EQEs) have already surpassed the 20% milestone for both red and green colored perovskite LEDs. Lately, the blue perovskite LEDs have been reported to achieve an EQE higher than 12%.
With the fantastic material quality, perovskite material can achieve a very high photoluminescent quantum efficiency (PLQY); therefore, the internal QE for perovskite LEDs can also reach the level as high as more than 90%. As a result, the key solution to the further enhancement of the perovskite LEDs performance lies in the light extractions/ outcoupling for perovskite LEDs.
During the past few years, our group has devoted ourselves to the development of nanophotonic strategies for the performance enhancement of the perovskite LEDs. The strategies include two main categories. The first kind is to use a nanophotonic substrate for perovskite LEDs devices. The structure we designed was a combination of a nanodome coupler and the photonic crystal optical antennas. When the geometry of the structure was properly optimized, the light originally trapped inside the active layer can be first coupled into the photonic crystals. After that, the photonic crystals, working as optical antennas, can convert the guided modes to the leaky modes and finally couple out the leaky modes to the air. With

this delicate strategy, we successfully improved the EQE of the perovskite LEDs from about 8% to 17.5%, which was the record for the $MAPbBr_3$ based perovskite LEDs at that time.
The second category of the nanophotonic strategies is making nanostructured active materials instead of using the nanostructured out-coupling substrates. With the exploration of varieties of nanostructures, we finally decided to use the nanowire arrays for the perovskite LEDs study. Very intriguingly, we found a solution method with the nanoporous template for perovskite nanowires growth. By studying the growth with different template geometries, we found out that the nanowire growth had a strong relationship with the capillary effect. Then we carefully designed the template thickness and the nanowire lengths, and we made the three-dimensional nanowire arrays based perovskite LEDs. Compared to the planar counterparts, the nanowire-based perovskite LEDs showed an enhanced EQE (from 11% to 16%), which is due to the improved light coupling inside the nanowires (from about 20% to about 45%). More importantly, the operational stability of the nanowire-based perovskite LEDs was also enhanced (T50 increased from 9 min to 35 min). And the long-term stability of the nanowire-based perovskite LEDs was also increased with an enhancement factor of 3 times. It's also worth noting that, the mechanical robustness of the nanowire-based perovskite LEDs was also enhanced a lot due to the protection of the porous template, and much fewer cracks were caused inside nanowires during bendings when compared to the planar counterparts. With the above mentioned two nanophotonic strategies for perovskite LEDs performance (both light-coupling efficiency and stability) enhancement, we demonstrated the advantages of applying nanostructures in perovskite LEDs. By further developing the perovskite material qualities and meanwhile improving the deposition techniques that are more compatible with nanostructures, we believe the EQEs of perovskite LEDs can be further improved to a much higher milestone soon. Last but not least, the nanophotonic strategies we developed here are not just limited to LEDs; they might be also applied for other device applications such as solar cells, photodetectors, and lasers.

6:15 AM F.EL02.03.08
Late News: Inkjet-Printed Metal Halide Perovskite LEDs Felix Hermerschmidt[1], Florian Mathies[2], Vincent Schröder[2], Carolin Rehermann[2], Nicolas Zorn Morales[1], Eva Unger[2,3] and Emil List-Kratochvil[1,2]; [1]Humboldt-Universität zu Berlin, Germany; [2]Helmholtz-Zentrum Berlin, Germany; [3]Lund University, Sweden

Solution-processable metal halide perovskites have sparked major interest for their use in (opto)electronic applications, but until now metal halide perovskite light emitting diodes (PeLEDs) have not been fabricated by inkjet printing. This is because of the difficulty in printing defect-free perovskite films as opposed to other printable optoelectronic materials.
Our work represents the first demonstration of inkjet-printed PeLEDs by specifically templating the crystallization behaviour within the perovskite. This effect is achieved by adding KCl to the commonly used hole injection material poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) underneath the inkjet-printed perovskite layer, which significantly influences the device performance of the PeLEDs.
Firstly, the resulting "salty" PEDOT:PSS works as a seeding template to induce crystal nucleation of the metal halide perovskites inkjet-printed on top. It does so while having only a minor effect on the intrinsic electrical properties of the PEDOT:PSS. Secondly, the perovskite-polymer composite ink specifically developed for inkjet printing renders the commonly used antisolvent treatment unnecessary to induce favourable perovskite crystallization.
PeLEDs incorporating this PEDOT:PSS/KCl layer with the $MAPbBr_3$:PEG perovskite composite show greatly improved performance, predominantly due to improved crystallization compared to PeLEDs containing only PEDOT:PSS. In particular, KCl-modified PEDOT:PSS contact layers enabled the realization of inkjet-printed PeLEDs with a 30-fold increased luminance at the same operating voltage. Using this approach, the first inkjet-printed metal halide PeLEDs with comparable performance parameters to spin-coated reference devices were produced [1].

5:00 AM *F.EL02.04.01
Light-Emitting Metal Halide Perovskites and Perovskite-Related Hybrid Materials Biwu Ma; Florida State University, United States

Metal halide perovskites and perovskite-related hybrid materials have emerged as new classes of light emitting materials with exceptional structural and property tunability. In these materials, various types of molecular metal halide building blocks can be assembled to form distinct crystalline structures with different dimensionalities at the molecular level, ranging from zero-dimensional (0D) clusters, to one-dimensional (1D) wires, two-dimensional (2D) layers, and three-dimensional (3D) networks. The rich combinations of compositions and structures afford these materials with a wide range of optical characteristics, for instance, direct band narrow emissions from 3D metal halide perovskites, and below-gap broadband emissions from 0D organic metal halide hybrids. In this talk, I will present our recent efforts on the development and study of highly efficient metal halide based light emitting materials, from synthetic control to device integration. The major subjects will include (i) color tuning and surface passivation of metal halide perovskite nanocrystals, (ii) single crystalline multicomponent organic metal halide hybrids with white emissions, and (iii) the applications of metal halide perovskites and perovskite-related hybrid materials in light-emitting diodes and radiation detectors.

5:15 AM *F.EL02.04.02
High-Efficiency Perovskite LEDs and Their Applications Feng Gao; Linkoping Univ, Sweden

A major efficiency limit for solution-processed perovskite optoelectronic devices (e.g. light-emitting diodes, LEDs) is trap-mediated non-radiative losses. Defect passivation using organic molecules has been identified as an attractive approach to tackle this issue. We significantly enhance the interaction with defects sites and minimize non-radiative recombination losses. Consequently, we achieve high-performance near infrared perovskite LEDs (PeLEDs) with a high external quantum efficiency (EQE) of 21.6%. We find that our devices can also work efficiently in an emitting/detector switchable mode, with tens-megahertz speed for both functions. Benefiting from the small Stokes shift of perovskites, the diode shows high specific detectivity (>2×10^{12} Jones) at its peak emission (~ 800 nm), allowing optical signal exchange between two identical diodes. We further demonstrate the potential of the dual-functional diode for biomedicine diagnosis applications (as a monolithic heart pulse sensor) and for inter- and intra-chip bidirectional optical communications.

5:30 AM F.EL02.04.03
New Quantum Dot Precursor Chemistry for Controllable Modulation of Reactivity by Lewis Base Joonhyuck Park[1], Arun Jayaraman[1], Gyu Weon Hwang[2] and Hee-Sun Han[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Korea Institute of Science and Technology, Korea (the Republic of)

The optical and electronic properties of quantum dots (QDs) are mainly governed not only by their size distribution but also structural quality. Although the synthetic strategies for size control of QDs are well established for the last few decades, no systematic approach yet exists to achieve high structural quality nanocrystals. Here we show that reaction temperature and precursor reactivity must be independently tuned to achieve high crystallinity, uniform morphology, high quantum yield, and a well-defined core-shell structure. Reaction temperature governs the surface instability of QDs and lattice rearrangement. Precursor reactivity determines reaction kinetics at the surface, affecting the crystallinity and morphology of the resulting crystals. Prior to this work, the reactivity of conventional precursors has not been modulated in temperature-independent manner. As a result, the simultaneous optimization of reaction temperature and precursor reactivity has not been possible. Accordingly, growth conditions for QDs with various sizes and materials are optimized by trial-and-error. To allow temperature-independent modulation of precursor reactivity, we designed a new sulfur precursor employing a boron-sulfur bond, 9-mercapto-9-borabicyclo[3.3.1]nonane. The reactivity of the precursor is predictably modulated by the addition of a Lewis base, which modifies the boron-sulfur bond strength upon coordination to the boron atom. The new precursor chemistry enables the systematic optimization of growth conditions at a wide range of reaction temperatures. Adapting the growth method established here, high-quality QDs were grown from cores of various sizes and materials. The QD growth principles using the new design of precursors are universally applicable to different types of nanoparticles, including non-sulfur-based QDs. This work provides critical insights into the nanoparticle growth process, the design of new precursors, and the optimization of reaction conditions for high-quality QD synthesis.

5:40 AM F.EL02.04.04
Proton-Transfer-Induced 3D/2D Hybrid Perovskites Suppress Ion Migration and Reduce Luminance Overshoot Hobeom Kim[1], Joo Sung Kim[1], Jung-Min Heo[1], Mingyuan Pei[2], In-Hyeok Park[3], Zhun Liu[4], Hyung Joong Yun[5], Min-Ho Park[1], Su-Hun Jeong[1], Young-Hoon Kim[1], Jinwoo Park[1], Emad Oveisi[6], Satyawan Nagane[7], Aditya Sadhanala[7], Lijun Zhang[4], Jin Jung Kweon[1], Sung Keun Lee[1], Hoichang Yang[2], Hyun Myung Jang[1], Richard Friend[7], Kian Ping Loh[3], Mohammad Nazeeruddin[6], Nam-Gyu Park[8] and Tae-Woo Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Inha University, Korea (the Republic of); [3]National University of Singapore, Singapore; [4]Jilin University, China; [5]Korea Basic Science Institute, Korea (the Republic of); [6]École Polytechnique Fédérale de Lausanne, Switzerland; [7]University of Cambridge, United Kingdom; [8]Sungkyunkwan University, Korea (the Republic of)

Metal-halide perovskites (MHPs) has been considered as a promising candidate for solid-state light emission because of their superior optoelectronic properties such as extremely high color purity (full-width at half maximum (FWHM) ≈ 20 nm at room temperature), high photoluminescence quantum efficiency > 90%, and easily tunable bandgap.[1] Further, the efficiency of perovskite light-emitting diodes (PeLEDs) based on three-dimensional (3D) polycrystalline perovskites has been greatly increased reaching external quantum efficiency (EQE) over 20% within only 5 years since the first high-efficiency PeLEDs reported in 2015.[2–4] However, a short operational lifetime of PeLEDs has been a critical drawback for their practical applications and commercialization.[5] One of the most critical causes of the problem is ion migration. PeLEDs' behavior can be more significantly influenced by ion migration as it requires higher bias to operate compared to perovskite solar cells. Here, we demonstrate a proton-transfer-induced 3D/2D hybrid perovskite by adding a small amount of neutral molecule, benzylamine (BnA). The proton transfer from organic ammonium in a precursor to the added BnA enabled the crystallization of 2D perovskite without destroying the 3D phase. As a result, the lifetime of PeLEDs was highly extended by more than 20 times, and an overshooting of electroluminescence at the initial stage of device operation was extremely suppressed; the 2D perovskite passivates trap sites of the 3D perovskite and blocks possible pathways of ion migration in the emitter. We also identified the mechanism of the suppressed luminance overshooting and the lifetime extension by relating with the retarded reorientation of BnA^+ in the perovskite lattice. Our work provides a helpful guideline to improve the stability of PeLEDs with important insights regarding defect engineering.

Enhanced Stabilization and Easy Phase Transfer of $CsPbBr_3$ Perovskite Quantum Dots via Surface Ligand Engineering Sisi Wang, Liang Du, Zhicheng Jin and Hedi M. Mattoussi; Florida State University, United States

Colloidal nanocrystals made of all-inorganic lead halide cores, referred to as perovskite quantum dots (PQDs), exhibit quantum confinement of charge carriers. This endows these materials with size- and composition-dependent photophysical and electronic properties. They have been successfully grown using high temperature reaction routes. Along with organic metal halide compounds, PQDs are highly sought for applications that include light-emitting and photovoltaic devices. However, tangible progress in probing their fundamental properties and/or their integration in device design, has been hampered by issues of colloidal and photophysical instability. These problems can be traced to the ionic nature of the cores combined with the fast desorption rate of the surface capping ligands.

To address those problems, we introduce a promising surface coating strategy relying on a poly-zwitterionic polymer, where high affinity binding onto the QDs is driven by multi-coordinating electrostatic interactions with the ion-rich surfaces of $CsPbBr_3$ PQDs. The polymer ligands were synthesized by grafting a stoichiometric mixture of amine-modified sulfobetaine anchors and solubilizing motifs on a poly(isobutylene-alt-maleic anhydride), PIMA, via nucleophilic addition reaction. We find that this coating imparts enhanced colloidal stability to the nanocrystals over a broad range of solvent conditions and in powder form. It allows easy phase transfer of the PQDs to an array of solutions with varying polarities and properties. Additionally, this stabilization strategy preserves the photophysical and structural characteristics of the nanocrystals in a variety of polar solvents over a period extending to 1.5 years.

6:00 AM F.EL02.04.06

Equilibrium Crystal Shapes of InP Quantum Dots upon Ligand Adsorption and Synthesis Conditions Sangtae Kim[1], Hyeri Yoo[2,3] and Gyu Weon Hwang[2]; [1]Hanyang University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of); [3]Korea University, Korea (the Republic of)

InP quantum dots emerge as a non-toxic and industrially-applicable alternative to CdSe quantum dots in light-emitting materials. While the recent progress in synthesis and optimization of InP quantum dots led to quantum yields above 90%, the industrial goal of 95% quantum yield remains yet to be achieved, especially for the blue light-emitting quantum dots. As a viable strategy towards further optimizing quantum yields, reducing the trap states originating from the surfaces has been proposed. Dissimilar to CdSe quantum dots, controlling the surface facets and equilibrium crystal shapes of InP have been difficult, with largely spherical quantum dots synthesized and reported in the literature. In this work, we discuss and examine the thermodynamic stability of (100), (110) and (111) surfaces according to the ligand adsorption of CH_3COO^-, $P(CH_3)_3$ and CH_3NH_2, using density functional theory calculations. The change in equilibrium crystal shapes are examined with respect to the ligand species, concentration and the chemical potential of In, in order to account for the various synthesis conditions

SESSION F.EL02.05: Mechanism and Physics of Organic Light-Emitting Devices
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-EL02

5:00 AM *F.EL02.05.01
High-Performance Light-Emitting Devices Based on Metal Halide Hybrid Perovskites Toshinori Matsushima; Kyushu University, Japan

Metal halide perovskites have been widely used as the light absorber of solar cells, with the highest certified power conversion efficiency has reaching 25.2%, which is comparable to silicon-based solar cell technology. This high efficiency is inherent in perovskite's characteristics, such as high absorption coefficient, bandgap tunablity, long carrier diffusion length, high carrier mobility, and compatibility with simple solution processing or vacuum evaporation. By taking these characteristics, perovskites can be used as the emitter of light-emitting diodes (LEDs) and laser devices. In this context, we show our recent results on such optoelectronic applications based on perovskites.
We found that singlet and triplet excitons are formed in quasi-two dimensional perovskite films with many domains of different phase orders (Nat. Photon., 14, 70, 2020). When we used organic cations with the low triplet energy for the fabrication of quasi-two dimensional perovskite films, the triplets generated by the recombination of electrons and holes injected from electrodes are strongly quenched. On the other hand, the use of organic cations with the sufficiently high triplet energy enabled the generated triplets to be harvested for emission as a result of efficient reverse intersystem crossing. With this method, we demonstrated a four-fold increase in external quantum efficiency of quasi-two-dimensional perovskite LEDs.
To demonstrate the potential of using perovskites for other applications, we used the wide-energy-gap perovskite as the host layer of organic LEDs (Adv. Mater., 30, 1802662, 2018). We doped an organic fluorescent emitter into the perovskite host layer. The fluorescent molecules could exist at grain boundaries of perovskite films. Because of the better overlap between the emission band of the perovskite and the absorption band of the fluorescent molecules, the energy transfer from the perovskite to the organic emitter happened. We obtained low-voltage driving in the LEDs because of the high hole and electron mobilities of the perovskite. The radiative singlet exciton generation efficiency of the LEDs achieved ~40%, which is higher than the theoretical limit (25%) of emission from single excitons. We already demonstrated ~100% radiative singlet generation efficiency in a similar fluorescence/perovskite composite system.
To overcome poor carrier transport in organic films, we used the perovskite as the transport layers of organic LEDs (Nature, 572, 502, 2019). We were able to increase the total organic LED thickness by more than 10 times without reducing efficiency or operational durability or increasing driving voltage . This overturns 30 years of thinking that organic LEDs are limited to thin organic films. Additionally, some of thick organic LEDs with the perovskite transport layers had the same electroluminescence color from every viewing angle because of the absence of the optical interference. These results open new paths for low-cost, reliable, and uniform fabrication of organic LED displays and lighting.
We found that thresholds of amplified spontaneous emission under optical pumping strongly depend upon phase orders of perovskite films; thresholds decrease when a higher phase order is used and a typical three-dimensional perovskite with the highest phase order has the lowest threshold (Phys. Chem. Chem. Phys. 20, 15030, 2018). By embedding three-dimensional perovskite films into two-dimensional distributed feedback grating substrates, we saw lasing from the perovskite under optical pumping, with a peak width being lower than 1 nm (ACS Photon. 6, 460, 2019). We demonstrated a way of replicating grating patterns in lasing perovskite films on low-cost plastic substrates, which can reduce complexity and cost of the perovskite laser fabrication in the future (Appl. Phys. Lett. 115, 141106, 2019).

5:15 AM F.EL02.05.02
Colorless and Transparent OLED with Solution Processable Electron Transport Layer Je-Heon Oh and Jin-Woo Park;

Yonsei University, Korea (the Republic of)

Transparent displays have attracted considerable interest as the next-generation display technology in various fields, such as automotive industries, defense or military technology, and internet of things (IoT) applications. These applications require simultaneous projection or display of information and visibility of the surroundings through the device. However, the widely commercialized organic light-emitting diodes (OLEDs) are only used in semi-transparent displays due to their opaque and reflective metal thin film cathodes using Al and Ag despite the numerous excellent properties of OLEDs such as high color contrast, wide viewing angles and low-cost solution-based fabrication. For the transparent OLEDs (T-OLEDs), all the electrodes and organic functional materials in an OLED should be transparent. Especially, the opaque metal cathode should be replaced by a transparent material and blue EML materials owing to their wide electronic band gap sholud be used for the colorless characteristic. This study presents transparent organic light-emitting diodes (T-OLEDs) with excellent light-emission performance achieved by virtue of optically transparent functional layers. In this T-OLED, blue polymer poly(9,9-di-n-octylfluorenyl-2,7-diyl) (PFO) is used as a host material for the emission layer (EML) of the T-OLEDs, to achieve a high optical light transmittance in the visible range of the light spectrum. By controlled blending of the commercial emitting material Super Yellow with the PFO, the light-emission efficiency of the EML was significantly improved and the electroluminescence color could be changed from blue to green through a Förster resonance energy transfer (FRET). Furthermore, indium tin oxide (ITO) thin films was used not only as a transparent bottom anode but also as a transparent top cathode. Indium tin oxide (ITO) is one of the best candidates for transparent cathodes, owing to its excellent combination of optical transparency and electrical conductivity, along with its highly developed and mature deposition technology. However, the direct-current (DC) magnetron sputtering deposition approaches cause detrimental plasma damages to the organic layers ITO is deposited. Hence, solution-processable electron-transport composed of the zinc oxide (ZnO) nanoparticle layers and cesium carbonate-doped polyethyleneimine ethoxylated (d-PEIE), which aside from facilitating the efficient injection of electrons into the T-OLED, protected the organic emission layer (EML) of the T-OLED against the plasma damage during top ITO cathode sputtering deposition. Furthermore, semi-hydrophilic poly(methyl methacrylate) (PMMA) interlayer coated between the EML and ETL insured the good wettability and contact of the hydrophilic ETL with the hydrophobic EML. The even distribution of ZnO-NPs in the uniformly coated newly designed solution-processable composite ETL significantly enhanced the blue light emission performance of the conventionally structured T-OLED with top ITO cathode. The solution-processed T-OLED emitted the total maximum luminance (L_{max}) of about 2,417 cd m^{-2} (bottom ITO anode emission at 1,455 cd m^{-2} and top ITO cathode emission at 962 cd m^{-2}), total maximum current efficiency (ε_{max}) at 3.12 cd A^{-1} (bottom and top emissions at about 1.78 and 1.34 cd A^{-1}, respectively), and total maximum power efficiency (η_{max}) at 1.64 lm W^{-1} (bottom and top emissions at about 0.95 and 0.69 lm W^{-1}, respectively) while having a very high optical transmittance of around 85% at 550 nm light wavelength.

Electroluminescent Metal-Organic-Framework Films with Thermally-Activated Delayed Fluorescence Mariana Kozlowska[1], Ritesh Haldar[2], Marius Jakoby[3], Ian A. Howard[4,3], Christof Wöll[2] and Wolfgang Wenzel[1]; [1]Institute of Nanotechnology, Karlsruhe Institute of Technology, Germany; [2]Institute of Functional Interfaces, Karlsruhe Institute of Technology, Germany; [3]Institute of Microstructure Technology, Karlsruhe Institute of Technology, Germany; [4]Light Technology Institute, Karlsruhe Institute of Technology, Germany

Light-emission efficiency of organic light emitting diodes (OLEDs) strongly depends on the photophysical processes: charge recombination, population of triplet excitons, nonradiative decay, steered by the electronic structure of molecules, their orientation and morphology. Various techniques to enhance luminescence and device quantum yield were reported. Among them, incorporation of thermally activated delayed fluorescent (TADF) chromophores allowing to convert unwanted triplets to singlets through reverse intersystem crossing (RISC) is a promissing approach. Yet, controlled and stable assembly of TADF chromophores, modulating their functionality, is still not known, therefore, it is highly desirable to find a synthetic platform promoting the achievement of theoretically predicted device efficiencies.

Due to their vast chemical composition space, metal organic frameworks (MOFs) have emerged as a versatile class of functional materials with tunable properties for various applications. Here, we demonstrate new surface-anchored MOF (SURMOF) thin films with TADF activation, which results in efficient green electroluminescence of a LED device with luminance of 270 Cd/m^2 at 14.25 V. The TADF functionality of films originates from controlled aggregation of chromophores during their packing in a MOF scaffold. There, restriction of the rotational freedom of MOF linkers triggers new photophysical phenomena based on the “hot-exciton” RISC, enabling high population of singlet excited states and efficient SURMOF emitting layer [1].

In my talk, in depth explanation of the observed RISC processes and emission efficiency on the basis of the time-dependent

density functional theory calculations within quantum mechanics/molecular mechanics (QM/MM) approach will be given. The temperature dependence of RISC will be demonstrated as a function of the microscopic parameters between singlet and triplet excited states, i.e. energy splitting, reorganization energy and spin-orbit coupling, as predicted from the Marcus theory of charge transport. Perspectives of future computational screening of TADF chromophores [2] leading to a pronounced increase in luminescence of SURMOF-LEDs will be shown.

Modulation of Electronic, Structural and Photophysical Properties of Alkoxyphenyl Thiazolothiazole Based Materials for OLED Applications Abhishek Shibu, Carly Kwiatkowski, Sean Jones, Daniel Jones and Michael Walter; University of North Carolina at Charlotte, United States

Organic light emitting diodes (OLEDs) are becoming ubiquitous with applications in television and computer screens, smart windows and wearable diagnostic tools due to their high resolution, energy efficiency and novel flexibility. However, the growth of this $48Bn industry is facing stagnation due to dearth of suitable blue emitters. OLEDs need excellent red, green and blue emitters. Although the industry has high performing red and green emitters, the search is still ongoing for suitable blue emitters in solid state.
Presently, blue emission is obtained from rare-earth metal complexes which have complex synthesis routes and difficult processability. These materials have low thermal stability and poor operation lifetimes. As a result, the final devices are inefficient and expensive.
Among other potential candidates, thiazolothiazole (TTz) based materials have been widely reported as a molecular semiconductor that can emit blue. This blue emission has been used for a plethora of applications. TTzs are solution processible materials with facile synthesis routes using inexpensive and environment friendly precursors. They are thermally stable, and their planar structure enhances conduction of charge carriers in devices. Despite these properties, TTzs have been relatively unexplored for OLED applications. We hypothesize that TTz based materials can represent a new generation of affordable display materials with high device efficiency. In this study, we report the effect of different molecular spacers on electronic, structural and photophysical properties of seven novel TTz materials to help identify most suitable candidate for OLEDs.
We have explored the effect of molecular spacers on TTz packing, by resolving the crystal structures of the synthesized materials using single crystal X-ray diffractometry. Combined with fluorescence studies, we have thus correlated the tuning of inter-TTz core distances in a unit cell to their emission properties. We have determined their thermal stability using thermogravimetry and differential scanning calorimetry.
We have also determined their quantum yield and photoluminescence emission lifetime decay profiles. To establish exciton diffusion through these molecules, we have determined their singlet exciton diffusivity coefficient and the exciton diffusion length by employing a time resolved bulk quenching model with Monte Carlo eDiffusion computation simulation. We have also explored the molecular orientation of these materials in spin cast thin films using grazing incidence wide angle X-ray scattering. We establish the crystal orientation in thin films and how it affects charge mobilities in devices. This study will enable future researchers to engage in further possibilities with these materials, within and beyond the scope of OLEDs.

Late News: High Efficiency Pure Blue Fluorescent Organic Light Emitting Diode with CBP - BSB4 Emissive Layer Dhruvajyoti Barah, Inaganti N. Manoj, Subhamoy Sahoo, Haripriya Kesavan, Jayeeta Bhattacharyya and Debdutta Ray; Indian Institute of Technology Madras, India

We present a pure blue fluorescent organic light emitting diode (OLED) where the device structure is optimized to yield a Commission Internationale de l'Eclairage (CIE) coordinate of (0.15, 0.13) which is very close to the National Television Standards Committee (NTSC) standard of blue color (0.14, 0.08). The emissive layer (EML) is composed of a host-guest matrix of 4,4'-di[N-carbazolyl] diphenyl (CBP, host) and 4,4'-Bis[(N-carbazole) styryl] biphenyl (BSB4, guest). We show, from photoluminescence (PL) studies, a blue-shift in the emission spectrum of the host-guest matrix from that of the pristine guest molecules resulting in a pure blue emission suitable for display application. We demonstrate methods to balance the electron and hole concentration in the EML of the OLED in order to improve the efficiency and its roll-off and optimize the

device to obtain a maximum external quantum efficiency (EQE) of 4.08%. This is very close to the theoretical limit for EQE (5%) of fluorescent OLEDs without the use of any light extraction layer. This is achieved by the choice of organic materials and their thicknesses in the OLED stack. The charge carrier mobility and molecular energy levels of the organic materials are taken into consideration for this optimization.

Tailoring Phase Purity in 2D Halide Perovskites for High-Efficiency Optoelectronic Devices Aditya D. Mohite; Rice University, United States

Two-dimensional (2D) perovskites are a class of halide perovskites offering a pathway for realizing efficient and durable optoelectronic devices. One of key challenges has been the limited understanding of film formation, which have led to quasi-2D perovskite films with a high degree of polydispersity. Here we describe a novel technique, which leads to 2D perovskite thin-films with a high degree of phase purity as we go from precursors to thin-films. Photovoltaic devices fabricated with such films, yields an efficiency of 17.1% and 1.20V open-circuit voltage, while preserving 98% of their peak-performance after 800 hours under illumination without any external thermal management.

Metal Halide Perovskite Nanocrystals: Stability Improvement, Spectral Range Tuning via B-Site Substitution and Applications in Solar Energy Conversion Yueli Liu[1], Sudarsan Tamang[2], Dmitry Aldakov[3] and Peter Reiss[3]; [1]Wuhan University of Technology, China; [2]Sikkim University, India; [3]CEA Grenoble, France

Metal halide perovskite nanocrystals (MHP NCs) exhibit many novel and unique phenomena both in terms of photophysics and materials chemistry. For NIR emission and solar energy conversion, the use of all-inorganic $CsPbI_3$ NCs is especially appealing, combining a narrow band gap with improved stability due to the absence of volatile organic constituents. However, the cubic black phase of $CsPbI_3$ is not thermodynamically stable at room temperature and transformation to the yellow orthorhombic phase occurs. This problem can be overcome by the use of molecular iodine as the halogen source during synthesis. It results in an improved surface passivation of the NCs and long-term air- and phase-stability of $CsPbX_3$ NCs.
Substitution of lead by the lighter group-14 homologue tin enables to shift the absorption onset and photoluminescence peak further to the near infrared, beyond 900 nm. However, Sn^{2+} is much more prone to oxidation to the +IV state than Pb^{2+} and can give rise to the formation of undesired intraband trap states. In this regard, mixed $Cs(Pb,Sn)I_3$ NCs exhibit enhanced stability and further possibilities of luminescence and morphology control, which will be discussed. Complete substitution of lead is also possible with europium, which gives access to nanoparticles strongly emitting in the deep blue spectral range (400-420 nm).
Finally, the application of the obtained MHP NCs in two approaches for solar energy conversion will be presented. First, they are incorporated into mesoporous TiO_2, which constitutes to date the best performing electron transport material in perovskite solar cells. Efficient migration of the NCs into the mesoporous structure is achieved by means of interface engineering, enhancing at the same time significantly the electron injection rate. As a result, highly reproducible perovskite NC solar cells with an efficiency exceeding 14% could be obtained.
As an example for a further emerging application, the obtained air-stable MHP NCs can also be used as photocatalysts in organic syntheses. As an example, we demonstrate their use as efficient visible-light photocatalyst for the oxidative aromatization of a wide range of heterocyclic substrates.

5:30 AM F.EL02.06.04
Denatured M13 Bacteriophage-Templated Perovskite Solar Cells Exhibiting High Efficiency Il Jeon[1,2], Haosheng Lin[1], Yutaka Matsuo[1] and Jin-Woo Oh[2]; [1]The University of Tokyo, Japan; [2]Pusan National University, Korea (the Republic of)

The M13 bacteriophage, a nature-inspired environmentally friendly biomaterial, is used as the perovskite crystal growth template and the grain boundary passivator in perovskite solar cells. The amino groups and carboxyl groups of the four types

of amino acids on the M13 bacteriophage surface function as Lewis bases, interacting with the perovskite materials. The M13 bacteriophage-added perovskite films show a larger grain size and reduced trap-sites compared with the reference perovskite films. In addition, the existence of the M13 bacteriophage induces light scattering effect, which enhances the light absorption particularly in the long-wavelength region around 825 nm. Both the passivation effect of the M13 bacteriophage coordinating to the perovskite defect sites and the light scattering effect of the M13 bacteriophage intensify when the M13 virus-added perovskite precursor solution is heated at a temperature of 90 °C prior to the film formation. Heating the solution denatures the M13 bacteriophage by breaking their inter- and intra-molecular bondings. The denatured M13 bacteriophage-added perovskite solar cells exhibit a power conversion efficiency of 20.1% while the reference devices without the addition of the virus give a power conversion efficiency of 17.8%. The great improvement in efficiency comes from all of the three photovoltaic parameters, namely short-circuit current, open-circuit voltage, and fill factor, which corresponds to the perovskite grain size, trap-site passivation, and charge transport, respectively.

5:40 AM F.EL02.06.05
Study of The Synergetic Effects of Chloride and Surfactants Additions on Perovskite Crystallisation, in a Slot-Die Coating Process for Large-Scale Fabrication Sophie Bernard[1,2,3], Sébastien Juteau[1,2], Armelle Yaiche[1,2], Stefania Cacovich[4], Frederic Sauvage[3] and Jean Rousset[1,2]; [1]EDF R&D, France; [2]IPVF (Institut Photovotaïque d'Ile de France), France; [3]CNRS, UPJV Université Picardie Jules Verne, France; [4]CNRS UMR 9006, France

For the past ten years, perovskite solar cells have known a tremendous development among photovoltaic technologies, rapidly increasing from 3,8% [1] to 25.2% [2] power conversion efficiency (PCE). However, before transferring this technology to commercial applications, one of the main challenges to overcome is the fabrication of high quality perovskite absorber films on large surfaces. Various alternatives to spin-coating have been explored in the literature such as blade coating [3], inkjet coating [4], roll-to-roll [5] or spray coating [6]. But, slot-die coating is one of the most promising techniques. It is easily compatible with high rate fabrication technique like roll-to-roll and allows a sharp control over the uniformity on large surfaces.

In this work, we emphasis on the influence of the drying method upon the absorber properties. After the slot-die coating deposition, we chose to use a vacuum quench method, which allow a uniform extraction of the solvent, few minutes before annealing. The change of the quench system, from anti-solvent to vacuum aspiration, modify the speed with which the solvent is extracted. Then, it is possible to influence the crystallization mechanisms to fit the new drying environment by changing the perovskite ink composition. We herein propose a method to fabricate CsFA perovskite with a double-additives protocol, combining a surfactant and chloride addition through MACl.

A particular difficult challenge is to isolate the action of the surfactant and the chloride during crystallization. We combined PL and morphological characterisations, under different annealing and quench conditions, in order to successfully bring their respective effects out. For example, including MACl into precursor solutions seem to increase the film coverage and grain sizes during secondary grain growth, generating a smooth and pinhole-free perovskite layer with large grain size while surfactant enhance film uniformity and passivate surface defects. We reached over 16% PCE on small-scale cells (0.09 cm^2 aperture) with optimized ratio of chloride, thermal annealing and vacuum conditions.

This approach offers a better understanding of perovskite growth under large-scale fabrication conditions and is an important step towards industrial perovskite devices.

Ultrafast State-Resolved Pump-Probe Spectroscopy of $CsPbBr_3$ Nanocrystals Reveals Lineshape Dynamics and Quantum Confinement Colin Sonnichsen, Dallas Strandell, Patrick Brosseau and Patanjali Kambhampati; McGill University, Canada

Disorder is intrinsic to ionic systems and gives rise to specific electronic processes. In recently developed perovskite ionic crystals, this dynamic lattice disorder is inferred to give rise to properties of interest, such as defect tolerance. Here, the

elementary excitation of interest is the polaron, a localized lattice distortion. We employ state resolved pump-probe spectroscopy to monitor electron and lattice dynamics in bulk $CsPbBr_3$ perovskite nanocrystals. The data report spectral lineshape dynamics that monitor the system from optical birth through polaron formation and exciton formation to fully thermalized, confined exciton. The formation of quantum confined excitons arises from the liquid-like polaronic potential. This polaronic confinement creates a quantum drop, as opposed to physical confinement creating a quantum dot. Disorder is intrinsic to ionic systems and gives rise to specific electronic processes. Ligand-Engineered Perovskite Nanoparticles for Photovoltaic Application Seung Hyeon Jo[1], Soyeong Ahn[2] and Tae-Woo Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Pohang University of Science and Technology, Korea (the Republic of)

Metal halide perovskites (MHPs) are promising materials for active layers in solar cells (SCs) because they have outstanding advantages such as low exciton binding energy (~14 meV for $CH(NH_2)_2PbI_3$)[1] and high carrier mobility (100 $cm^2/(Vs)$)[2]. Despite the superior properties of MHPs, MHP polycrystalline (PC) bulk film based SCs had bad reproducibility due to bad surface morphology of MHP PC films. Furthermore, controlling the surface morphology of MHP PC films is very difficult because the environmental conditions such as temperature and moisture have a strong influence on the morphology. Here, we present MHP nanoparticles (NPs) synthesized by hot injection method and purified with ligand-engineering method. Moreover, perovskite NP layers with uniform morphology were fabricated by using a ligand washing method. The ligand engineering methods which reduce the amount of ligand improved the charge extraction/transport characteristics in MHP NP films. Also, more ligands can be removed by washing MHP NP films with organic solvent. The washing method is applied by dropping the organic solvent onto the film followed by subsequent spin-coating. Our research suggests a promising way to increase PCE of perovskite NP SCs.

6:10 AM F.EL02.06.08
A Near-Infrared Te-Doped GaAsSb Ensemble Nanowire Schottky Barrier Photodetector Shisir Devkota[1], Rabin Pokharel[1], Mehul Parakh[1], Sean Johnson[1], Priyanka Ramaswamy[1], Aubrey Penn[2,2], Lewis Reynolds[2] and Shanthi Iyer[1]; [1]North Carolina A&T State University, United States; [2]North Carolina State University, United States

In this work, we report on a systematic investigation of the effect of tellurium (Te)-doping on the morphological, optical, and electrical properties of the GaAsSb nanowires (NWs) grown by Ga-assisted molecular beam epitaxy (MBE) and realization of the ensemble device. Te-incorporation in the NWs was assessed qualitatively from the structural, optical, and electrical properties, whereas the quantitative assessment was made based on the dark I-V simulations. Schottky barrier ensemble photodetector (PD) fabricated by capitalizing on optimized Te-doped NW exhibited a broad spectral range with the longer wavelength cutoff at ~1.2 µm, responsivity in the range of 580- 620 A/W and detectivity in the 1-3x 10^{12} Jones. Padovani-Stratton parameter (E_{00}) revealed field emission mechanism being dominant current conduction mechanism, backed by the higher ideality factor. Low-frequency noise (LFN) spectroscopy revealed the generation-recombination noise being the dominant noise source attributed to the Te induced localized states. The doped GaAsSb NWs have tremendous potential for further improvement, paving the path for high-performance NIR photodetection applications.

Late News: Synthesis of Lead-Free FASnI-based Perovskite Nanoparticles for Solar Cell and Lighting Applications Zeying Chen[1,2,2] and Tara Dhakal[1,2,2]; [1]Binghamton University, United States; [2]Binghamton University, The State University of New York, United States

Metal halide perovskites with optimal opto-electronic properties contain lead (Pb). The replacement of lead with less toxic or nontoxic element, such as tin, has been studied in bulk thin film, but few in nanocrystal form. In this research, we synthesized

lead-free FASnI-based (FA: formamidinium) perovskite nanoparticles through the ligand-assisted reprecipitation method (LARP) at low temperature, and studied the impact of precursor solution molarity, the precursor solvent and the "poor" solvent on the phase of perovskite nanoparticle as well as optical properties. Different kinds of ligand were used and their function during the synthesis process were investigated. By controlling the molarity of precursor solution, we were able to tune the bandgap of FASnI-based perovskite from 700nm (1.77eV) to more than 830nm (1.49eV). For the same synthesis condition, the compositional variation of precursor solvent affected the phase of perovskite with either blue or red shift in PL spectra. For example, when 20% of DMSO was introduced into precursor solution, there is a ~70nm blue shift in photoluminescence spectra. A series of "poor solvents" were used in this research, such as chlorobenzene, chloroform, toluene, and hexane, among which the synthesis with toluene exhibited the better performance. With the interplay between precursor molarity, type of solvents, and ligands, we were able to achieve a low temperature synthesis of single phase $FAPbI_3$ nanoparticles. The PL, XRD and TEM data will be presented along with synthesis details.

Status and Prospects of Colloidal Quantum Dot Lasers Victor I. Klimov; Los Alamos National Laboratory, United States

Colloidal semiconductor quantum dots (CQDs) are attractive materials for realizing highly flexible, solution-processable optical gain media with readily tunable operational wavelengths [1, 2]. However, CQDs are difficult to use in lasing due to extremely short optical gain lifetimes limited by nonradiative multicarrier Auger recombination [3]. This, in particular, is a serious obstacle for realizing cw optically and electrically pumped lasing devices. Recently, we have explored several approaches for mitigating the problem of Auger decay by taking advantage of a new generation of core/multi-shell CQDs with a radially graded composition that allow for considerable (nearly complete) suppression of Auger recombination [4, 5]. Using these specially engineered CQDs, we have been able to realize optical gain with direct-current electrical pumping [4], which has been a long-standing goal in the field of colloidal nanostructures. Further, we have applied these dots to practically demonstrate the viability of a '*zero-threshold optical gain*' concept using not neutral but negatively charged particles wherein the pre-existing electrons block either partially or completely ground-state absorption [5, 6]. Such charged QDs are optical-gain-ready without excitation, which has allowed us to reduce the lasing threshold to record-low values that are well below the fundamental single-exciton-per-dot limit [6]. Most recently, we have developed CQD devices that operate as both an electroluminescent (EL) structure and a distributed feedback optically pumped laser [7]. By carefully engineering a refractive-index profile across the device stack, we have been able to demonstrate low-threshold lasing even with a very thin EL-active region, which comprises only three monolayers of the QDs. Yet another recent advance has been the realization of CQD-LEDs that achieve ultrahigh current densities exceeding 1,000 A cm^{-2}. This has allowed us to inject ~10 excitons per dot and thereby realize population inversion of both the ground-state (1S) and the excited-state (1P) transitions. All of these recent developments suggest that CQD laser diodes (QLDs) are just around the corner. The availability of such devices will benefit numerous fields from integrated photonic circuits and optical interconnects to lab-on-a-chip platforms and wearable devices.

On-Chip Light-Emitting Diodes and Lasers Integrated in the Final Back-End Processing Step John P. Murphy, Alex J. Grede, Hoyeon Kim, Robert Cawthorn and Noel C. Giebink; The Pennsylvania State University, United States

Silicon photonic integrated circuits operating at visible and near-infrared wavelengths have enormous application potential; however, a scalable on-chip light source remains elusive. We address this challenge by introducing a new paradigm for halide perovskite light-emitting diodes (LEDs) and lasers that enables them to be integrated on silicon in a final solution processing step in the back-end-of-line (BEOL). In contrast to traditional sandwich-type device architectures, our approach makes use of co-planar interdigitated electrodes with ~100 nm spacing that facilitates both low voltage current injection and first order distributed feedback for lasing. This strategy overcomes the limited compatibility of perovskite materials with silicon processing by essentially pre-fabricating all components for LEDs and lasers expect light-emitting materials so that they become functional once the perovskite is deposited from solution in the last step.
We demonstrate this approach by fabricating methylammonium lead iodide (MAPI) perovskite LEDs on SiO_2/Si using alumina-coated Au interdigitated electrodes patterned by electron beam lithography. Despite the nominally-symmetric electrical structure of the devices, we achieve bipolar injection and bright MAPI electroluminescence with turn-on voltages below 2V. We propose that ionic conduction in MAPI, which is often viewed as detrimental for photovoltaics, is advantageous in this case because it can be exploited to break the electrical symmetry of the device by accumulating ions at the anode and cathode contacts so that the resultant interfacial band-bending facilitates hole and electron injection, respectively. We go on to investigate the operation of these devices under GHz bandwidth electrical pulsing enabled by an on-chip graded-impedance matching network and discuss the remaining hurdles that must be overcome to achieve electrically-pumped lasing.

Lasing in the Space Charge-Limited Current Regime—Implications for Organic and Halide-Perovskite Laser Diodes Alex J. Grede and Noel C. Giebink; The Pennsylvania State University, United States

Organic and halide-perovskite semiconductors are capable of low threshold optically-pumped lasing over a wide range of wavelengths. Combined with their capacity for non-epitaxial deposition, these materials could facilitate a new range of coherent light sources for integrated photonics if electrically-pumped lasing can be established. In contrast to mature III-V laser diode technology where gain is achieved by diffusion current in a pn junction, the active layer in organic lasers cannot be doped because the dopants severely quench emission, and simply doping perovskites remains an ongoing challenge to begin with. In both cases, this means that gain will need to be achieved in an undoped active layer by a space charge-limited (SCL) *drift* current – a fundamentally different regime for diode lasing than III-V lasers operate in. While unipolar SCL current frequently occurs in organic materials and bipolar SCL current has been claimed in some organic light-emitting diodes, the implications of bipolar SCL current for lasing in organic and perovskite semiconductors has not been explored. Here, we establish analytical bounds on the threshold current, voltage, and power density for laser diodes operating in the bipolar SCL current regime. This formalism also provides useful insight into scaling relationships for SCL lasing in regard to electric field strength, carrier concentrations, recombination uniformity, and the impact of mobility imbalance on bimolecular quenching processes such as exciton-polaron annihilation (organics) and Auger recombination (perovskites). Importantly, we show how sub-Langevin recombination in perovskite semiconductors implies substantially higher threshold current density than in organics and motivates the need for quantum dot/well-like architectures to exploit carrier concentration/funneling effects. Our results establish basic bounds for the operation of organic and perovskite laser diodes and provide analytical guidelines for designing devices and identifying materials that are best suited for lasing in the SCL current regime.

5:35 AM F.EL02.07.04
Room-Temperature Lasing in Colloidal Nanoplatelets via Mie-Resonant Bound States in the Continuum Mengfei Wu[1], Son Tung Ha[1], Sushant Shendre[2], Emek Durmusoglu[2], Weon-Kyu Koh[2], Diego Abujetas[3], José Sánchez-Gil[3], Ramon Paniagua Dominguez[1], Hilmi Volkan Demir[2] and Arseniy Kuznetsov[1]; [1]Institute of Materials Research and Engineering, A*STAR, Singapore; [2]LUMINOUS! Centre of Excellence for Semiconductor Lighting and Displays, Nanyang Technological University, Singapore; [3]Instituto de Estructura de la Materia (IEM-CSIC), Consejo Superior de Investigaciones Científicas, Singapore

Solid-state room-temperature lasing with tunability in a wide range of wavelengths is desirable for many applications. To achieve so, besides an efficient gain material with a tunable emission wavelength, a high quality-factor optical cavity is essential. Here, we combine a film of colloidal CdSe/CdZnS core-shell nanoplatelets with square arrays of nanocylinders made of TiO_2 to achieve optically-pumped lasing at visible wavelengths and room temperature. The all-dielectric arrays support bound states in the continuum (BICs), which result from lattice-mediated Mie resonances and boast infinite quality factors in theory. In particular, we demonstrate lasing from a BIC that originates from out-of-plane magnetic dipoles oscillating in phase. By adjusting the diameter of the cylinders, we tune the lasing wavelength across the gain bandwidth of the nanoplatelets. The spectral tunability of both the cavity resonance and nanoplatelet gain, together with efficient light confinement in BICs, promises low-threshold lasing with wide selectivity in wavelengths.

Identifying Spin Alignment between Coherent Light-Emitting Excitons Occurring in Amplified Spontaneous Emission in Perovksites Miaosheng Wang; The University of Tennessee, Knoxville, United States

Amplified spontaneous emission (ASE) have become a common phenomenon in hybrid perovskites by establishing coherent light-emitting states. This paper reports a new phenomenon where spin alignment is occurred between coherent light-emitting excitons in the ASE regime in the perovskites. It is observed that the ASE exhibits higher and lower amplitudes when spin alignment is operated differently by using circularly and linearly polarized pumping. This shows as an increase on ASE amplitude upon switching pumping beam from linear to circular polarization, leading to a positive △ASE. Essentially, this positive △ASE identifies that the orbital magnetic dipoles between coherent light-emitting excitons are conserved during ASE development, realizing spin-aligned coherent light-emitting excitons. Furthermore, increasing pumping fluence gives rise to an enhancement on △ASE phenomenon, proportionally following the ASE trend. This result indicates that the spin alignment can be gradually established between coherent light-emitting excitons by increasing pumping density. Clearly, our studies present a fundamental understanding on spin alignment between coherent light-emitting excitons towards developing spin-dependent lasing actions in metal halide perovskites.

Late News: Whispering-Gallery Mode Lasing in Perovskite Nanocrystals Chemically Bound to Silicon Dioxide Microspheres Nathaniel J. Davis; Victoria University of Wellington, New Zealand

Cesium lead halide perovskite nanocrystals exhibit high photoluminescence quantum efficiencies and tunability across the visible spectrum. This makes these crystals ideal candidates for solar panels, light-emitting diodes, lasers, and especially nanolasers. Due to the versatility of cation substitution in perovskite nanocrystals, they can be grown on amine-functionalized silicon dioxide nanoparticles, where the amine linker replaces the standard cation structure. Selectively growing luminescent nanocrystals on spherical silicon dioxide microspheres results in the opportunity to populate whispering-gallery modes in these spherical silica microspheres. In this case, the nanocrystal halide composition can be used to selectively tune the emission wavelength mode, and microsphere radius to tune the mode spacing. This silicon dioxide attachment also adds to the overall stability of the system. Through photoluminescence microscopy measurements, we show whispering gallery modes in individual perovskite-coated microspheres for $CsPbBr_3$ and $CsPbI_3$ nanocrystals on 9.2 μm diameter silica spheres and compare these to theoretically predicted optical modes. In $CsPbBr_3$, we provide evidence that these modes will lase under optical excitation, with a threshold of 750 $\mu J/cm^2$. This study presents a novel system that, through optimization, could be a promising pathway to achieve facile and stable perovskite nanolasers.

Photon Upconversion—Effect of Material Dimensionality Zachary VanOrman and Lea Nienhaus; Florida State University, United States

Photon upconversion describes the process of shortening the wavelength of the light emitted upon irradiation, resulting in a gain in photon energy. To comply with energy conservation laws, this occurs by combining two or more low energy photons through triplet states. Since triplet states are ‘spin-forbidden’, so-called sensitizers are required to indirectly populate the triplet state. Triplet sensitizers span a broad range of material classes including from metal-organic complexes, nanomaterials and bulk films. Understanding the energy transfer mechanism is crucial for the advancement of optoelectronic devices based on this process. In particular, tailoring the role of trap states in the sensitizer is key to further increase the device efficiency. The exact triplet sensitization mechanism varies depending on several factors including: (i) the absolute alignments of the sensitizer and acceptor energy levels. (ii) The exciton binding energy in the sensitizer, resulting in excited states in form of excitons or free carriers. (iii) Energetic polydispersity of a sample, which varies the energetic driving force for triplet transfer. I will present the current understanding of the triplet sensitization mechanism based on sensitizer materials with different dimensionalities including 0D quantum dots, 1D nanorods and 2D nanoplatelets and highlight the differences of each upconversion system. We obtain upconversion efficiencies exceeding 15% for quantum dot based green-to-blue

upconversion and 5% for nanoplatelet-based green-to-blue upconversion.

5:15 AM F.EL02.08.03
Green-to-Blue Triplet Fusion Upconversion Sensitized by Anisotropic CdSe Nanoplatelets Zachary VanOrman, Alexander S. Bieber, Sarah Wieghold and Lea Nienhaus; Florida State University, United States

Photon upconversion (UC) resulting in blue and ultraviolet wavelengths has been studied for application in photocatalysis, as these high energy wavelengths could be transiently generated from lower energy excitation, thus avoiding photobleaching effects. Specifically, this can occur through the process of triplet-triplet annihilation based upconversion (TTA-UC), where the combination of two spin-triplet states results in a higher energy spin-singlet excited state. TTA-UC, however, requires triplet sensitization from another source, as triplets cannot be directly excited, as given by spin-selection rules.
We investigate 2D CdSe nanoplatelets (NPLs) as potential triplet sensitizers in a TTA-UC scheme. NPLs only have one dimension of quantum confinement, allowing for finer control of the band gap emission. Additionally, as NPLs have not been substituted for QDs previously, we looked to examine if their unique properties, like their giant oscillator strengths and ability to form stacks and other microstructures, would have an effect on TTA-UC.
We investigated the NPLs as a triplet sensitizer while taking advantage of 9-anthracenecarboxylic acid (ACA) as a transmitter ligand to increase the efficiency of energy transfer between the sensitizer and the triplet annihilator, 9,10-diphenylanthracene, while comparing a system sensitized by a CdSe QD for the sake of comparison. While NPL stacking and parasitic singlet back transfer still limit the achievable UC efficiency, we obtain a promising UC quantum yield of 5.4% and a low efficiency threshold, I_{th} = 237 mW/cm^2.[1]

5:25 AM F.EL02.08.05
Optical Properties of Alloyed Quantum Dots: Experiment and Simulation Erick I. Hernandez Alvarez, Andre Schleife and Andrew M. Smith; University of Illinois at Urbana-Champaign, United States

Quantum dots (QDs) are popular materials for applications that require stable photoluminescence with narrow-band emission. Biological imaging applications impose restrictions on QD size, while significant advantages are gained by tuning emission to the biological near-infrared (NIR) window (700 - 2000 nm) where tissue transparency is high and autofluorescence noise is low. Mercury cadmium chalcogenide alloy QDs are promising materials for these applications because their emission wavelength can be tuned continuously throughout the visible and NIR spectra through cation exchange-mediated alloying without changing the QD physical dimensions. However, precise selection of emission wavelengths through alloying remains challenging. In this context, atomic scale modeling of QD photophysical properties with varying size and composition can inform experimental QD designs. Here we combine first principles simulations of alloyed zinc blende $Hg_xCd_{1-x}(S,Se)$ QDs with experimental results to describe the optical properties of these materials. First we present experimental results for a series of size- and composition-controlled $Hg_xCd_{1-x}S$ and $Hg_xCd_{1-x}Se$ QDs, including optical spectra and materials analysis. We further apply density functional theory to compute the ground state properties and simulated optical spectra of QDs with varying size and composition. In this talk, we will interpret the combination of results from both approaches to inform alloyed QD design.

5:35 AM F.EL02.08.06
Combining Machine Learning and First-Principles Methods for the Accurate Calculation of Emission Spectra of Realistic-Size Quantum Dots Sungwoo Kang[1], Yongwook Kim[2], Eunjoo Jang[2], Youngho Kang[3] and Seungwu Han[1]; [1]Seoul National University, Korea (the Republic of); [2]Samsung Advanced Institute of Technology, Korea (the Republic of); [3]Incheon National University, Korea (the Republic of)

Semiconductor quantum dots (QDs) have attracted significant interest for wide color gamut display applications. Narrow emission linewidths are required to be achieved for the optical performance. As synthetic techniques have been improved, inhomogeneous linewidths can be reduced close to the single-dot level. However, the ultimate limit and the mechanism of homogeneous broadening of QDs are not clarified yet.
In this study, we develop ab initio method to calculate the single-dot emission spectra of QDs originated from exciton-

phonon coupling (EPC) [1]. We calculate emission linewidths of core CdSe QDs, and demonstrate that the results are consistent with the CdSe/$Cd_xSe_{1-x}Ze_x$ QD [2]. In addition, the effect of charged surface traps on linewidth is studied. The partial Huang-Rhys factors of QDs show that the acoustic modes are dominant in EPC for perfectly passivated QDs, while the contribution of optical modes becomes significant with surface defects due to the internal field.
Next, to simulate actual-size InP/ZnSe core/shell QD (3,506 atoms), we develop the theoretical framework combining machine learning and density functional theory (DFT) calculations: the structural relaxation and phonon calculations are performed by neural network potential (NNP), and the exciton is described by constrained DFT in single-particle level. We train NNP over reference structures made of various bulk, surface, and interface of InP and ZnSe using SIMPLE-NN code [3]. Trained NNP is tested for ZnSe QD and InP/ZnSe QD, not included in the training set, and verified to provide a precise description of phonon spectra in similar accuracy to DFT. Combining trained NNP with DFT, we calculate the emission spectrum of InP/ZnSe QD, and find that the result is in good agreement with the experimental measurement on the same size of InP/ZnSe/ZnS QD [4,5]. In addition, we find that the contribution of optical modes significantly increases when introducing ZnSe shell due to the mismatch between electron and hole wave functions.

5:45 AM F.EL02.08.07
Nanocrystal Precursor Incorporating Separated Reaction Mechanisms for Nucleation and Growth to Unleash the Full Potential of Heat-Up Synthesis Joonhyuck Park[1], Arun Jayaraman[1], Xudong Wang[2], Jing Zhao[2] and Hee-Sun Han[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]University of Connecticut, United States

In the past few decades, many products incorporating quantum dots (QDs) have been introduced to the market. This has led to increasing demands for a simple, economical, and scalable synthesis method to produce high-quality core/shell QDs. The heat-up approach, involving bulk delivery of precursors at low temperature, is simple, scalable, and less sensitive to mixing limitations compared to the commonly used injection method. Its applications, however, have been limited because it inevitably yields a strong overlap between the nucleation and growth stages. We addressed this long-standing problem by introducing a new type of precursor having separated reaction paths for nucleation and growth. Unlike existing precursors, which employs a shared intermediate for both reactions, the new precursor have well-separated reaction mechanisms for growth and nucleation; growth proceeds via surface-assisted bond cleavage while nucleation requires the formation of metal-sulfur clusters in solution. Moreover, this precursor chemistry embeds an efficient mechanism to suppress nucleation during growth, enabling nucleation-free growth even at high precursor concentrations. Another unique benefit is temperature-independent tunability of precursor reactivity; the reactivity of the new precursor can be controllably tuned by chemical additives. By independently varying reaction temperature and precursor reactivity, researchers can systematically identify the optimal growth condition for various cores. We show that the new precursor grows high quality shells during heat up synthesis, comparable to those prepared by the continuous injection protocol. Lastly, we established a simple, economical, and scalable scheme for core/shell QDs by streamlining quantitative core synthesis and heat-up-based shell growth using the new precursor. The chemical insight obtained from this work inspires the design of other new precursors to unleash the full potential of heat-up synthesis as well as the development of a synthesis scheme that yields scale-independent reaction outcomes.

Electron Field Emission Behavior of Nitrogen Doped Graphene Quantum Dots Synthesized by Pulsed Laser Ablation Muhammad Shehzad Sultan[1], Vladimir I. Makarov[1], Muhammad Sajjad[2], Wojciech Jadwisienczak[3], Brad R. Weiner[1] and Gerardo Morell[1]; [1]University of Puerto Rico - Río Piedras, United States; [2]Indiana University Northwest, United States; [3]Ohio University, United States

Electron field emission is a process where the electrons are ejected from the material surface through quantum mechanical tunneling under the effect of high electric field. There is a great deal of research on the field emission properties of various nanomaterials, for example carbon nanomaterials, metal oxides, metal nitrides and metal tips. Among these cold cathode materials, carbon nanomaterials including carbon nanotubes (CNTs), graphene and diamond-like carbon are extensively investigated in order to seek high current density, stable and long-life cold cathodes. As expected, the carbon nanomaterials display unique advantages in field electron emission and carbon nanomaterials can potentially be used in cold-electron-source-based vacuum micro/nanoelectronics. Nitrogen doped graphene quantum dots (N-GQDs), chemically stable and with

potentially low toxic zero-dimensional nanostructure, are extensively studied in various fields, especially in energy storage, bio-imaging, photodetectors. So far the electron field emission behavior of individual N-GQDs has not been studied so in this research, a facile synthesis of nitrogen doped graphene quantum dots (N-GQDs) and its electron field emission performance will be carried out. Transmission Electron Microscopy (TEM), X-ray Photoelectron Spectroscopy (XPS), Raman and FTIR Spectroscopy, UV-vis and PL Spectra characterizations were carried out to study the structural and optical properties of as synthesized N-GQDs. The Current vs. Voltage (J–E) Curve of the N-GQDs Coated on Si Substrate was measured and Fowler–Nordheim (FN) plot was analyzed to check the Emission Stability of the N-GQDs Cathode with the objectives to achieve Outstanding Emission Stability of the N-GQDs Cathode and Low Turn-on Field (E_{to}) and Threshold Field (E_{th}).

Dielectric Confinement and Excitonic Effects in Two-Dimensional Nanoplatelets Alexander Efros[1], B. Ji[2], E. Rabani[3], R. Vaxenburg[4], D. Azulay[2], U. Banin[2] and O. Millo[2]; [1]U.S. Naval Research Laboratory, United States; [2]The Hebrew University of Jerusalem, Israel; [3]University of California, Berkeley, United States; [4]Howard Hughes Medical Institute, United States

Quasi-two-dimensional (2D) semiconductor nano-platelets manifest strong quantum confinement with exceptional optical characteristics of narrow photoluminescence peaks with energies tunable by thickness with monolayer precision.[1] We employed scanning tunneling spectroscopy (STS) in conjunction with optical measurements to probe the thickness-dependent band gap and density of excited states in a series of CdSe nanoplatelets.[2] The tunneling spectra, measured in the double-barrier tunnel junction cofiguration, reveal the effect of quantum cofinement on the band gap taking place mainly through a blue-shift of the conduction band edge, along with a signature of 2D electronic structure intermixed with finite lateral-size and/or defects effects. The STS fundamental band gaps are larger than the optical gaps as expected from the contributions of exciton binding in the absorption, as confirmed by theoretical calculations. The calculations also point to strong valence band mixing between the light- and split-off hole levels. Strikingly, the energy difference between the heavy-hole and light-hole levels in the tunneling spectra are significantly larger than the corresponding values extracted from the absorption spectra. We have shown that this difference is mainly connected with enhancing of dielectric confinement of light holes relative to the heavy hole observed in STS measurement and an increase of light hole exciton binding energy relative to heavy hole exciton binding energy observed in absorption spectra.[2]

Late News: Circular Dichroism in Non-Chiral Metal Halide Perovskite Nanostructures Peter C. Sercel[1], Valy Vardeny[2] and Alexander Efros[3]; [1]California Institute of Technology, United States; [2]The University of Utah, United States; [3]U.S. Naval Research Laboratory, United States

We have demonstrated theoretically that non-chiral perovskite layers can exhibit circular dichroism (CD) in the absence of a magnetic field and without chiral activation by chiral molecules [1]. The exciton dispersion in orthorhombic perovskites in the presence of Rashba spin-orbit terms creates helical exciton states, which are split from each other. The splitting can be described as a Zeeman effect in an effective magnetic field, whose direction and magnitude depend on the exciton momentum. The selective excitation of these states by helical light gives rise to CD. Using experimentally determined material parameters, we calculate significant circular dichroism of order 30% in orthorhombic perovskites under off-normal, top illumination.These calculations suggest the effect is observable and CD can be measured in non-chiral perovskite nanostructures such as layered-2D perovskites or nanoplatelets.

Excitonic and Vibrational Phenomena in Emerging 2D Light-Emitting Materials William Tisdale; Massachusetts

Institute of Technology, United States

In this talk, I will present recent results from our lab exploring the excitonic and vibrational properties of emerging 2D light-emitting materials, including hybrid organic-inorganic perovskites, few-layer black phosphorous, and hybrid chalcogenides. Topics may include: 1) interlayer vibrational coupling and superlattice modes of layered 2D structures; 2) tunable exciton binding energy in layered perovskites; 3) origin of broadband emission in multilayer (n>2) lead halide perovskites; and 4) demonstration of novel materials with strong excitonic anisotropy.

5:45 AM F.EL02.09.05
Light-Induced Magnetism in Mn-Doped $CsPbI_3$ Perovskite Quantum Dots Tian Qiao[1], Daniel P. Rossi[2], Xiaohan Liu[1], Mohit Khurana[1], Alexey Akimov[1,3,4] and Dong Hee Son[1,2]; [1]Texas A&M University, United States; [2]Center for Nanomedicine, Korea (the Republic of); [3]Russian Quantum Center, Russian Federation; [4]PN Lebedev Institute RAS, Russian Federation

Magnetic doping of semiconductor quantum dots has generated new materials that can couple magnetism with light, which are attractive for various applications such as spintronics. Here, we report the synthesis of strongly quantum-confined $CsPbI_3$ quantum dots doped with paramagnetic Mn^{2+} ions and the characterization of their optical and magneto-optic properties evidencing the creation of light-induced magnetism. The magnetic order of the dopant ions forms via exchange interaction of the dopants and long-lived dark exciton at cryogenic temperatures. At the temperature of 5 K, $CsPbI_3$ quantum dots exhibited photoluminescence (PL) from dark exciton PL with lifetime of 1.5 microsecond in the absence of Mn dopant indicating that the lowest exciton state in this system is dipole forbidden dark state, which is beneficial in obtaining longer-lived light-induced magnetism. In Mn-doped $CsPbI_3$ quantum dots, the dark exciton PL lifetime decreased by 30 %, which is similar to the effect of applying external magnetic field, suggesting the creation of magnetic order from the doped paramagnetic Mn^{2+} ions. Comparison of the temperature-dependent PL spectra of Mn-doped and undoped $CsPbI_3$ quantum dots showed that Mn-doped quantum dots have smaller PL energy due to magnified Zeeman splitting under light-induced magnetism. Our results suggest Mn-doped $CsPbI_3$ quantum dots, combined with long-lived dark ground exciton state, could become a promising material platform for obtaining optically generated magnetism.

5:55 AM F.EL02.09.06
Structure-Property Relationships for 2D Halide Perovskites with Large Cage Cations Xiaotong Li[1], Yongping Fu[1], Pedesseau Laurent[2], Peijun Guo[3], Shelby Cuthriell[1], Ido Hadar[1], Jacky Even[2], Claudine Katan[2], Constantinos Stoumpos[1], Richard D. Schaller[3], Elad Harel[1] and Mercouri G. Kanatzidis[1]; [1]Northwestern University, United States; [2]University of Rennes, France; [3]Argonne National Laboratory, United States

In 2D perovskites, the choice of the A-site perovskitizer cations is not entirely limited by the so-called Goldschmidt tolerance factor. The stabilizing effect of the spacer cations makes it possible to tolerate larger A-site cations as perovskitizers. By solving the single-crystal structures of $(BA)_2(A)Pb_2I_7$ where BA = butylammonium, and A = methylammonium (MA), formamidinium (FA), dimethylammonium (DMA) or guanidinium (GA), we have proven that the relatively large DMA and GA can serve as the A-site cation of 2D perovskites despite the fact that they are too large to formally satisfy the Goldschmidt rule. As the size of the A-site cations across these compounds increases, the Pb−I bonds are elongated, which reduces the orbital overlap of Pb s- and I p-orbitals, thus decreasing the electronic bandwidths and increasing the bandgaps, as confirmed by DFT calculations. This increases the local distortions of the PbI_6 coordination environment and leads to a decrease of PL intensity and shortening of PL lifetime. The expanded cages also result in soft and anharmonic lattices, as supported by Raman spectra. Exciton-exciton annihilation processes occur in these systems with the rates being slower in the structures with larger A cations.

6:05 AM F.EL02.09.08
Late News: Transfer of Direct to Indirect Bound Excitons by Electron Intervalley Scattering in Cs2AgBiBr6 Double Perovskite Nanocrystals Amrita Dey, Alexander F. Richter, Tushar Debnath, He Huang, Lakshminarayana Polavarapu and Jochen Feldmann; Ludwig-Maximilians-Universität, Germany

Lead halide perovskites have gained a lot of popularity in the field of optoelectronics in recent times. Where the toxicity of lead remains a major issue, an emerging non-toxic alternative proposed is lead-free double perovskites with the generic stoichiometric formula $A_2M^IM^{III}X_6$. In double perovskite the divalent lead is replaced with one monovalent (M^I) and one trivalent (M^{II}) metal cation. $Cs_2AgBiBr_6$ is one the stable double perovskite with an indirect bandgap where the optical properties and the charge carrier relaxation processes are not fully understood. We applied time-resolved photoluminescence and differential transmission spectroscopy to explore the photo-excited charge carrier dynamics within the indirect band

structure of $Cs_2AgBiBr_6$ nanocrystals. We observed a high energetic emission at the direct bandgap, alongside the emission from the indirect bandgap transition. We assigned this emission to the radiative recombination of the direct bound excitons originating due to trapping of holes. Due to the electron intervalley scattering process, the emission maximum from this direct bound excitons redshifts over 1 eV within 10 ps, leading to its transfer from direct to indirect bound exciton. We conclude that this direct bound exciton has giant oscillator strength which causes the higher energetic emission to occur at the direct bandgap despite the prevailing intervalley scattering process. These results expand the current understanding of the optical properties and the charge carrier relaxation process in double perovskites family, thus, facilitating the further development of optoelectronic devices harnessing lead-free perovskites.

6:15 AM F.EL02.09.09
Late News: Growth of Perovskite CsPbBr3 Nanocrystals and Their Formed Superstructures Revealed by *In Situ* Spectroscopy He Huang; Ludwig-Maximillians-Universitat Munchen, Germany

Metal halide perovskites have attracted substantial interest due to their promising properties for optoelectronic applications. Despite much progress made in the field, the exact growth mechanism of perovskite nanocrystals (*e.g.* $CsPbBr_3$) remains elusive and further improvement of their controllable synthesis is challenging. Herein, we point out different phenomena during the processes of growth, cooling and purification of high-quality $CsPbBr_3$ nanocrystals using in-situ PL spectroscopy. The as-synthesized materials have been further characterized by time-resolved transient differential transmission and photoluminescence spectroscopies. Using X-ray scattering, we confirm that nanocrystals form superstructures during the process of cooling already in dispersion, which is frequently ignored. The purification process is explained by a proposed model based on the self-size-selection. On the one hand, such superstructures pave a potential pathway to the fabrication of high-quality devices such as LEDs. On the other hand, the approach to reveal their formation process benefits the comparison and understanding of the difference between nanocrystals and supercrystals. The fact that superstructures form already during synthesis may also apply to the different perovskite systems and thus help to improve the quality of as-prepared nanocrystals.

Late News: Semiconductor Nanocrystal Scintillators for Fast Neutron Imaging Kyle M. McCall[1,2], Kostiantyn Sakhatskyi[1,2], Eberhard Lehmann[3], Bernhard Walfort[4], Adrian Losko[5], Federico Montanarella[1,2], Maryna Bodnarchuk[1,2], Franziska Krieg[1,2], Yusuf Kelestemur[1,2,6], David Mannes[3], Yevhen Shynkarenko[1,2], Sergii Yakunin[1,2] and Maksym V. Kovalenko[1,2]; [1]ETH Zürich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [3]Paul Scherrer Institut, Switzerland; [4]RC Tritec AG, Switzerland; [5]Forschungs-Neutronenquelle Heinz Maier-Leibnitz, Germany; [6]Atilim University, Turkey

Radiographical imaging with X-rays, gamma-rays, and thermal neutrons (~25 meV) has transformed fields including medical imaging, industrial inspection, and nuclear security over the past century. Fast neutron (> 1 MeV) imaging is a rising technique which benefits from the high penetration capabilities of fast neutrons which offer low interaction cross sections relative to other radiation sources. This penetrative power makes fast neutrons ideal for imaging large-scale objects such as large fossils, nuclear fuel, and as-built plane turbines, but widespread application of fast neutron imaging is hindered by inefficient fast neutron detection. The current detection scheme is based on detection of recoil protons generated by neutrons scattering off hydrogen, with the leading material in the field consisting of ZnS:Cu embedded in hydrogen-dense plastic. However, these scintillation plate detectors rely on microscale phosphors with drawbacks including significant light scattering at the plastic-phosphor interface, strong absorption of (and sensitivity to) gamma-rays, and long-lived afterglows on the order of minutes. Thus, alternative solutions are required to enhance the performance of detectors for fast neutron imaging.

Separately, the development of semiconductor nanocrystals (NCs) has ushered in a golden age for nanoscale emissive materials with quantum yields near unity and enhanced recombination rates for short decay times, promising maximal detector efficiency while eliminating problematic afterglow. Here, we demonstrate the efficacy of nanocrystals as scintillators for fast neutron imaging, utilizing colloidal nanocrystals in hydrogen-dense solvents to detect recoil protons generated by scattering of fast neutrons. The light yield, spatial resolution, and neutron-*vs*.-gamma sensitivity of several representative compositions are compared, including both chalcogenide (CdSe and $CuInS_2$)-based and halide perovskite-based NCs, revealing the key parameters for optimized fast neutron detection.

$FAPbBr_3$ NCs exhibit the brightest total light output at 19.3% of the commercial ZnS:Cu(PP) standard (consisting of ZnS:Cu embedded in PP = polypropylene), the light output of the other compositions ranged from 1.5% for $CuInS_2$ NCs to 6.0% for CdSe/CdS quantum dots. Colloidal NCs also showed significantly lower gamma-ray sensitivity than ZnS:Cu, with the ratio of detected neutrons to gamma-rays ranging from 2.2 in $CsPbBrCl_2$:Mn NCs to 4.1 for $CsPbBr_3$ NCs, well above the 1.0-1.1

reported for ZnS:Cu(PP). This permits the use of less gamma-ray shielding and therefore enables a higher flux of fast neutrons, for example, 79% of the $FAPbBr_3$ light yield results from neutron-induced radioluminescence and hence the neutron-specific light yield of $FAPbBr_3$ is 30.4% of that of ZnS:Cu(PP), despite the tenfold higher phosphor load of ZnS:Cu(PP). Metal blocks with sharp edges were used to estimate the spatial resolution, with the high Stokes shift $CsPbBrCl_2$:Mn NCs offering the best spatial resolution at ~2.6 mm while that of $FAPbBr_3$ NCs is doubled at ~5.2 mm due to reabsorption and re-emission. Importantly, all NCs showed no evidence for afterglow on the order of seconds, in contrast to the minutes-long afterglow of the ZnS:Cu(PP) standard. Concentration and thickness-dependent measurements highlight the importance of increasing concentrations and reducing self-absorption, yielding design principles to optimize and foster an era of NC-based scintillators for fast neutron imaging.

6:35 AM F.EL02.09.11
Water Stable 1D Hybrid Tin(II) Iodide Emits Broad Light with 36% Photoluminescence Quantum Yield Ioannis Spanopoulos[1], Ido Hadar[1], Weijun Ke[1], Peijun Guo[2], Siraj Sidhik[3], Mikaël Kepenekian[4], Jacky Even[4], Aditya D. Mohite[3], Richard D. Schaller[1] and Mercouri G. Kanatzidis[1]; [1]Northwestern University, United States; [2]Argonne National Laboratory, United States; [3]Rice University, United States; [4]Univ Rennes, France

Low dimensional (2D, 1D, 0D) lead halide materials have proven to be quite promising in terms of strong broad light emission with PLQY values above 90%, rendering them suitable for solid state lighting applications. These materials in order to be utilized in real applications must be environmentally stable and of non-toxic composition. Tin(II) based compounds pose as an excellent choice for addressing toxicity issues, however they are moisture and oxygen sensitive.
Addressing the above concerns, we report a new air-stable one-dimensional (1D) hybrid tin(II) halide material $(DAO)Sn_2I_6$ (DAO: 1,8-octyldiammonium), that is resistant to water for more than 15h.[1] The material exhibits a sharp absorption edge at 2.70 eV and a strong broad orange light emission centered at 634 nm, with a full width at half maximum (FWHM) of 142 nm (0.44 eV). The corresponding emission has a high photoluminescence (PL) quantum yield (PLQY) of at least 20.3% at RT, being among the highest reported for lead-free low-dimensional 2D and 1D perovskites and metal halides, which is coupled by a very long PL lifetime of 582 ns. Additionally, the PL emission intensity and linewidth is constant over a very broad temperature range (145-415 K), underscoring the beneficial high temperature PL robustness. The corresponding CIE chromaticity coordinates are (0.55, 0.42), with a correlated color temperature (CCT) of 1822 K (warm orange light), and a color-rendering index (CRI) value of 75, meaning that this material is suitable for outdoor lighting.
We further evaluated the ability of $(DAO)Sn_2I_6$ to fabricate thin films, the first step prior to device assembly. Apparently, the corresponding films exhibited the same optical properties of the bulk crystals, yet enhanced with an improved PLQY of 36%, and a much longer PL lifetime of 1100 ns, for a 60 nm thick film. These results demonstrate the versatile nature of hybrid halide materials, laying the path for the design of next generation of water stable lead-free semiconductors.

Photocatalytic Inactivation of Escherichia Coli under UV Light Irradiation Using Large Surface Area Anatase TiO2 Quantum Dots Faheem Ahmed and Adil Alshoaibi; King Faisal University, Saudi Arabia

In this study, high specific surface areas (SSAs) of anatase titanium dioxide (TiO2) quantum dots (QDs) were successfully synthesized through a novel one-step microwave–hydrothermal method in rapid synthesis time (20 min) without further heat treatment. XRD analysis and HR-TEM images showed that the as-prepared TiO2 QDs of approximately 2 nm size have high crystallinity with anatase phase. Optical properties showed that the energy band gap (Eg) of as-prepared TiO2 QDs was 3.60 eV, which is higher than the standard TiO2 band gap, which might be due to the quantum size effect. Raman studies showed shifting and broadening of the peaks of TiO2 QDs due to the reduction of the crystallite size. The obtained Brunauer–Emmett–Teller specific surface area (381 m2 g−1) of TiO2 QDs is greater than the surface area (181 m2 g−1) of commercial TiO2
nanoparticles. The photocatalytic activities of TiO2 QDs were conducted by the inactivation of Escherichia coli under ultraviolet light irradiation and compared with commercially available anatase TiO2 nanoparticles. The photocatalytic inactivation ability of E. coli was estimated to be 91% at 60 μg ml−1 for TiO2 QDs, which is superior to the commercial TiO2 nanoparticles. Hence, the present study provides new insight into the rapid synthesis of TiO2 QDs without any annealing treatment to increase the absorbance of ultraviolet light for superior photocatalytic inactivation ability of E. coli.

Design Strategies for Achieving Efficient Wide Bandgap Halide Perovskite Phosphors via Analysis of the Halide Double Perovskite $Cs_2NaBiCl_6$:Mn^{2+} Orange-Emitting Phosphor System Jackson Majher[1], Matthew Gray[1], Amanda Strom[2] and Patrick Woodward[1]; [1]The Ohio State University, United States; [2]University of California, Santa Barbara, United States

Recently wide bandgap halide double perovskites have emerged as promising phosphor materials for white light LED applications. These materials demonstrate enhanced photoluminescence properties compared to bulk $APbX_3$ ($A = NH_3CH_3^+$, Cs; X = Cl, Br, I) perovskites due in large part to their higher exciton binding energy, thereby reducing extensive nonradiative decay at defects and grain boundaries. $Cs_2NaBiCl_6$ is an example of a halide double perovskite which in the pure form exhibits no photoluminescence. Upon doping Mn^{2+} into the lattice (0.06-7.2 mol%) bright orange luminescence emerges under UV excitation originating from the $^4T_1$ to $^6A_1$ transition of Mn^{2+} ions in an octahedral environment. Analysis of absorption and excitation measurements indicate absorption of the host material is dominated by localized $6s^2$ to $6s^16p^1$ transitions of Bi^{3+} ions, indicating a zero-dimensional electronic structure. The localized nature of Bi^{3+} absorption in the perovskite structure is identified as a crucial component for efficient energy transfer to Mn^{2+} sites. Partial replacement of Cl^- with Br^- in the structure forming $Cs_2NaBiCl_{6-x}Br_x$:Mn^{2+} is demonstrated to relax the crystal field around Bi^{3+} ions thereby shifting the excitation range towards the visible where it can be excited by conventional GaInN blue LEDs. Lessons learned in this study extend towards several other double perovskite and perovskite-derivative materials, including systems exhibiting intrinsic luminescence via self-trapped excitons as well as activator-doped materials. Routes to optimize photoluminescence in these systems are addressed.

Annealing Effects on the Optical and Luminescent Properties of tErbium Doped AZO Thin Films Paul Llontop, Miguel Piñeiro, Kevin Lizárraga, Jan Amaru Töfflinger, Rolf Grieseler and Jorge A. Guerra; Pontificia Universidad Catolica del Peru, Peru

Rare-earth doped wide bandgap (WBG) semiconductors have attracted great attention as efficient luminescent materials for optoelectronic applications, such as photon downshift, down- and up-conversion systems, a new generation of low voltage light-emitting devices, non-contact luminescent temperature sensors and photonic structures.

However, these luminescent mechanisms have yet to be successfully implemented in transparent conductive oxide (TCO) films with a WBG, such as indium tin oxide (ITO) or aluminum zinc oxide (AZO) which often form part of these devices. Such optically active TCOs would therefore be advantageous for these applications since layers of the same TCO are already being used in said devices.

Our work focuses on the production and characterization of terbium (Tb) doped AZO thin films, keeping a high optical transmittance in the visible region and exhibiting Tb related luminescent properties. The effect of Tb doping on the optical and luminescent properties was investigated for different post-deposition annealing conditions. Films were produced on silicon and fused silica substrates by radiofrequency magnetron co-sputtering employing high purity AZO and Tb targets and a rotary sample holder. After deposition, samples were annealed between 200°C - 1000°C in steps of 100°C. The annealing processes were carried out in air or argon atmosphere. Optical transmittance, photoluminescence (PL) and energy dispersive X-ray spectroscopy experiments were made after each annealing step. Characteristic Tb^{3+} related light emission peaks were found in the as grown, as well as in the annealed samples. To the best of our knowledge, this is the first demonstration of Tb^{3+} emission in AZO as host matrix. Absorption coefficient, band gap and Urbach energies were estimated using computational methods and models developed in our group. Furthermore, temperature dependent PL experiments, ranging from 80K to 530K, were carried out on representative samples to discuss possible energy transfer mechanisms between Tb^{3+} ions and AZO matrix.

Structure–Property Correlation, Luminescence Enhancement and Excited-State Dynamics in Near-Infared Emitting Gold Nanoclusters Qi Li; Stanford University, United States

The origin of the near-infrared photoluminescence (PL) from thiolate-protected gold nanoclusters (Au NCs, <2 nm) has long been controversial, and the exact mechanism for the enhancement of quantum yield (QY) in many works remains elusive. It is still a major challenge for researchers to map out a definitive relationship between the atomic structure and the PL property and understand how the Au kernel and Au–S surface contribute to the PL of Au NCs.

Herein, we first provide a paradigm study to address the above critical issues. By using a correlated series of "mono-cuboctahedral kernel" Au NCs and combined analyses of steady-state, temperature-dependence, femtosecond transient absorption, and Stark spectroscopy measurements, we have explicitly mapped out a kernel-origin mechanism and clearly elucidate the surface–structure effect, which establishes a definitive atomic-level structure–emission relationship. A ∼100-fold enhancement of QY is realized via suppression of two effects: (i) the ultrafast kernel relaxation and (ii) the surface vibrations. The new insights into the PL origin, QY enhancement, wavelength tunability, and structure–property relationship constitute a major step toward the fundamental understanding and structural-tailoring-based modulation and enhancement of PL from Au NCs.
Furthermore, we report the emergence of a photo-induced structural distortion accompanied by an electron redistribution in a series of bi-tetrahedral gold nanoclusters. Such unexpected slow process of excited-state transformation results in near-infrared dual emission with extended photoluminescent lifetime. We demonstrate that this dual emission exhibits highly sensitive and ratiometric response to solvent polarity, viscosity, temperature and pressure. Thus, a versatile luminescent nano-sensor for multiple environmental parameters has been developed based on this strategy. Furthermore, we fully unravel the atomic-scale structural origin of this unexpected excited-state transformation, and demonstrate control over the transition dynamics by tailoring the bi-tetrahedral core structures of gold nanoclusters.

Intense Microsecond-Lived Dark Exciton Emission from Strongly Quantum Confined Perovskite Nanocrysals Dong Hee Son; Texas A&M University, United States

Dark exciton as the lowest-energy (ground) exciton state in metal halide perovskite nanocrystals is a subject of much interest. This is because the superior performance of perovskites as the photon source combined with long lifetime of dark exciton is very attractive for the applications such as quantum information processing. However, the direct observation of the long-lived dark exciton emission confirming the accessibility to dark ground exciton state has remained elusive. In this presentation, we discuss the observation of the intense photoluminescence (PL) from dark exciton with lifetime of 1-10 microsecond in strongly confined $CsPbBr_3$ nanocrystals of varying dimensionality of confinement. Strongly confined quantum dots, nanowires and nanoplateletes of cesium lead halide perovskite showed dark exciton emission that dominates the PL at cryogenic temperatures with bright-dark splitting energy (ΔE) of ~20 meV, which contrasts to the behavior of weakly confined nanocrystals that exhibit little dark exciton PL. The lifetime of dark exciton PL shortened under magnetic field as expected. ΔE increased with increasing quantum confinement giving an easier access to the dark exciton PL at the higher temperatures, which is also consistent with the prediction from the earlier theoretical prediction. This work establishes the potential of strongly quantum confined perovskite nanostructures as the excellent platform to harvest the benefits of extremely long-lived and intense dark exciton PL.

Late News: Green Solvent Assisted Synthesis of Cesium Bismuth Halide Perovskite Nanocrystals and Insights into the Effects of Slow and Fast Anion Exchange Rates Rana Faryad Ali, Byron Gates and Irene Andreu; Simon Fraser University, Canada

The replacement of lead in halide perovskites with alternative halide perovskite materials has been driven by the concerns of lead toxicity. Lead-free all-inorganic cesium bismuth halide ($Cs_3Bi_2X_9$) perovskites nanocrystals have attracted much attention in recent years due to their air-stability and the relatively non-toxic nature of bismuth. Common solvents used to prepare $Cs_3Bi_2X_9$ nanomaterials under ambient conditions have included dimethyl sulfoxide (DMSO) and dimethylformamide (DMF), which are also desired to be avoided for their own hazards. Herein, we demonstrate a facile, sonication-assisted approach for the preparation of all-inorganic cesium bismuth iodide ($Cs_3Bi_2I_9$) perovskite nanocrystals (NCs) using propylene carbonate as a green solvent. The photoluminescence (PL) spectra of the $Cs_3Bi_2X_9$ NCs are further tuned from 410 to 550 nm by controlling the composition of the NCs through anion exchange reactions using tetraalkylammonium halides as a source of halide ions. The rate of reaction for the anion exchange process significantly influences the dimensions of the resulting NCs in contrast to their parent $Cs_3Bi_2I_9$ NCs. Absolute photoluminescence quantum efficiency (PLQE) of the $Cs_3Bi_2I_9$ NCs was also determined, and their PL emission was determined to be predominately due to exciton recombination processes. The NCs also exhibited an excellent air-stability for at least 150 days.

5:00 AM *F.EL02.10.01
Nanoscale Effects in Metal Halide Perovskites for Light-Emitting Applications. Laura Herz; University of Oxford, United Kingdom

Organic-inorganic metal halide perovskites have emerged as attractive materials for light-emitting and light-harvesting devices. We discuss the fundamental processes that have underpin light-matter interactions enabling these applications.

Photon recycling is shown to slow charge losses from thin hybrid perovskite films, depending on light outcoupling. Interestingly, for thin films comprising a quasi-two-dimensional (2D) perovskite region interfaced with a 3D MAPbI perovskite layer the blue-shifted emission originating from quasi-2D regions overlaps significantly with the absorption spectrum of the 3D perovskite, allowing for highly effective "heterogeneous photon recycling". We show that this combination fully compensates for the adverse effects of electronic confinement, yielding quasi-2D perovskites with highly efficient charge transporting properties.
We further discuss how vibrational, charge-carrier recombination and mobility is altered in thin films of perovskite nanocrystals films with respect to the bulk film. We show in thin films, carrier mobilities are still mostly dominated by intra-particle motion rather than inter-particle hops.
In tunable bandgaps across the entire visible light emission range, we discuss the mechanisms underlying detrimental halide segregation in mixed halide lead perovskites.

Toward On-Demand Electrically-Driven Single-Photon Source That Can Be Triggered in Less Than 0.2 ns Igor A. Khramtsov and Dmitry Y. Fedyanin; Moscow Institute of Physics and Technology, Russian Federation

On-demand single-photon sources (SPSs) operating at room temperature under electrical pumping play a crucial role in the emerging quantum applications ranging from linear quantum computing [1] to unconditionally secure communication lines [2]. Color centers in silicon carbide are now considered as a promising platform for the realization of such electrically-pumped SPSs operating at room temperature. In the steady-state, they are brighter than other quantum emitters, such as color centers in diamond or epitaxial quantum dots [3]. At the same time, steady-state emission of single photons almost does not have practical quantum applications, and an on-demand SPS is highly needed. However, very little is known about how to control, dynamically tune and quickly switch on and off the single-photon electroluminescence (SPEL) of color centers in SiC that will allow to meet the on-demand requirement when exactly one photon is emitted per excitation pulse.
Here, we propose and numerically demonstrate the SiC gate-tunable single-photon emitting diode (GT-SPED) with a silicon antisite near stacking fault (Si_C-SF) defect placed underneath the gate [4]. Its emission can be controlled via source/drain and gate contacts. When no voltage is applied to the gate, the GT-SPED acts as a conventional p-i-n single-photon emitting diode, where the SPEL of Si_C-SF cannot be switched between ON and OFF states fastly due to the high diode capacitance. However, if one applies voltage to the gate contact and change it in the range of several volts at a fixed source voltage, he can not only control and dynamically tune the SPEL of SiC-SF center from 0.16 Mcps (OFF state) to 40 Mcps (ON state) but what is more important, switch between ON and OFF states of SiC-SF SPEL in less than 0.2 ns, which is less than the radiative lifetime of the SiC-SF center and other defects in solids. These possibilities allow to trigger single-photon emission from the Si_C-SF center by applying small voltage pulses to the gate contact. If the width of such a voltage pulse is chosen

correctly, a single photon will be emitted with the probability of multiphoton events of less than 2%. Hence, the proposed device lays the solid foundation for the development of electrically-driven on-demand single-photon sources operating at room temperature.

Enhanced Room Temperature Photoluminescence Quantum Yield in Morphology-Controlled J-Aggregates Surendra B. Anantharaman[1,2], Joachim Kohlbrecher[3], Gabriele Raino[4,5], Sergii Yakunin[4,5], Thilo Stöferle[6], Jay Patel[1], Maksym V. Kovalenko[4,5], Rainer F. Mahrt[6], Frank Nuesch[1,2] and Jakob Heier[1]; [1]Swiss Federal Laboratories for Materials Science and Technology, Empa, Switzerland; [2]École Polytechnique Fédérale de Lausanne EPFL, Switzerland; [3]Paul Scherrer Institute, Switzerland; [4]ETH Zürich, Switzerland; [5]Swiss Federal Laboratories of Materials Science and Technology, Empa, Switzerland; [6]IBM Research–Zurich, Switzerland

Narrow-band photoluminescence (PL) together with high quantum efficiency from organic molecules is essential for high-color-purity emitters. Supramolecular assemblies like J-aggregates are promising materials due to their narrow PL signal with full-width at half maximum <20 nm. However, their microcrystalline nature and coherent exciton migration results in strong nonradiative exciton recombination at the grain boundaries that diminish the photoluminescence quantum yield (PLQY), and possibilities for improving the crystallinity by tuning the growth mechanism are limited. Here, two distinct routes to grow different J-aggregate morphologies like platelets and lamellar crystals with improved crystallinity by surface-guided molecular assembly are demonstrated, thereby suppressing nonradiative decay and improving PLQY (upto 5% at room temperature). Both platelets and lamellar crystals show similar absorbance at room temperature. However, temperature-dependent PL studies show sevenfold (twofold) higher PLQY for lamellar films compared to platelets at 6 K (300 K). Using time-resolved PL spectroscopy, different nonradiative decay pathways are identified.[1]
Revisiting the J-aggregates formation in solution, we demonstrate that cyanine J-aggregates can reach an order of magnitude higher photoluminescence quantum yield (increase from 5% to 60%) in blend solutions of water and alkylamines at room temperature.[2] By means of time-resolved photoluminescence (TRPL) studies we show an increase in the exciton lifetime as a result of the suppression of non-radiative processes. Small-angle neutron scattering studies suggest a necessary condition for the formation of such highly emissive J-aggregates: the presence of a sharp water/amine interface for J-aggregate assembly and the coexistence of nanoscale-sized water and amine domains to restrict the J-aggregate size and solubilize monomers, respectively.

Terahertz Emission with Plasmonic Photomixer in an InGaAs-Based Dual-Grating-Gate High-Electron-Mobility Transistor Tomotaka Hosotani, Akira Satou and Taiichi Otsuji; Tohoku University, Japan

Plasmonic terahertz (THz) emitters are expected as on-chip and coherent THz sources. Up to the present, THz emissions stimulated by plasmonic instability with dc-current-driven Doppler-shift (DS) type and electron-transit-time (ETT) type have been experimentally observed in high-electron-mobility transistors (HEMTs). These instabilities could stimulate resonant-mode THz emission. Here we experimentally investigate the dc-current-driven plasmonic boom instability, the third plasmonic instability that occurs when the electron drift velocity exceeds the plasma velocity. The plasmonic boom instability generates shockwaves so that it stimulates rather broadband THz emission. To obtain a coherent narrow-band emission, a pertinent cavity structure needs to be installed. We use an original dual-grating-gate (DGG) HEMT structure based on an InGaAs high electron mobility channel under photoexcitation of photomixed dual-cw infrared (IR) lasers irradiation.

The InGaAs DGG-HEMT photomixer incorporates two types of grating-gate electrodes having a finger size of 100 nm and spacing between the adjacent fingers of 200 nm. The DGG structure modulates the electron drift velocity and plasma velocity in a complementary manner. One gate G1 (the other gate G2) are high (low) biased working as plasmonic cavities (as high-field, depleted regions) wherein the plasma velocity is higher (lower) than the electron drift velocity. The difference frequency (δf) of the dual-cw-IR lasers was set around the plasmon resonant frequency determined by the G1 grating finger size and the electron density. As above mentioned, the plasmonic boom instability generates a shockwave of rather broadband plasmonic displacement current. Since the photomixed dual-cw-IR lasers irradiation generates coherent narrow spectral photocurrent component around the frequency δf, one can expect the broad plasmonic ac current could be injection-locked to the photogenerated δf component, resulting in an enhanced coherent THz emission around δf. We set δf at 2, 3, and 4 THz. The THz emission from the fabricated device was measured at 100K using a Fourier Transform IR (FTIR) spectrometer and a 4.2-K cooled Si bolometer.
The bias for G1 (VG1) was set at 0 V whereas that for G2 (VG2) was set at -0.5 V. The drain bias (VD) was set at 1V. We compared the THz emission beyond the background blackbody radiation at a fixed biases (VG1, VG2, VD) condition among the different photomixed δf conditions. With laser irradiation, rather broad THz emissions were observed. The observed spectral peaks are mostly independent of δf because of rather high-level of thermally-excited incoherent plasmons. However, the emission spectra for $\delta f = 2$ and 4 THz exhibited a higher intensity at a narrow frequency range around 4-to-6 THz than that for $\delta f = 3$ THz. To see these intensity differences in detail, the enhancement of mono-peak emission around 5 THz showed a weak blue shift from the emission for $\delta f = 2$ THz to that for $\delta f = 4$ THz. From these results, in the plasmonic cavities under G1 region, plasmonic resonant modes are situated close to 2 and 4 THz, and a plasmonic anti-resonant mode is situated close to 3 THz. It is worth noting that neither DS type nor ETT type current-driven instability emission could originate such an observed broadband emission. Since the drift velocity could exceed the plasma velocity at the cavity boundaries between G1 and G2, the results suggest that the photomixing-originated THz emission is amplified by stimulated emission of plasmons originated by the plasmonic boom instability.
In summary, the radiation spectra observed at 100K showed two distinctive emission components beyond the black-body radiation, one promoted by δf-independent thermally excited incoherent plasmons and the other promoted by δf-dependent coherent plasmons. The results suggest the occurrence of the plasmonic instability stimulated by the dc current flow in the channel.

5:45 AM F.EL02.10.05
Temperature-Independent Dielectric Constant In $CsPbBr_3$ Nanocrystals Revealed by Linear Absorption Spectroscopy Wenbi Shcherbakov-Wu[1], Peter C. Sercel[2,3], Franziska Krieg[4,5], Maksym V. Kovalenko[4,5] and William Tisdale[1]; [1]Massachusetts Institute of Technology, United States; [2]Center for Hybrid Organic Inorganic Semiconductors for Energy, United States; [3]California Institute of Technology, United States; [4]ETH Zürich, Switzerland; [5]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

$CsPbBr_3$ nanocrystals (NCs) have attracted much attention over the past five years due to their exceptional optoelectronic properties and potential applications in devices such as light-emitting diodes (LEDs), lasers, and single-photon emitters. However, their fundamental photophysical properties, especially at low temperatures, are still under active debate. To date, almost all of the reports have used photoluminescence (PL) alone to infer the lattice dynamics in these materials. Here, we measure both the temperature-dependent (35 K - 300 K) absorption and PL spectra of zwitterionic ligand-capped $CsPbBr_3$ NCs with four different edge lengths (L = 4.9 - 13.2 nm). The excitonic transitions observed in the absorption spectra can be explained with an effective mass model considering the quasicubic NC shape and non-parabolicity of the electronic bands. We observe a temperature-dependent Stokes shift; while the trend is similar to the Stokes shift observed in both $MAPbBr_3$ and $CsPbBr_3$ single crystals, it does not approach zero at cryogenic temperatures, pointing to an additional contribution intrinsically present in the NCs. Surprisingly, the effective dielectric constant determined from the best fit model parameters is independent of temperature, contrary to the previous report that the change in dielectric constant leads to the Stokes shift temperature dependence. Overall, our study sheds light on the fundamental lattice dynamics in these materials, and can potentially be used to guide future material optimization for device applications.

5:55 AM F.EL02.10.07
How Exciton Localization Enhances Radiative Recombination in Manganese-Doped Perovskite Nanocrystals Sascha Feldmann[1], Bartomeu Monserrat[1], Richard Friend[1] and Felix Deschler[2]; [1]University of Cambridge, United Kingdom; [2]Technische Universität München, Germany

Chemical doping of perovskites holds promise for enhancing luminescence efficiencies, which is crucial for applications such as efficient light-emitting diodes (LEDs). Using transient optical spectroscopy we study the recombination dynamics in manganese-doped $Cs(Mn:Pb)(Cl,Br)_3$ perovskite nanocrystals. We find an increased excitonic radiative recombination rate

upon doping, together with reduced non-radiative losses. Supported by ab initio calculations, we propose the enhanced luminescent recombination to arise from an increased electron hole overlap induced by the dopant ions. Thus, the stronger exciton localization leads to a higher probability of luminescent decay, important for optimising LED efficiencies.

Band Gap Tuning in Halide Perovskites Selina Olthof[1,2]; [1]University of Cologne, Germany; [2]Shaanxi Normal University, China

In recent years, the interest in halide perovskites rose at a rapid pace due to their tremendous success in the field of photovoltaic while other fields, like light emitting diodes, show great potential as well. One intriguing property of this material class is the wide tunability of the band-gap that can be induced by changing the perovskite composition. While changes in band gap are regularly reported, it is unclear how the respective conduction and valence band positions change and what the underlying origins of these changes are. Knowing the band positions is however crucial for device design, i.e. ensuring efficient charge transport across the various interfaces.
In this talk, I will present our results regarding variations in valence and conduction band position for a wide variety of lead and tin based perovskites [1]. Next to the primary ABX3 type composition, also mixed metal structures will be shown. Using a combination of photoelectron spectroscopy and density functional theory we are able to explain the origin of these energy level and band gap changes based on changes in hybridization strength, atomic level positions, and lattice distortion.

Controlling Light Emission in Halide Perovskite Device Structures Samuel D. Stranks; University of Cambridge, United Kingdom

Halide perovskites exhibit a smorgasbord of emission properties, including tunable emission energies, linewidths and luminescence yields through judicious composition and dimensionality choice. This opens up a number of exciting applications in lighting and displays, as well as highly efficient solar cells. Achieving absolute control over the emission properties will further enable these novel semiconductors.

In this talk, I will cover recent developments in our group focusing on the light emission from halide perovskite semiconductors. I will demonstrate several approaches to dynamically control energy or charge transfer processes and ultimately tune emission colour, yields and carrier recombination by tuning either the 2D/3D components, halide components on the surface and/or bulk of thin films, or synthesizing well-passivated nanoplatelet structures. I will also show that local chemical variations in alloyed perovskites used in solar cells allow accumulation of photo-excited holes in small regions, leading to high emission yields even at low carrier densities in those regions. Finally, I will present new optical spectroscopy approaches to quantify luminescence yields and related device parameters in both solar cells and light-emitting diodes, providing unique insight into power loss processes in devices.

SESSION F.EL02.11: Light-Emitting Devices for Wearable Technologies

Aromatic Interaction-Induced Nonpolar Organogels for Soft, Efficient and Stable Perovskite Nanocomposites and Their Applications in Intrinsically Stretchable Light-Emitting Devices Jae-Man Park and Jeong-Yun Sun; Seoul National University, Korea (the Republic of)

Existing gels are mostly polar, whose nature limits their role in soft devices. The intermolecular interactions of the nonpolar polymer-liquid system are typically weak, which makes the gel brittle or opaque. Here we report highly soft and transparent nonpolar organogels. Even though their elements are only carbon and hydrogen, their elastic modulus (~30 kPa), transparency (~98 %), and stretchability (~1000 %) are comparable to common soft hydrogels. A key strategy is introducing aromatic interaction into the polymer-solvent system, resulting in a high swelling ratio that enables efficient plasticization of the polymer networks. As a proof of applicability, soft perovskite nanocomposites are synthesized, where the organogels are in-situ polymerized with the two types of perovskite nanocrystals: physically dispersible or chemically addressable. The highly nonpolar environment of organogels enables stable formation and preservation of highly concentrated perovskite nanocrystals without mechanical sacrifice, and especially the chemically anchored perovskite-nonpolar organogel nanocomposites show high photoluminescence quantum efficiency (PLQE) that reaches 92.1 %, while their luminescence properties are environmentally stable against air, water, acid, base, heat, ultraviolet light, and mechanical deformation. Furthermore, when exposed to water, the chemically anchored nanocomposites show luminescence increasing behavior that their PLQE reaches near unity (~99.8 %) and is maintained for more than 110 days, which performance in the form of elastomeric perovskite emitters has not been reported. These superb properties enable the demonstration of fully soft electroluminescent devices that stably emit bright and pure green light under diverse deformations with no luminescence hysteresis. The aromatic interaction-induced nonpolar organogels may enable a step forward in soft optoelectronics.

Direct Growth of Light-Emitting III–V Nanowires on Flexible Plastic Substrates Vladislav Khayrudinov[1], Maxim Remennyi[2], Vidur Raj[3], Prokhor Alekseev[2], Boris Matveev[2], Harri Lipsanen[1] and Tuomas Haggren[1,3]; [1]Aalto University, Finland; [2]Ioffe Institute, Russian Federation; [3]The Australian National University, Australia

Semiconductor nanowires are routinely grown on high-priced crystalline substrates as it is extremely challenging to grow directly on plastics and flexible substrates due to high temperature requirements and substrate preparation. At the same time, plastic substrates can offer many advantages such as extremely low price, light weight, mechanical flexibility, shock and thermal resistance, and biocompatibility. We explore the direct growth of high-quality III−V nanowires on flexible plastic substrates by metal-organic vapor phase epitaxy (MOVPE). We synthesize InAs, InP, InSb and InAlAs nanowires on polyimide and show that the fabricated NWs are optically active with strong light emission in the mid-infrared range. We create a monolithic flexible nanowire-based p−n junction device on plastic in just two fabrication steps. Overall, we demonstrate that III−V nanowires can be synthesized directly on flexible plastic substrates inside a MOVPE reactor, and we believe that our results will further advance the development of the nanowire-based flexible electronic devices.

5:35 AM F.EL02.11.04
Ultrathin Perovskite Light-Emitting Diodes for Foldable and Conformable Light Sources Junho Kim, Eungjun Kim, Hanul Moon and Seunghyup Yoo; KAIST, Korea (the Republic of)

Highly flexible ultrathin light sources and displays can play a key role in realizing future optoelectronic devices owing to their outstanding form factors. They may be utilized in wearable, body-attachable, and imperceptible electronic devices. Foldable displays are a good example of such devices that make most of such form-factor advantages. With the emerging interest in folding displays, it is expected that the market of foldable devices is growing bigger and bigger over the next few decades. Organic light-emitting diodes (OLEDs) or quantum-dot light-emitting diodes (QLEDs) are regarded as promising candidates for foldable displays because these light-sources are surface-emitting and their low-temperature processing is compatible with flexible substrates. Among these light-sources, perovskite light-emitting diodes (PeLEDs) exhibit excellent light-emitting properties such as high color purity thanks to their exceptional optoelectronic properties. For example, PeLEDs using organic-inorganic hybrid perovskite as light-emitting material have shown not only high external quantum efficiency over 20% but also narrow full width at half maximum (FWHM). For their superb material properties, several studies have been conducted to realize highly flexible light sources using perovskite as a light-emitting material. However, the bending radii in most of the initial attempts were larger than 1mm, which is the bench-mark number desired by foldable or imperceptible devices. Even if the bending radius was smaller than 1mm, the devices had shown a quick degradation upon repeated bending cycles.

In this study, we propose ultrathin perovskite light-emitting diodes using a substrate formed from UV-curable resins. In order to reduce the bending radius below 1mm, the thickness of the substrate should be decreased to a few tens of microns. Mechanical design has been done carefully to retain the device performance even after the repeated bending test by considering the crack onset strain (COS) for each layer. To this end, we measured COS for each layer including the perovskite emitting layer. The COS value of the perovskite layer is found to be ca. 3%, which is greater than that of typical transparent conductive oxides. Furthermore, to overcome any fabrication issues such as carrier leakage or solution penetration between a substrate and a carrier substrate, we ensured each layer to be formed as uniform as possible.

With these considerations, we were able to fabricate foldable perovskite light-emitting diodes that were shown to retain its EQE after 10,000 repeated bending cycles at the bending radius as small as 0.1 mm. The overall thickness was 20 μm including the top encapsulation layer which was used for forming a neutral plane in the middle of the device, as well as protecting the device from ambient air. We believe the proposed foldable perovskite light-emitting diodes can be an important component for wearable or body-attachable devices, which can play a key role in realizing human-centric Internet-of-Things (IoT) applications.

SESSION F.EL02.12/F.EL08.12: Joint Session: Light Emission Mechanisms and Processes

Alloying and Slicing Halide Double Perovskites Adam Slavney[1], Bridget Connor[1], Kurt P. Lindquist[1], Linn Leppert[2], Jeffrey Neaton[3] and Hemamala Karunadasa[1,4]; [1]Stanford University, United States; [2]University of Twente, Netherlands; [3]Lawrence Berkeley National Laboratory, United States; [4]SLAC National Accelerator Laboratory, United States

Halide double perovskites provide a flexible platform for manipulating electronic structure through synthetic design. I will present some recent studies from our group, where we have attempted to increase the compositional and structural complexity of halide perovskites through chemical substitution. In our quest to understand the electronic structure of double perovskites, we developed a simple model that allows us to predict the bandgap symmetry based on chemical composition. Our work constructs an intuitive picture of how the molecular orbitals of metal-hexahalide coordination complexes give rise to electronic bands in the extended perovskite lattice and describes how these molecular orbitals vary across the bands to give rise to the overall band structure. Although the effects of quantum confinement of Pb and Sn perovskites have been well studied, 2D analogs of 3D double perovskites are notably lacking. I will present a series of 2D double perovskites and discuss the optical and electronic consequences of dimensional reduction of the 3D double perovskite lattice to 2D derivatives.

5:15 AM *F.EL02.12/F.EL08.12.02
Hot Carriers in Halide Perovskites Tze Chien Sum; Nanyang Technological University, Singapore

Halide Perovskites exhibit outstanding light-harvesting and emissive properties. Presently, record power conversion efficiencies (PCE) >25% in solar cells and external quantum efficiencies (EQE) >20% in light-emitting devices have been demonstrated. The perovskite field has since expanded well beyond photovoltaics and LEDs into other optoelectronic domains of lasers, x-ray detectors, memristors etc. Emerging frontier areas include multiphoton, multi-exciton generation and hot carrier applications. In this talk, I will focus on the hot carrier phenomena in halide perovskites and our recent work in this area.

5:30 AM *F.EL02.12/F.EL08.12.03
Defects Engineering and Photophysical Processes in 2D Perovskites Annamaria Petrozza; Istituto Italiano di Tecnologia, Italy

Low-dimensional perovskites are rapidly emerging due to their distinctive emission properties. Here, first I will present the fundamental properties of pristine 2D perovskites, such as the nature of the primary photo-excitations, their relaxation through electronic states and their diffusion across thin films. Such properties will be correlated and modulated by the structural characteristics of the 2D perovskites. Then, I will discuss the possibility of perovskite doping by controlled addition of impurity ions which may enable new electronic, magnetic, and optical performances. I will explore new doping

strategies based on transition and rare earth metals for tuning of the emission wavelength (from UV to NIR, further extending the typical range covered with perovskites) and luminescent enhancement. The suitability of doping for the realization of 4 level perovskite lasers will be assessed. Doping with heterovalent ions will be tested to selectively increase *p* and *n* type conductivity of the material. The addition of alkaline-earth metals as B-site dopants will be tested to improve the material stability

5:45 AM F.EL02.12/F.EL08.12.04
High-Efficiency Blue Photoluminescence in the $Cs_2NaInCl_6:Sb^{3+}$ Double Perovskite Phosphor Matthew Gray[1], Shruti Hariyani[2], T. Amanda Strom[3], Jackson Majher[1], Jakoah Brgoch[2] and Patrick Woodward[1]; [1]The Ohio State University, United States; [2]University of Houston, United States; [3]University of California, Santa Barbara, United States

In this report, the photoluminescent properties of a lead-free double perovskite $Cs_2NaInCl_6$ doped with Sb^{3+} are explored. The host crystal structure is a cubic double perovskite with Fm-3m symmetry, a = 10.53344(4) Å, and rock salt ordering of Na^+ and In^{3+}. It is a wide bandgap compound (Eg ≈ 5.1 eV), and substitution with Sb^{3+} leads to strong absorption in the UV due to localized $5s^2 \rightarrow 5s^15p^1$ transitions on Sb^{3+} centers. Radiative relaxation back to the $5s^2$ ground state, via a $^3P_1 \rightarrow {}^1S_0$ transition, leads to intense blue luminescence, centered at 445 nm, with a photoluminescent quantum yield of 79%. The Stokes shift of 0.94 eV is roughly 33% smaller than it is in the related vacancy ordered double perovskite Cs_2SnCl_6. The reduction in Stokes shift is likely due to a change in coordination number of Sb^{3+} from 6-coordinate in $Cs_2NaInCl_6$ to 5-coordinate in Cs_2SnCl_6. In addition to the high quantum yield, $Cs_2NaInCl_6:Sb^{3+}$ exhibits excellent air/moisture stability and can be prepared from solution; characteristics make it a promising blue phosphor for applications involving near-UV excitation.

5:55 AM F.EL02.12/F.EL08.12.07
Tuning the Photophysical Behavior of 2D Perovskites by Engineering the Nature of the Organic Component Ferdinand C. Grozema; Delft University of Technology, Netherlands

Two-dimensional (2D) halide perovskites are a class of emitter materials that are enjoying growing attention recently. The materials are related to 3D halide perovskites but either part or all of the small A-site cations are replaced by large organic molecules with an amonium binding moiety, for example butylamonium or phenyl-ethylamonium. This (generally) leads to the formation of a layered structure where a layer of metal-halide octahedra is formed and the large organic cations separate the layers from each other. Mixing of large and small A-site cations can lead to quasi-2D multi-layer materials where multiple layers of metal halide octahedra are separated by the organic molecules, for instance forming Ruddlesden-Popper or Dion-Jacobson structures. The emissive properties of these materials are intricately linked to the structural dynamics and formation of possible defects in the inorganic layers.

In this work we explore how modifications of the large organic amonium ion can affect the structural dynamics of the inorganic layer, combining molecular dynamics simulations with time-resolved spectroscopy. Using time-resolved fluorescence and ultrafast transient absorption spectroscopy we have studied the photophsyical behavior of 2D perovskites with a range of different organic cations inorder to gain insight in the relation between the structure and the exciyted state dynamics, These measurements indicate marked differences that can not solely be attributed to changes in the average structure of the materials.

To explain these differences we have performed classical molecular dynamics simulations for a variety of structures, for instance aliphatic alkyl chains, amonium ions containing aromatic moieties such as phenyls or perylene, but also di-functional ions containing two binding sites that can connect to an inorganic pervskite layer on both sides. The results indicate that there are marked differences between the different structures in terms of their structural rigidity. Multi-layer Ruddlesden-Popper structures are generally more rigid than single layers, however, the rigidity of the single layer structures can be strongly enhanced by engineering of the interactions between organic cations, for instance by introduction of large conjugated ions. In addition, di-functional ligands resulting in Dion-Jacobson like structures also lead to more rigid structures. Comparison with the experimental results allows us to derive some design rules that indicate how engineering of the organic part of the structure can help in improving the the emissive properties of the materials that is mostly due to the inorganic layer structure.

F.EL02.13.01
Triple-Wavelength Emission from Mn^{2+}/Yb^{3+} Codoped $CsPbCl_3$ Perovskite Nanocrystals and Luminescent Solar Concentrator Applications Tong Cai, Junyu Wang and Ou Chen; Brown University, United States

Doping metal ions into lead halide perovskite nanocrystals (NCs) has attracted great attention over the past few years due to the emergence of novel properties relevant to optoelectronic applications. Current studies focus mostly on doping a single type of metal ions into the host perovskite NCs, while few research efforts have been made on simultaneous doping more than one type of metal ions into the same perovskite hosts and to study their synergic effects with intra-particle energy transfer processes. Here, a facile synthesis of Mn^{2+}/Yb^{3+} codoped $CsPbCl_3$ NCs through a hot-injection technique is firstly reported. Owing to the completely separated energy relaxation channels among the intrinsic bandgap (BG), Mn^{2+} and Yb^{3+} dopant emissions, the obtained Mn^{2+}/Yb^{3+} codoped $CsPbCl_3$ perovskite NCs exhibit a unique triple-wavelength emission profile simultaneously covering UV/blue (BG-PL), visible (Mn-PL) and NIR (Yb-PL) spectral regions. By optimizing the dopant concentrations, the total photoluminescence quantum yield (PL QY) of the codoped NCs can reach up to ~125.3% due to quantum cutting effects. Mechanism studies reveal different natures of emission mechanisms can be involved in a single batch of Mn^{2+}/Yb^{3+} codoped perovskite NCs: (i) electronic inter-band transition (BG-PL); (ii) electronic transition of ion centers within local molecular complexes (Mn-PL); and (iii) defect-induced energy transfer and subsequent quantum cutting scheme (Yb-PL). Owing to the high PL QYs and minimal reabsorption loss, the codoped perovskite NCs are demonstrated to be used as efficient emitters in luminescent solar concentrators, with greatly enhanced external optical efficiency compared to that of using solely Mn^{2+} doped $CsPbCl_3$ NCs. Therefore, co-doping both Mn^{2+} and Yb^{3+} ions into perovskite NCs can serve as a unique model system for studies of host-to-dopant and inter-dopant energy transfer mechanisms, as well as associated radiative and non-radiative decay pathways at each step. Most importantly, such codoped NCs with multiple emission channels hold a high potential to be applied in a wide range of applications, including multiplexed biological labelling and sensing, multi-channel photodetectors, stimuli-responsive inks for coding, encryption and decryption, and photon management devices in the future.

F.EL02.13.02
Control of Excitonic Spin States via Magnetic Interactions with Transition-Metal Dopants in Ruddlesden-Popper Hybrid Perovskites Jonathan Zerhoch, Timo Neumann, Martin S. Brandt, Jonathan Finley, Andreas Stier and Felix Deschler; Walter Schottky Institut and Physik-Department, Technische Universität München, Germany

Combining the advantageous electrical and optical properties of semiconductors with magnetic characteristics gives access to extraordinary phenomena and applications. Fully inorganic dilute magnetic semiconductors (DMS) have been known for decades, which show diverse functionalities like control of magnetism by electrical fields. The material class of DMS is obtained by introducing a substantial number of magnetic ions to an otherwise non-magnetic host semiconductor.
Due to their outstanding optoelectronic properties and high defect tolerance, organo-metal halide perovskites form an ideal system for efficient magnetic doping. We produced a selection of magnetic perovskites using simple solution processing techniques by doping of the host material, Ruddlesden-Popper hybrid perovskite ($(PEA)_2PbX_4$ with X = Cl, Br, I), with different magnetic ions like Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+} and Eu^{2+}. We investigated the influence of both halides and magnetic impurities on the long-range magnetic ordering of the materials with respect to the structural and optical properties. We investigate how localized excitons couple with the magnetic moments of the introduced impurities by detecting a dependence of the emitted lights polarization on the magnetization. We perform structural, magnetic, optical and magneto-optical temperature-dependent measurements to verify a successful magnetic doping of the perovskite and to show how photoluminescence and magnetization properties relate.

F.EL02.13.04
Illuminating the Structural and Optical Changes Behind Photo-Induced Degradation in Mixed-Halide Perovskites Gabriel C. Halford, Annie Gomez, Jill Mankoff and Rebecca Belisle; Wellesley College, United States

While mixed-halide perovskites are ideal for use in tandem solar cells due to their tunable band gap, they are limited

by reversible photo-induced degradation. While the impacts of photo-induced segregation on optical properties have been well documented, the underlying impacts on perovskite structure remain less clear. Structural changes that result in optical changes may come from halide migration and subsequent segregation in the perovskite. Utilizing grazing-incidence wide angle x-ray scattering (GIWAXS), we have observed in situ reversible structural changes that occur over time scales of 30 minutes to an hour in mixed-halide methylammonium perovskite thin films as a result of light soaking at approximately 1 sun intensity. Looking at a range of different compositions with varying ratios of bromine to iodine, we are able to observe the kinetics of photo-induced unmixing of mixed-halide perovskites and the formation of multiple distinct crystalline phases.. Data taken in the dark after illumination demonstrates the reversibility of this process, as the crystal structures relax back to approximately their original structure. Analyzing the x-ray diffraction data, we see multiple distinct phases we quantify as bromine-dominated and iodine-dominated crystal structures. Correlating our x-ray diffraction results with in situ photoluminescence, we are able to present a timeline of photo-induced halide segregation that captures changes in local structure with observed optoelectronic performance. Photoluminescence shifts occur during photo-induced halide segregation such that majority iodine films shift toward lower intensity, lower energy peaks and majority bromine films shift toward higher intensity, lower energy peaks. While optical changes appear to occur before structural changes are visible in the GIWAXS data, both optical and structural changes saturate at time scales approaching one hour. Looking forward we may be able to demonstrate whether this is a surface or a bulk phenomenon. Understanding the origins of the structural changes behind photo-induced degradation could help find strategies to mitigate the optical changes it causes to produce more stable mixed-halide perovskite solar cells. Overall, this work demonstrates more fully the correlation between structural and optical changes related to light-induced halide migration and gives the possibility of finding targeted solutions to minimizing degradation.

F.EL02.13.05
High Affinity Polysalt Ligands Promote Long Term Stability While Enhancing the Quantum Yields of $CsPbBr_3$ Nanocrystals Sisi Wang, Liang Du and Hedi M. Mattoussi; Florida State University, United States

Recently, cesium lead halide perovskite quantum dots (PQDs) have generated tremendous interests, due to the great promise they offer for use in optoelectronic applications. However, their poor colloidal stability, which can be traced to the ionic nature of the crystal cores and the high desorption rates of the native ligands, has impeded progress in fundamental research and slowed integration of such materials in devices. Developing novel surface ligands with strong coordination to both passivate surface traps and enhance fluorescence performance, while improving colloidal stability is urgently needed. Here, we detail the synthesis of a new family of multifunctional polymer ligands and their use for surface engineering of the $CsPbBr_3$ nanocrystals. The ligand synthesis relies on the ring opening reaction between distinct nucleophiles and poly(isobutylene-alt-maleic anhydride), PIMA. The modular ligand stoichiometrically displays multiple ammonium and/or imidazolium anchors for coordination onto PQD surfaces, along with several alky chains with different length to promote affinity to various organic solvents. The results show that the PQDs coated with those polysalts exhibit great colloidal stability and significantly enhanced photoluminescence. The coating also allows the resulting colloids to be dispersed a wide range of solvent conditions, including ethanol and methanol, while maintaining strong fluorescence and preserving the nanocrystal integrity after ligand substitution.

F.EL02.13.06
Polar Solvent Mediated Shape Control of $CsPbBr_3$ Perovskite Nanocrystals for Applications in LEDs Arkajyoti Chakrabarty, Parvez Akhtar, Samridhi Satija, Upanshu Gangwar, Jitendra Kumar, Madhusudan Singh and Sameer Sapra; IIT Delhi, India

Nanocrystals (NCs) with different shapes, are of tremendous interest to material chemists, and precise control of their shapes and sizes through colloidal synthetic routes, with further solution-processability of the NCs, provides us with a great opportunity to tune their optoelectronic behaviour for advanced applications.[1] Interestingly, polar solvents are known to play crucial roles in determining the shapes of $CsPbBr_3$ perovskite NCs owing to the prevailing anisotropic growth conditions. However, to induce polar environment in the perovskite synthesis, a suitable precursor soluble in the desired polar solvent, is primarily required. In this work, we describe an efficient, MeOH-soluble steroidal Cs-precursor: cesium cholate and the different shapes of $CsPbBr_3$ NCs (nanorods, nanocubes and nanoplatelets) obtained from it, utilizing miniscule amount of polar solvents (methanol and methanol-water) in conjunction with commonly used 1-octadecene solvent and varying the reaction temperatures (90 °C and 180 °C). The resulting NCs exhibit very high photoluminescence (PL) quantum yields (94% for nanoplatelets and 96% for nanocubes), due to mitigation of Br vacancies by large cholate molecules, slowing down the complex nucleation and lattice construction processes in the synthetic pathway.[2] To study the application of these

luminophores for application in perovskite light emitting diodes (PeLEDs), powdered $CsPbBr_3$ nanocubes were dispersed in toluene at different concentrations to prepare inks. Inks were spin-coated at different speeds (500, 1000 and 1500 rpm) and film quality was optimized to produce uniform and pinhole free films on an ITO substrate. Thin films produced at optimal deposition conditions and ink compositions were characterized using thin film photoluminescence measurements at 325 nm. A sharp and highly intense peak at 514 nm was observed. Initial device fabrication employing a spin-coated hole transport layer (poly (9-vinylcarbazole), and an electron transport layer (2,2′,2"-(1,3,5-Benzinetriyl)-tris(1-phenyl-1-*H*-benzimidazole)) produced promising initial results. These initial results with perovskite nanocubes based thin films invite more studies of complete devices, possibly with other nanomaterial geometries (nanorods and nanoplatelets).

Chemically-Casted MoO_3 Hole Transport Active Layer for Perovskite Solar Cells Taliya Gunawansa, Messaoud Bahoura and Sangram K. Pradhan; Norfolk State University, United States

Perovskite solar cells (PSCs) are promising contenders in the solar cell technology market having achieved photo-conversion efficiencies greater than 25%. The role of the hole transport layer in perovskite solar cells is essential for incredible enhancement of their significant photo-conversion efficiency. Iron oxide is one of the interesting hole transport materials that can potentially improve the performance; however, the frequently used chemical synthesis technique of the micaceous iron oxide (MiO) precursors is very toxic, harmful and time-consuming. Molybdenum dioxide (MoO_3) is a commonly studied hole transport layer utilized in perovskite solar cell; This study analyzes a chemically casted process preferably hot-casting technique to prepare a non-toxic molybdenum dioxide precursor that would fabricate a highly effective and densely packed MoO_3 films. Various temperatures below 100 ^oC results in intermittent deposition of the MoO_3 films. When the hot-casting temperature is increased, the MoO_3 thin film are uniformed and resulted in greater charge extraction and insignificant light soaking. Photoluminescence spectroscopy (PL), ultraviolent-visible spectroscopy (UV-VIS), and scanning electron microscopy (SEM) are the characterization techniques utilized to observe the opto-electronic properties of the MoO_3 films. The capacitance, frequency dispersion, and leakage current measurements display stable performance of the MoO_3 perovskite solar cells.

F.EL02.13.08

Material Development And Emission Spectroscopy of Mn Doped CsPbCl3 Bulk Crystals and Nanoparticles for Light Source Applications Uwe Hommerich[1], Jihaad Barnett[1], Kesete Ghebreyessus[1], Al Amin Kabir[1], Khalid Hampton[1], Samuel Uba[1], Ikemefuna Uba[1], Demetris Geddis[1], Clayton S. Yang[2], Sudhir Trivedi[2], Seth Fraden[3] and S. Ali Aghvami[3]; [1]Hampton University, United States; [2]Brimrose Technology Corporation, United States; [3]Brandeis University, United States

Manganese doped inorganic halide perovskites continue to be of current interest for applications in light emitting devices and down-converters in solar cells. In this work we prepared Mn doped $CsPbCl_3$ (Mn: CPC) bulk crystals and nano-particles (NPs) and compared their emission properties. Bulk crystals were grown from the melt by vertical Bridgman technique and NPs were synthesized using a microwave assisted method. Under ultra-violet excitation at 350 nm, bulk crystal and NPs of Mn: CPC exhibited a broad orange emission centered at ~605 nm at room temperature. The broadband emission was assigned to the intra-3d transition $^4T_1 \rightarrow {}^6A_1$ of Mn^{2+} ions incorporated in the CPC host lattice. The Mn^{2+} emission lifetimes were nearly exponential with values of 1.07 ms for NPs and 0.73 ms for the bulk crystal. Mn: CPC NPs also showed exciton emission peaking at ~402 nm, whereas the bulk crystal exhibited no significant emission near the band edge. Instead, the bulk material of Mn: CPC revealed a weak below-gap emission in the 450-550 nm region suggesting the existence of defect states. The excitation spectra for the orange Mn^{2+} emission from Mn: CPC NPs and bulk crystals were significantly different indicating distinct excitation pathways. The excitation spectrum of the orange Mn^{2+} emission for Mn: CPC NPs showed excitonic structure similar to the absorption spectrum suggesting energy transfer from excitons to Mn^{2+} ions. In contrast, UV excitation was less efficient for the bulk Mn: CPC crystal and the excitation was dominated by well defined below-gap excitation bands centered at ~425 and ~530 nm. More details of the material preparation emission spectroscopy, and initial hybrid LED experiments will be discussed at the conference.

F.EL02.13.09

Red Light Emitting Ytterbium Activated $Sr_3Al_2O_6$ Nanophosphor for LED Applications Chitra Mallela; Tumkur

University, India

Present study analyses the salient features of the newly synthesized phosphor powders of 1, 3, 5, 7, 9 and 11 molar concentrations of Ytterrbium activated Strontium Aluminate by solution Combustion method using Urea. The prepared phosphors were calcined at 950degree celcius for 4 hours. The Powder X-ray diffraction (PXRD) profiles of nanophosphors showed crystalline face centered cubic phase. The average crystallite sizes of the phosphors were in the range 34 to 48 nm. The samples showed pores and voids on their surface that formed by the escaping gases during the combustion method. The morphology showed the inherent nature of combustion process. The Scanning electron microscope (SEM) images showed non-uniform and irregular shapes of the particles. The Particle sizes were further confirmed by Transmission electron microscope (TEM). Energy dispersive analysis of X-ray techniques were used to study the structural characteristics of calcined phosphors. Fourier infrared spectral studies were carried out to evaluate the stretching and vibrational bonds in the product. They showed an absorption peak at 1456 cm^{-1} that indicates the formation of crystallized Strontium Aluminate and a sharp peak at 3670 cm^{-1} due to the presence of AlO_4 group in the powders. Energy dispersive X-ray analysis (EDAX) with SEM image, revealed the uniform distribution of Yb^{3+} ions. The energy band gaps of the prepared phosphors from Kubelka-Munk plots of the Diffused reflectance Studies (DRS) were found to be in the range 5.31 eV to 5.78 eV. The Photoluminescence studies showed an emission peak at 708 nm when phosphors were excited with 355 nm. All the phosphors were found to emit red light as their Commission Internationale de L'Eclairage (CIE) co-ordinates have fallen in red region of chromaticity diagram. The average correlated color temperature of the phosphors was found to be 3950 degree Kelvin.

Support for the Self-Trapped-Exciton Hypothesis in Multi-Layered (n > 1) Two-Dimensional Lead Iodide Perovskites Watcharaphol Paritmongkol, Eric Powers, Nabeel Dahod and William Tisdale; Massachusetts Institute of Technology, United States

Two-dimensional (2D) lead halide perovskites have been shown to exhibit broadband or white-light emission under certain conditions. Broadband emission in lead iodide 2D perovskites has been alternately attributed to self-trapped excitons (STEs) or permanent structural defects and/or impurities. Here, we investigate the photophysical characteristics of broadband emission in six different multi-layered (n > 1) 2D lead iodide perovskites as a function of sample temperature from 5 K to 300 K. We distinguish shallow defect-associated emission from a broad near-infrared (NIR) spectral feature, which we assign to the STE. Sub-gap photoexcitation experiments and NIR transient absorption spectroscopy rule out permanent structural defects as the origin of this feature. When we varied the thickness (n = 2, 3, 4), A-site cation (methylammonium vs. formamidinium), and organic cation spacer (butylammonium vs. hexylammonium vs. phenylethylammonium), we found that the temperature dependence of broad NIR emission was strongly correlated with both the strength of electron-phonon coupling and the extent of structural deformation of the ground state lattice, strongly supporting the assignment of this spectral feature to a STE.

F.EL02.13.12
Thermal Impact on InAs Quantum Dots Covered by Different Capping Layers in GaAs/AlGaAs Structures Georgiy Polupan[1], Ricardo Cisneros Tamayo[2], Tetyana V. Torchynska[1], Íngrid. J. Íngrid. J. Guerrero Moreno1[1] and Arturo Escobosa Echavarria[3]; [1]Instituto Politecnico Nacional, Mexico; [2]Universidad Politécnica del Valle de México,, Mexico; [3]CINVESTAV-IPN, Mexico

InAs quantum dots (QDs) embedded in MBE grown GaAs/$Al_{0.30}Ga_{0.70}As$/AlGaInAs heterostructures have been investigated in as grown state and after thermal annealing at 640ºC or 710ºC for two hours. Two types of QD structures with the different compositions of AlGaInAs capping layers (GaAs (#1) or $Al_{0.10}Ga_{0.75}In_{0.15}As$ (#2)) and the same composition of buffer layers ($In_{015}Ga_{0.85}As$) are compared and studied by means of photoluminescence (PL), X-ray diffraction (XRD) and high resolution HR-XRD methods. XRD and HR-XRD techniques are applied with the aim to control the crystal structures, the material compositions and elastic strains in quantum well (QW) layers.

The highest PL intensity, smaller PL band half width and lower energy of ground state (GS) emission are detected in the structure with the $Al_{0.10}Ga_{0.75}In_{0.15}As$ capping layer. Thermal annealing leads to the shift of PL spectra into higher energy range and the value of this shift is more essential in the structure with the $Al_{0.10}Ga_{0.75}In_{0.15}As$ capping layer as well.

The variation of GS emission peak versus temperature has been monitored within the range of 10-450K for as grown and annealed states and it compared with temperature shrinkage of band gap in the InAs and GaAs bulk crystals. It permits to reveal the QD composition that in #2 was closer to InAs than in #1. Finally, the reasons of PL spectrum transformation at

annealing, the mechanism of PL thermal decay, and the advantages of the QD structure with strain reduced $Al_{0.10}Ga_{0.75}In_{0.15}As$ capping layer have been analyzed and discussed. The composition variation of QDs and QWs at annealing has been modeled using the simulation of HR-XRD results with Xpert Expitaxy software.

Superparamagnetic Properties of Metal-Free Nitrogen Doped Graphene Quantum Dots Synthesized by Pulsed Laser Ablation Muhammad Shehzad Sultan[1], Vladimir I. Makarov[1], Muhammad Sajjad[2], Wojciech Jadwisienczak[3], Brad R. Weiner[1] and Gerardo Morell[1]; [1]University of Puerto Rico - Río Piedras, United States; [2]Indiana University Northwest, United States; [3]Ohio University, United States

In this study, we developed a novel approach to synthesize high-quality metal-free Nitrogen-doped graphene quantum dots (N-GQDs) with high quantum yield, via irradiation of s-triazene in a solution with benzene by using pulsed laser. The TEM, HRTEM, XPS, XRD, Raman spectroscopy and FTIR were carried out to observe the morphology, size distribution, crystalline structure and to prove successful doping of GQDs with nitrogen atoms. Furthermore, for the first time, to our knowledge, their magnetic properties were investigated. The results indicate that N-GQDs exhibit superparamagnetic behavior. The specific size, shape and zigzag edge structure of N-GQDs were considered to explain the origin of the observed magnetism. The magnetization dependence led to estimating the N-GQD material magnetic permeability for different ambient temperatures. From the zero-field-cooled (ZFC) and field-cooled (FC) magnetization measurements, carried out at 50 Oe magnetic field strength, we estimated the blocking temperature T_B to be around 300 K. Based on the experimental data analysis, the magnetic permeability, number of correlated spins per single N-GQD, and number density of superparamagnetic N-GQD per gram of material were estimated. The excellent superparamagnetic properties together with optical properties manifested by N-GQDs have the potential to lead to high performance biomedical applications.

Highly Stable Luminescent Encapsulation Material Using Quantum Dot/Siloxane Hybrid for Reliable and Wide Color Gamut Light-Emitting Diode Junho Jang, Da-Eun Yoon, Doh C. Lee and Byeong-Soo Bae; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Semiconducting nanocrystals, also known as quantum dots (QDs), are a promising color converting materials for next-generation display application due to their unique photophysical properties such as size-dependent color tunability, narrow spectral bandwidth, and high photoluminescence (PL) quantum yield (QY). However, the vulnerability of QDs to oxygen and moisture is a huge obstacle to practical applications. The commercialized QD for display has been a form of color converting QD films in liquid crystal display (LCD) backlight unit (BLU) using blue light-emitting diode (LED) (*i.e.*, On-Surface type), where QDs were physically blended in polymer matrixes sandwiched between two barrier layers. It is more desirable for LCD BLU using LEDs encapsulated the QDs directly into the packaging (*i.e.*, On-Chip type) in terms of performance, amount of QDs, and cost. Nevertheless, LEDs that are directly encapsulated by QDs have not been used in display applications due to their fatal instability. Therefore, reliable LEDs using highly stable luminescent encapsulation material that contains uniformly dispersed QDs in optical resin should be developed without additional protecting layers (such as SiO_2 or Al_2O_3) and ligand-exchange processes.
Herein, we developed luminescent LED encapsulation material (TSE-QD) using CdSe/CdZnS core/shell QDs (passivated by oleic acid) dispersed in a thermally resistant sol-gel derived siloxane matrix with high refractive index (> 1.57) [1,2]. The TSE-QD was fabricated via hydrosilylation of QD dispersed siloxane resin that was synthesized via *in situ* sol-gel reactions of silane precursors in the presence of QDs. The QDs were uniformly distributed in a linear-structured siloxane matrix in which functional groups of siloxane matrix is chemically cross-linked with ligands of the surface on QDs, and retained their initial optical properties during the fabrication processes [3]. Notably, we achieved dramatically enhanced thermal (at 120 ºC in ambient air) and chemical stability (in acid or base solutions and alcohol) without additional barrier films and ligand-exchange process. We demonstrated a natural-white emitting LED using a blue LED chip directly encapsulated (*i.e.*, On-Chip type) by yellow-emitting TSE-QD that consist of red and green QDs in a siloxane matrix. Fabricated white LED exhibited wide color gamut (116% of NTSC 1931), excellent reliability (under 85 ºC & 85% relative humidity), and high photostability (under continuous blue light irradiation).

F.EL02.13.16

$Cs_4Cd_{1-x}Mn_xBi_2Cl_{12}$—A Vacancy Ordered Halide Perovskite Phosphor with High Efficiency Orange-Red Emission Noah P. Holzapfel[1], Jackson Majher[1], T. Amanda Strom[2], Curtis Moore[1] and Patrick Woodward[1]; [1]The Ohio State

University, United States; [2]University of California Santa Barbara, United States

The structural, optical, and magnetic properties of the vacancy-ordered quadruple perovskites $Cs_4CdBi_2Cl_{12}$ and $Cs_4MnBi_2Cl_{12}$ and their solid solution have been investigated. Both compounds are found to crystallize with *R*-3*m* space group symmetry that arises from ordering of Bi^{3+}, Mn^{2+}/Cd^{2+}, and cation vacancies into layers that run perpendicular to the <111> direction of the cubic perovskite structure. Magnetic measurements reveal that $Cs_4MnBi_2Cl_{12}$ is paramagnetic down to 2 K with a Weiss constant of −2.88(3) K and an effective moment of 5.840(1) μ_B. This compound exhibits weak orange-red luminescence, which involves Bi^{3+} ions absorbing near UV photons followed by energy transfer to Mn^{2+} ions and finally radiative decay that is attributed to a spin-forbidden $^4T_1(G)$ to $^6A_1(S)$ d–d transition. The emission peak is centered near 605 nm and has a full-width-half-maximum of ~90 nm and a photoluminescent quantum yield (PLQY) of ~ 4%. The isostructural $Cs_4CdBi_2Cl_{12}$ is neither magnetic nor does it show detectable photoluminescence at room temperature. Replacing Mn^{2+} with Cd^{2+} to form $Cs_4Cd_{1-x}Mn_xBi_2Cl_{12}$ leads to a zero-dimensional electronic structure that inhibits energy migration to defect sites where non-radiative decay can occur, increasing the room temperature PLQY to 57% in the x = 0.27 sample. $Cs_4Cd_{1-x}Mn_xBi_2Cl_{12}$ phosphors are easily synthesized from solution, free of rare-earth ions, and possess emission spectra that compare favorably to narrow-band red emitting phosphors based on Eu^{2+} ions.

F.EL02.13.17
Fluorene-Based Organic Phosphorescent Materials for LECs C KY, Maxime Remond, Donghwan Kim and Eunkyoung Kim; Yonsei University, Korea (the Republic of)

Fluorene-based organic phosphorescent materials (OPMs) were explored for organic light-emitting electrochemical cells (LECs) taking advantages of their tunability in color and film processibility. TO tackle the problem of the apparent low emission efficiency of OPMS, compared to inorganic or organometallic materials, fluorene unit was designed as a π-bridge between halogen and n-π transition groups. These OPMs provided a long-lived phosphorences at film state, possibly due to enhanced intersystem crossing (ISC) to the triplet state in the optimized structure. Thus OPMs were applied to light-emitting cells (LECs) along with a host and electrolyte, to show the highest luminescence among the organic phosphorescent LECs up to date. Synthesis of OPMs, mechanism of enhanced emission, and fabrication details on LECs will be presented.

F.EL02.13.18
Synthesis of Efficient Blue Emitting $CsPb(Br/Cl)_3$ Nanoparticles via Post-Treatment with Short Organic Ligands and LED Fabrication Jang Kyung Yeon, Jinwoo Park and Tae-Woo Lee; Seoul National University, Korea (the Republic of)

Perovskite nanoparticles (PeNPs) are promising emitters owing to their high color purity, low-cost synthesis, and facile wavelength control with halide composition control. However, chloride-based blue-emitting colloidal PeNPs have suffered from low photoluminescence quantum efficiency (PLQE) due to chloride-induced defect states. Their low PLQE hinders their use of blue-emitting devices.
In this work, we propose a method to improve the efficiency of blue PeNPs. At first, blue-emitting perovskite was synthesized by the hot injection method. Near Unity PLQE of as-synthesized PeNPs was obtained. For the efficient perovskite light-emitting diodes (PeLEDs), additional washing steps are required to remove excess ligands on the surface. But after washing steps, the PLQE rapidly decreased to ~50% because of surface defects.
A simple post-treatment process using short organic ligands solution was done after washing steps. PLQE increased again because the halide anions passivate defect sites. Moreover, those short organic ligands do not impede charge injection. By these methods, highly efficient blue-emitting PeNPs with PLQE > 92 % and high device efficiency of 2% was obtained.

F.EL02.13.19
Water Passivation of Perovskite Nanocrystals Enables Air-Stable Intrinsically-Stretchable Color-Conversion Layers for Stretchable Displays Huanyu Zhou[1], Jinwoo Park[1], Yeongjun Lee[1], Jae-Man Park[1], Jin-Hoon Kim[2], Joo Sung Kim[1], Hyeon-Dong Lee[1], Seung Hyeon Jo[1], Xue Cai[1], Lizhu Li[3], Xing Sheng[3], Hyung Joong Yun[4], Jin-Woo Park[2], Jeong-Yun Sun[1] and Tae-Woo Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of); [3]Tsinghua University, China; [4]Korea Basic Science Institute, Korea (the Republic of)

Despite organic light-emitting diode (OLED) technology has already left an indelible mark on the display industry, conventional OLEDs are still susceptible to degradation when exposed to air. A greater hurdle is to achieve the stretchable OLED as protecting devices from the penetration of moisture and oxygen is even more difficult under stretching. Here, we propose an air-stable intrinsically stretchable display without using any encapsulations by integrating a stretchable light-emitting device (SLED) with a stretchable color conversion layer that contains perovskites nanocrystals (PeNCs). PeNCs

normally decay when exposed to air; counterintuitively, the moisture-assisted surface passivation of PeNCs is first observed. This work is believed to stimulate considerable research on fundamental aspects of PeNCs and furthermore into the practical applications both in academia and industries. The above-mentioned SLED can also open new ways toward intrinsically stretchable OLEDs.

F.EL02.13.20
***In Situ* Fabrication of Highly Luminescent Halide Perovskite Thin Films Incorporating Organic Dispersing Agent** Eojin Yoon and Tae-Woo Lee; Seoul National University, Korea (the Republic of)

Recently, lead halide perovskite nanoparticles became promising candidates for light emitters due to narrow full-width at half maximum (FWHM), solution processability, easily tunable bandgap.[1] Excitons are well confined with the aids of long passivating ligands promoting radiative recombination, thus, lead halide perovskite nanoparticles exhibit high photoluminescence quantum yield (PLQY). [2] However, the synthesis of perovskite nanoparticles is complicated requiring several centrifugations and production yield is low because only the small amount of precipitate is utilized by reprecipitation method.
So, we took *in-situ* strategy for synthesizing perovskite nanoparticles by incorporating bulky ligand, phenyl ethyl ammonium bromide (PEABr).[3] To achieve stable in situ fabricated perovskite nanoparticles, dispersion of PEABr is essential because PEABr aggregates form local quasi-2D structure.[4] Here, we successfully synthesized perovskite nanoparticles by exploiting crown additive of 1,4,7,10,13,16-Hexaoxacyclooctadecane (18-crown-6) as a dispersing agent. From UV-vis spectroscopy, it was confirmed that low n phases (~440 nm) considerably decreased with 18-crown-6 and the average lifetime also enhanced due to reduced defect sites. Moreover, temperature-dependent PL represented increased exciton binding energy from 24.6 to 63.9 (meV) owing to the fine dispersion of PEABr and dielectric confinement effect. Finally, with optimized concentration, highly bright perovskite films with maximum PLQY of 93.036 % could be achieved, which is 47 times higher than pristine films.

F.EL02.13.21
Core-Shell Structure Perovskite Nanoparticles with Atomic Surface Passivation for Highly-Efficient Pure-Red Emitting Perovskite Light-Emitting Diodes Jinwoo Park, Sinil Choi, Sungjin Kim, Joo Sung Kim and Tae-Woo Lee; Seoul National University, Korea (the Republic of)

Perovskite nanoparticles (PeNPs) is attractive next-generation sources for light-emitting diodes (LEDs) due to their efficient luminescent, solution processability, tunable bandgap and extremely high color purity which is superior to conventional light emitters (e.g. organic emitters, traditional quantum dots). However, due to halide segregation, emmision wavelength shift while LED operation and precise control of emission wavelength is limited. Here, we develop facile atomic surface defect passivation method exploited post-synthesis treatment using high bandgap perovskite precursor. With this strategy, we synthesized color-stable and pure-red-emitting $CsPbI_3$ PeNPs with 630 nm of peak emission wavelength with core-shell structure. Highly efficient PeNP LEDs without electroluminescence wavelength shift was also demonstrated.

F.EL02.13.22
Late News: Maximizing the Photoluminescence Intensity in Quasi 2D Perovskites Through Surface Passivation of Defect States - Yukta and Soumitra Satapathi; Indian Institute of Technology Roorkee, India

Quasi two-dimensional (2D) perovskites are currently considered as materials of choice for light emitting diodes (LEDs) due to their unique optoelectronic properties such as strong exciton binding energy, multiple quantum well structure, and reasonable ambient stability for practical applications. Tremendous progress has been achieved in 2D perovskites LEDs in terms of external quantum efficiency (EQE) (~17%), luminescence (6785 cd/m^2) and stability through compositional and device engineering. However, the excessive surface defect states generated due to the reduced crystal size, the presence of un-coordinated Pb^{+2} ions or shallow vacancy defects generated by MA or halide ions at the surface and grain boundaries,

limits the radiative recombination and in turn the electro-luminescence (EL) efficiency of the LEDs. It has been realized that surface passivation with suitable organic/inorganic moieties can play a vital role in overcoming the adverse effect of defect states through their interaction with uncoordinated ions and can improve the stability.
In the present work, we have chosen n=4 composition quasi-2D perovskite $(BA)_2(MA)_3Pb_4Br_{13}$ films as emissive layer by optimal phase engineering and have shown the order of magnitude enhancement of radiative emission after passivating them with two different molecules namely- triphenyl phosphine oxide (TPPO) and an insulating polymer polymethyl methacrylate (PMMA). Both the steady state and time resolved study confirm up to 400% enhancement in fluorescence intensity and improved average lifetime (=19.4 ns) after surface passivation. Additionally, the effect of passivating agents on film morphology and radiative emission efficiency is studied in details. Also, the interaction mechanism between layered perovskite and passivating agents has been probed with FTIR spectroscopy, XPS and KPFM study. Our systematic investigation with detailed mechanistic study will pave the way for further development of the highly efficient LEDs.

Late News: Quantum Confinement in Type I Heterostructure of Hybrid Lead Halide Perovskite Embedded in Organic Matrix Amrita Dey[1,2], Shivam Singh[2] and Dinesh Kabra[2]; [1]Ludwig-Maximilians-Universität, Germany; [2]Indian Institute of Technology Bombay, India

The type I heterostructure forms between Organic semiconductor molecule (4,4'-bis[9-dicarbazolyl]-2,2'-biphenyl [CBP] and bathocuproine [BCP]) and methylammonium lead halide ($MAPbX_3$), assists easy growth of perovskite nanocrystals (PNCs) in an organic matrix. Herein, we present the modulation of electronic states of $MAPbX_3$ PNCs (MA = $CH3NH3^+$ and X= Br^- and I^-) as a function of crystallite size. This results in the growth of $MAPbX_3$ PNCs of tunable sizes from ~110 nm to ~10 nm in the organic semiconductor matrix. A blue shift is observed in the photoluminescence peak (PL_{max}) energy over a range of ~200 meV for $MAPbI_3$ PNCs embedded in the BCP matrix. However, PL_{max} energy tunes over ~32 meV only with a similar volumetric concentration in the case of $MAPbBr_3$ PNCs in the same BCP matrix. Moreover, the PL blue shift is even lower in the case of the CBP matrix in comparison with the BCP matrix for both the perovskites. This discrepancy could be resolved by determining the resultant crystallite size using X-ray diffraction studies and the Debye–Scherrer formula. Results about the blue shift in the PL peak can be explained using the classic particle-in-a-box versus excitonic Bohr radius model under a weak confinement regime.

Hot Carrier Optoelectronics with 2D Transition Metal Dichalcogenides Goki Eda; National University of Singapore, Singapore

One of the most distinct features of van der Waals (vdW) heterostructures based on two-dimensional (2D) materials is the ultrafast photo-induced interlayer charge transfer, which is known to occur in sub-picosecond time scales. Such ultrafast dynamics offers promise for the realization of novel hot carrier optoelectronic devices where non-thermalized photocarriers are harnessed to achieve unconventional functions. In this talk, we will discuss a few examples of hot carrier optoelectronic phenomena in heterostructures of 2D transition metal dichalcogenides. First, we will discuss realization of near-infrared (NIR) to visible light upconversion in a metal-insulator-semiconductor (MIS) vdW heterostack tunnel diode [1]. We show that the upconversion is enabled by interlayer transfer of non-thermalized photoexcited holes and its dynamics can be tuned by orders of magnitude by applied electric fields. Second, we will discuss unique photoresponse of these MIS devices arising from hot carriers generated by efficient exciton-exciton annihilation (EEA) in monolayer MoS_2 [2]. We describe how EEA can result in highly energetic electrons and holes due to uneven distribution of annihilation energies following energy- and momentum-conserving scattering.

Revealing Defect Passivation Mechanisms in Sb_2Se_3 David Tilley; University of Zurich, Switzerland

Antimony selenide (Sb_2Se_3) has emerged as a strong candidate for practical water splitting due to its suitable bandgap, excellent optoelectronic properties, and resistance to photocorrosion in strongly acidic electrolyte solutions. In this talk, I will discuss the synthesis of Sb_2Se_3 thin films by selenization of antimony metal and the photoelectrochemical properties of these films after coating with a molybdenum sulfide hydrogen evolution catalyst. The performance of these photocathodes was greatly enhanced by a relatively low temperature sulfurization treatment with elemental sulfur, greatly improving the photovoltage and the fill factor. The origin of the improvement upon sulfurization was investigated with time-resolved microwave conductivity (TRMC) measurements and photoluminescence. TRMC of our Sb_2Se_3 reveals high mobilities of the photogenerated charge carriers (>10 $cm^2\ V^{-1}\ s^{-1}$) and a low trap density, in contrast to other emerging photoelectrochemical materials such as Fe_2O_3, $CuFeO_2$, and $BiVO_4$. We find that the sulfurization treatment of the Sb_2Se_3 thin films yields improved charge carrier lifetimes. Not only is surface recombination curtailed, but deep traps in the bulk are eliminated (most likely Sb-Se antisite defects), which reduces non-radiative recombination of the photogenerated charge carriers. A low temperature sulfurization treatment is thereby identified as a simple method to remove bulk traps in Sb_2Se_3 thin films.

2:35 PM *F.EL03.02.08
New Low-Dimensional Metal Chalcogenides and Their Optoelectronic Properties Mercouri G. Kanatzidis; Northwestern University, United States

Two-dimensional (2D) materials have seen a surge of interest ever since the discovery of graphene, a single 2D layer of carbon atoms (graphene), more than a decade ago. 2D chalcogenides are a fundamental class in the study of low-dimensional science and their synthesis is an important goal of solid state chemistry. The presentation will focus on how novel chalcogenides can form using design concepts such as the “dimensional reduction”. The new materials exhibit diverse

centrosymmetric and noncentrosymmetric structures that lead to a variety of attractive optoelectronic properties such as direct bandgaps, high X-ray absorption, neutron detection and strong nonlinear optical responses.

3:00 PM *F.EL03.03.01
Optical Properties and Refractive Uses of Phase-Change Phenomena in Layered Chalcogenides Rafael Jaramillo; Massachusetts Institute of Technology, United States

Layered chalcogenides hold promise for manipulating light in confined geometry, such as in photonic integrated circuits, where key material properties include strong and controllable light-matter interaction, and limited optical loss. Layered materials feature strong anisotropy and a panoply of polymorphs that suggest a rich design space for highly-nonperturbative photonic integrated devices based on functional martensitic transformations: phase changes and ferroelastic domain switching. These phenomena are manifest in materials with band gap above the photonics-relevant near-infrared (NIR) spectral band (~ 0.5 – 1 eV), meaning that they can be harnessed in refractive (*i.e.* non-absorptive) applications.

Transition metal dichalcogenides (TMDs) offer a vast composition space within which to optimize refractive index contrast, optical loss, and switching energy. We are using a strategy of alloy design to optimize new, active materials for optical phase shifters. We will present our theoretical predictions of thermodynamics and optical properties of binary systems of sulfur-based TMDs: ZrS_2-MoS_2, TiS_2-MoS_2, TiS_2-ZrS_2, and MoS_2-CrS_2. We will present our experimental measurements of the NIR optical properties of single crystals. We will then present progress on making large-area thin films of sulfur-based TMDs, including the theoretically-predicted alloys, by a two-step method of metal sulfurization. Finally, we will present the optical properties and phase-change functionality of our designed TMD alloy thin films.

We will also present an alternative paradigm of strong, non-perturbative refractive index modulation: electric field-driven ferroelastic domain switching in low-symmetry layered materials. We predict that in materials such as SnSe, a sufficiently-strong electric field will induce rotation between equivalent crystallographic domains, with strong refractive index contrast for linearly-polarized light. We will present simulation-based design of photonic integrated devices utilizing the trirefringence of materials such as SnSe and black phosphorous, and experimental results demonstrating non-thermal domain switching triggered by fast laser pulses.

Chemical Trends and Electronic Engineering of V-VI-VII Metal Chalcohalides Aron Walsh[1,2]; [1]Imperial College London, United Kingdom; [2]Yonsei University, Korea (the Republic of)

Metal chalcohalides are candidates for next-generation technologies including energy conversion, information storage, and quantum computing. I will present an exploration of V-VI-VII ternary chalcohalides, where V = Sb, Bi; VI = O, S, Se, Te; and VII = F, Cl, Br, I. These include the photoferroic compound SbSI [1,2] and the solar fuels photoelectrode BiOBr [3,4]. We consider 32 elemental combinations in 4 spacegroups using a combination of density functional theory (structural and thermochemistry) and many-body QSGW theory (relativistic electronic band structures). The materials are found to exhibit a wide range of electronic structures and bandgaps from metallic to over 5 eV. The large spin-orbit coupling in the heavy cations strongly influences the electronic structure. This research is part of a collaboration with the groups of David Scanlon (UCL) and Mark van Schilfgaarde (KCL), and used the UK National Supercomputer ARCHER.

Synthesis of Two-Dimensional Materials via Chemical Vapor Deposition Jing Kong; Massachusetts Institute of Technology, United States

In recent years tremendous efforts have been devoted to the research on two dimensional materials. Their unique structures and remarkable properties have offered great potential for a wide range of applications in electronics, optoeletronics, valleytronics, catalysis, etc. The synthesis of high quality large area mono- and few-layer 2D materials is highly desirable for their applications. In this talk I will present our recent development on novel 2D material and structures, together with further understanding regarding the chemical vapour deposition (CVD) synthesis process of monolayer MoS2.

7:18 PM *F.EL03.07.02
Systematic Exploration of Structure and Properties in Homologous Series of Nanoscale Chalcogenide Superlattices Sage Bauers[1], Danielle Hamann[2], Dennice Roberts[1], Andriy Zakutayev[1] and David Johnson[2]; [1]National Renewable Energy Laboratory, United States; [2]University of Oregon, United States

An exciting prospect for 2D materials is their ability to be integrated into heterostructures, where the selection and sequencing of stacked layers facilitate tailored properties. One form of such heterostructures are non-epitaxial chalcogenide superlattices with constituents interleaved at nanometer length scales. These materials can be prepared from amorphous—but intentionally layered—thin films which are gently heated to crystallize into a superlattice that mimicks the layer sequence of the precursor. Such facile synthesis enables superlattices with nearly limitless permutational flexibility, allowing for systematic explorations of how different layer arrangements affect the structure and properties of the composite material.

This talk will primarily focus on materials containing *n* monolayers of $TiSe_2$ interleaved with *m* monolayers of PbSe and/or SnSe in a repeating superlattice. These structures can be described by the chemical formula $[(MSe)_{1+\delta}]_m[TiSe_2]_n$, where M=Sn or Pb and δ is a compositional misfit parameter. We will discuss several homologous series wherein the relative fractions of constituents are successively modified by changing the integral number of layers (*m* and *n*).

Changes to $[(MSe)_{1+\delta}]_m[TiSe_2]_n$ layer sequencing induce changes to the composite materials' semi-metallic transport properties . In both $[(PbSe)_{1+\delta}]_m[TiSe_2]_n$ and $[(SnSe)_{1+\delta}]_m[TiSe_2]_n$ electrons exchanged between the layers are the primary source of mobile carriers while the amount of charge exchange required to equilibrate the chemical potential across the interface is dependent on the thicknesses and identities of layers. Thus, *m* and *n* can be used to tune the carrier density with minimal change to carrier mobility since no ionized dopants are introduced into conduction paths. In some cases, the sequencing can also affect the local structure within the layers. For example, in $[(PbSe)_{1+\delta}]_m[TiSe_2]_n$ superlattices both constituents are structurally rigid and insensitive to the thickness of the layers. Conversely, in $[(SnSe)_{1+\delta}]_m[TiSe_2]_n$ the nanolayers of SnSe exhibit a rich polymorphism dependent on thickness, which is attributed to a combination of low polymorph energies and strong interfacial interactions with $TiSe_2$.

Motivated by successful synthesis of superlattice materials in several selenide systems, we have recently reported on $[(SnS)_{1+\delta}]_m[TaS_2]_1$ superlattices, marking the first application of this synthesis approach to sulfur-based chemistries. As part of this work, we employ graded precursor films that enable parallel preparation of multiple stacking sequences with similar monolayer control. These results are a promising first step towards similar systematic investigation of structure and properties in another chalcogenide class.

A Method to Reliably Measure Energy Conversion Efficiency without Making Contact for Confirmation of Thermoelectric Figure-of-Merit Zhifeng Ren; University of Houston, United States

Thermoelectric figure-of-merit (ZT) is the overall most important physical quantity for a thermoelectric material. It ultimately determines the energy conversion efficiency. However, over the years, higher and higher ZTs were reported without confirmation since it requires zero-resistance contact that is as difficult as, if not more than, the material improvement. Therefore, how to confirm the ZT of any material without making the needed contact is urgently needed. In

this report I will present our detailed study on reliable efficiency measurement on materials without making the needed contact.

Optical Properties of Transition Metal Dichalcogenide Bilayers Xiaoqin E. Li; The University of Texas at Austin, United States

Optical properties of atomically thin transition metal dichalcogenides are dominated by exciton resonances exhibiting large oscillator strength and binding energies. In vertically stacked bilayers, a host of new exciton resonances emerge, lending new opportunities to discover new science and enable new devices. In this talk, I will focus on how moire superlattices change exciton resonances and diffusion. We discovered recently that phonon spectra are renormalized in moire superlattices as well. A rich variety of properties can be controlled by tuning the twist angle between the bilayers. I make some comparisons between samples that are grown using chemical vapor deposition and those prepared by mechanical exfoliation and stacking. Our work is supported by DOE under grant DE-SC0019398, NSF DMR-1808042, DMR-1720595, and the Welch Foundation F-1662.

9:00 AM *F.EL03.02.06
Chirality-Dependent Second Harmonic Generation of MoS_2 Nanoscroll with Enhanced Efficiency Qingkai Qian[1], Rui Zu[1], Qingqing Ji[2], Jing Kong[2], Venkatraman Gopalan[1] and Shengxi Huang[1]; [1]The Pennsylvania State University, United States; [2]Massachusetts Institute of Technology, United States

Second harmonic generation (SHG), as a nonlinear optical effect, has important applications in photonics for frequency conversion and light modulations. Materials with high SHG efficiency and reduced dimensions are favorable for integrated photonics and novel nonlinear optical applications. Here, we fabricate MoS_2 nanoscrolls with different chiralities and study their SHG performances. As a 1D material, MoS_2 nanoscroll shows reduced symmetry and strong chirality dependency in the polarization-resolved SHG characterizations, which is in stark contrast with the 2D MoS_2 layers. This SHG performance can be well explained by the coherent superposition theory of second harmonic field of the nanoscroll walls. MoS_2 nanoscrolls with certain chiralities in our experiment can have SHG intensity up to 98 times stronger than that of monolayer MoS_2. The same chirality-dependent SHG can be expected for nanoscrolls or nanotubes composed of other non-centrosymmetric 2D materials, such as WS_2, WSe_2, and hBN. The characterization and analysis results presented here can also serve as a non-destructive technique to determine the chiralities of these nanoscrolls and nanotubes.

On the Nature of the Surface of Semiconductor Nanocrystals Patanjali Kambhampati; McGill University, Canada

By virtue of their size, the surface must be one of the dominant aspects of semiconductor nanocrystals. Yet the surface remains the most poorly understood aspect of their basic science. Here, we exploit simple temperature dependence photoluminescence and electron transfer theory to rationalize the nature of surface emission from all nanocrystals. Moreover this work enables prediction of how to rationally generate white light from a single nanocrystal by virtue of mixing emission

from the excitonic core and the self trapped excitonic states at the surface.

5:10 AM F.EL03.01.02
Transrotational Bent-Lattice Nanostructures in Crystallizing Amorphous Nanothin Films Revealed by TEM Vladimir Y. Kolosov; Ural Federal University, Russian Federation

The paper summarizes our recent TEM (transmission electron microscopy) studies and main former data on novel microcrystals, nanostructures with unexpected, dislocation independent, regular internal bending of the crystal lattice planes [1]. Usually it is revealed in thin films or layers after amorphous – crystalline transitions. Such **perfect crystals/grains with regularly bent lattice** (built up by simultaneous ***trans***lation and small regular ***rotation*** of the unit cell) **demonstrate a new *"transrotational"*** [2] **type of solid state order realized in thin films.** It is primarily dislocation independent and takes place round an axis (or 2 axes) lying in the film plane of the growing crystal. The maximal values correspond to essential lattice orientation gradients (up to 300 degrees per μm) resulting to several whole rotations for the crystal about 10 μm in length (in film plane).
Thin (10 - 100 nm) crystallized areas with transrotation we study vary from small crystals (0.1 - 100 microns), ribbons, whiskers or spherulites to large-scaled polycrystalline areas with a complex texture. They are grown by heat treatment (or by self-organization upon aging) and local annealing by focused electron/laser beam in amorphous films most easily formed for chalcogenides. The films were prepared primarily by vacuum evaporation mostly with thickness or/and composition gradients across TEM grids (to study these factors directly). We used mainly TEM, primarily bend-contour method [3], *in situ* studies, and HREM. Correlative TEM-AFM studies were also performed.
The geometry and the magnitude of transrotation can be regulated by film preparation and crystallization conditions, orientation of the crystal nucleus, sublayers, composition and film thickness.
In situ studies in particular include HREM of amorphous-crystalline interface propagation and multiple reversible local transformations "amorphous – transrotational crystalline" inside the fingers in *Se*-based vacuum deposits. Dynamic changes of TEM diffraction contrast fit the mechanism of transrotation formation based on the surface nucleation that we proposed earlier.
Atomistic mathematical model (based on instrument of conformal transformations) for the atom positions in "transrotational" single crystal and the probable physical reasons are discussed. Transrotational microstructure can be considered as an intermediate one between amorphous and crystalline structures (likewise the structure of liquid crystals, intermediate between crystalline structure and liquid one). We suppose it as one of the reasons for easy phase changes in chalcogen-based films that tend to crystallize in such manner. Transrotational crystals have been eventually recognized/studied in a large variety of thin film systems and well-known chalcogenide compositions [4, 5] used for non-volatile memory and prospective for other kinds of storage and phase-change materials applications (including photonics).
Opposite to other unusual regular nano aggregations of atoms widely recognized by the community in recent 35 years (quasi-crystals, fullerenes and nanotubes and alike nano derivatives as well as graphene-like layers) our less known "transrotational" crystals/structures are less confined in dimensions. Bent atom layers in fine areas can be described as similar to that of hypothetical 2+D halves (180°) of endless (continuous in film plane) multiwall nano- tubes/onions/tori.
The transrotation phenomenon is the basis for novel lattice-rotation crystal nanoengineering of functional, smart thin-film materials including tunable and switchable low-D structures with some features suitable also for strain engineering.

Understanding the Optical Properties of Monolayer Transition Metal Mono- and Dichalcogenides Materials Nicholas Pike[1,2] and Ruth Pachter[2]; [1]UES, Inc., United States; [2]Air Force Research Laboratory, United States

With the advent of applications for two-dimensional materials in electronics and photonics, a number of theoretical investigations on the optical properties of have emerged. However, these investigations often focus on the linear optical properties with very few focused on the nonlinear optical properties of these two-dimensional materials. For example, measurements on the second harmonic generation (SHG) in monolayer transition metal dichalcogenides (TMDs), primarily MoS_2, WS_2, and WSe_2, have shown promise due to the large second-order susceptibilities. SHG measurements of stacked twisted TMD bilayers, as well as from transition metal monochalcogenide (TMM) monolayers, e.g. GaSe and InSe, have also been reported. Yet, theoretical predictions of these second-order quantities are scarce. Here, we summarize a theoretical analysis of the linear and nonlinear susceptibilities of a series of monolayer TMDs and TMMs in comparison to experiment.

Aspects on the importance of including spin-orbit coupling and many-body effects to study excitonic effects in these materials will be discussed in detail. Finally, results for TMD and TMM heterostructures will be described, particularly with respect to the optical response upon changing the relative orientation of the stacked monolayers.

5:30 AM F.EL03.01.04
Strain-Induced Spontaneous Centroidal Voronoi Tessellation in Few-Layer MoS_2 Yichao Zhang, Moon-Ki Choi, Ellad Tadmor and David J. Flannigan; University of Minnesota, United States

Due to the anisotropic bonding states inherent to transition metal dichalcogenides (TMDs), these materials can withstand as large as 10% elastic strains and display an associated wide range of variable optical and electronic properties [1]. In addition to interests in fundamental behaviors, such properties have driven efforts to develop strain-tunable devices and applications. While spontaneous wrinkle formation in few to monolayer specimens generates local strain variations, controllable and predictable strain-pattern requires rational engineering design and processing principles [2,3]. Nascent approaches have focused on either whole-flake deformation (*e.g.*, indirect handling of elastomer substrates) or single, site-specific mechanical indentation to modulate the global or local strain through repeatable stress application [4,5]. Spatially periodic strain patterning has been introduced to produce predictable, highly-symmetric local structural modulations in a passive, non-continuous manner, *e.g.*, through flake deposition on periodic nanostructures [6,7], or through moiré patterns in twisted layered heterostructures [8,9]. In this way, local strain patterning can be controlled by manipulating nanostructure geometry and patterning periodicity.

Here we report a method for highly-symmetric, spontaneous strain patterning of few-layer MoS_2 using patterned holey substrates based on the principle of tessellation. In this approach, uniformly-spaced substrate holes of the same size, arranged in a hexagonal array throughout the substrate, serve as the tessellation seeds. The resulting tessellation pattern with six-fold symmetry is well-described by centroidal Voronoi tessellation (CVT). In a TEM bright-field image, the tessellation manifests as strongly-scattering bend contours between the holes forming three-fold vertices at the center of sets of three holes. Further, twelve-fold bend contours, indexed to first- and second-order Bragg spots, radiate from the seeds and arise from curvature of the crystal over the hole, as confirmed with correlated bright- and dark-field imaging. Atomistic simulations of a bilayer MoS_2 crystal on a holey substrate show a change in the relative height and display similar bend contour patterns in the hole region [10]. Spatially-averaged strains of 2% to 4% are present, as determined with selected-area diffraction. Further, spatial mapping of relative strain was obtained with nanobeam electron diffraction with a 10-nm beam size. Strains were maximal near the hole centers with a steep decrease toward the substrate, as observed in both experiment and simulation, before increasing again when approaching the hexagonal tessellation patterns over the substrate. In addition to spontaneous formation, tessellated strain-patterning is also influenced by polymer residue from crystal transfer for thicker flakes within the holes. These results suggest a simple, highly-repeatable method based on the principles of CVT for producing highly-symmetric, strain-patterned films of high regular periodicity in TMDs, other layered materials, and generally in ultrathin films and crystals [11].

5:40 AM F.EL03.01.05
Structural Origin of Size and Parity Effects Observed by NanoDSC in 2D Organic Metal Chalcogenides—Atomic Resolution Crystallography via Diffraction and *Ab Initio* Calculation Jie Zhao, Zichao Ye, Kisung Kang, Scott J. McCormack, Yu-Tsun Shao, Mike Efremov, Andre Schleife, Jian-Min Zuo, Waltraud M. Kriven and Leslie Allen; University of Illinois at Urbana-Champaign, United States

The emerging characteristics of two categories of nanoscale materials with increasing interests, organic metal chalcogenides

(OMC) and two-dimensional (2D) van der Waals layers, can both be elucidated by studying the structure-property-relationship of 2D metal alkanethiolate layers. A detailed study of the crystal structure of this inorganic-organic hybrid system is critical to understand its size and odd/even effect observed in properties such as melting point/enthalpy (NanoDSC), luminescence, and band structures. Crystallography determination with atomic resolution is often challenging for beam-sensitive hybrid materials that do not grow into large scale single crystals (e.g. silver alkanethiolate, AgSCn, in this work). Here we describe a novel methodology combining synchrotron powder X-ray diffraction, nanobeam electron diffraction, and *ab initio* calculations. Unit cell level information and atomic coordinates of Ag-S segments are well uncovered by diffraction techniques, whereas density functional theory calculations suggest the complete atomic basis including the light/soft organic segments. Crystallography results of AgSCn (n=2-10) show odd/even effect in lamellar thickness consistent with prior experiments. Our preliminary findings of AgSCn structure suggest modifications to the initial simplified model, and consists of three segments: (i) Ag-S backbone: we first report an inorganic backbone deformation modulated by organic chain length, as a result of lattice mismatch between Ag-S framework and the epitaxial hydrocarbon chains that incline towards optimal packing. Such modulation probably leads to various optical luminescence properties inherent in the argentophilic interactions found in the backbone, an emerging topic in gold/silver chemistry. (ii) Interlayer interface: the structural origin of odd/even effect in this layered OMC system lies in the parity-dependent C-H orientations and H-H interactions exhibited among the terminal methyl groups. The resulting denser packing of odd-chain interface explains its higher melting enthalpy. (iii) Alkyl chains: the epitaxial accommodation between the backbone structure (sp^3 hybridized sulfur bonding) and the density of alkyl chains triggers the evolution of local chain tilting and twisting towards the optimal packing with longer chain length. This further provides clues that drive the similar variations of chain configurations in other hybrid systems such as self-assembled monolayers.

Late News: Room-Temperature Ferromagnetism in Single Layers of MoSe2 Decorated with Manganese Oxide Nanoparticles Nalaka A. Kapuruge, Vijaysankar Kalappattil, Florence A. Nugera, Valery O. Jimenez, Manh-Huong Phan and Humberto R. Gutierrez; University of South Florida, United States

Ferromagnetism in two-dimensional (2D) van der Waals materials has attracted increasing attention due to its potential for developing a new generation of spintronic devices. One route that has been explored to induce 2D ferromagnetism is substitutional doping in transition metal dichalcogenides (TMD) with V or with magnetic atoms. In this work, we propose an alternative approach that consists in decorating 2D TMD materials with nanoparticles of manganese oxide. The nanoparticles were deposited on the surface of monolayer $MoSe_2$ using a chemical vapor deposition technique. Micro-Raman and PL spectroscopy were used to study their optical properties; while the morphology, chemical composition and thickness of the samples were characterized via SEM, STEM and AFM, respectively. Magnetic measurements reveal a weak ferromagnetic behavior in individual $MoSe_2$ films, probably arising from the presence of selenium vacancies. Similarly, weak ferromagnetism is observed for MnO_x nanoparticles deposited on a SiO_2 substrate. However, when the MnO_x nanoparticles are deposited on 2D $MoSe_2$, the hybrid $MnO_x/MoSe_2$ system displays enhanced room-temperature ferromagnetism, suggesting a strong magnetic exchange coupling between the two material components. A detailed analysis on the temperature dependence of saturation magnetization and coercive field indicates stronger magnetic coupling at lower temperatures. Our results provide an alternative route to induce room-temperature ferromagnetism in 2D systems.

SESSION F.EL03.02: Optoelectronic Properties of Low-Dimensional Chalcogenides

F-EL03

5:00 AM F.EL03.02.01
Hybrid Exciton-Plasmon-Polaritons in van der Waals Semiconductor Gratings Huiqin Zhang[1], Bhaskar Abhiraman[1,1], Qing Zhang[2], Jinshui Miao[1], Kiyoung Jo[1], Stefano Roccasecca[1], Mark W. Knight[3], Artur Davoyan[4] and Deep M. Jariwala[1]; [1]University of Pennsylvania, United States; [2]National University of Singapore, Singapore; [3]Northrop Grumman Corporation, United States; [4]University of California, Los Angeles, United States

Van der Waals materials and heterostructures that manifest strongly bound exciton states at room temperature are of great promise for optoelectronic applications. 2D transitional metal dichalcogenides (TMDCs) of Mo and W are of particular interest since the strong exciton binding manifests in high refractive indices and extinction coefficients near the exciton resonance. Light-exciton interaction has been extensively studied in monolayer direct-band gap TMDC films (Schneider et al. 2018, *Nat. Comm.*; Brar et al. 2018, *Chem. Soc. Rev.*). Nevertheless, light-interaction with monolayer films is challenged by the very large disparity between optical wavelength and film thickness; without an external cavity, a TMDC monolayer only achieves 8-10% exciton resonance absorption.

In this work, we demonstrate that nanostructured, multilayer transition metal dichalcogenides by themselves provide an ideal platform for excitation and control of excitonic modes, paving the way to exciton-photonics. We first study reflection spectra of unpatterned micromechanically exfoliated WS_2 flakes on a template-stripped Au substrate. For a WS_2 thickness of 15 nm, we observe an avoided crossing of the A-exciton resonance and an optical cavity mode with a large splitting energy of 170 meV. We then introduced periodic one-dimensional gratings into the WS_2 with e-beam lithography and dry-etching. We measured spectra for grating periods ranging from 300 to 750 nm, WS_2 thicknesses from 5 to 30 nm, and grating widths from 200 to 300 nm. In these heterostructures, we observed hybrid modes in addition to strong dispersion of optical cavity modes and several orders of plasmon polariton modes. For a period of 600 nm, a grating width of 300 nm, and a WS_2 thickness of 10 nm, we observe exciton couplings to optical grating and optical cavity modes with strengths of 116 meV and 89 meV respectively. In addition, we observe complete suppression of the inherently strong exciton absorption resonance as a result of coupled optical modes and their interference. We supplement these experimental results with transfer matrix calculations and finite-difference time-domain simulation. We also model the resonances of this heterostructure with a coupled oscillator model; with this model, we recreate the exciton resonance suppression we observe in experiment, showing that the suppression is indeed due to two polaritonic couplings.

Our results highlight a previously unexplored aspect of TMDC excitonics and optics, opening a new regime in exploring strong light-matter interactions where the TMDC serves as a host for both excitonic and cavity modes (without the need for an external cavity). This work paves the way to a next generation of integrated exciton optoelectronic nano-devices and applications in light generation, computing, and sensing.

Binary Superlattices of Plasmonic and Excitonic Nanocrystals for Infrared Optical Metamaterials Sarah Brittman, Nadeemullah A. Mahadik, Syed Qadri, Patrick Y. Yee, Joseph Tischler and Janice E. Boercker; U.S. Naval Research Laboratory, United States

Self-assembled nanocrystal superlattices offer exceptional control over the coupling between nanocrystals, just as solid-state crystals tailor the bonding between atoms. Because nanocrystals are much smaller than the wavelength of light, superlattices that integrate nanocrystals of different properties (e.g. metals, semiconductors, dielectrics) have the potential to generate new light-matter interactions that are not achievable in natural materials [1,2].

In this work [3], we add infrared plasmonic $Cu_{2-x}S$ nanocrystals to the relatively limited library of materials that have been successfully incorporated into binary superlattices. We create a variety of binary superlattices with small plasmonic ($Cu_{2-x}S$) nanocrystals and large excitonic (PbS) nanocrystals, both resonant in the infrared. Then, by controlling the surface chemistry of large $Cu_{2-x}S$ nanocrystals, we are able to produce structurally analogous superlattices of large $Cu_{2-x}S$ and small PbS nanocrystals. Transmission electron microscopy (TEM) and grazing-incidence small-angle X-ray scattering (GISAXS) are used to characterize the superlattices. This synthetic achievement is the first step toward understanding how infrared

plasmonic and excitonic nanocrystals couple in well-defined lattices that display a variety of symmetries and stoichiometries.

Hot Carrier Optoelectronics with 2D Transition Metal Dichalcogenides Goki Eda; National University of Singapore, Singapore

One of the most distinct features of van der Waals (vdW) heterostructures based on two-dimensional (2D) materials is the ultrafast photo-induced interlayer charge transfer, which is known to occur in sub-picosecond time scales. Such ultrafast dynamics offers promise for the realization of novel hot carrier optoelectronic devices where non-thermalized photocarriers are harnessed to achieve unconventional functions. In this talk, we will discuss a few examples of hot carrier optoelectronic phenomena in heterostructures of 2D transition metal dichalcogenides. First, we will discuss realization of near-infrared (NIR) to visible light upconversion in a metal-insulator-semiconductor (MIS) vdW heterostack tunnel diode [1]. We show that the upconversion is enabled by interlayer transfer of non-thermalized photoexcited holes and its dynamics can be tuned by orders of magnitude by applied electric fields. Second, we will discuss unique photoresponse of these MIS devices arising from hot carriers generated by efficient exciton-exciton annihilation (EEA) in monolayer MoS_2 [2]. We describe how EEA can result in highly energetic electrons and holes due to uneven distribution of annihilation energies following energy- and momentum-conserving scattering.

Direct Hot Carrier Collection in Monolayer WS2 Pan Adhikari[1], Peijian Wang[2], Kanishka Kobbekaduwa[1], Hao Zeng[2] and Jianbo Gao[1]; [1]Clemson University, United States; [2]University at Buffalo, The State University of New York, United States

Hot carriers have significant impact to energy conversion/storage and photodetection. For instance, a hot carrier solar cell will lead to a ~ 67 % power conversion efficiency (PCE) to overcome the famous Schockley-Queisser (SQ) limit. For purposes of energy conversion and storage, the hot carriers trigger a more energetic and dynamic chemical reaction to split the water molecules and generate hydrogen molecules, leading to an efficient photoelectrochemical (PEC) cell. This is particular important and urgent to 2D transition metal dichalcogenides (TMDCs) family, such as MoS2, WS2, MoSe2 and MoTe2, which have great potential applications in quantum emitters, high performance photo or chemical detector and lithium-ion batteries. However, collecting and utilizing the hot carriers remains one of major challenges in ultrafast phenomena in quantum materials because the hot carriers have a super-short lifetime within couple picoseconds.

In this report, we directly collected hot carrier in monolayer WS2 semiconductor as a photocurrent using ultrafast photocurrent spectroscopy. The hot carriers generation is resulted from the multiple exciton Auger recombination, demonstrated by the ultrafast photocurrent dependence on laser intensity, and temperature.

5:45 AM *F.EL03.02.06
Chirality-Dependent Second Harmonic Generation of MoS_2 Nanoscroll with Enhanced Efficiency Qingkai Qian[1], Rui Zu[1], Qingqing Ji[2], Jing Kong[2], Venkatraman Gopalan[1] and Shengxi Huang[1]; [1]The Pennsylvania State University, United States; [2]Massachusetts Institute of Technology, United States

Second harmonic generation (SHG), as a nonlinear optical effect, has important applications in photonics for frequency conversion and light modulations. Materials with high SHG efficiency and reduced dimensions are favorable for integrated photonics and novel nonlinear optical applications. Here, we fabricate MoS_2 nanoscrolls with different chiralities and study their SHG performances. As a 1D material, MoS_2 nanoscroll shows reduced symmetry and strong chirality dependency in the polarization-resolved SHG characterizations, which is in stark contrast with the 2D MoS_2 layers. This SHG performance can be well explained by the coherent superposition theory of second harmonic field of the nanoscroll walls. MoS_2 nanoscrolls with certain chiralities in our experiment can have SHG intensity up to 98 times stronger than that of monolayer MoS_2. The same chirality-dependent SHG can be expected for nanoscrolls or nanotubes composed of other non-centrosymmetric 2D materials, such as WS_2, WSe_2, and hBN. The characterization and analysis results presented here can also serve as a non-destructive technique to determine the chiralities of these nanoscrolls and nanotubes.

Direct Optical and Electronic Imaging of Atomically-Thin Semiconductor-Metal Buried Interfaces Kiyoung Jo[1], Joseph Orr[2], Jinshui Miao[1], Huiqin Zhang[1] and Deep M. Jariwala[1]; [1]University of Pennsylvania, United States; [2]Villanova University, United States

Metal contacts to two-dimensional (2D) semiconductors are critical for high performance and highly scaled devices. Yet, despite several years of effort they remain unoptimized and poorly understood from the perspective of metal semiconductor interface chemistry. Most existing studies rely on cross section electron microscopy images or device transport both of which are indirect ways to measure contact resistance. A key reason for this is because metal-semiconductor contacts are buried interfaces which are difficult to probe directly, at least in the case of bulk semiconductors. However, 2D semiconductors such as transition metal dichalcogenides (TMDCs) of Mo and W offer a unique opportunity to directly probe the metal semiconductor interface from the semiconductor side due to the atomically thin nature of the semiconductor.[1] In this talk, we will present spatially varying electrical and optical characteristics of TMDC-bulk metal buried interface using a simple metal-assisted flipping technique that inverts the interface for direct electronic and optical access of the buried interface.[2] Using a combination of scanning Kelvin Probe Force Microscopy (KPFM), conductive-AFM and tip enhanced Raman and Photoluminescence Spectroscopy (TERS/TEPL) we concurrently map surface potential, conductivity, charge density dependent-vibration and emission spectra of the interface with ~20 nm spatial resolution. We use three different Au deposition methods (Thermal, e-beam, Sputter) to compare and contrast the quality of different contacts in addition to direct van der Waals stamping. We observe that thermal metal evaporation results in formation of the most uniform, ohmic and lowest resistance contacts ($1.49*10^6$ Ω) in comparison to e-beam evaporation ($7.20*10^8$ Ω), whereas van der Waals stamping forms Schottky contacts ($5.00*10^{11}$ Ω). KPFM and TERS data of each buried interfaces reveals distinct change of carrier concentration as a function of evaporation technique.[3] We attribute different levels of metal semiconductor intimacy at the interface and different levels of defect creation during metal evaporation to these differences in contact quality. Our result highlights the importance of metal deposition schemes and paves a path forward towards engineering low resistance contacts and also presents a facile method for probing them in atomically thin channel materials.

New Low-Dimensional Metal Chalcogenides and Their Optoelectronic Properties Mercouri G. Kanatzidis; Northwestern University, United States

Two-dimensional (2D) materials have seen a surge of interest ever since the discovery of graphene, a single 2D layer of carbon atoms (graphene), more than a decade ago. 2D chalcogenides are a fundamental class in the study of low-dimensional science and their synthesis is an important goal of solid state chemistry. The presentation will focus on how novel chalcogenides can form using design concepts such as the “dimensional reduction”. The new materials exhibit diverse centrosymmetric and noncentrosymmetric structures that lead to a variety of attractive optoelectronic properties such as direct bandgaps, high X-ray absorption, neutron detection and strong nonlinear optical responses.

Valley-Mechanical Transduction in 2D Semiconductors Haokun Li, King Yan Fong and Xiang Zhang; University of California, Berkeley, United States

The interaction of macroscopic mechanical object with electron charge and spin plays an important role in today’s

information technology and fundamental studies of quantum mechanics. Recently emerged valleytronics encodes information to the electron valley degree-of-freedom and promises exciting applications in computation and communication. Exploring the interplay between the valley physics and macroscopic mechanics will bring new perspectives for valley information processing and exploration of the quantum-classical boundary. Here, for the first time, we realize valley-mechanical interaction in a monolayer MoS_2 resonator and demonstrate direct transduction of the valley information to mechanical states. The valley-mechanical coupling is achieved by exploiting the magnetic moment of valley carriers with a magnetic field gradient. We optically populate the valleys and observe the resulting mechanical actuation using laser interferometry. We are thus able to control the valley–mechanical interaction with the pump laser, the magnetic field gradient and temperature. Our experiment lays the foundation for a new class of valley-controlled mechanical devices. It also facilitates hybridization of valley pseudospin with other quantum information carriers such as two-level qubits and microwave photons.

6:35 AM F.EL03.02.10
Bandgap Tuning of Monolayer and Bilayer MoS_2 for Broadband UV-VIS-NIR Photodetection Using an Electric Double Layer Device Structure Roda Nur[1,2], Takashi Tsuchiya[2], Mitsuru Takenaka[1,2] and Kazuya Terabe[2]; [1]The University of Tokyo, Japan; [2]National Institute for Materials Science, Japan

Transition Metal Dichalcogenides (TMDCs) have been under intensive research due to their unique electronic and optoelectronic properties. Due to their layered structure via weak van der Waals interactions, their bandgap can be modified by the number of layers[1] which directly impacts the range of wavelengths it can intrinsically detect. For the case of MoS_2, monolayer has a direct bandgap of 1.8 eV with a cut-off wavelength of red light (~690 nm) and bulk has an indirect bandgap of 1.2 eV with a cut-off wavelength of ~1 μm. Photodetectors using MoS_2 as a photoactive material have been reported to offer very large responsivities (high light sensitivity) in photodetection applications[2]; however, the larger bandgaps of monolayer and bilayer MoS_2 limits its ability to detect wavelengths deeper in the near-infrared band. One technique to lower the bandgap of these materials is to introduce a very large perpendicular electric field. Unfortunately, conventional dielectric materials like SiO_2 and high-k metal oxides like HfO_2 and Al_2O_3 cannot provide the required high electric fields to enable this effect. However, the use of an electric double layer (EDL) device structure can offer nano-gap capacitances resulting in generating very large electric fields. In this study, we investigated the bandgap tuning of monolayer and bilayer MoS_2 utilizing an electrical double layer device structure. In this structure, under the application of an applied gate bias, Li^+ ions migrate in the electrolyte layer to form an EDL with MoS_2. As a result, we were able to detect NIR wavelengths and characterize its photoresponse behavior. We further confirmed our results with Density Functional Theory. This work shows the possibility of extending the intrinsic light detection of low dimensional chalcogenide materials for future optoelectronic devices.

6:45 AM F.EL03.02.11
Tellurium Doped III-V Dilute Nitride GaAsSbN NW Heterostructure for Room-Temperature Photodetector Applications in the Near-Infrared Region Rabin Pokharel[1], Priyanka Ramaswamy[1], Shisir Devkota[1], Kendall Dawkins[1], Aubrey Penn[2,2], Matthew Cabral[2,2], Lewis Reynolds[2] and Shanthi Iyer[1]; [1]North Carolina A&T State University, United States; [2]North Carolina State University, United States

Nanowire (NW) based photodetectors in the near-infrared wavelength range is of great interest for next-generation single-photon-sources and photodetectors to be used in quantum networks, nanophotonic integrated circuits and solar cell applications. Bandgap engineering in the near-infrared region is facilitated by large bandgap bowing and increased electron confinement upon dilute (<2%) nitrogen incorporation. By leveraging these advantages, this work showcases optimized intrinsic and tellurium (Te)-doped dilute nitride GaAsSbN NW based photodetection. Compensation of point defects in the doped configuration is evidenced by a significant improvement in photoluminescence characteristics, Raman vibrational mode shifts, and spectral shape with improved photodetector device performance relative to intrinsic dilute nitride NWs. Transmission electron microscopy was used further to quantify the quality and composition of NW heterostructures, confirming a planar-defect-free zincblende crystal structure. The first successful demonstration of vertically aligned Te-doped GaAsSbN NW based PD device with a responsivity of ~5 A/W (@860 nm) on single NW configuration and ~3800 A/W (@1100 nm) on an ensemble NW device is reported. Further, a detectivity of 3.2×10^{10} Jones in ensemble configuration was confirmed from low-frequency noise characteristics. The responsivity of these NWs is comparable with the best reported values in this wavelength region, though the detectivity needs significant improvement. Encouraging prospects are seen for further bandgap engineering of this material system to develop improved quality and multicolor photodetection spanning the entire near-infrared-region range with potential for further red-shifting photodetection capability to 1.55 μm. **A** gallium

telluride (GaTe) captive source is used as the Te-dopant and molecular beam epitaxy (MBE) is the enabling technology that is used to realize Ga-catalyzed nanowires in axial configuration.

6:55 AM F.EL03.02.12
Low-Dimensional Sulvanites for Optoelectronic Applications Cheng-Yu Lai[1], Mimi Liu[1], Chen-Yu Chang[1], Gurpreet Singh Selopal[2,3] and Daniela R. Radu[1]; [1]Florida International University, United States; [2]Centre Énergie Materiaux Télecommunications (INRS-EMT), Canada; [3]Institute of fundamental and Frontier Sciences (IFFS) University of Electronic Science and Technology, China

The family of ternary chalcogenide compounds Cu3MX4 (where M is V, Nb, or Ta and X is S, Se, Or Te), also known as sulvanites, recently came to light due to their possible multiple uses in optoelectronic devices. [1-3] The compounds are isostructural and crystallize in the cubic structure with space group P- 43m . They are characterized by significant values of refractive index, high ionic and electronic conductivity, as well as remarkable photoconductivity and photoluminescence.[4] Some reports show that Cu_3TaS_4 is transparent in the visible region, having an absorption onset in the range of 2.8-3.0 eV, which could prove useful in light modulators, solar cells, optoelectronic and photocatalytic devices. [1,3] In general, the sulvanites are p-type semiconductors and show ionic conductivity that is attributed to a small number of interstitial Cu(I) ions. [5,6]
To take advantage of these excellent optoelectronic properties, processability of these materials would be highly desirable. We demonstrated facile solution-phase routes[7] to synthesize the entire sulfide and selenide suite of compounds, revealing fascinating nanocrystal morphologies, from 2D nanoplates to cubic and pyramidal quantum dots. Photoluminescence measurements reveal strong light emission in both vanadium and niobium compounds. Synthetic and characterization data will be presented in detail, and free-form sensor applications will be discussed.

7:05 AM F.EL03.02.14
Electrostatically Gated Multi-Functional WSe_2 Transistor to Enable Multi-Bit Communication Schemes Kartikey M. Thakar and Saurabh Lodha; Indian Institute of Technology, Bombay, India

There has been a surge in research interests in two-dimensional (2D) materials, and transition metal dichalcogenides (TMDs) in particular, owed to their unique physical, electrical and optical properties. [1,2] Although 2D materials are not at the par with present technologies in terms of device performance, they easily outperform them in terms of functionality in both electronic and optoelectronic applications. TMDs provide a plethora of novel physical properties such as flake-thickness dependent band structure, improved light-matter interaction and easy tuning of transport properties. With the possibility to go below 1-nm channel thickness, mechanically flexible devices and ease of making heterostructures, they have emerged as attractive candidates for next generation (opto)electronic technology.
Tungsten diselenide (WSe_2) has been studied in detail due to its ambipolar transport, large carrier mobility values and good optical response. [3,4] In addition, we can easily dope the TMD channel with electrostatic gating providing us with freedom to easily tune the device performance with applied voltages. [5]
In this abstract, we present a simple yet effective method to leverage the ability to electrostatically tune the device transport to achieve a multi-functional device. The device consists of two set of gates – one to control the WSe_2 channel and two

shorted gates under each contact to control the Schottky contact barriers. We are able to achieve not only conventional n-FET and p-FET characteristics, but also ambipolar as well as anti-ambipolar current trends with help of specific gate biasing schemes. Such device can be readily used for modulation of input signals (applied at the two gates) to get phase and frequency coded output current waveforms. Clubbed with an option to illuminate the channel, we can achieve an increased degree of freedom in device operation. We have been able to demonstrate in-phase, out-of-phase and double frequency signals on both ambipolar and anti-ambipolar current trends under dark and illumination condition. These waveforms have been experimentally demonstrated to be useful in two distinct 2-bit symbol encoding schemes. One of these schemes involves transition between ambipolar to anti-ambipolar transport in dark condition using electrostatic gating. This is not possible in conventional ambipolar or anti-ambipolar devices reported on 2D materials due to lack of tunable operation limited by device architecture. The other scheme uses illumination status along with frequency coding to identify frequency shift enabled by light-tunable anti-ambipolar current transport.
We further analysed the output current waveforms to better understand the information coding possibilities. By using a combination of phase, frequency and amplitude coding, we can potentially achieve up to 4-bit coded symbols with appropriate input gate-bias signals and illumination status (on/off). 2-bit and 3-bit transmission schemes are also examined with the same methodology. Phase-amplitude and phase-frequency polar plots are created to observe the constellation chart for any given transmission scheme.
To summarize, a novel device operation is proposed to leverage the tunable operation of 2D TMD channel material enabling both ambipolar and anti-ambipolar transport in the same device. With proper gate biasing schemes and incorporating illumination, we can generate distinct output current waveforms that can be used as modulated signals for multi-bit communication schemes.

Low-Dimensional Chalcogenides Materials: Physical Properties and Device Applications Han Wang; University of Southern California, United States

Recent research progress has led to the successful synthesis of numerous low dimensional chalcogenides materials that demonstrate unique electronic and optical properties. In this talk, I will discuss our work in studying the ferroelectric, optical and phonon properties of such materials including $CuInP_2S_4$ and $BaTiS_3$. The former demonstrates interesting ferroelectric properties in its layered van der Waals crystal lattice and the latter exhibits quasi-1-dimensional crystal structure giving rise to strong linear dichroism in the infrared and visible wavelength as well as unique phonon properties. I will also discuss the device applications of the respective materials, specifically the application of ferroelectric $CuInP_2S_4$ in non-volatile memory and infrared detectors based on $BaTiS_3$. The promising future research directions, challenges and their potential applications in electronics and photonics technologies will also be discussed.

This work is support in part by the Army Research Office (Grant no. W911NF1910111) and the National Science Foundation (Grant no. ECCS-1653870).

7:30 AM F.EL03.02.16
Late News: High Broadband Photoconductivity of Few-Layered MoS2 Field-Effect Transistor Measured in Multi-Terminal Method—Effect of Contact Resistance Priyanka Das[1], Jawnaye Nash[1], Micah Webb[1], Raelyn Burns[1], Varun Mapara[2], Govinda Ghimire[1], Daniel Rosenmann[3], Ralu Divan[3], Denis Karaiskaj[2], Stephen McGill[4], Anirudha Sumant[3], Qilin Dai[1], Paresh Ray[1], Bhausaheb Tawade[5], Dharmaraj Raghavan[5], Alamgir Karim[6] and Nihar Pradhan[1]; [1]Jackson State University, United States; [2]University of South Florida, United States; [3]Argonne National Laboratory, United States; [4]National High Magnetic Field Laboratory, United States; [5]Howard University, United States; [6]University of Houston, United States

Among the layered two dimensional semiconductors, molybdenum disulfide (MoS_2) is considered to be an excellent candidate for applications in optoelectronics and integrated circuits due to the layer-dependent tunable bandgap in the visible region, high ON/OFF current ratio in field-effect transistors (FET) and strong light-matter interaction properties. In this study, using multi-terminal measurements, we report high broadband photocurrent response (R) and external quantum

efficiency (EQE) of few-atomic layered MoS_2 phototransistors using multi-terminal measurements, fabricated on a SiO_2 dielectric substrate and encapsulated with a thin transparent polymer film of Cytop. The photocurrent response was measured using a white light source as well as monochromatic light of wavelength λ = 400 nm - 900 nm. We measured responsivity in 2-terminal con- figuration as high as $R = 1\times10^3$ A/W under white light illumination with optical power P_{opt} = 0.02 nW. The R value increased to 3.5×10^3 A/W when measured using a 4-terminal configuration. Using monochromatic light on the same device, the measured values of R were 10^3 and 6×10^3 A/W under illumination of λ = 400 nm when measured in 2- and 4-terminal methods, respectively. The highest EQE values obtained using λ = 400 nm were 10^5 % and 10^6 % measured in 2- and 4-terminal configurations, respectively. The wavelength dependent responsivity decreased from 400 nm to the near-IR region at 900 nm. The observed photoresponse, photocurrent-dark current ratio (PDCR), detectivity as a function of applied gate voltage, optical power, contact resistances and wavelength were measured and are discussed in detail.

7:40 AM F.EL03.02.17
Late News: Quasi-BIC Resonant Enhancement of Radiative Rate in Two-Dimensional Molybdenum Diselenide for Active Metasurfaces Melissa Li, Souvik Biswas, Cora Went and Harry Atwater; California Institute of Technology, United States

Active metasurfaces composed of tunable subwavelength structures enable versatile light manipulation on ultrathin devices. Previously, electrically gated indium tin oxide-based metasurfaces have demonstrated dynamic amplitude and phase control of reflected light. However, these devices operate at around 1550nm, which limits their applications to infrared optoelectronics. Two-dimensional transition metal dichalcogenides (2D TMDs) are promising candidates for phase and amplitude modulation of visible light due to their strong excitonic resonances in the visible.
Here, we investigate the gate-tunability of the complex index and the corresponding phase and amplitude modulation of the reflected light from 2D Molybdenum Diselenide ($MoSe_2$). Our structure uses the large excitonic reflectivity that is dominated by radiative decay at low temperatures. By measuring the gate dependent change in the reflectivity of the $MoSe_2$, we develop a model for the change in the complex dielectric function. We then enhance the emission of the TMD by integrating the monolayer with a metasurface comprised of subwavelength AlGaAs cylinders that support high quality factor quasi bound states in the continuum (BIC) modes. The subwavelength structure is based on a cylinder that utilizes the destructive interference between optical modes to obtain a significant enhancement in the quality factor of the cavity. The gate tunability of the $MoSe_2$ monolayer coupled to the high Q resonator allows us to electrically modulate the phase and amplitude of the reflected light. This monolayer TMD-based active metasurface could be a potential platform for ultrathin visible light modulators.

F-EL03

5:00 AM *F.EL03.03.01
Optical Properties and Refractive Uses of Phase-Change Phenomena in Layered Chalcogenides Rafael Jaramillo; Massachusetts Institute of Technology, United States

Layered chalcogenides hold promise for manipulating light in confined geometry, such as in photonic integrated circuits, where key material properties include strong and controllable light-matter interaction, and limited optical loss. Layered materials feature strong anisotropy and a panoply of polymorphs that suggest a rich design space for highly-nonperturbative photonic integrated devices based on functional martensitic transformations: phase changes and ferroelastic domain switching. These phenomena are manifest in materials with band gap above the photonics-relevant near-infrared (NIR) spectral band (~ 0.5 – 1 eV), meaning that they can be harnessed in refractive (*i.e.* non-absorptive) applications.

Transition metal dichalcogenides (TMDs) offer a vast composition space within which to optimize refractive index contrast, optical loss, and switching energy. We are using a strategy of alloy design to optimize new, active materials for optical phase shifters. We will present our theoretical predictions of thermodynamics and optical properties of binary systems of sulfur-based TMDs: ZrS_2-MoS_2, TiS_2-MoS_2, TiS_2-ZrS_2, and MoS_2-CrS_2. We will present our experimental measurements of the NIR optical properties of single crystals. We will then present progress on making large-area thin films of sulfur-based TMDs, including the theoretically-predicted alloys, by a two-step method of metal sulfurization. Finally, we will present the

optical properties and phase-change functionality of our designed TMD alloy thin films.

We will also present an alternative paradigm of strong, non-perturbative refractive index modulation: electric field-driven ferroelastic domain switching in low-symmetry layered materials. We predict that in materials such as SnSe, a sufficiently-strong electric field will induce rotation between equivalent crystallographic domains, with strong refractive index contrast for linearly-polarized light. We will present simulation-based design of photonic integrated devices utilizing the trirefringence of materials such as SnSe and black phosphorous, and experimental results demonstrating non-thermal domain switching triggered by fast laser pulses.

5:15 AM *F.EL03.03.02
Optical Properties of Transition Metal Dichalcogenide Bilayers Xiaoqin E. Li; The University of Texas at Austin, United States

Optical properties of atomically thin transition metal dichalcogenides are dominated by exciton resonances exhibiting large oscillator strength and binding energies. In vertically stacked bilayers, a host of new exciton resonances emerge, lending new opportunities to discover new science and enable new devices. In this talk, I will focus on how moire superlattices change exciton resonances and diffusion. We discovered recently that phonon spectra are renormalized in moire superlattices as well. A rich variety of properties can be controlled by tuning the twist angle between the bilayers. I make some comparisons between samples that are grown using chemical vapor deposition and those prepared by mechanical exfoliation and stacking. Our work is supported by DOE under grant DE-SC0019398, NSF DMR-1808042, DMR-1720595, and the Welch Foundation F-1662.

5:30 AM F.EL03.03.03
Reconfigurable Linear and Nonlinear Focusing Using All-Dielectric Metalenses Based on Phase-Change Materials Muliang Zhu, Sajjad Abdollahramezani, Omid Hemmatyar and Ali Adibi; Georgia Institute of Technology, United States

Metalenses are flat surfaces that incorporate subwavelength structures to replace conventional bulky curved lenses. Metasurfaces with the capability of manipulating light-matter interaction at subwavelength are the core components of the metalenses that attract broad research attention. Metalenses are more convenient to be designed with tunable foci than conventional lenses with additional tunability brought by nanoscale features. Nonlinear metalenses are rarely investigated compared to linear counter-parts due to limited efficiency. However, to our interest, nonlinear metalenses provide a future platform for applications in nonlinear information processing, all-optical higher-order Fourier transformations, short laser pulse diagnostics, *etc*. [1]. Moreover, metalenses conveying information at both linear and nonlinear frequencies could potentially reveal more information of the imaging object. Generating nonlinear signal confocal with linear signal is difficult to realize for conventional high-index material due to material dispersion. Low-loss phase change chalcogenides such as Antimony Sulfide (Sb_2S_3), which introduces substantial change in the refractive index with high-speed thermal-controllable phase changes [2] in addition to intrinsic large third-order nonlinearities, are potential candidates for efficient reconfigurable-foci metalenses that can realize third-harmonic generation (THG) signal co-focusing with the linear signal. We demonstrate a reconfigurable all-dielectric metalens by making use of a unique dispersion relationship between the amorphous state and the crystalline state of Sb_2S_3. The device works at the fundamental wavelength (λ_f) of 950 nm, where the refractive index of amorphous Sb_2S_3($n_{a\text{-}Sb2S3}$) at λ_f is close to that of crystalline Sb_2S_3 ($n_{c\text{-}Sb2S3}$) at THG wavelength (λ_{THG}) whereas $n_{c\text{-}Sb2S3}$ at λ_f is close to $n_{a\text{-}Sb2S3}$ at λ_{THG}. The principle of phase delay makes THG signal from the metalens of one crystallinity state confocal with the transmitted fundamental signal of the other crystallinity state. The reconfigurable metalens can inspire effective capture of double-frequency imaging of objects.

5:00 AM F.EL03.04.01
Cu/$Cd_{0.5}Zn_{0.5}S$ on a Fixed Bed Photocatalytic Reactor for CO_2 Reduction Shengjie Bai and Liejin Guo; Xi'an Jiaotong University, China

The photo-induced conversion of CO_2 to chemical fuels in aqueous solution is limited by the electron transfer efficiency and the mass transfer of the reactants. Herein, Cu was decorated on a $Cd_{0.5}Zn_{0.5}S$ twin nanocrystals by photo-deposition, and fixed it on a gas dispenser for photocatalytic CO_2 reduction (CO2RR). The quartz gas dispenser was used as a support for fixing catalysts, which accelerated the diffusion and mass transfer of CO_2 in the electrolyte, thus increasing the energy conversion efficiency of the reaction. $Cd_{0.5}Zn_{0.5}S$ provides photovoltage for driving photocatalytic reactions. While Cu provides active sites for the conversion of CO_2. Compared with undecorated $Cd_{0.5}Zn_{0.5}S$, Cu/$Cd_{0.5}Zn_{0.5}S$ have a smaller band gap (~ -1.98 eV) and a higher selectivity for multi-carbon products (78%). Among the products, the selectivity of ethanol and acetic acid were 45% and 30%, respectively. Moreover, this work provides an efficiently strategy to integrate synthesis and assembly for photocatalytic conversion CO_2.

5:10 AM F.EL03.04.02
Selective Vapor Phase Syntheses of Low-Dimensional Metal Chalcogenides for Catalytic Water Splitting Lasse Jurgensen, Michael Frank, David Graf, Veronika Brune, Isabel Gessner and Sanjay Mathur; University of Cologne, Germany

Investigation of the interplay of metal-organic chemistry will enrich the state-of-the-art of chemical vapor deposition (CVD) technology and open new possibilities for the generation of nanostructured metal sulfide and selenide nanostructures. Therefore, novel *single-source* precursors exhibiting high volatility and defined thermal decomposition under (plasma-enhanced) CVD conditions through targeted synthesis strategies are reported to elaborate the **precursor chemistry** – **materials synthesis** – **functional property** chain. Synergistic reactivity and sufficient stability through unique ligand design to provide a precise control over compositional purity of metal chalcogenides in CVD deposits without additional chalcogenide sources. CVD-grown ME_x (M = Fe, Co, Ni, Cu, Sn, In; E = S, Se) 2 D nanostructures were tested towards their (electro)catalytic applications, particular in the oxygen evolution reactions (OER). The presented CVD data opens new possibilities in the vapor phase synthesis of chalcogenide nanostructures facilitating the application as mutable earth abundant electro- or photocatalysts in OER and hydrogen evolution reactions (HER).

5:20 AM F.EL03.04.03
Late News: Understanding the Photocatalytic Activity of La5Ti2AgS5O7 and La5Ti2CuS5O7—Computational Insights Katarina Brlec[1,2], Christopher Savory[1,2] and David O. Scanlon[1,2,3]; [1]Department of Chemistry, UCL, United Kingdom; [2]Thomas Young Centre, United Kingdom; [3]Diamond Light Source Ltd, United Kingdom

Hydrogen gas is one of the most important chemical precursors with a wide variety of uses. Currently, over 90% of hydrogen is produced using energy-intensive hydrocarbon reforming. Photocatalytic water splitting introduces an alternative, environmentally friendly pathway for hydrogen production. Water is split into hydrogen and oxygen using energy provided from the absorption of light photons by a photocatalytically active semiconductor. Thermodynamically, splitting of water requires 1.23 eV of energy per molecule of water. However, to overcome the associated overpotential, in semiconductors this energy requirement corresponds to an optimum band gap of 1.8 eV to 2.2 eV. [1] The electronic band structure of a promising material must allow for good mobility of charge carriers as well as align the band edges so that they straddle the redox window of water. [2]

$La_5Ti_2AgS_5O_7$ (LTA) and $La_5Ti_2CuS_5O_7$ (LTC) were experimentally shown to exhibit photocatalytic activity for both oxidation and reduction of water. [3,4] The complex crystal structures of systems exhibit one-dimensional chains of perovskite-like Ti-centred octahedra and rock-salt-like metal sulphide tetrahedra. Some experimental studies show the systems' electronic structure could support high mobility of charge carriers through the structure via these one-dimensional channels. [4]

To better understand the photocatalytic activity, we investigated the electronic structure of bulk LTA and LTC using plane wave density functional theory (DFT) with hybrid functionals as implemented in Vienna ab initio Simulation Package. Low effective charge carrier masses in b-directions were observed with spatial separation of the band edges centred on the Ti octahedra and metal tetrahedra, which confirmed good mobility of charge carriers along the one-dimensional channels with lowered probability of recombination taking place.

All non-polar symmetric surfaces up to a maximum Miller index of 2 were then evaluated to obtain their surface energies and

band alignments using generalised gradient approximation (GGA) and hybrid functionals. Wulff constructions based on the GGA surface energies visualised predicted nanoparticle shape, matching the experimental descriptions of crystallites. Combining the Wulff shapes with hybrid DFT band alignment showed the largest surfaces on the sides of columnar shapes had inadequate band edge alignment, so only the ends of crystallites were suitable for photocatalysis. This gave an important insight as photocatalytic activity of LTA and LTC would be greatly improved if the particles length in b-direction decreased in combination with an increase in the area of columnar crystallites' blunt ends which have more suitable band alignment.

Late News: Computational Exploration of Low-Dimensional Chalcogenide and Oxychalcogenide Photocatalysts Syam Kumar[1], Heesoo Park[2], Akinlolu Akande[1], Stefano Sanvito[3] and Fadwa El Mellouhi[2]; [1]Institute of Technology Sligo, Ireland; [2]Hamad Bin Khalifa University, Qatar; [3]Trinity College Dublin, Ireland

Chalcogenides have recently attracted attention as alternate materials for photonic applications suffering less from stability and toxicity issues encountered in lead halide perovskites [1]. Also, in the past few years, the computer–aided design of metal chalcogenide semiconductors led to the discovery and synthesis of very promising compounds for numerous application such as light absorbers in the thin–film photovoltaic devices [2–4]. In this presentation, aiming at in–depth exploration for light absorbers and related devices, we discuss the potential of Nb– and Ta–based perovskites ($NaMO_{(3-x)}Q_x$; M = Nb, Ta and Q = S, Se) [3], and Bi-based chalcogenides ($ABiX_{2/3}$; A = Na, K and X = O, S) [5] for photocatalysis on the grounds of their structural and electronic dimensionality. Our interest focuses on the potential of these materials for hydrogen production from photocatalytic water splitting as well as CO_2 conversion.

To select a photocatalyst, one must look into its photon absorption and charge separation, governed by their electronic properties such as the bandgap, band edge positioning, and the photogenerated charge carrier mobility. Although our density functional theory (DFT) calculation at the Heyd-Scuseria-Ernzerhof functional (HSE06) indicates the materials as good light absorbers, the analysis of effective masses of the charge carriers, along with the electronic dimensionality, imply that several of the considered compounds exhibit a reduced electronic dimensionality despite showing high structural dimensionality.

Analysis of the effective masses of the photogenerated charge carriers along the dominant directions or channels of charge transport show that most of the Bi–chalcogenides, except $NaBiS_3$ and $KBiS_3$, could perform well as photocatalysts in terms of charge separation and transport. Even more promising, Nb– and Ta–perovskites have lower effective masses of the photogenerated charge carriers than their Bi–based compounds indicating their superior carrier transport properties. Turning into assessing the electrochemical performance of the Nb–/Ta– and Bi–based chalcogenides for hydrogen evolution reactions and CO_2 conversions, we investigated the band edge alignments with respect to O_2/H_2O, H^+/H_2, CO_2/CO, $CO_2/HCHO$, CO_2/CH_3OH, and CO_2/CH_4 redox levels considering aqueous media of different pH (acidic, neutral and alkaline), for photocatalysis reactions. This work provides a comprehensive insight into the Nb–/Ta– and Bi–based compounds on the grounds of relevant properties for hydrogen evolution and CO_2 conversion reactions, calling for a careful analysis of both structural and electronic dimensionality metrics.

Heavy-Metal-Free Quantum Dot Inks for Thin-Film Solar Cells Filip Dinic, Larissa Levina and Oleksandr Voznyy; University of Toronto, Canada

A newer generation of solar cells is emerging based on solution-processed materials, primarily PbS colloidal quantum dots (CQD) and lead halide perovskites. However, both contain toxic lead, posing significant safety concerns. Here, we propose to utilize chalcogenide based colloidal quantum dot (CQD) inks to achieve scalable and low-cost solution processing of the state-of-the-art photovoltaic materials. CQDs are used as a means in obtaining bulk direct bandgap semiconductors, which have been demonstrated to be highly efficient light absorbing layers by means of thermally annealing and sintering the QDs

The key challenges in this field revolve around improving CQD packing and further reducing the defect densities. We will demonstrate that inorganic atomic ligands can eliminate the need for organic long chain ligands required for colloidal stability. Furthermore, these inorganic ligands can be used as abundant passivating agents while promoting the sintering of CQDs in the resulting films. We will demonstrate proof-of-principle results with PV devices based on lead-free chalcogenide based CQDs, primarily CuInS2.

5:10 AM F.EL03.05.02
Chemical Variation Dependent Growth Behavior of Sb_2Se_3 Thin Films by Close-Space Sublimation Liping Guo and Feng Yan; The University of Alabama, United States

Sb_2Se_3 has emerged as a promising absorber material for photovoltaic applications owing to its excellent optoelectronic properties such as suitable bandgap and high absorption coefficient as well as its low-toxic and earth-abundant constituents. Sb_2Se_3 is comprised of quasi-one-dimensional (Q1D) ribbons stacked by weak van der Waals (vdW) interactions without dangling bonds, rendering the Sb_2Se_3 grain boundries (GBs) self-passivated and intrinsically benign. Various growth techniques have been used for the Sb_2Se_3 absorber layer growth, such as close-space sublimation (CSS). However, due to the fast sublimation rate and confined CSS chamber space, the evaporated gas lacks a full and uniform mixture before condensing on the substrates. In the meantime, Se has a much higher saturated vapor pressure than that of Sb_2Se_3, making Se element release first during CSS deposition and dominates the chamber gas at the very initial stage. As a result, the chemical composition (ratio of Se and Sb) of the gas mixture varies with time, causing the deposited films at different growth stages to exhibit different chemical compositions. In this work, the chemical composition (Se and Sb), microstructure, and device performance of Sb_2Se_3 films deposited at different growth stages were systematically investigated. It is demonstrated that the chemical variation dependent growth behavior can be used to control the carrier transport and lead to improved device performance. The work also paves a way to further improve the device performance of Sb_2Se_3 based photovoltaic devices by tuning the scaleable vapor deposition.

5:20 AM F.EL03.05.03
Controlling the Preferred Orientation of Layered BiOI Solar Absorbers Rob Jagt[1], Tahmida Huq[1], Katharina Börsig[1], Daniella Sauven[1], Lana C. Lee[1], Judith MacManus-Driscoll[1] and Robert Hoye[2]; [1]University of Cambridge, United Kingdom; [2]Imperial College London, United Kingdom

Bismuth oxyiodide (BiOI) has gained attention for photovoltaics, photocatalysis and photodetectors owing to its composition of non-toxic elements, tolerance to point defects, and highly-suitable optical properties.[1,2] But like many other bismuth-based compounds, BiOI is a layered material with anisotropic transport properties, making control over the preferred orientation critical for achieving optimal device performance. In this work, we develop new insights into the growth mechanism of BiOI synthesized by chemical vapor deposition (CVD) and show how the preferred orientation can be controlled. By adjusting the

precursor and substrate temperatures to tune whether or not we are in a nucleation- or growth-controlled regime, we reproducibly vary the ratio of the (001) and (110) orientations by over two orders of magnitude. As a result, we achieve highly c-axis oriented films, which leads to less shunting than a/b-axis oriented films, resulting in improved open-circuit voltages from a median value of 0.7 V (a/b-axis oriented) to 0.9 V (c-axis oriented) in BiOI solar cells. More broadly, the described mechanisms can be used to control the preferred orientation in other low-dimensional materials, which will be important for achieving improved performance across a wide variety of devices.

Emerging Chalcogenides for Photovoltaics David O. Scanlon; University College London, United Kingdom

The field of photovoltaics is undergoing a surge of interest following the recent discovery of the lead hybrid perovskites as a remarkably efficient class of solar absorber. Of these, methylammonium lead iodide (MAPI) has garnered significant attention due to its record breaking efficiencies, however, there are lingering concerns surrounding its long-term stability and toxicity. Compounding these problems is a more fundamental limitation: the hybrid perovskite structure shows a severe lack of compositional tunability. Beyond minor changes to the halide and A site composition it has not been possible to significantly supersede the original MAPI formulation, because the hybrid perovskite structure is not accommodating to significant changes to composition of the A or B sites.[1]
Many of the excellent properties seen in hybrid perovskites are thought to derive from the $6s^2$ electronic configuration of lead, a configuration found in a range of post-transition metal compounds.[2] In this presentation I will outline our computational studies on Sb_2Se_3, a material which has displayed power conversion efficiencies approaching 10% from a limited number of studies,[3] and GeSe, a semiconductor who's fundamental band gap has been the source of much debate. Our results highlight the complex nature of the defect chemistry of the "simple" binary Sb_2Se_3,[4] explain why as deposited Sb_2Se_3 is n-type,[5] and rationalise the nature of the band gap of GeSe. Revealing Defect Passivation Mechanisms in Sb_2Se_3 David Tilley; University of Zurich, Switzerland

Antimony selenide (Sb_2Se_3) has emerged as a strong candidate for practical water splitting due to its suitable bandgap, excellent optoelectronic properties, and resistance to photocorrosion in strongly acidic electrolyte solutions. In this talk, I will discuss the synthesis of Sb_2Se_3 thin films by selenization of antimony metal and the photoelectrochemical properties of these films after coating with a molybdenum sulfide hydrogen evolution catalyst. The performance of these photocathodes was greatly enhanced by a relatively low temperature sulfurization treatment with elemental sulfur, greatly improving the photovoltage and the fill factor. The origin of the improvement upon sulfurization was investigated with time-resolved microwave conductivity (TRMC) measurements and photoluminescence. TRMC of our Sb_2Se_3 reveals high mobilities of the photogenerated charge carriers (>10 $cm^2\ V^{-1}\ s^{-1}$) and a low trap density, in contrast to other emerging photoelectrochemical materials such as Fe_2O_3, $CuFeO_2$, and $BiVO_4$. We find that the sulfurization treatment of the Sb_2Se_3 thin films yields improved charge carrier lifetimes. Not only is surface recombination curtailed, but deep traps in the bulk are eliminated (most likely Sb-Se antisite defects), which reduces non-radiative recombination of the photogenerated charge carriers. A low temperature sulfurization treatment is thereby identified as a simple method to remove bulk traps in Sb_2Se_3 thin films.

6:00 AM F.EL03.05.06
Impact of Pre Annealing Synthesis and Post Deposition Treatments With IA and IVA Group Elements in Sb_2Se_3 Thin-Film Solar Cells Pedro Vidal-Fuentes[1], Yudania Sánchez González[1], Joaquim Puigdollers[2], Alejandro Pérez Rodríguez[1,3], Victor Izquierdo-Roca[1] and Edgardo Saucedo[2]; [1]Catalonia Institute for Energy Research (IREC), Spain; [2]Polytechnic University of Catalonia (UPC), Spain; [3]Universitat de Barcelona, Spain

Sb_2Se_3 is becoming a relevant thin film chalcogenide semiconductor with different technological applications such as:

superconductivity, electronic component, electrode for sodium-ion batteries, photodetectors and as photovoltaic (PV) absorber. In particular, Sb_2Se_3 have recently experienced incredible progresses as emerging photovoltaic material with a certified record efficiency of 9.2%. This technology has a promising interest due to good optoelectronic properties, earth-abundant and low toxicity constituents. Additionally, the quasi one-dimensional atomic structure provides interesting properties like improved charge carrier transport and minimization of grain boundaries recombination.

Up to date, most of the works in literature have been focused on device structure modifications, synthesis conditions optimization and understanding the fundamental properties of the material itself, to obtain the best self-standing photovoltaic performance. But little attention has been paid on explore new strategies to include extrinsic element that modify the physico-chemical properties of the devices (like doping, recrystallization, passivation, etc.) in order to improve the optoelectronic properties of the devices. In other more mature thin film PV technologies as $Cu(In,Ga)Se_2$, $Cu_2ZnSn(S,Se)_4$, the inclusion of extrinsic elements by pre annealing synthesis (PAS) and post deposition treatment (PDT) during the device fabrication have a critical role in the improvement of the optoelectronics properties. These approaches are critical for high efficiency $Cu(In,Ga)Se_2$ technology, where the inclusion of alkali based treatments (Rb and Na) are critical to achieve record PCE up to 23%, or in the case of the $Cu_2ZnSnSe_4$ based in sputtered metallic precursor, the introduction of nanometric Ge layer before the synthesis of the absorber and the soft thermal treatment after the synthesis of the complete devices allow to homogenize the material and achieve PCE over 11%, close to record devices.

In this work we propose to explore the effects of the PDT and PAS approaches to include IA and IVA group elements into the Sb_2Se_3 and analyze the effects on its properties. In this case we explored the possibility of alkali inclusion with LiF, NaF and KF, as well as Ge and Sn, using PVD processes. Our synthesis process consists on the reactive annealing under Se atmosphere of antimony layers to obtain a Glass/Mo/Sb_2Se_3/CdS/i-ZnO/ITO system in substrate configuration. In the case of alkali-fluorides we compare post deposition treatments (PDT), consisting in the deposition of alkali fluorides by thermal evaporation on top of the as growth SLG/Mo/Sb_2Se_3 stack and then performing a further soft annealing routine; with pre annealing treatments (PAS) in which the alkali-fluorides are thermally evaporated on top of the Sb layers prior to Sb_2Se_3 synthesis. In the case of Ge and Sn the approach is more flexible and we could explore the PAS and PDT together with the inclusion of $GeSe_2$ and SnSe during the reactive annealing, in order to obtain more homogeneous incorporation. Additionally, the study is complemented with a wide characterization of the Sb_2Se_3 layers and devices using morphological and physico-chemical characterization (XRF, XRD and Raman spectroscopy), and with a complete analysis of the impact of the doping strategies correlated with the optoelectronic characterization (JV, IQE, CV) of the solar cells.

In the case of the IA inclusion, the optoelectronic characterization shows an improvement of the J_{sc} for NaF and LiF PDT treatments, and a V_{oc} increment for NaF PDT treatment, while KF is detrimental for the device performance. The NaF PDT allows slightly increase the power conversion efficiency from the 4.5% for reference devices to 4.9%. In the other hand the case of IVA inclusion, the effect of the SnSe approach do not show impact in the device performance in comparison with a huge degradation observed for the Sn PAS approach.

6:10 AM *F.EL03.05.07
Chemical Trends and Electronic Engineering of V-VI-VII Metal Chalcohalides Aron Walsh[1,2]; [1]Imperial College London, United Kingdom; [2]Yonsei University, Korea (the Republic of)

Metal chalcohalides are candidates for next-generation technologies including energy conversion, information storage, and quantum computing. I will present an exploration of V-VI-VII ternary chalcohalides, where V = Sb, Bi; VI = O, S, Se, Te; and VII = F, Cl, Br, I. These include the photoferroic compound SbSI [1,2] and the solar fuels photoelectrode BiOBr [3,4]. We consider 32 elemental combinations in 4 spacegroups using a combination of density functional theory (structural and thermochemistry) and many-body QSGW theory (relativistic electronic band structures). The materials are found to exhibit a wide range of electronic structures and bandgaps from metallic to over 5 eV. The large spin-orbit coupling in the heavy cations strongly influences the electronic structure. This research is part of a collaboration with the groups of David Scanlon (UCL) and Mark van Schilfgaarde (KCL), and used the UK National Supercomputer ARCHER.

Design, Stability and Properties of Binary and High Entropy Transition Metal Dichalcogenide Alloys John D. Cavin and Rohan Mishra; Washington University in St. Louis, United States

The diverse properties of transition metal dichalcogenides (TMDCs) make them a materials platform where alloying is an attractive option for tuning properties such as band gaps, charge density waves, superconductivity, and electrochemical activities. Of the many possible combinations of TMDCs, the small subset of Mo- and W-based quasi-binary semiconducting alloys has garnered widespread attention. Outside this limited subset, the synthesizability of alloys remains largely unknown. Furthermore, the usage of multiple principal elements to form so-called high entropy alloys (HEAs) of TMDCs has not been previously explored. Using first-principles calculations, we present a comprehensive analysis of the stability of 25 quasi-binary transition metal- and chalcogen-site TMDC alloys and a select number of 4- and 5-component transition metal-site TMDC HEAs. Critically, we expand knowledge of TMDC alloys beyond group VI transition metals Mo and W to include group V transition metals V, Nb, and Ta, opening the possibility of magnetic, superconducting, and charge density wave phases. We verify our stability predictions through evidence of the successful synthesis of many alloys, including new group VI quasi-binary alloys,[1] and the first synthesized TMDC HEA. First-principle calculations are also used to explain exciting experimental tuning of properties including thermal expansion, catalytic activity, and charge density wave transitions.

Vapour Phase Formation of Freestanding One-Dimensional Molybdenum Disulphide Matthias K. Grosch, Sanjay Mathur, Thomas Fischer and Rene Weißing; University of Cologne, Germany

Transition metal dichalcogenides (TMDCs) are of continuing research interest because of their interesting opto-electronical properties as well as catalytic application potential[1]. While two-dimensional TMDCs are well investigated one-dimensional micro and nanostructures are sparsely described in literature[2]. When structured in one-dimension these materials offer great potential for catalytic applications like the hydrogen evolution reaction (HER)[1] as they posses the materials intrinsic catalytic property while having additionally a high aspect-ratio. Herein, we report the synthesis of micro and nano-scaled one-dimensional molybdenum disulphide by vapour phase. A proposed mechanism for one dimensional growth is given and discussed.

Tertiary Hierarchical Complexity in Assemblies of Chiral Nanoclusters Haixiang Han, Yuan Yao and Richard Robinson; Cornell University, United States

Low-dimensional metal chalcogenides with atomic homogeneity are emerging as promising materials due to their unique electronic and optical properties. One of the most interesting behaviors of such ultrasmall inorganic nanocrystals is their ability of self-assembly into higher level structure complexity, which is dictated by the intra/inter molecular interactions through the surfactant ligands. Here, we demonstrate the synthesis and assembly of atomically precise 1.2 nm sulfur-bridged

copper (SB-Cu) clusters with tertiary hierarchical complexity, characterized and confirmed with high accuracy through single-crystal X-ray diffraction. The primary structure is clockwise/counterclockwise chiral caps and cores. The caps and cores combine to form full clusters and, due to the cap-core interaction, only two enantiomeric isomers are formed (secondary structure). A tertiary hierarchical architecture is achieved through the self-assembly of alternating enantiomers. More importantly, the hierarchical assembly of SB-Cu clusters is inherently conductive due to the conjugated MBO ligand (MBO = 2-Mercaptobenzoxazole) and the effective intermolecular interactions. The SB-Cu cluster has a characteristic absorption peak at 333 nm and emission at 380 nm, both of which, due to the conductivity of the SB-Cu clusters network, could vary in response to photoirradiation at different wavelengths. These clusters and assemblies make for an interesting nanomaterial for photoconductive devices and optical applications.

5:30 AM F.EL03.06.04
Selenization of Ultrathin Pt Layers for $PtSe_2$ Growth in Molecular Beam Epitaxy Maria Hilse, Ke Wang and Roman Engel-Herbert; The Pennsylvania State University, United States

$PtSe_2$ was recently proposed as promising material for low-power, high-performance, and ultra-thin-body electronic application because of its sizeable band gap up to 1.2 eV, high carrier mobility in the order of 1,000 cm^2/Vs, stability in air, and possibility of low-temperature fabrication compatible with CMOS back-end-of-line (BEOL) processing. First experimental values of its high carrier mobility of 210 cm^2/Vs, that outperforms other 2-dimensional materials such as black phosphorus, MoS_2 and WSe_2, demonstrate the great potential of optimizing the deposition process in order to grow high-quality $PtSe_2$ material. This work employed molecular beam epitaxy (MBE) to take advantage of its excellent in-situ control and monitoring capabilities to shine light on the kinetic processes involved and to optimize material properties, a strategy that is proven to produce high-quality and large size layers of various transition metal chalcogenides.
In the first step, we show growth of ultrathin Pt layers on c-plane Al_2O_3. We demonstrate how deposition parameters affect the morphology and crystallinity of the Pt films. In-situ reflection high energy electron diffraction (RHEED) and ex-situ atomic force microscopy (AFM) show single crystal film growth with smooth surfaces for growth in the temperature range from 300 to 600 °C, which is confirmed by X-ray diffraction (XRD) and transmission electron microscopy (TEM). We are addressing the epitaxial orientation relationship between Pt and the substrate and determine the growth to proceed in an island growth mode as observed by RHEED, XRD, and TEM.
In the second part we demonstrate the BEOL compatible selenization process done in MBE by exposing optimized Pt layers of 3 nm and 3 monolayer (ML) thickness to Se flux. We discuss the influence of Pt layer configuration and substrate temperature on the selenization process. For 3 nm thick Pt layers, selenization in the optimum temperature range of 200 to 300 °C leads to the formation of epitaxial, smooth, single crystal, $PtSe_2$ as determined by RHEED, AFM and Raman investigation. We elucidate the epitaxial orientation relationship between $PtSe_2$ and the underlying Pt as presented in RHEED. We find however from RHEED and Raman, that the thickness of the so formed $PtSe_2$ is limited to the mono/few-layer regime regardless of the selenization temperature and the Se flux exposure time. We conclude that the reason for the observed self-limited selenization process in the MBE environment is the compared to other physical vapor deposition techniques extremely small Se flux accessible within MBE. With the goal to form a layer of purely $PtSe_2$ on the Al_2O_3 by the selenization method, we report on the transformation process of 3 ML thick Pt films by Se flux exposure. Using RHEED, AFM and Raman, we still find the transformation rate to be smaller than 100 %, in addition we see that the crystal quality of the $PtSe_2$ is inferior compared to the $PtSe_2$ layers formed by selenization of 3 nm thick Pt films. However, we present a post-selenization annealing process in Se atmosphere that enhances the crystallinity of the $PtSe_2$ significantly as confirmed by Raman investigation.

5:40 AM F.EL03.06.05
Precisely Controlled Surface Charge Transfer Doping for Enhancing Electrical Performance of MoS_2-FETs Using Selective Inkjet-Printing Inho Jeong[1,2], Minwoo Song[3], Gyu-Tae Kim[2], Takhee Lee[3] and Seungjun Chung[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of); [3]Seoul National University, Korea (the Republic of)

Chemical vapor deposition (CVD)-grown molybdenum disulfide(MoS_2), one of the most widely used transition metal dichalcogenides (TMDs), have attracted much attention as an emerging semiconductor layer to realize field-effect transistors (FETs) and thin-film optoelectronic devices due to its unique characteristics, such as a high carrier mobility, chemical and thermal stability, absence of dangling bond, and tunable electronic energy band depending on a number of layers.[1] For the last decade, there have been a lot of effort for tuning its intrinsic properties and enhancing device performance via surface charge transfer doping, with exploring its fundamental electrical characteristics.[2,3] The surface charge transfer doping follows the charge transfer mechanism between deposited dopants and host materials which allows to modulate the electrical and optical characteristics of the TMDs by tuning the Fermi level.[4] Especially, the one of the key advantage of surface

charge transfer doping is that the electronic structure of the host materials is not changed. This doping strategy is typically conducted via a solution-immersion or vapor-phase doping methods to deposit organic dopants onto the surface of TMDs. However, because the modulation of their electrical characteristics are only determined by immersion time and the dopant concentration, therefore, the effective amount of dopants which critically affects the characteristics of host MoS_2 cannot be precisely controlled.[5]
In this presentation, we will report surface charge transfer doping by using drop-on-demand selective inkjet printing with the use of benzyl viologen (BV) as a surface charge transfer donor. To perform a reliable doping process onto CVD-grown MoS_2 with inkjet printing, we will report how to obtain a stable BV ink droplet considering a specific range of the inverse Ohnesorge number, which is a dominant parameter to determine inkjettability. In addition, systematically analyzed the solvent characteristics depending on the organic dopant candidates will be presented. With these efforts, we can enhance the electrical performance of MoS_2-FETs via surface charge transfer doping using inkjet printing which allows precisely controlled effective doping concentrations.

Synthesis of Two-Dimensional Materials via Chemical Vapor Deposition Jing Kong; Massachusetts Institute of Technology, United States

In recent years tremendous efforts have been devoted to the research on two dimensional materials. Their unique structures and remarkable properties have offered great potential for a wide range of applications in electronics, optoeletronics, valleytronics, catalysis, etc. The synthesis of high quality large area mono- and few-layer 2D materials is highly desirable for their applications. In this talk I will present our recent development on novel 2D material and structures, together with further understanding regarding the chemical vapour deposition (CVD) synthesis process of monolayer MoS2.

6:05 AM F.EL03.06.07
III-V Heterostructure N-Type Contacts to CVD Monolayer MoS2 Aravindh Kumar, Alvin Tang, Pranav Ramesh and Krishna Saraswat; Stanford University, United States

As transistor channels scale below 100 nm, the drive current would be limited by the contact resistance. Transition metal dichalcogenides, including MoS2, are promising candidates for ultra-short (< 10 nm) channels as they are immune to mobillity degradation in the < 5nm thickness regime, due to the absence of surface roughnesss scattering. When making metal contacts to MoS2, the metal Fermi level pins slightly below the conduction band edge, leading to n-type Schottky contacts. On the other hand, the problem of n-type contacts has been solved in InAs, a III-V semiconductor, since the metal Fermi level pins above the conduction band edge, leading to ohmic contacts. In this study, we discuss the fabrication of heterostructure contacts to MoS2 by depositing InAs on to monolayer MoS2. The MoS2 has been synthesized at 850 C using the Chemical Vapor Deposition technique and InAs is deposited using the Metalorganic-CVD technique. We fabricate Transmission Line Model (TLM) structures using electron-beam lithography to extract the contact resistance and to study the contacts using temperature-dependent current-voltage (I-V) measurements. We also model the interface using Density Functional Theory (DFT) to gain insight into the physics at the interface.

6:15 AM F.EL03.06.08
Novel Synthetic Path to Ternary and Quaternary 2D Chalcogenides and Optoelectronic Applications Mahyar Mohammadnezad[1], Mimi Liu[2], Gurpreet Singh Selopal[1], Fabiola Navarro-Pardo[1], Zhiming M. Wang[3], Barry Stansfield[1], Haiguang Zhao[4], Cheng-Yu Lai[2], Daniela R. Radu[2] and Federico Rosei[1]; [1]Centre Énergie Materiaux Télecommunications (INRS-EMT), Canada; [2]Florida International University, United States; [3]Institute of Fundamental and Frontier Sciences, University of Electronic Science and Technology of China, China; [4]Qingdao University, China

Reduced dimensionality in known chalcogenides such as the quaternary $Cu_2ZnSnSe$ (CZTSe), enhances the usefulness of these materials, including this known photovoltaic material. Past reports of platinum (Pt)-free counter electrodes for dye-sensitized solar cells (DSSCs) showed that they lacked the high surface area and electrocatalytic activity that could truly drive Pt replacement. CZTSSe, a sulfo-selenide kesterite was synthesized in a cascade reaction path to CZTSe, starting with the binary SnSe2 nanosheets that were sequentially treated with copper and zinc in solution. The templated synthesis enabled

retention of the morphology, thus resulting in stand-alone, large area, CZTSSe nanosheets. CZTSSe nanosheets deposited on fluorine-doped tin oxide (FTO) substrates were used as Pt replacement in a dye-sensitized solar cell, yielding a power conversion efficiency of (5.73%), comparable to the performance of a cell using a Pt-based CE (5.78%).[1] An excellent electrocatalytic performance (4.60%)[1] was also recorded for a CZTSSe/carbon paper (CP) utilized as a replacement of Pt/FTO-free CE. Fabrication of CZTSSe nanosheets as well characterization data will be presented.

6:25 AM F.EL03.06.09
Synthesis of Blue-Emitting Silver Phenylselenolate in Thin Film and Crystal Forms Watcharaphol Paritmongkol, Wenbi Shcherbakov-Wu, Woo Seok Lee and William Tisdale; Massachusetts Institute of Technology, United States

Silver phenylselenolate (AgSePh) is an emerging two-dimensional semiconducting member of a hybrid metal-organic chalcogenolate family. In addition to its two-dimensional structure with high exciton binding energy, strong in-plane anisotropy, and a narrow emission spectrum at 467 nm, AgSePh can be synthesized by a scalable vapor-phase method as well as a solution-phase reaction. Here, we show by testing 24 solvents – with different polarities, boiling points and functional groups – that complexation between silver cations and solvent molecules is the key to an increasing size of AgSePh crystals. With the introduction of amine solvents, we are able to increase the size of AgSePh thin films prepared by the vapor-phase tarnish reaction from ~200 nm to >1 μm and that of AgSePh crystals grown by the solution-phase biphasic reaction from ~3 μm to >150 μm. Moreover, the addition of solvent vapors to the vapor-phase tarnish reaction allows the control of crystal orientations between perpendicular and parallel to substrates' surfaces. The improved syntheses reported in this work will allow easy integrations of AgSePh in both thin-film electronic and nanoelectronic applications and the exploration of strong excitonic anisotropy.

6:35 AM F.EL03.06.10
Easy Fabricated Large Area Thin Film Based Thermo-Electric Generator for Waste Heat Harvesting to Electricity Sangram K. Pradhan, G Kogo and Messaoud Bahoura; Norfolk State University, United States

Highly crystalline and conformal growth of metal dichalcogenide based large surface area thin films thermoelectric generator were successfully grown on different substrates using RF sputtering technique. Surface morphology, crystal structure, and electrical properties of both p and n type thin films have been studied thoroughly. X-ray diffraction data revealed that crystallites of MoS_2 and WS_2 films are highly oriented in 00l plane with grain size distribution ranging from 40nm-130nm. Surface roughness study from AFM confirms that it increases with rise in substrate temperature and it plays a big role in electronic and phonon scattering. Interestingly, MoS_2 films also shows low thermal conductivity at room temperature and strongly favors achievement of higher thermoelectric figure of merit value of up to 1.98. Raman spectroscopy data shows two distinct MoS_2 vibrational modes at 380 cm^{-1} for E^1_{2g} and 410 cm^{-1} for A_{1g}. Thermoelectric transport studies further demonstrated that MoS_2 films show p-type thermoelectric characteristics, while WS_2 is an n-type material. We demonstrated high efficient pn-junction thermoelectric generator device for waste heat recovery and cooling applications.

6:45 AM F.EL03.06.11
Designing Non-Enzymatic Electrochemical Sensors for Human Health Monitoring from Nanostructured Chalcogenide Composites Harish Singh and Manashi Nath; Missouri University of Science and Technology, United States

Body-integrated electronic sensing devices is getting great attention in field of human healthcare. Especially, wearable health monitoring sensors allows access to effective and affordable diagnostic tools for sensitive, rapid and accurate detection for biologically relevant molecules such as dopamine (DA) and glucose. In this current work, efforts have been made to develop non-enzymatic direct electrochemical sensors based on transition metal chalcogenides electrocatalyst loaded on flexible polymeric film and graphitic substrate for DA and glucose. Among all the niche applications and properties of transition metal chalcogenides, recently these materials have gained attention due to their favorable electrochemical properties owing to tunable redox behavior of the transition metal center. Binary metal selenides and tellurides grown on different flexible substrates through electrodeposition, hydrothermal synthesis as well as by chemical vapor deposition exhibits exceptional activity for DA detection and electrocatalytic glucose oxidation at low applied potential. These chalcogenides also show enhanced sensing parameters including low limit of detection for glucose concentration and high sensitivity (~19 mA mM^{-}

^{1} cm^{-2} for copper selenide catalyst).The electrochemical studies shows long-term stability as well as sensitivity with a detection region from 5 nm to 2 μM, rapid response time to a set of DA concentrations with excellent reproducibility. Furthermore, for practical application, human blood serum was also tested for accurate detection of DA and glucose level. The results suggested that such nanostructured metal chalcogenides-based sensor may be a potential candidate for electrochemical detection of DA and glucose in practical analysis. Through these studies, we have explored transition metal chalcogenides as electrocatalysts for dopamine sensing and direct glucose oxidation along with an understanding of their structure-property relationship.

6:55 AM F.EL03.06.12

ALD of $MoSe_2$ Using New Precursors Raul Zazpe[1,2], Richard Krumpolec[3], Jaroslav Charvot[4], Ludek Hromadko[1,2], Hanna Sopha[1,2], Martin Motola[1], David Pavlinak[3], Milos Krbal[1], Filip Bures[4] and Jan Macak[1,2]; [1]Center of Materials and Nanotechnologies, Faculty of Chemical Technology, University of Pardubice, Czechia; [2]Central European Institute of Technology, Brno University of Technology, Czechia; [3]R & D Center for Low-Cost Plasma and Nanotechnology Surface Modifications, Department of Physical Electronics, Faculty of Science, Masaryk University, Czechia; [4]Institute of Organic Chemistry and Technology, Faculty of Chemical Technology,University of Pardubice, Czechia

2D semiconductor transition metal dichalcogenides (TMDs) have attracted considerable attention due to their layered structure, suitable band gap for visible light absorption, high carrier mobility, electrochemically active unsaturated edges and relatively good stability against photocorrosion [1]. Recently, 2D $MoSe_2$ has been gaining considerable interest due to its higher electrical conductivity as compared to MoS_2, its wider inter-layer distance (~0.65 nm), narrow bandgap (1.33–1.72 eV), high resistance to photo-corrosion, high surface area layer, electrochemically active unsaturated Se-edges and close to zero Gibbs free energy edges for hydrogen adsorption.These properties are promising for different applications of $MoSe_2$ including hydrogen evolution [2], photocatalysis [3] and Li-ion batteries [4]. However, their low light absorption efficiency, recombination issues of the photogenerated electron–hole pairs and slow charge transfer of the intrinsic semiconducting 2H-phase are a handicap. An efficient strategy to surpass those intrinsic limitations are hybrid nanostructures using conducting supporting materials. In this regard, anodic TiO_2 nanotubes (TNTs) are excellent photoactive supporting material providing a high surface area, unique directionality for the charge separation, and highly effective charge collection [5]. Accordingly, we present anodic TiO_2 nanotubes homogenously decorated with $MoSe_2$ nanosheets by atomic layer deposition (ALD). In parallel, we address the current scarcity of convenient ALD Se precursors by the synthesis a set of new selenium precursors - alkysilyl $(R_3Si)_2Se$ and alkytin $(R_3Sn)_2Se$, and cyclic silylselenides compounds. Those Se precursors were extensicely characterized and their reliability as ALD Se precursors explored [6,7]. Several compounds exhibited promising results to be convenient ALD Se precursor as will be presented in the presentation. The synthesis of the $MoSe_2$ nanosheets and their composites with TiO_2 NTs, their physical and electrochemical characterization, and encouraging results in electrochemical characterization, hydrogen evolution reaction (HER) and photocatalysis will be presented and discussed.

Late News: Charge Transport in MBE-Grown MoTe2 Bilayers with Enhanced Stability Provided by AlOx Capping Zuzanna W. Ogorzalek[1], Bartlomiej Seredyński[1], Slawomir Kret[2], Adam Kwiatkowski[1], Krzysztof Korona[1], Magdalena Grzeszczyk[1], Janusz Mierzejewski[1], Dariusz Wasik[1], Wojciech Pacuski[1], Janusz Sadowski[1,2,3] and Marta Gryglas-Borysiewicz[1]; [1]University of Warsaw, Poland; [2]Polish Academy of Sciences, Poland; [3]Linnaeus University, Sweden

$MoTe_2$ is a transition metal dichalcogenide (TMD), which has been intensively studied in the last few years. It exists in several crystalline phases among which the semimetallic T_d and semiconducting 2H exhibit numerous intriguing physical properties. It is well known however, that $MoTe_2$ shows significant sensitivity to air, which makes ex-situ experiments, involving sample preparation and processing, very challenging. [1-3] The question of stability is especially important in the

case of ultra-thin, single and few-layer samples, which provide access to the most interesting physics.
In this paper we address the problem of low stability of $MoTe_2$ and propose a very efficient protective capping, that stabilizes transport properties of the layers. A molecular beam epitaxy technique has been used to grow ultra-thin $MoTe_2$ films in 2H-semiconducting phase on large area GaAs (111)B substrates. A transmission electron microscopy study reveals the high quality of the $MoTe_2$ films. Directly after the growth, $MoTe_2$ films have been in-situ capped with a thin (3 nm) layer of Al, which oxidizes after exposure to ambient conditions. This oxide serves as a protective layer to the underlying $MoTe_2$ and it is thin enough to make good-quality electrical contacts. Wide range temperature resistivity studies showed that charge transport in $MoTe_2$ is realized by hopping with an anomalous hopping exponent of $x \approx 0.66$, reported also previously for ultra-thin, metallic layers. We demonstrate that this approach provides a significant improvement of the $MoTe_2$ stability. Upon exposure to pure nitrogen and air atmospheres, the resistivity of unprotected sample changes by more than 900%, whereas the protected sample shows electrical stability at the level of 1% over one week and 5% in the timescale of several months. [4]

Late News: Atomically Precise Fabrication of 1D Transition Metal Chalcogenides Inside Nanotubes Yusuke Nakanishi[1], Naoyuki Kanda[1], Zheng Liu[2], Yasumitsu Miyata[1], Kazutomo Suenaga[2] and Nori Shinohara[3]; [1]Tokyo Metropolitan University, Japan; [2]AIST, Japan; [3]Nagoya University, Japan

Since the discovery of buckminsterfullerene in 1985, nanocarbon materials have played a crucial role in modern materials science. Recently, significant efforts have been redirected towards exploring 'post-nanocarbons'. Over the past decade, 2D layers of transition metal chalcogenides (TMCs) have been widely recognized as 'beyond graphene' owing to their versatile chemistry. On the other hand, their 1D counterparts such as nanoribbons, nanotubes, and nanowires could exhibit the unique electrical and optical properties, significantly distinct from 2D TMCs as well as 1D nanocarbons. However, exploring their potential has been hampered by their limited availability. Although these materials have been prepared using chemical and lithographic methods, the reliable production of well-defined 1D TMCs remains a significant challenge.
Here we report atomically precise fabrication of 1D TMCs within carbon/boron-nitride nanotubes (CNTs/BNNTs). Chemical reactions confined inside the NTs promote and stabilize the bottom-up growth of 1D TMCs, allowing their easy handling and characterization. We found that choosing suitable precursors and diameters of the host NTs provides a variety of morphologies including nanoribbons, nanotubes, and nanowires. Atomic-level transmission electron microscopy enabled us to observe dynamic torsions of the nanowires inside CNTs, not seen in the bulk (M. Nagata et al., ***Nano Lett.*** 2019; N. Kanda et al., ***Nanoscale*** 2020). Furthermore, we have recently investigated electronic structures of 1D TMCs within BNNTs. Our findings suggest that these 1D TMCs could provide new building blocks for future nanoelectronics.

7:25 AM F.EL03.06.15
Late News: Electron Transport of Transition Metal Chalcogenide Nanowire Networks Hiroshi Shimizu[1], Jiang Pu[2], Hong En Lim[1], Yusuke Nakanishi[1], Zheng Liu[3], Takahiko Endo[1], Taishi Takenobu[2] and Yasumitsu Miyata[1]; [1]Tokyo Metropolitan University, Japan; [2]Nagoya University, Japan; [3]National Institute of Advanced Industrial Science and Technology, Japan

Transition metal chalcogenide (TMC) nanowires have attracted much attention in recent years because of their one-dimensional (1D) metallic properties and electronic device applications [1-5]. To date, many groups have reported the preparation and properties of individual and bundled TMC nanowires including as Mo_6S_6[2], Mo_6Se_6[3], and Mo_6Te_6 [4,5]. Recently, our group has achieved large-area growth of TMC nanowires using chemical vapor deposition (CVD) [6]. Depending on the affinity with substrate surface, this technique also enables network formation of either aligned atomically thin two-dimensional (2D) sheets or random network of three dimensional (3D) bundles composing of individual nanowires. For these samples, it is expected that the morphology such as bundle size will strongly affect the electron transport properties of TMC nanowire networks.
In this study, we have investigated the temperature dependence electron transport of WTe nanowire networks with different bundle sizes. The samples were grown on SiO_2 or Al_2O_3 surface using CVD, and the network formation was confirmed using scanning electron microscope (SEM). At room temperature, the sheet resistances of samples vary from 2 kΩ to 75 MΩ depending on the nanowire density and bundle size. The thick bundle network shows a metallic behavior from room temperature to 20 K, whereas a power-law dependence is observed for the thin bundle network. In the presentation, we will discuss a possible mechanism derived from 1D metallic behavior for the power-law dependence.

5:00 AM F.EL03.07.01
Structural Modeling of 2D van der Waals Materials via X-Ray Dynamical Diffraction Simulation—Application to an Intrinsic Antiferromagnetic Topological Insulator Yorí G. Camillo da Silva[1], Celso I. Fornari[2], Sergio L. Morelhao[1], Philipp Kagerer[2], Sebastian Sebastian Buchberger[2], Hendrik Bentmann[2] and Friedrich Reinert[2]; [1]University of Sao Paulo, Brazil; [2]Julius-Maximilians-Universität Würzburg, Denmark

Two-dimensional (2D) van der Waals (vdW) materials has experienced an explosive growth after graphene, and new familes of 2D systems and block-layered bulk materials have been discovered [1]. The possibility of tuning their electronic properties via structural parameters make the layered vdW materials attractive from both fundamental and device engineering points of view. However, the weakness of vdW interlayer forces lead in general to systems undergoing drastic changes as a function of subtle variation in growth conditions. Finding controllable fabrication processes of such systems has proven challenging [2,3]. Within the scope of exploiting intriguing phenomena related to topological surface states and symmetry-breaking magnetic states, epitaxy of topological insulator materials having atomic layers of Mn has been pursued [4].
Simulations of X-ray scattering and diffraction are well-established procedures for structural analysis at nanometer and subnanometer length scales of layered materials, ranging from amorphous films to crystalline ones such as epitaxial layers on single-crystal substrates. Higher are the ordering in stacking sequences of the atomic layers, the more pronounced are the diffracted intensities at higher angles allowing more refined model structures. X-ray theories are well comfortable at the limiting cases, either amorphous films or perfect periodic layer sequences, that is crystalline films. However, in developing new materials and processing technologies, layered materials with random layer sequences of large d-spacing can often be found. Combined with the very high dynamical range of advanced X-ray sources and instruments, this kind of material represent a challenging in theoretical approach for X-ray diffraction simulation [5].
In this work, we describe how to adapt a general recursive equation for simulating X-ray dynamical diffraction in layered materials to the case of thin films of MnxBi2Te3+x grown by molecular beam epitaxy on BaF2 (111) substrates as a function of MnTe source temperature. The films are staking of n vdW bounded MnBi2Te4 septuple layers (SLs) where the occurance of m Bi2Te3 quintuple layers (QLs) lead to composition x = n/(n+m). Interface quality, random stacking sequences, surface finishing, and evolution of defects during growth are parameters investigated by curve fitting with the recursive equation. It demonstrates the effectiveness of this approach for describing X-ray diffraction in layered systems ranging from random to perfect periodic stacking sequences of atomic layers.

Systematic Exploration of Structure and Properties in Homologous Series of Nanoscale Chalcogenide Superlattices Sage Bauers[1], Danielle Hamann[2], Dennice Roberts[1], Andriy Zakutayev[1] and David Johnson[2]; [1]National Renewable Energy Laboratory, United States; [2]University of Oregon, United States

An exciting prospect for 2D materials is their ability to be integrated into heterostructures, where the selection and sequencing of stacked layers facilitate tailored properties. One form of such heterostructures are non-epitaxial chalcogenide superlattices with constituents interleaved at nanometer length scales. These materials can be prepared from amorphous—but intentionally layered—thin films which are gently heated to crystallize into a superlattice that mimicks the layer sequence of the precursor. Such facile synthesis enables superlattices with nearly limitless permutational flexibility, allowing for systematic explorations of how different layer arrangements affect the structure and properties of the composite material.

This talk will primarily focus on materials containing *n* monolayers of $TiSe_2$ interleaved with *m* monolayers of PbSe and/or SnSe in a repeating superlattice. These structures can be described by the chemical formula $[(MSe)_{1+\delta}]_m[TiSe_2]_n$, where M=Sn or Pb and δ is a compositional misfit parameter. We will discuss several homologous series wherein the relative fractions of constituents are successively modified by changing the integral number of layers (*m* and *n*).

Changes to $[(MSe)_{1+\delta}]_m[TiSe_2]_n$ layer sequencing induce changes to the composite materials' semi-metallic transport properties . In both $[(PbSe)_{1+\delta}]_m[TiSe_2]_n$ and $[(SnSe)_{1+\delta}]_m[TiSe_2]_n$ electrons exchanged between the layers are the primary source of mobile carriers while the amount of charge exchange required to equilibrate the chemical potential across the interface is dependent on the thicknesses and identities of layers. Thus, *m* and *n* can be used to tune the carrier density with minimal change to carrier mobility since no ionized dopants are introduced into conduction paths. In some cases, the sequencing can also affect the local structure within the layers. For example, in $[(PbSe)_{1+\delta}]_m[TiSe_2]_n$ superlattices both constituents are structurally rigid and insensitive to the thickness of the layers. Conversely, in $[(SnSe)_{1+\delta}]_m[TiSe_2]_n$ the nanolayers of SnSe exhibit a rich polymorphism dependent on thickness, which is attributed to a combination of low polymorph energies and strong interfacial interactions with $TiSe_2$.

Motivated by successful synthesis of superlattice materials in several selenide systems, we have recently reported on $[(SnS)_{1+\delta}]_m[TaS_2]_1$ superlattices, marking the first application of this synthesis approach to sulfur-based chemistries. As part of this work, we employ graded precursor films that enable parallel preparation of multiple stacking sequences with similar monolayer control. These results are a promising first step towards similar systematic investigation of structure and properties in another chalcogenide class.

Data-Driven Creation of an Inorganic Nanotube Database Felix Tim Bölle, August E. G. Mikkelsen, Tejs Vegge and Ivano E. Castelli; Technical University of Denmark, Denmark

Reducing dimensionality has led to a new realm of materials exhibiting interesting structural, electronic, and catalytic properties. While two-dimensional materials are the focus of many theoretical and experimental research groups, one-dimensional materials are less well studied. Most of the theoretical work on 1D materials is focused on explaining phenomena at the atomic scale rather than performing a high-throughput search of new inorganic nanotube materials.

Here, we investigate by means of density functional theory (DFT) sub-nanometer tubes that exhibit different properties compared to their 2D counterparts while being selective in size and composition. These nanotubes are obtained by rolling up 2D Janus dichalcogenide sheets, where the strain between the two sides of the 2D layer is the driving force for the formation of the nanotube. We will elucidate designing rules to produce nanotubes with controlled dimensions and to guide the search towards nanotubes that can be used in a variety of applications. In detail, we focus on properties like bandgaps, stabilities, and adsorption energies that lead to predictive models assisting in designing new nanotubes before doing DFT calculations. The generalization from existing data helps to accelerate the search for novel materials for applications in batteries, (photo-)catalysis, chemical storage, and nanofluidics.

5:35 AM F.EL03.07.04
Assessing the Defect Tolerance of Non-Tetrahedral I_2-II-IV-VI_4 Chalcogenides Andrea Crovetto[1,2], Sunghyun Kim[3], Moritz Fischer[1], Nicolas Stenger[1], Aron Walsh[3], Ib Chorkendorff[1] and Peter Vesborg[1]; [1]Technical University of Denmark, Denmark; [2]Helmholtz-Zentrum Berlin, Germany; [3]Imperial College London, United Kingdom

The Cu_2BaSnS_4 (CBTS) and Cu_2SrSnS_4 (CSTS) compounds have been recently investigated as wide band gap photovoltaic absorbers for tandem solar cells. Unlike their parent compound Cu_2ZnSnS_4, which crystallizes in a fully tetrahedral zincblende-like structure, the large size of Sr and Ba leads to a less-than-3D trigonal structure in CBTS and CSTS. While Cu and Sn remain tetrahedrally coordinated, Ba and Sr are 8-fold coordinated, and their coordinating S atoms form square antiprisms with open spaces between them.

By combining photoluminescence experiments and first-principles defect calculations, we show that the defect properties of CBTS and CSTS are staggeringly different from the defect properties of the much-investigated CZTS compound. Such differences can be explained in terms of their unconventional crystal structure, as well as in terms of cation size mismatch. We demonstrate that the sub-band gap tail states plaguing CZTS photoabsorbers have almost completely disappeared in both CBTS and CSTS. Nevertheless, a high density of (probably interstitial) defects are observed deep into the band gap, due to the open spaces available in the complex crystal structure of CBTS and CSTS.

Based on these observations, we develop a theory to explain the defect properties of a large set of I_2-II-IV-VI_4 chalcogenide semiconductors and predict the most promising chemical spaces to find defect-tolerant compounds. Our analysis includes defects responsible for sub-band gap tail states, as well as defects responsible for deep recombination centers.

Machine Learning for Deep Elastic Strain Engineering of Electronic Band Structure of 3D and Low-Dimensional Materials Zhe Shi[1], Ming Dao[1], Evgenii Tsymbalov[2], Alexander Shapeev[2], Ju Li[1] and Subra Suresh[1,3]; [1]Massachusetts Institute of Technology, United States; [2]Skolkovo Institute of Science and Technology, Russian Federation; [3]Nanyang Technological University, Singapore

Nanoscale specimens of electronic materials as diverse as 2D graphene and MoS_2 and 3D silicon and diamond are known to be deformable to large strains without inelastic relaxation. The introduction of strain within the elastic regime has become a widely employed strategy for providing unique and exciting electronic and photonic properties in both 3D and low-dimensional materials. These discoveries harbinger a new age of deep elastic strain engineering of the band structure and device performance of electronic materials. Many possibilities remain to be investigated as to what graphene can do as the most versatile 2D material or what semiconductor materials such as MoS_2 and hBN can offer after overcoming their present commercial immaturity.

Deep elastic strain engineering explores full six-dimensional (6D) space of admissible nonlinear elastic strain and its effects on physical properties. However, the complexity of controllably engineering materials properties by strains necessitates first-principles computations to first screen for a desirable figure-of-merit and then design an optimal straining pathway. The reduced dimension strain space accessible to low-dimensional materials would thus become easy to navigate if we have the model for the much larger 6D strain space. In our work, to map the 6D strain space fully, we first developed a general method that combines machine learning and ab initio calculations to guide strain engineering whereby properties and performance for 3D and 2D materials could be designed. This method invokes machine learning algorithms and utilizes a limited amount of ab initio data for the training of a surrogate model, predicting electronic bandgap within an accuracy of 8 meV [1]. On top of this, attempts have been made by us in developing a more versatile machine learning framework that adopts convolutional neural networks, solid-state physics informed data representation scheme, and a new active learning algorithm to discover the indirect-to-direct bandgap transition in a material by scanning the entire strain space [2]. Through this framework, we considerably improve the state-of-the-art set by ourselves and achieve enhanced performance in every front, including more accurate bandgap and band structure prediction, band extrema detection, and effective mass calculation. Combining this method with experimentally validated finite-element simulations, we identified the most energy-efficient strain pathways that would reversibly transform an ultrawide-bandgap material, such as hBN or diamond, to a metalized state without phonon stability [3]. Our approach could also be used in finding phase transitions within six-dimensional strain space for different crystallographic orientations of a target material. As an example, we explored the phonon-instability conditions that promote phase transition to graphite in diamond.

The fast and reliable inference of the proposed model opens a path towards analyzing and scrutinizing general band structures (electronic, phonon, magnon, photonic bands) in the vast 6D strain space. Our AI-driven model is even easier to be applied for studying 2D materials such as chalcogenides that are accessible to a lower strain space dimension, auguring unique opportunities for tailoring low-dimensional materials properties via strain engineering for electronic, photonic, quantum and energy applications.

Computational Design of Thermodynamically-Enhanced Metathesis Reactions for Difficult-to-Synthesize

Chalcogenides and Pnictides Wenhao Sun[1] and Akira Miura[2]; [1]University of Michigan, United States; [2]Hokkaido University, Japan

Complex inorganic materials are usually synthesized by an 'addition' approach, whereby simple precursors are reacted to form a target multicomponent phase. However, if the simple precursors are already very stable themselves, then there may be little free energy left to drive a chemical reaction to a higher-component phase, which often results in slow kinetics and long-lived reaction impurities. Here, we demonstrate that metathesis reactions operate in a fundamentally different synthesis paradigm. Instead of a conventional reaction of M + X --> MX, a metathesis reaction is driven by a salt byproduct like NaCl, in a reaction typified by MCl + NaX --> MX + NaCl. Because Na+ and Cl- are separated in the precursor, but are then rejoined in the product, these metathesis reactions are often highly exothermic. The inclusion of additional species like Na+ and Cl- can also relocate the 'thermodynamic sink' of the phase diagram to a new composition—enhancing structure-selectivity towards a target multicomponent phase. Here, we demonstrate how metathesis reactions facilitate the synthesis of metastable ternary molybdenum nitrides [1] and the difficult-to-synthesize MgCr2S4 thiospinel chalcogenide for Mg-battery applications [2]. Not only can metathesis reactions facilitate the synthesis of the desired phase, they are also routes to low-dimensional nanoparticles and nano-porous compounds. The additional degrees of freedom afforded by including extra elements into the synthesis reaction opens up a vast and promising design space for creative new metathesis reactions to chalcogenides and pnictides.

Late News: DFT, GW and BSE Calculations for Charged Defects in N-Doped Monolayer WS2 Anne Marie Z. Tan[1], Yuanxi Wang[2], Qingkai Qian[2], Shengxi Huang[2] and Richard Hennig[1]; [1]University of Florida, United States; [2]The Pennsylvania State University, United States

Two-dimensional (2D) semiconducting transition metal dichalcogenides (TMDCs) have attracted extensive research interests for applications in optoelectronics, spintronics, photovoltaics, and catalysis. Just as in bulk semiconductors, 2D semiconductors contain both intrinsic defects, e.g., vacancies and antisites, and extrinsic defects, e.g., substitutional and interstitial dopants and impurities. Due to the reduced electronic screening in 2D materials, point defects are expected to have an even stronger impact on the electronic properties of these systems compared to in bulk semiconductors. Understanding the effect of defects, dopants, and impurities and how they respond to synthesis and processing conditions is critical to fully realize the potential of 2D TMDCs for applications in electronic and optoelectronic devices.

In this talk, we present first-principles calculations at multiple theory levels to investigate the energetics, electronic structure, and optical response of nitrogen-doped monolayer WS_2. We perform density-functional theory (DFT) calculations with the PBE, SCAN, and HSE functionals to determine the defect formation energies and charge transition levels (CTLs), utilizing the Freysoldt-Neugebauer charge correction [1] to restore the appropriate electrostatic boundary conditions for charged defects in 2D materials. Many-body perturbation theory calculations within the *GW* approximation using a novel convergence acceleration technique provide accurate quasiparticle levels to correct the DFT band edge positions and CTLs. We show that it is energetically favorable for N atoms to substitute at S sites, forming a paramagnetic defect with a CTL close to the middle of the bandgap. When aligned to a common electrostatic potential reference, the absolute position of the CTL remains almost consistent across all levels of theory, while the positions of the band edges exhibit a strong dependence. Finally, we model the optical response of N-doped WS_2, including excitonic effects, by solving the Bethe-Salpeter equation on top of *GW*. Based on our results, we suggest possible optical transitions between the defect level and the valence or conduction bands, which may be observable with photoluminescence and other optical spectroscopy techniques. The approach used in this study can be extended to study other defects and dopants in WS_2 and other 2D TMDCs [2].

A Method to Reliably Measure Energy Conversion Efficiency without Making Contact for Confirmation of Thermoelectric Figure-of-Merit Zhifeng Ren; University of Houston, United States

Thermoelectric figure-of-merit (ZT) is the overall most important physical quantity for a thermoelectric material. It ultimately determines the energy conversion efficiency. However, over the years, higher and higher ZTs were reported without confirmation since it requires zero-resistance contact that is as difficult as, if not more than, the material improvement. Therefore, how to confirm the ZT of any material without making the needed contact is urgently needed. In this report I will present our detailed study on reliable efficiency measurement on materials without making the needed contact.

5:15 AM F.EL03.08.02
Layer Dependent Thermal Properties of WSe2 Annie Xian Zhang; Stevens Institute of Technology, United States

Following the interest in graphene since its first isolation by mechanical exfoliation in 2004, the broader family of two dimensional (2D) materials has been the subject of extensive attention thanks to their unique properties and atomically thin structure. In particular, transition metal dichalcogenides (TMDC) materials have shown unique optical and electrical properties, such as band structure transitions, semiconducting transport behavior, and strong photoluminescence, which are distinct from those of graphene and other carbon allotropes. TMDC materials are also intriguing for optical, electrical, and thermoelectric applications, especially in few-layer forms. Although electron transport in TMDC materials has been widely studied, there have been only limited experimental data published on thermal transport in WSe_2 which is the crucial parameter in their thermoelectric applications. Therefore, more robust experiments and modeling are needed to explain this trend or to provide more accurate values. Meanwhile, the large disparity in thermal conductivities predicted by theory also motivates further experimental investigation. Here we demonstrate an improved experimental method for measuring thermal conductivities of thin TMDCs. This is used to provide new measurements of the thermal conductivity of single-, bi-, and tri-layer WSe_2 (1L, 2L, 3L WSe_2). The systematic experimental results enable comparisons of experimental results between different layer number, different material conditions.

The optothermal Raman technique has been the most successful method for measurement of thermal conductivity of 2D materials. In this technique, a laser is focused at the center of a flake and used to measure the position of a Raman-active mode. As the laser power is increased, the sample is heated, which enables red-shift Raman mode due to thermal softening. Thermal modeling can then be used to extract the thermal conductivity from the measured shift rate.

The thermal modeling used for determination of thermal conductivity requires additional input of a number of parameters: the rate of mode softening with temperature; optical absorption; and the thermal conductance of the supported area of the flake. However, in previous work, typically only the mode softening rate is directly measured, whereas the values of other parameters are derived from published values or assumed. Here we present measurements of the thermal conductivity of WSe_2 in which all of these parameters are determined experimentally. Molecular Dynamics simulations are performed to confirm the thermal transport properties trend from 1L to 3L, and supports the theoretical model building.

In conclusion, we have used optothermal Raman technique to study thermal transport properties of 1L to 3L WSe_2, an emergent efficient thermoelectric material. This work addresses several important issues in the measurement of thermal conductivity of the 2D materials WSe_2 using Raman spectroscopy. We derive the thermal conductivity values of 1L to 3L WSe_2 and their interfacial thermal conductance with substrate. These results are of significance to discover the thermal transport properties of 2D transition metal dichalcogenides with thermoelectric applications, and thus develop the efficient 2D thermoelectric materials.

Two-Dimensional Layered Germanium Monochalcogenides as Anode in Metal-Ion Batteries Shakir Bin Mujib, Maren Ellis, Sophie Justus, Porter Herold and Gurpreet Singh; Kansas State University, United States

In this work, we investigate two-dimensional (2D) sheets of germanium sulfide (GeS) and germanium telluride (GeTe) as promising high-capacity and stable materials for energy storage. GeS and GeTe with layered structures are prepared via a simple liquid-phase exfoliation approach. As-synthesized 2D nanosheets can effectively increase the electrolyte-electrode interface area and facilitate metal ion transport. As a result, GeS and GeTe nanosheets deliver a high areal capacity of 1.76 mAh cm^{-2} and 1.05 mAh cm^{-2}, respectively as anodes in lithium-ion batteries (LIBs). Further analysis of GeS and GeTe in sodium-ion batteries (SIBs) and potassium-ion batteries (KIBs) suggest that layered germanium monochalcogenides can be potential anodes in other metal-ion batteries.

Two-Dimensional Nanosheet Inks Using Zwitterion Dispersants for Biocompatible and Scalable Inkjet Printing Hyeokjung Lee, Seung Won Lee, Chanho Park, Kyuho Lee and Cheolmin Park; Yonsei University, Korea (the Republic of)

Inkjet printing of two-dimensional (2D) transition metal dichalcogenide (TMD) nanosheets fabricated by liquid-phase exfoliation (LPE) allows simple, low-cost, and mass-producible photo-electronic devices. Many LPE processes involving toxic and environmentally hazardous solvents; however, dispersants have restricted the extent of applications of 2D-TMD inks. Herein, various 2D-TMD nanosheets, including MoS_2, $MoSe_2$, WS_2, and WSe_2, in addition to few-layered graphene, are inkjet-printed using a LPE process based on zwitterionic dispersants in water. Zwitterions with cationic and anionic species are water-soluble, while alkyl chain moieties associated with two ionic species adhere universally on the surface of TMD nanosheets, resulting in high throughput liquid exfoliation of the nanosheets. The zwitterion-assisted TMD nanosheets in water are successfully employed as an ink without the need for additives to adjust the viscosity and surface tension of the ink for use in an office inkjet printer; this gives rise to A4 scale, large-area inkjet-printed images on diverse substrates, such as metals, oxides, and polymer substrates patchable onto human skin. The development of mechanically flexible, biocompatible-printed arrays of photodetectors with pixelated $MoSe_2$ channels and conductive graphene electrodes on a paper exhibits a photocurrent ON/OFF ratio of approximately $10^{3.8}$ and photocurrent switching of 500 ms.

F.EL03.09.03
Effect of Bilayer Growth on the Thermoelectric Properties of Sb_2Te_3 / $Bi_{0.4}Sb_{1.6}Te_3$ Thin Film Andrew W. Howe, Mamadou T. Mbaye, Sangram K. Pradhan and Messaoud Bahoura; Norfolk State University, United States

Thermoelectric devices based on Sb_2Te_3 and related alloys are of great interest to academia, industry, and government due to their efficiency in low-temperature applications such as micro-heating and small-scale refrigeration. The search for high performing thermoelectric devices is dominated by manipulating the electronic structure to boost the power factor through an increase in the density of states and/or reduction of the lattice thermal conductivity to maintain a large enough temperature gradient. Superlattice structures are long heralded as potential candidates to increase the thermoelectric power factor as well as significantly reduce the lattice thermal conductivity. In this report, we compare the thermoelectric properties of bilayer p-type Sb_2Te_3 / $Bi_{0.4}Sb_{1.6}Te_3$ film and single layer p-type $Bi_{0.4}Sb_{1.6}Te_3$ film of the same thickness. Preliminary Hall effect measurements showed that the carrier concentration of our bilayer and $Bi_{0.4}Sb_{1.6}Te_3$ samples fall within the desired values common to heavily doped semiconductors. Carrier mobility and electrical conductivity are higher for our bilayer than the single-layer film. We noted a significant increase in the Seebeck coefficient values of our bilayer, 202 μV/K compared to 130 μV/K for our single-layer film. NanoTR thermoreflectance measurements revealed a significant reduction in the overall thermal conductivity of our bilayer system compared to our single-layer film. The low thermal conductivity reduction can be associated with, not only species intermixing -which allows phonon scattering events- interfacial boundary scatterings. When these observations are combined into a device, we would expect to see a great jump in the overall efficiency while maintaining the ease of fabrication allowing for quick scaling of production.

Dimensionality Effects on Drift Resistivity of Nanoscale Phase-Change Memory (PCM) Cells in Reset State Kazimierz

J. Plucinski; Military University of Technology, Poland

Although the device physics related to the operation of PCM (Phase change Memory) have been widely studied since its discovery in the 1960s, questions relating to the nature of the physical principle responsible for the resistivity drift is still controversial [1, 4].
These problems are deepening at the transition to the nanoscale in the construction of PCM memory [2, 3].
Drift resistivity of the PCM in reset state in terms of subthreshold conductivity is analyzed.
This subthreshold conductivity is analyzed with respect to nanoscaling effects, especially:
the contribution of tunneling and trapping to electrical transport;
contribution of ballistic transport and diffusive transport;
analysis of the scattering in relation to dimension and mean free path in amorphous GST;
limitation of Poole-Frankel approach.

The results are verified on the base of present models of the subthreshold conduction and drift resistivity in reset state of the PCM memory [e.g. 4, 5].

Distinct Magneto-Raman Signatures of Spin-Flip Phase Transitions in CrI_3 Amber McCreary[1], Thuc Mai[1], Franz Utermohlen[2], Jeffrey Simpson[1,3], Kevin Garrity[1], Xiaozhou Feng[2], Dmitry Shcherbakov[2], Yanglin Zhu[4], Jin Hu[5], Daniel Weber[2], Kenji Watanabe[6], Takashi Tanigochi[6], Joshua Goldberger[2], Zhiqiang Mao[4], Jeanie Lau[2], Yuanming Lu[2], Nandini Trivedi[2], Rolando Valdes Aguilar[2] and Angela Hight Walker[1]; [1]National Institute of Standards and Technology, United States; [2]The Ohio State University, United States; [3]Towson University, United States; [4]The Pennsylvania State University, United States; [5]University of Arkansas–Fayetteville, United States; [6]National Institute for Materials Science, Japan

The discovery of 2-dimensional (2D) materials, such as CrI3, that retain magnetic ordering at monolayer thickness has resulted in a surge of both pure and applied research in 2D magnetism. In this talk, I will detail our magneto-Raman spectroscopy study on multilayered CrI3, focusing on two additional features in the spectra that appear below the magnetic ordering temperature and were previously assigned to high frequency magnons. Instead, we conclude these modes are actually zone-folded phonons. We observe a striking evolution of the Raman spectra with increasing magnetic field applied perpendicular to the atomic layers in which clear, sudden changes in intensities of the modes and their polarization dependence are attributed to the interlayer ordering changing from antiferromagnetic to ferromagnetic at a critical magnetic field. Our work highlights the sensitivity of the Raman modes to weak interlayer spin ordering in CrI3.

Optical Spectroscopy of Antiferromagnetic Two-Dimensional Materials Hyeonsik Cheong; Sogang University, Korea (the Republic of)

Two-dimensional magnetic van der Waals materials have attracted much interest recently. Magnetism in low dimensional systems is an interesting topic for the fundamental physics, and atomically thin magnetic materials are promising candidates for novel spintronic devices. Antiferromagnetic 2-dimensional materials are particularly interesting both for fundamental physics and also for antiferromagnetism-based spintronic devices. However, traditional research tools such as neutron scattering to probe antiferromagnetic ordering cannot be employed for atomically thin materials due to the small sample volume. Although magneto-optical Kerr effect measurements can be used to monitor the magnetic ordering in ferromagnetic materials, the lack of net magnetization precludes the use of the Kerr effect in probing antiferromagnetic ordering. Optical spectroscopy is becoming increasingly important for the study of antiferromagnetic 2-dimensional materials. Raman spectroscopy, for example, has been established as an invaluable tool to probe the magnetic transition in antiferromagnetic van der Waals materials as it has been found that the magnetic ordering can be reliably monitored by Raman spectroscopy [1]. Furthermore, recent spectroscopic studies revealed a novel coherent state in some of these materials stabilized by the antiferromagnetic ordering. In this presentation, I will review recent achievements in the study of antiferromagnetism in 2 dimensions using optical spectroscopy. $FePS_3$ exhibits an Ising-type antiferromagnetic ordering down to the monolayer limit, in good agreement with the Onsager solution for a 2-dimensional order-disorder transition [2]. The transition temperature remains almost independent of the thickness from bulk to the monolayer limit, indicating that the weak interlayer interaction has little effect on the antiferromagnetic ordering. On the other hand, $NiPS_3$, which shows an XXZ-type antiferromagnetic ordering in bulk, exhibits antiferromagnetic ordering down to 2 layers with a slight decrease in the transition temperature, but the magnetic ordering is suppressed in the monolayer limit [3]. Furthermore, an almost resolution-limited, sharp optical transition was observed in photoluminescence and optical absorption measurements on $NiPS_3$, which is interpreted as being due to a novel excitonic state coupled with the antiferromagnetic ordering [4]. Furthermore, a Heisenberg-type antiferromagnet $MnPS_3$ also exhibits ordering down to 2 layers [5] with a weak dependence of the Néel temperature on the thickness [6].

Electrostatic Control of Magnetism in 2D $Cr_2Ge_2Te_6$ Goki Eda; National University of Singapore, Singapore

Electrical manipulation of spin in a magnetic material is a fundamental challenge for future spintronics. In this respect, recent discoveries of gate-tunable magnetism in ferromagnetic two-dimensional (2D) materials such as CrI_3 and Fe_3GeTe_2 demonstrate that they are an excellent platform for the study of interplay between charge and magnetic order. In this talk, we will discuss electrostatic control of $Cr_2Ge_2Te_6$ (CGT), a van der Waals ferromagnetic semiconductor, in an electric double-layer transistor (EDLT) geometry [1]. We show that degenerately electron-doped CGT exhibits peculiar magnetoresistance (MR) curves with pronounced hysteresis and abrupt switching features, which is characteristic of spontaneous magnetic order. Remarkably, the hysteresis persists up to 200 K, well above the Curie temperature of 61 K for pristine CGT, indicating enhancement of exchange energy by free carriers. Further, we find that the easy axis of the doping-induced ferromagnetic state lies in the 2D plane, in contrast to the out-of-plane easy axis of the pristine material. We will discuss the role of doping on the magnetic anisotropy and prospects for observing similar effects in other magnetic 2D materials.

Synthesis of Iron-Doped Monolayer MoS_2 Enabling Room Temperature Ferromagnetism Shichen Fu[1], Kyungnam Kang[1], Kamran Shayan[2,1,1], Anthony Yoshimura[3], Siamak Dadras[2], Siwei Chen[1], Lihua Zhang[4], Na Liu[1,1], A. Nick Vamivakas[2], Vincent Meunier[3], Stefan Strauf[1,1] and Eui-Hyeok Yang[1,1]; [1]Stevens Institute of Technology, United States; [2]University of Rochester, United States; [3]Rensselaer Polytechnic Institute, United States; [4]Brookhaven National Laboratory, United States

Inspired by the recent discovery of ferromagnetism in two-dimensional atomically thin layers, such as chromium triiodide (CrI_3)[1,2], chromium germanium telluride ($Cr_2Ge_2Te_6$)[3], and other van der Waals materials[4–6] has moved the emphasis of studies from bulk crystals to low-dimensional materials. Two-dimensional semiconductors, including transition metal dichalcogenides, are of interest in electronics and photonics but remain nonmagnetic in their intrinsic form. Previous efforts to form two-dimensional dilute magnetic semiconductors utilized extrinsic doping techniques[7], bulk crystal growth[8] or liquid precursor based chemical vapor deposition[9], detrimentally affecting uniformity, scalability, or Curie temperature (T_C).

Here, we demonstrate successful in situ substitutional doping of Fe atoms into MoS_2 monolayers via low-pressure chemical vapor deposition (LPCVD)[10]. We uncover an unambiguous Fe-related spectral feature in the luminescence of Fe:MoS_2 monolayers, which is stable up to room temperature. The origin of the Fe-related luminescence peak is further supported by results obtained from a density functional theory (DFT) calculation of dipole-allowed transitions. In addition, we find that monolayer Fe:MoS_2 displays ferromagnetism by probing the hysteresis in the magnetic circular dichroism (MCD) of the Fe-related emission. Moreover, by using nitrogen-vacancy center magnetometry and magnetization measurement using superconducting quantum interference devices (SQUID), we provide clear evidence for room temperature ferromagnetism in our synthesized Fe:MoS_2 monolayers and also quantitatively determine a 0.5 ± 0.1 mT local magnetic field.

5:55 AM F.EL04.09.05

The Influence of Global and Local Magnetic Fields on the Optical Properties of Lamellar Semiconductors Adam K. Budniak[1], Ellenor Geraffy[1], Esty Ritov[1], Faris Horani[1], Yaron Amouyal[1], Szymon J. Zelewski[2], Robert Kudrawiec[2] and Efrat Lifshitz[1]; [1]Technion-Israel Institute of Technology, Israel; [2]Wroclaw University of Science and Technology, Poland

Magnetism is a topic of a wide interest since the discoveries of motors/generators, through magneto-resistance and up to modern times, where low dimensional materials offer a support for new magnetic phenomena. The talk will focus on the influence of magnetic moments and magnetism on the optical magneto-properties of semiconductors in an ultimate two-dimensional limit found in van der Waals transition metal phosphorous tri-chalcogenides. A few types of magnetic properties will be discussed: the long-range magnetic order, ferromagnetism, anti-ferromagnetism or special spin textures; an interfacial developed Rashba spin-orbit effect; nuclear spin Overhauser effect; magnetic polaron, all gaining special stabilization by the size confinement and a shape anisotropy. The mentioned intrinsic fields lead to a lift of energy or momentum degeneracy at band-edge states with selective spin orientation in the ground or/and excited state, being of a special interest in emerging technologies of spin-electronics and quantum computation. The lecture will include the study of *long-range magnetic order and valley effects in single layer of metal phosphor tri-chalcogenide compounds*. Metal phosphor tri-chalcogenides with the general chemical formula MPX_3 (M=metal, X=chalcogenide) closely resembling the metal di-chalcogenides, but the metal being paramagnetic elements, while one-third of them are replaced by phosphor pairs. The metal ions within a single layer produce a ferromagnetic or anti-ferromagnetic arrangement, endowing those materials with unique magnetic and magneto-optical properties. Most recent magneto-optical measurements will be reported, exposing the existence of valley degree of freedom in a few MPX_3 (e.g., $FePS_3$, $MnPS_3$), that reveals a protection of the spin helicity of each valley however, the coupling to an anti-ferromagnetism lifts the valleys' energy degeneracy. The phenomenon was also examined in magnetically doped diamagnetic MPX_3 layers. The results indicated the occurrence of coupling between photo-generated carriers and magnetic impurities and the formation of magnetic polaron.

Late News: Air-Stable 2D Magnets Harvested from Iron-Rich Talc Minerals Aleksandar Matkovic[1], Kevin P. Gradwohl[1], Oleg E. Peil[2], Apoorva Sharma[3], Markus Kratzer[1], Jakob Genser[4], Evelin Fisslthaler[5], Daniel Knez[5], Christoph Gammer[6], Ferdinand Hofer[5], Alois Lugstein[4], Ronald Bakker[1], Johann Raith[1], Lorenz Romaner[2], Georgeta Salvan[3], Dietrich R. Zahn[3] and Christian Teichert[1]; [1]University of Leoben, Austria; [2]Materials Center Leoben, Austria; [3]Chemnitz University of Technology, Germany; [4]TU Wien, Austria; [5]Graz University of Technology, Austria; [6]Austrian Academey of Sciences, Austria

Since the first reports on intrinsically magnetic two-dimensional (2D) materials in 2017 [1,2], the price-to-pay for accessing their monolayers is the lack of ambient stability and that magnetic ordering persists only at cryogenic temperatures.
We discovered in a mineral aggregate – mainly composed of hematite, magnetite, and chalcopyrite – soft layers of which macroscopic flakes easily could be peeled off that stuck to a permanent magnet. Employing mechanical exfoliation, we succeeded in thinning and transferring micrometer sized – mainly hexagonally shaped – flakes to SiO_2 substrates. Energy-dispersive x-ray spectroscopy (EDS) revealed magnesium and silica as major components of the flakes. Raman spectroscopy indicated the presence of hydroxide groups, pointing towards talc, a hydrated magnesium phyllosilicate mineral. Long-term EDS and Raman revealed that in the flakes about 10 % of the Mg atoms are substituted by Fe. With atomic force microscopy, a minimum flake thickness of 1 nm was determined indicating cleavage down to a talc monolayer. Combined magnetic force microscopy and superconducting quantum interference device magnetometry measurements imply that Fe-rich talc exhibits superparamagnetic behavior in the explored Fe concentration range. As convincingly demonstrated by electron diffraction, the Fe-rich flakes are also showing long-term stability under ambient conditions in contrast to the 2D magnets reported so far.

Late News: Computational Prediction of Strong Anisotropy and Magnetostriction in Two-Dimensional Stoner Ferromagnet MnTe Biswas Rijal[1], Joshua T. Paul[2], Michael Ashton[3] and Richard G. Hennig[1]; [1]University of Florida, United States; [2]Argonne National Laboratory, United States; [3]Max-Planck-Gesellschaft, Germany

We identify through chemical substitutions and density-functional theory (DFT) calculations a family of 27 metastable single-layer transition metal monochalcogenides, MX (M = Mn, Co, Ni, Cu, Rh, Pd, Ag, Cd, Au; X = S, Se, Te), whose structures are based on the monolayer form of bulk layered CuTe. DFT calculations with the generalized-gradient PBE and hybrid HSE06 functionals of these 20 materials in four candidate 2D structures determine the thermodynamic stability and groundstate structure and characterize their electronic properties. We predict that the CuTe parent compound is indeed the

most stable structure of this family. Thirteen of these two-dimensional (2D) materials display sufficiently low formation energies to be stable as free-standing 2D materials and could be mechanically exfoliated from their bulk parent phases, while several more could be grown on substrates. All the stable 2D materials are metallic, and 2D MnTe, CoS, and CoSe are magnetic. We determine that MnTe exhibits a particularly large magnetocrystalline anisotropy, a preferred out-of-plane magnetization, and strong magnetostriction. These materials may be suitable for applications as metallic contacts and wires in nanoscale or magnetic layers in semiconductor and spintronics devices.

Topological and Quantum Phenomena in 2D Layered Materials Jeanie Lau; The Ohio State University, United States

As a material's thickness is reduced to a single or few atomic layers, the interplay of quantum confinement, electronic interactions and Berry's curvature endow it with properties that are often dramatically different from the bulk. A particularly striking aspect of these materials is the tunability – the carrier density, Coulomb interaction strength, spin orbit coupling, band gaps, effective mass, and band structure can be tuned by stacking, proximity, gating and twisting. New quantum collective phases, such as ferromagnetism, superconductivity, quantum Hall and quantum spin Hall insulators, with topologically non-trivial attributes, also emerge in the monolayer or few-layer limit. In this tutorial, I will introduce and review the latest development in two-dimensional materials as quantum materials, the unexpected emergent phases in these systems, experimental techniques to explore these phases, and their applications towards quantum information science.

9:00 AM BREAK

9:15 AM *
Challenges in the Growth and Fabrication to Topological Materials for Quantum Devices Anthony Richardella and Nitin Samarth; The Pennsylvania State University, United States

The discovery of topological phases in strongly spin orbit coupled materials has been accompanied by a broad range of predictions of exotic physics. Some, such as the quantum anomalous Hall effect (QAHE) in magnetically doped topological insulators, have been unambiguously demonstrated, while others like Majorana fermion excitations, have been far harder distinguish from more trivial phenomena. And new topological materials such as Dirac and Weyl semimetals have continued to broaden the range of materials in which novel quantum effects have been observed. In this tutorial, we will give a background to the range of topological phases and materials that have been identified and discuss the promise and challenges of using them for applications ranging from spin torque memory devices to topological quantum computing. Among these are the challenges of raising the observable temperatures of effects such as QAHE, common defects in the growth of van der Waals layered materials and heterostructures, and the prediction and identification of promising next generation materials.

10:30 AM *
"Straintronics" and "Twistronics"—New Paradigms for Tuning the Electronic Correlations in Two-Dimensional van de Waals Materials by Architected Nanostructures Nai-Chang Yeh; California Institute of Technology, United States

There has been a surge of research activities in the studies of two-dimensional (2D) crystals of van der Waals (vdW) materials and heterostructures because of their novel properties and great promises for technological applications. The physical properties 2D vdW materials are highly susceptible to their structural distortions and interlayer coupling, which opens up new opportunities to manipulate the electronic, magnetic and optical properties of these materials. In this tutorial, we will first review a new paradigm of *straintronics* that involves nanoscale strain engineering of 2D materials by means of architected nanostructures, which can either create desirable pseudo-magnetic fields in monolayer graphene for tunable electronic correlations, or modify the spatial distributions of energy gaps in monolayer semiconducting transition-metal

dichalcogenides (TMDs) for tunable excitonic lifetimes. We will also review the paradigm of *twistronics* that involves controlling the relative twist angle of different monolayers of 2D crystals to achieve Moiré potentials that can result in correlated electronic phases such as Mott insulator, superconductivity and ferromagnetism. Finally, we will describe realistic devices, with tunable electronic correlations based on the aforementioned paradigms, that manifest a range of intriguing quantum phenomena such as quantized Landau levels, quantum valley Hall effect and quantum anomalous Hall effect, all in the absence of external magnetic fields.

THz-Driven Irreversible Topological Phase Transition in Monolayer $MoTe_2$ Keith A. Nelson; Massachusetts Institute of Technology, United States

The availability of intense tabletop terahertz-frequency pulses and simple field-enhancement structures that enable peak electric fields of tens of MV/cm have ked to demonstrations of highly nonlinear THz-induced responses from a wide variety of materials. THz-driven electronic, magnetic, and structural phase transitions and domain switching have illustrated novel possibilities for control over collective properties and dynamics. In experiments on single-layer and few-layer $MoTe_2$, we have found that irradiation with just one sufficiently strong THz pulse induces an irreversible phase transition [1]. The initial, noncentrosymmetric 2H phase disappears, as shown by the disappearance of characteristic Raman lines and second harmonic generation. After further THz irradiation, the topological insulator phase appears, revealed by its distinct Raman spectrum. Single-shot measurements of the $MoTe_2$ evolution as a function of time after THz irradiation reveal complex dynamics over many-picosecond time scales. Theoretical calculations show that the transition is induced through THz-induced liberation of carriers which stabilize the new phase and reduce the energy barrier between the two phases. The result illustrates the prospects for THz control over complex multiphase landscapes in quantum materials.

Conformal, Area-Specific and Switchable Graphene Nanowrinkles Teri W. Odom; Northwestern University, United States

Selective patterning and functionalization of graphene can produce spatially-defined properties. Buckling or wrinkling of graphene on polymeric substrates enables a direct approach to tune the physical properties without lithographic steps, and the resulting curvature of the wrinkles can control local chemical reactivity. However, most buckling methods have been limited by the range of wavelength tunability, only global control of the wrinkled patterns, and delamination and cracks in the graphene. This talk will describe a scalable approach to achieve area-specific reactivity and patterning of conformal graphene wrinkles. We will discuss how a fluoropolymer layer sandwiched between graphene and different polymer substrates can facilitate crack-free and switchable graphene nanostructures. Such patterned areas with different curvatures show different reactivities based on a plasma fluorination reaction. Our approach for large-area, fine control over graphene wrinkle topographies has prospects for other two-dimensional electronic materials and optoelectronics and plasmonics applications.

6:18 PM *F.EL04.13/F.MT06.03.04
Quantum Anomalous Hall Effect in Intrinsic Magnetic Topological Insulator $MnBi_2Te_4$ Yuanbo Zhang; Fudan University, China

In a magnetic topological insulator, nontrivial band topology conspires with magnetic order to produce exotic states of matter that are best exemplified by quantum anomalous Hall (QAH) insulators and axion insulators. Up till now, such magnetic topological insulators are obtained by doping topological insulators with magnetic atoms. The random magnetic dopants, however, inevitably introduce disorders that hinder further exploration of topological quantum effects in the material. We resolve this dilemma by probing quantum transport in $MnBi_2Te_4$ thin flake—a topological insulator with intrinsic magnetic order. In this layered van der Waals crystal, the ferromagnetic layers couple anti-parallel to each other, so bulk $MnBi_2Te_4$ is an antiferromagnet. Atomically thin $MnBi_2Te_4$, however, becomes ferromagnetic when the sample has odd number of septuple layers (a septuple layer represents a single structural unit in the out-of-plane direction). We observe zero-field QAH effect in a five-septuple-layer specimen; an external magnetic field further enhance the QAH quantization by forcing all layers to align ferromagnetically. $MnBi_2Te_4$ therefore becomes the first intrinsic magnetic topological insulator exhibiting QAH effect.

11:31 AM *F.EL04..16.01
Enabling 2D Heterostructure Development with Atomic Resolution Imaging—Studies of Twist Reconstruction and Degradation Sarah J. Haigh, David Hopkinson, Nick Clark, Astrid Weston and Yichao Zou; University of Manchester, United Kingdom

2D materials and their heterostructures provide an exciting playground for pioneering science. In this talk I will demonstrate how atomic resolution scanning transmission electron microscopy (STEM) imaging and analysis is being used to support the advancement of these systems.

For example, I will discuss new results revealing the structural relaxation that occurs when two transition metal dichalcogenide (TMDC) monolayers are misoriented by a small twist (rotation angle). Many high profile experimental measurements of the exciting physics present in twisted TMDCs have necessarily neglected the potential for local structural relaxation. We have used atomic resolution STEM to reveal that TMDCs bilayers twisted to a small angle, less than ~3 degrees, reconstruct into energetically favourable stacking domains separated by a network of stacking faults, and that this behaviour is more complex than is observed in graphene [1]. For crystal alignments close to 3R stacking, we find that a tessellated pattern of mirror reflected triangular 3R domains while for alignments close to 2H stacking, stable 2H domains dominate, with nuclei of an earlier unnoticed metastable phase limited to ~ 5nm in size. This appears as a kagome-like pattern at twist angles less than 1 degree, transitioning to a hexagonal array of screw dislocations separating large-area 2H domains as the twist angle approaches 0 degrees. Tunneling spectroscopy measurements reveals that such reconstruction creates strong piezoelectric textures and pseudo-magnetic fields, opening new avenues for engineering of 2D material properties on the nanometre scale [1].

As the range of 2D materials increases rapidly, many of those with the most the promising magnetic or optoelectronic properties are found to be unstable in air or moisture, which makes fabrication challenging and hampers their use. Even relatively stable 2D crystals like MoSe2 and WSe2 are found to have perfect interfaces only when processed in an inert environment [2]. These materials can be stabilised to ambient conditions by encapsulating with stable 2D layers, such as graphene and hexagonal boron nitride. [3] For example, we have applied the encapsulation approach to study the presence and behaviour of point and extended defects in the 2D monochalcogenides, GaSe and InSe which are of interest due to their relatively high electron mobilities, strong second harmonic generation and quasi-direct bandgap when reduced to the monolayer limit.[4] Nonetheless the properties of InSe and GaSe crystals often degrade on exposure to air, light, and/or moisture, thought to be the result of oxidation induced defects. We have used atomic resolution STEM together with electron energy loss spectroscopy (EELS) and energy dispersive X-ray spectroscopy to characterise individual point and extended

defects in InSe and GaSe [5]. We observe that both materials contain multiple point and extended defects, even when exfoliated in argon and encapsulated in graphene. Point vacancies are observed to be healable under the electron beam, while extended defects and stacking faults have symmetries not found in bulk samples and which could be used to tune the properties of 2D post-transition-metal monochalcogenide materials for optoelectronic applications. We also demonstrate the nanopatterning of black phosphous using electron beam lithography via etching protocols developed in the STEM [6], and recent work revealing oxidation induce improvement of superconductivity in few layer TaS2 [7].

Twistronic Structures and Moire Superlattices in Homo- & Heterobilayers of Transition Metal Dichalcogenides Vladimir Falko; University of Manchester, United Kingdom

We apply a multiscale modelling approach to study moiré superlattice in twisted homo- and heterobilayers of transition metal dichalcogenides (TMD), taking into account the interlayer hybridisation of the electronic orbital and lattice reconstruction due to stacking-dependent adhesion. First of all, we develop DFT-parametrized interpolation formulae for interlayer adhesion energies of $MoSe_2$, WSe_2, MoS_2, and WS_2 with both parallel and antiparallel orientation of their unit cells and arbitrary offset of the honeycomb lattices in the adjacent layers. Then, we combine those interpolation formulae with elasticity theory and analyze the bilayer lattice relaxation into mesoscale domain structures. We find that 3R and 2H stacking domains develop for, respectively, bilayers with parallel (P) and antiparallel (AP) orientation of the monolayer unit cells, separated by a network of dislocations, for twist angles $\theta < \theta_P \sim 2.5$ and $\theta < \theta_{AP} \sim 1$. Such lattice reconstruction has been verified by STEM imaging. We also show that the triangular domain structures of P-oriented homobilayers would manifest itself in local tunnelling characteristics of marginally twisted. For AP bilayer, we show that the deformation of the lattices around domain walls (which resemble twist dislocations oriented along the planes of in bulk 2H crystals) generate piezo-electric charges, reaching local density up to $\pm 0.5 \times 10^{12} e/cm^2$ at the junctions of the honeycomb domain wall network. Finally, we use DFT modelling of bandstructure of bilayers with various stacking configurations and interlayer distances to develop and parametrise interpolation formulae for the interlayer hoping between the layers for the relevant parts of the Brillouin zone, and, then, establish the electronic structure of the bilayeracross the moire supercell, taking into account the piezolectric potentials.

Surface and Strain Control of 2D Materials—From Fundamental Properties to Nanomanufacturing Joel W. Ager[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

In the monolayer limit transition metal dichalcogenides (TMDs) such as MoS_2 and WS_2 have direct bandgaps, leading to significant interest in the use of these materials for opto-electronic applications. Their internal photoluminescence (PL) quantum efficiency (QE) is a sensitive measure of their quality. While some III-V thin films and II-VI quantum dot structures can achieve near-unity values of this metric, most semiconductor materials have QEs which are much smaller. We have discovered that treatment of sulfur-based TMDs with an organic superacid dissolved in a non-polar solvent suppresses non-radiative recombination at low pump powers, leading to near 100% QE. [1]. Similar, near-unity, QE values can be achieved via electrostatic gating by lowering the Fermi level to near mid-gap to suppress the formation of non-radiative trions [2]. Tuning of band parameters with strain is a common motif in semiconductor devices. Chemical vapor deposition of some monolayer TMDs on thermal expansion coefficient mismatched substrates can induce strains on the order of 1%, in spite of the weak van der Waals interaction [3]. Larger strains can be envisioned: Au grows epitaxially on MoS_2 with a predicted mismatch strain of 10% [4]. Further, the strain is predicted to be confined to the monolayer in contact with the Au, while other layers in the structure remain unstrained. This effect weakens the bonding between the top layer and the bulk [5], which enables exfoliation of large areas of monolayer material with defined patterns [6,7]. Further optimization of this nano-manufacturing process has improved the yield to nearly 50% and has led to the ability to form defined TMD heterostructures [8].

Interplay Between Intra- and Inter-Layer Interactions in Stacked Two-Dimensional Crystals Young-Woo Son; Korea Institution for Advanced Study, Korea (the Republic of)

Interlayer interactions in stacked 2D crystals are one of key ingredients in exhibiting their qualitative distinct physical properties, differing from their single layer physics [1]. For example, a well-known 2D quantum spin Hall insulating transition metal dichalcogenide (TMDC) can show either topological Weyl metallic phase or trivial one depending on a minute stacking order difference [1,2]. Recent advances in fabricating stacked 2D crystals enable us to perform controlled studies on interesting electronic, magnetic and topological properties in low dimensional heterostructures. In this talk, I will first discuss interplay between intralayer correlation, interlayer interaction, and magnetism in layered materials [3-5]. To understand magnetic properties, I will introduce a new computationally efficient method to calculate various correlation effects in layered materials [3]. Another interesting examples revealing intriguing interlayer interactions will be discussed for graphene bilayer systems [6,7] and TMDCs [8]. For a graphene bilayer system with a rotation angle of 30 degrees, it is shown that a quasicrystalline order through a perfect incommensurate interlayer interaction shows localized 12 fold resonant states with fractal scaling [6]. For a bilayer MoS2 system, I will demonstrate a intrinsic coupling between strain and shear in the system that can alter its low energy Raman modes, thereby providing a way to obtain its almost all fundamental mechanical constants through light-matter interactions.

Imaging Carrier Inhomogeneities in Active 2D Material Devices Samuel Berweger; National Institute of Standards and Technology, United States

Scanning microwave microscopy (SMM, often called scanning microwave impedance microscopy, sMIM) is a scanning probe implementation that can directly probe free carriers with nanometer spatial resolution using tip-localized GHz fields. With the subsurface sensitivity inherent to near-field techniques and the ability to measure electrically isolated systems, SMM is well-suited for studying electronic inhomogeneities in 2D semiconducting materials and their devices. We begin by highlighting SMM measurements of photogenerated free carriers in transition metal dichalcogenide lateral heterostructures.

We then focus on the application of SMM to studying ambipolar field effect transistors of 2D films of the 1D van der Waals material tellurium (tellurene). Tellurene can be solution processed, exhibits high bipolar mobilities, and is stable under ambient conditions, which makes it an attractive alternative to conventional 2D semiconductors. We combine SMM with a differential implementation to image spatial variations in conductivity as well as the associated carrier type as a function of

the applied backgate voltage in tellurene devices. We reveal spatial inhomogeneities in carrier type and conductivity and show that the measured backgate-dependent device conduction minimum in fact arises from the simultaneous coexistence of n-type and p-type regions in an overall minimum conductivity configuration. We further show that the spatial inhomogeneities in conductivity and carrier type in four-terminal devices results in differing transport characteristics between different terminals across the same device in well-defined backgate-controlled p-type and n-type conduction channels. While these results highlight the challenges facing the reproducible fabrication of 2D material devices, the possibilities of solution-based doping and deterministic weighting of multiple inputs into the same device hold future promise.

1:11 PM *F.EL04.12.01
What Governs the "Efficiency" of Liquid Phase Exfoliation of Layered Crystals? Claudia Backes; Heidelberg University, Germany

Liquid phase exfoliation has become an important top down production technique giving access to large quantities of nanosheets in colloidal dispersion. Importantly, this is a highly versatile technique that can be applied to numerous layered materials from graphite to transition metal dichalcogenides, h-BN, III-VI semiconductors, hydroxides etc. All materials can be exfoliated in a similar way using aqueous surfactant or suitable solvents as stabilisers. Nanosheets in dispersion are extremely polydisperse with broad lateral size and thickness distributions. To narrow size and thickness distributions, liquid cascade centrifugation has proven to be a powerful tool for efficient size selection yielding nanosheet dispersions with well-defined dimensions.
Building on these established methodologies of exfoliation and size selection, it became possible in recent years to adress some fundamental questions regarding the exfoliation process, such as: In which way is the yield, nanosheet size and layer number dependent on the liquid medium? What is a good descriptor for the exfoliation efficiency and what does it depend on? What is the role of defects? In this talk, these fundamental questions will be addressed and a picture of the current understanding will be drawn.

8:01 AM *F.EL04.09.02
Optical Spectroscopy of Antiferromagnetic Two-Dimensional Materials Hyeonsik Cheong; Sogang University, Korea (the Republic of)

Two-dimensional magnetic van der Waals materials have attracted much interest recently. Magnetism in low dimensional systems is an interesting topic for the fundamental physics, and atomically thin magnetic materials are promising candidates for novel spintronic devices. Antiferromagnetic 2-dimensional materials are particularly interesting both for fundamental physics and also for antiferromagnetism-based spintronic devices. However, traditional research tools such as neutron scattering to probe antiferromagnetic ordering cannot be employed for atomically thin materials due to the small sample volume. Although magneto-optical Kerr effect measurements can be used to monitor the magnetic ordering in ferromagnetic materials, the lack of net magnetization precludes the use of the Kerr effect in probing antiferromagnetic ordering. Optical spectroscopy is becoming increasingly important for the study of antiferromagnetic 2-dimensional materials. Raman spectroscopy, for example, has been established as an invaluable tool to probe the magnetic transition in antiferromagnetic van der Waals materials as it has been found that the magnetic ordering can be reliably monitored by Raman spectroscopy [1]. Furthermore, recent spectroscopic studies revealed a novel coherent state in some of these materials stabilized by the antiferromagnetic ordering. In this presentation, I will review recent achievements in the study of antiferromagnetism in 2 dimensions using optical spectroscopy. $FePS_3$ exhibits an Ising-type antiferromagnetic ordering down to the monolayer limit, in good agreement with the Onsager solution for a 2-dimensional order-disorder transition [2]. The transition temperature remains almost independent of the thickness from bulk to the monolayer limit, indicating that the weak interlayer interaction has little effect on the antiferromagnetic ordering. On the other hand, $NiPS_3$, which shows an XXZ-type antiferromagnetic ordering in bulk, exhibits antiferromagnetic ordering down to 2 layers with a slight decrease in the transition temperature, but the magnetic ordering is suppressed in the monolayer limit [3]. Furthermore, an almost resolution-limited, sharp optical

transition was observed in photoluminescence and optical absorption measurements on $NiPS_3$, which is interpreted as being due to a novel excitonic state coupled with the antiferromagnetic ordering [4]. Furthermore, a Heisenberg-type antiferromagnet $MnPS_3$ also exhibits ordering down to 2 layers [5] with a weak dependence of the Néel temperature on the thickness [6].

Distinct Magneto-Raman Signatures of Spin-Flip Phase Transitions in CrI_3 Amber McCreary[1], Thuc Mai[1], Franz Utermohlen[2], Jeffrey Simpson[1,3], Kevin Garrity[1], Xiaozhou Feng[2], Dmitry Shcherbakov[2], Yanglin Zhu[4], Jin Hu[5], Daniel Weber[2], Kenji Watanabe[6], Takashi Tanigochi[6], Joshua Goldberger[2], Zhiqiang Mao[4], Jeanie Lau[2], Yuanming Lu[2], Nandini Trivedi[2], Rolando Valdes Aguilar[2] and Angela Hight Walker[1]; [1]National Institute of Standards and Technology, United States; [2]The Ohio State University, United States; [3]Towson University, United States; [4]The Pennsylvania State University, United States; [5]University of Arkansas–Fayetteville, United States; [6]National Institute for Materials Science, Japan

The discovery of 2-dimensional (2D) materials, such as CrI3, that retain magnetic ordering at monolayer thickness has resulted in a surge of both pure and applied research in 2D magnetism. In this talk, I will detail our magneto-Raman spectroscopy study on multilayered CrI3, focusing on two additional features in the spectra that appear below the magnetic ordering temperature and were previously assigned to high frequency magnons. Instead, we conclude these modes are actually zone-folded phonons. We observe a striking evolution of the Raman spectra with increasing magnetic field applied perpendicular to the atomic layers in which clear, sudden changes in intensities of the modes and their polarization dependence are attributed to the interlayer ordering changing from antiferromagnetic to ferromagnetic at a critical magnetic field. Our work highlights the sensitivity of the Raman modes to weak interlayer spin ordering in CrI3.

Monolayer Half-van der Waals Heavy Metals Enabled by Confinement Heteroepitaxy Alexander Vera[1], Siavash Rajabpour[1], Timothy Bowen[1], Boyang Zheng[1], Wilson Yanez Parreno[1], Hesham El-Sherif[2], Chaoxing Liu[1], Nabil M. Bassim[2], Nitin Samarth[1], Vincent Crespi[1] and Joshua Robinson[1]; [1]The Pennsylvania State University, United States; [2]McMaster University, Canada

Due to relativistic effects, heavy metals (Pb, Bi, etc.) demonstrate strong spin orbit coupling (SOC) effects, making them promising elemental precursors to broken spin degeneracy and non-trivial topology. Atomically thin heavy metal layers exhibit large Rashba effects, translating to large spin Hall angles suitable for spin pumping, memory, and other spintronic applications. Atomically thin lead (Pb) in particular may support superconductivity along with non-trivial topology, potentially serving as a route to exotic superconducting states. However, typical synthesis techniques do not provide a platform for scalable, stackable, and air-stable 2D metals, necessary for *ex-situ* device work. To answer this challenge, we demonstrate the synthesis of an air-stable 1ML-Pb with strong (~500meV) spin splitting within a graphene/silicon-carbide interface through confinement heteroepitaxy. We expect this material to exhibit a large spin Hall angle suitable for spintronic applications.

Electrostatic Control of Magnetism in 2D $Cr_2Ge_2Te_6$ Goki Eda; National University of Singapore, Singapore

Electrical manipulation of spin in a magnetic material is a fundamental challenge for future spintronics. In this respect, recent discoveries of gate-tunable magnetism in ferromagnetic two-dimensional (2D) materials such as CrI_3 and Fe_3GeTe_2 demonstrate that they are an excellent platform for the study of interplay between charge and magnetic order. In this talk, we will discuss electrostatic control of $Cr_2Ge_2Te_6$ (CGT), a van der Waals ferromagnetic semiconductor, in an electric double-layer transistor (EDLT) geometry [1]. We show that degenerately electron-doped CGT exhibits peculiar magnetoresistance (MR) curves with pronounced hysteresis and abrupt switching features, which is characteristic of

spontaneous magnetic order. Remarkably, the hysteresis persists up to 200 K, well above the Curie temperature of 61 K for pristine CGT, indicating enhancement of exchange energy by free carriers. Further, we find that the easy axis of the doping-induced ferromagnetic state lies in the 2D plane, in contrast to the out-of-plane easy axis of the pristine material. We will discuss the role of doping on the magnetic anisotropy and prospects for observing similar effects in other magnetic 2D materials.

Large-Area Growth of 2D Layered Materials—Chalcogenides, Oxides and Halides Kibum Kang; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The 2D layered materials are the potential components in next-generation semiconductor devices and quantum devices. For the integration of 2D layered materials into such functional devices, it is necessary to develop a high-quality large-area growth process.
In this talk, I will introduce the MOCVD growth of 2D layered materials, including transition metal dichalcogenides, metal oxides, and metal halides. Furthermore, I will discuss the MOCVD grown 2D layered materials and their heterostructures that could potentially be utilized in a single-photon source for quantum devices.

9:41 AM *F.EL04.14.11
Electronics with Nobel Metal Dichalcogenides Applications Georg Düsberg; Universität der Bundeswehr München, Germany

Two-dimensional materials such as transition metal dichalcogenides (TMDs) are intensively investigated because of their potential applications in future electronics. So far mainly group six (Mo/W) TMDs have been investigated, which show thickness depend electronic and optical properties. Metal-to-semiconductor transitions, high mobilities, and high potential for various sensing applications, now raised interest to the group 10 (Pt/Pd) TMDs or Nobel Metal Dichalcogenides (NMDs).
In this presentation, the low temperature synthesis of various TMDs by thermally assisted conversion (TAC) is presented. [1] The composition and morphology of the resulting large-scale layers are investigated by a multitude of characterization techniques including Raman spectroscopy, [2] AFM and X-ray photoelectron spectroscopy (XPS). In particular, the low temperature TAC synthesis PtSe2 potentially allows back end of line (BEOL) integration compatible with silicon technology. The effects of growth on the underlying substrates or investigated by TOF-SIMS and transmission electron microscopy. Further, as pre-pattered structures can be grown by the TAC, which allows to fabricate electronic devices using standard micro-fabrication technology. [3] PtSe2 has shown potential for a range of novel electronics devices. Examples for high performance chemical sensors, [1] IR-photodetectors[4] and MEMS[5] devices based on PtSe2 will be presented.

Tailoring 2D Chalcogenide Interfaces for Heterostructure Growth and Device Optimization Lincoln J. Lauhon; Northwestern University, United States

Understanding and control of surfaces and interfaces is necessary to exploit the potential of 2D metal chalcogenides in electronics and optical devices. The ubiquity and scalability of vapor-phase processing in particular provides a wealth of opportunities, from the growth of van der Waals heterostructures to the chemical tailoring of interfaces to optimize device performance, including devices made from "composite" 2D materials such as those printed from inks. This talk will describe research to leverage interfaces for devices via two routes: atomic layer deposition (ALD) of metal oxides to modify dichalcogenide properties and pulsed chemical vapor deposition of ferroelectric monochalcogenides. In prior work, tuning of ALD oxide stoichiometry was shown to tune the Fermi level of MoS_2. [1] More recently, in situ monitoring of MoS_2 and $MoSe_2$ transistor performance during deposition of an oxide dielectric enabled the disentangling of changes in carrier concentration and mobility during the alternating dosing of the metal-organic precursor and oxidant.[2] Intriguingly, we find a substantial enhancement in field effect mobility with sub-monolayer coverage. Variable temperature transport measurements indicate that charged impurity scattering is reduced by screening even prior to formation of a complete dielectric, pointing to the importance of seeding conditions in maximizing mobility. Vapor deposition processes also provide scalable routes to van der Waals heterostructures whose properties can be engineered by band-offsets and dimensionality. Building on prior work demonstrating low-temperature epitaxy of SnS on MoS_2[3], a range of processing conditions were explored to understand how SnS film morphology is influenced by substrates including amorphous SiO_2, mica, MoS_2, and hexagonal boron nitride (hBN). Control over film thickness and morphology is particularly important to harness the in-plane ferroelectricity of SnS for devices. Large area monolayer regions are readily achieved on MoS_2 substrates by targeting temperatures and purge times that enhance selective growth at edges. Due to the relative inertness of the vdW surface of hBN, modified surface preparation and pulsing schemes are necessary to favor lateral growth of SnS, and monolayers growth is more challenging. However, isolated islands of epitaxial SnS on hBN are relatively easy to achieve, providing a path towards highly scaled memristive devices based on ferroelectric switching.

Lithium-Ion Electrolytic Substrates—TMD Growth and 1V High-Performance Transistors and Amplifiers Md. Hasibul Alam and Deji Akinwande; The University of Texas at Austin, United States

This talk will present our latest progress on materials, transistor and memory devices based on 2D atomically-thin films. In particular, we explore a new substrate, namely, solid lithium-ion electrolytic substrates, for the direct growth and realization of high-performance TMD devices and amplifiers. Electrostatic gating with ionic liquids (ILs), leading to the accumulation of high surface charge carrier densities, has been often exploited in thin-film transistors. However, the intrinsic liquid nature of ILs inhibit it from constituting an ideal platform. In this regard, a lithium-ion solid electrolyte, often used for battery applications, offers similar advantages as ionic-liquids, with the added benefit of solid-state compatibility. With the solid electrolyte, we demonstrate its application in high-performance n-type MoS2 and p-type WSe2 transistors with sub-threshold values approaching the ideal limit of 60 mV/dec and complementary inverter amplifier gain of 34, the highest among comparable amplifiers with a 1 V power supply. These results establish lithium-ion substrates as a promising alternative to ionic liquids for the study of thin-film devices.

4:41 PM *F.EL04.03.01
Probing Two-Dimensional Materials Using Focused Angle-Resolved Photoemission Spectroscopy Jyoti Katoch; Carnegie Mellon University, United States

Two-dimensional (2D) materials offer the freedom to create novel condensed matter systems, with unique properties, by mechanically assembling different (or same) 2D materials layer-by-layer to form atomically sharp vertical or lateral heterostructures. The van der Waals (vdW) heterostructures with small lattice mismatch and a relatively small twist angle between the constituent layers, have shown to exhibit coexisting complex phases of matter including Mott insulating state, superconductivity, bound quasiparticles, and topological states. In addition, the extreme surface sensitivity of two-dimensional (2D) materials provides an unprecedented opportunity to engineer the physical properties of these materials using external perturbations. In this talk, I will discuss the utilization of angle-resolved photoemission spectroscopy (ARPES) with high spatial resolution to investigate the electronic band structure of 2D heterostructures and their devices. This can shed light on the intricate relationship between controlled external perturbations, substrate, and electronic properties of 2D materials [1, 2]. In particular, I will discuss our *in-operando* nanoARPES results that exhibit highly tunable many-body effects in graphene devices [3] and tunable van Hove singularities in twisted bilayer graphene [4].

"Valley Noise" and Rydberg Excitons in Monolayer Semiconductors—Insights from (Really) High Magnetic Fields Scott Crooker; National High Magnetic Field Lab, United States

Much of the current interest in atomically-thin transition metal dichalcogenide (TMD) semiconductors such as MoS_2 and WSe_2 is driven by the physics of coupled spin & valley degrees of freedom and the potential for new spin- and valley-based devices. This talk will discuss recent optical studies that probe the valley-related physics of electrons, holes, and excitons in monolayer TMD semiconductors.

In a first study [1,2], we measure the polarized magneto-absorption spectra of high-quality exfoliated TMD monolayers in very large magnetic fields to 91 tesla, which allows to follow the diamagnetic shifts of not only the 1*s* ground state of the neutral exciton but also its excited 2*s*, 3*s*, ..., *ns* Rydberg states. The energies and diamagnetic shifts provide a direct determination of the effective (reduced) exciton masses and also the dielectric properties of these monolayer semiconductors – fundamental material parameters that until now were available only from theoretical calculations. Moreover, we also measure other important material properties, including exciton binding energies, exciton radii, and free-particle bandgaps. These results provide essential and quantitative parameters for the rational design of opto-electronic van der Waals heterostructures incorporating 2D semiconductor monolayers.

In a second study, we introduce an entirely passive, noise-based approach for exploring intrinsic valley dynamics in monolayer TMD semiconductors [3]. Under conditions of strict thermal equilibrium, we use optical Faraday rotation to "listen" to the thermodynamic fluctuations of the valley polarization in a Fermi sea of resident electrons or holes, due to their spontaneous scattering between the *K* and *K'*. Frequency spectra of this valley noise reveal narrow Lorentzian lineshapes and therefore very long intrinsic valley relaxation, especially for holes (~microseconds). These results provide quantitative measurements of intrinsic valley dynamics, free from any external perturbation, pumping, or excitation.

Isotropic and Anisotropic Polaritons in van der Waals Materials Qiaoliang Bao and Qingdong Ou; Monash University, Australia

Polaritons, hybrid light-matter excitations, enable nanoscale control of light. Particularly large polariton field confinement and long lifetimes can be found in graphene and van der Waals materials, opening new avenues for low-loss photonic applications. Here, we present our recent progress in the discovery on engineering of these nanoscale polaritons in 2D materials [1,2]. First, plasmon polaritons arising from graphene and topological insulators were investigated in graphene/Bi_2Te_3, topological insulator Bi_2Te_3, graphene nanoribbon and 3D graphene using either spectroscopic or real space imaging techniques [3-6]. We show how the plasmonic coupling happens in two Dirac materials, how high-order plasmonic modes are observed in 3D graphene structure, how multiple plasmonic modes at sub-wavelength are achieved in graphene nanoribbon and how edge chirality controls the plasmonic shift.
We would also like to highlight our progress on the observation of anisotropic and ultra-low-loss polariton propagation along the surface of natural vdW material α-MoO_3 [7]. We visualized and verified phonon polaritons with elliptic and hyperbolic in-plane dispersion, which have been theoretically predicted but never experimentally observed in natural materials before. To better utilize the low-loss directional polaritons, we developed a chemical intercalation method to reversibly control and switch the phonon polaritons while maintaining their long lifetimes [8]. Combined with photolithography, spatially controlled polariton switching was achieved with various in-plane heterostructure configurations and patterns. Most recently, we show

how the hyperbolic polaritons in α-MoO_3 thin slabs were delicately manipulated by controlling the interlayer twist angle [9]. We experimentally observed tunable topological transitions from open (hyperbolic) to closed (elliptical) dispersion contours in twisted α-MoO_3 bilayers at a photonic magic twist angle. The theoretical analysis showed these transitions of in-plane hyperbolic polaritons are controlled by a topological quantity. At the transitions, the photonic dispersion of the resulting topological polaritons flattens, exhibiting low-loss tunable polariton canalization and diffractionless propagation.
In summary, biaxial van der Waals semiconductors like α-MoO_3[7, 9] and V_2O_5[10] represent an emerging family of material supporting exotic polaritonic behaviors and these natural-born hyperbolic materials offer an unprecedented platform for controlling the flow of energy at the nanoscale.

Nanophotonics with Low-Dimensional Excitonic Materials Deep M. Jariwala; University of Pennsylvania, United States

The isolation of a growing number of two-dimensional (2D) materials has inspired worldwide efforts to study their fundamental physical properties and integrate distinct 2D materials into van der Waals (vdW) heterostructures.[1-2] While the few atoms thick structure of 2D semiconductors naturally makes their electronic structure quantum confined, it also has profound implications on their optical properties.[3-4] Further being 2D in nature it also presents opportunities for engineering them into 0D and 1D quantum confined structures.[5] My talk will discuss our group's more recent work on optical phenomena and photonic devices made from 2D semiconductors. I will present how 1D nanostructuring of excitonic 2D semiconductors into nanophotonic dielectric gratings can enable exploration of new regimes of light-matter confinement including formation of hybrid exciton-plasmon-polariton states.[6] I will extend this discussion of light-matter interaction to excitonic/dielectric superlattices which are scalable over large areas. I will extend this concept to other excitonic materials and show dynamic tunability of their optical properties. If time permits, I will also discuss new approaches and methods for nanostructuring 2D semiconductors down to ~5 nm lateral dimensions with superior control of crystallinity and structure.[7] I will conclude by giving a broad perspective on future prospects of 2D materials from fundamental science to applications.

F-EL04

5:00 AM F.EL04.01.01
Two-Dimensional Gadolinium Oxide Nanoplates as T_1 MRI Contrast Agents Jake Villanova[1], Nasim Taheri[2], Gary Stinnett[3], Arash Bohloul[2], Xiaoting Guo[1], Edward Esposito[1], Zhen Xiao[1], Deanna Stueber[1], Carolina Avendano[2], Paolo Decuzzi[4,5], Robia Pautler[3] and Vicki L. Colvin[1]; [1]Brown University, United States; [2]Rice University, United States; [3]Baylor College of Medicine, United States; [4]The Methodist Research Institute, United States; [5]Instituto Italiano di Tecnologia, Italy

Gadolinium-containing nanocrystals as T_1 MRI contrast agents (CA) offer the potential for intracellular accumulation, active targeting, and clearance pathways that avoid the kidneys. However, the most efficient T_1 relaxation mechanism requires that water protons come within a few angstroms of surface Gd^{3+}, a difficult condition to meet as these surfaces are necessarily covered with polymers that prevent aggregation in biological environments. This problem is resolved with two-dimensional Gd_2O_3 nanoplates (GONP) which, due to their shape, possess accessible edge Gd^{3+} for inner-sphere water interactions. A novel sulfonated surface coating further contributes to water-surface exchange and second-sphere interactions while also providing colloidal stability over a wide range of conditions. At clinically relevant field strengths (≥ 1.4 T), these nanoplates exhibit ionic T_1 relaxivities an order of magnitude greater (r_1 = 63.0 mM-$Gd^{-1}s^{-1}$ at 1.4 T) than commercial gadolinium-

chelates and significant performance even at 9.4 T (r_1 = 32.6 mM-$Gd^{-1}s^{-1}$). Systematic size and magnetic field dependence studies suggest while inner-sphere relaxation processes at nanoplate edges contribute to r_1, second-sphere interactions are also important and become more significant at higher fields. Nanoplates are readily taken into cells where they maintain contrast performance and exhibit minimal cytotoxicity. *In vivo*, nanoplates preferentially accumulate in the liver and their circulation half-life is 1.5 times faster than commercial gadolinium-chelates. These features allow for the novel demonstration that nanoscale T_1 MRI contrast agents can be applied to detect non-alcoholic fatty liver disease (NAFLD) in mice.

5:10 AM F.EL04.01.02
Bio-Imaging with Photoluminescence of Single-Layer MoS_2 Transistor Yuhei Hayamizu, Takakazu Seki and Sakaya Tezuka; Tokyo Institute of Technology, Japan

Visualizing biological activity in real time poses a novel way for biosensing. Single-layer Molybdenum disulfide (MoS_2) shows strong photoluminescence (PL) under photo-excitation due to its direct bandgap property [1]. The PL intensity of MoS_2 transistors has been demonstrated to change with the internal electron density by applying a back-gate voltage [2]. It has also been reported that the PL intensity of mechanically exfoliated MoS_2 was modulated by pH changes in aqueous solution [3]. In this work, we demonstrate pH-sensitive photoluminescence of single-layer MoS_2 grown by chemical vapor deposition (CVD). While CVD MoS_2 grown from MoS_2 powder did not have a strong pH sensitivity, MoS_2 grown from MoO_2 powder exhibited a sensitivity to the solution pH in its PL intensity [4]. Next, we utilized the single-layer MoS_2 as the active layer of an imaging sensor to monitor the activity of individual bacteria by the MoS_2 PL. For the demonstration, we employed Lactobacillus. It is one of the most studied probiotic bacteria which consumes glucose and produces lactic acid by fermentation. The bacteria were placed on a single-layer MoS_2 and its PL intensity was monitored in real time. Experiments were performed in the following ways. For device fabrication, CVD MoS_2 grown on a Si substrate was transferred onto a cover glass with patterned gold micro-electrodes. An electrolyte solution was place on the MoS_2 with electrode. A reference electrode was also inserted into the solution to apply a voltage between the MoS_2 and the reference electrode. Using these three electrodes, the MoS_2 acted as an electrochemical transistor. The PL image was observed through the cover glass by an inverse microscope with an oil immersion lens under a controlled voltage of the reference electrode. The PL intensity of the MoS_2 transistor was modulated by the applied voltage from the reference electrode in the buffer solution. As decreasing the voltage at the reference electrode, the PL intensity was appeared at a threshold voltage and increased monotonically. We observed that the threshold voltage changed depending on the concentration of lactic acid in the bulk solution. Next, we placed a solution of Lactobacillus rhamnosus GG (LGG) onto MoS_2. We found that LGG specifically adhered onto MoS_2 rather than glass substrate. PL images of MoS_2 with LGG showed a pattern that correlates with LGG adhesion. The contrast of the PL images was tuned via the applied voltage. Furthermore, PL intensity at the vicinity of the adhered LGG changed over time, which is probably due to a change of lactic acid concentration. We assume that the local pH change caused by the lactic acid possibly modulated the carrier density in MoS_2. In this work, we demonstrated that PL imaging of MoS_2 has the potential to visualize activity of living individual bacteria label-freely [5].

Atomically-Thin Sensing Surfaces from 2D Materials for Detecting Cellular Gaps Volodymyr Koman, Xun Gong, Naveed Bakh and Michael Strano; Massachusetts Institute of Technology, United States

Cellular layers play critical role as barriers, filters, and membranes in our bodies. The performance of cellular layers is found to be determined by the properties of individual cellular gaps. Yet these gaps often fall below the diffraction limit, hampering their detection. Here, we develop a novel sensing modality, where the diffusion of a harmless chemical tracer is used to reveal cellular gaps in human umbilical vein endothelial cellular (HUVEC) layers. For the readout, we employ atomically-thin and optically-active MoS2, whose two-dimensional form-factor enables it to serve as an array of 20,164 wireless sensors over 420×420 μm^2 area. A rigorous screening of 30 analytes identifies several tracer candidates with MoS2 dynamic range spanning over five orders of magnitude in tracer concentration. In a single layer of HUVEC cells, we find local spots with diffusivities ranging from 1×10^{-9}-3×10^{-8} cm^2/s that are spatially correlated with immunofluorescence of vascular endothelial (VE)-cadherin proteins found on cell membrane. These spots correspond to breaks in nanoscale cellular junctions with <40 nm in length. This platform enables future studies on properties and dynamics of cellular gaps of various tissues.

5:30 AM F.EL04.01.05
MXene Nanopores with In-Plane Cation Reservoir for High-Resolution Biomolecular Sensing Mehrnaz Mojtabavi[1], Armin VahidMohammadi[2], Wentao Liang[3] and Meni Wanunu[1]; [1]Northeastern University, United States; [2]University of Connecticut, United States; [3]Kostas Advanced Nano-Characterization Facility, United States

Nanopore biosensing technology has been developed over the past two decades as a label-free, single-molecule sensing platform of biopolymers (DNA, RNA, and proteins). In this technology, a nanometer-sized pore, either a naturally-occurring biological channel self-assembled in an organic membrane (biological nanopore) or a synthetically-fabricated channel in a solid-state membrane (solid-state nanopore), is the only liquid junction between two buffer bath chambers. A charged biopolymer, such as DNA, is then threaded through the nanopore by applying a voltage across the nanopore, resulting in partial physical obstruction of the pore detected as a transient drop in the ionic current. This event is used to electrically and/or optically probe structural features of the DNA or determining its nucleic acid sequence. A key feature in this technology is the geometry of the nanopore (diameter and thickness in solid-state nanopores) that defines the total sensing resolution. For instance, two geometric requirements for DNA sequencing are a pore with comparable geometry to the width of a single strand of DNA (~1 nm in diameter), and a pore thickness of 0.5 nm (distance between bases on a DNA strand) to provide single base resolution. The one-atom-thick monolayer graphene with a thickness of 0.3 nm has been a candidate for this application since it was first introduced in 2010[1]. However, despite the atomically-thin pore, a phenomenon known as "access resistance" still dominates, producing a sensing region longer than the physical pore thickness and reducing the resolution[2]. Moreover, other challenges associated with graphene nanopores such as surface hydrophobicity and poor mechanical stability have phased out its application in nanopore technology.
Recently, we have demonstrated that "MXene nanopores" with high mechanical robustness, long-time stability, and low-noise ion current recordings could serve as an alternative to graphene[3]. MXenes are an emerging family of two-dimensional transition metal carbides and nitrides with a general formula of $M_{n+1}X_nT_x$ (i.e. $Ti_3C_2T_x$), where M is a transition metal, X represents carbon or nitrogen (n=1, 2, and 3), and T_x indicates different functional groups (O, OH, F) present on MXene surface. An intriguing property of MXenes is the ability to accommodate various kinds of organic molecules and cations into their interlayer spacing which has led to the high performance of MXenes electrodes and films in energy storage and sensing applications. In this work, we have harnessed this property of $Ti_3C_2T_x$ MXene along with its in-plane electrical conductivity to engineer a novel nanopore sensing device with increased sensing resolution by eliminating the access resistance. In this design, bilayer $Ti_3C_2T_x$ films serve as an embedded electrode and reservoir of cations, intercalated in the interlayer space, and support membrane of the nanopore, where the cations enter the pore from within the plane of the membrane rather than the bulk solution. By elimination of the access resistance contribution, this technology could reach the resolution of detecting three DNA bases at the pore sensing region, surpassing the commercially available nanopore technology with sensing resolution of four bases at the pore constriction.

Lithium-Ion Electrolytic Substrates—TMD Growth and 1V High-Performance Transistors and Amplifiers Md. Hasibul Alam and Deji Akinwande; The University of Texas at Austin, United States

This talk will present our latest progress on materials, transistor and memory devices based on 2D atomically-thin films. In particular, we explore a new substrate, namely, solid lithium-ion electrolytic substrates, for the direct growth and realization of high-performance TMD devices and amplifiers. Electrostatic gating with ionic liquids (ILs), leading to the accumulation of high surface charge carrier densities, has been often exploited in thin-film transistors. However, the intrinsic liquid nature of ILs inhibit it from constituting an ideal platform. In this regard, a lithium-ion solid electrolyte, often used for battery applications, offers similar advantages as ionic-liquids, with the added benefit of solid-state compatibility. With the solid electrolyte, we demonstrate its application in high-performance n-type MoS2 and p-type WSe2 transistors with sub-threshold

values approaching the ideal limit of 60 mV/dec and complementary inverter amplifier gain of 34, the highest among comparable amplifiers with a 1 V power supply. These results establish lithium-ion substrates as a promising alternative to ionic liquids for the study of thin-film devices.

Large Area Monolayer MoS_2 and WS_2 Field-Effect Transistors—A Statistical Approach Amritanand Sebastian, Rahul Pendurthi, Tanushree Choudhury, Joan Redwing and Saptarshi Das; The Pennsylvania State University, United States

Field-effect transistors (FETs) based on atomically thin transition metal dichalcogenides (TMDs) such as molybdenum disulfide (MoS_2) and tungsten disulfide (WS_2) have attracted immense attention in the scientific community due to their superior electronic properties.[1] The immense promise provided by the TMD FETs needs to be complemented by a thorough statistical and benchmarking study of relevant device parameters. In this regard, we report a comprehensive study of the carrier transport in monolayer MoS_2 and WS_2, which were grown over a large area using metal-organic chemical vapour deposition (MOCVD) process. 160 WS_2 FETs and 230 MoS_2 FETs with channel length ranging from 100 nm to 5 μm were investigated for benchmarking field-effect carrier mobility, maximum current, threshold voltage, saturation velocity, device linearity, contact resistance, subthreshold slope (SS), current, ON/OFF ratio, and drain induced barrier lowering (DIBL). Our study shows low device-to-device variation owing to high growth quality. We are also able to demonstrate record high carrier mobility of 33 $cm^2V^{-1}s^{-1}$ in WS_2 FETs, with over 1.5X improvement compared to the best reported in the literature. [2-4] This work also demonstrates the first comprehensive statistical study on WS_2 films, showing comparable performance to MoS_2 films. Our experimental demonstrations confirm the technological viability of two dimensional (2D) semiconductors for use in commercial electronics.

Probing Two-Dimensional Materials Using Focused Angle-Resolved Photoemission Spectroscopy Jyoti Katoch; Carnegie Mellon University, United States

Two-dimensional (2D) materials offer the freedom to create novel condensed matter systems, with unique properties, by mechanically assembling different (or same) 2D materials layer-by-layer to form atomically sharp vertical or lateral heterostructures. The van der Waals (vdW) heterostructures with small lattice mismatch and a relatively small twist angle between the constituent layers, have shown to exhibit coexisting complex phases of matter including Mott insulating state, superconductivity, bound quasiparticles, and topological states. In addition, the extreme surface sensitivity of two-dimensional (2D) materials provides an unprecedented opportunity to engineer the physical properties of these materials using external perturbations. In this talk, I will discuss the utilization of angle-resolved photoemission spectroscopy (ARPES) with high spatial resolution to investigate the electronic band structure of 2D heterostructures and their devices. This can shed light on the intricate relationship between controlled external perturbations, substrate, and electronic properties of 2D materials [1, 2]. In particular, I will discuss our *in-operando* nanoARPES results that exhibit highly tunable many-body effects in graphene devices [3] and tunable van Hove singularities in twisted bilayer graphene [4].

Visualizing Ultrafast Lattice Dynamics in Photoexcited 2D Heterostructures Using Femtosecond Electron Diffraction Aditya Sood[1], Jonah Haber[2], Johan Carlstroem[3], Elizabeth Peterson[2], Alexander Reid[4], Xiaozhe Shen[4], Marc Zajac[1], Suji Park[4], Michael Kozina[4], Emma Regan[2], Jie Yang[4], Stephen Weathersby[4], Feng Wang[2], X.J. Wang[4], Tony Heinz[1], Jeffrey Neaton[3], Felipe da Jornada[1], Aaron Lindenberg[1] and Archana Raja[3]; [1]Stanford University, United States; [2]University of California, Berkeley, United States; [3]Lawrence Berkeley National Laboratory, United States; [4]SLAC National Accelerator Laboratory, United States

Two dimensional (2D) van der Waals semiconductors are exciting candidates for next generation optoelectronics. The layer-by-layer assembly of 2D monolayers enables the creation of heterostructures with unique and controllable properties. It has been shown previously that photoexcitation of 2D heterostructures induces ultrafast charge transfer across the van der Waals junction on timescales faster than 100 fs, resulting in the formation of interlayer excitons. However, the coupling between this charge transfer process and thermal excitations of the lattice is so far unexplored. Here, using mega electron volt (MeV) ultrafast electron diffraction (UED), we make the first direct measurements of atomic vibrations within the individual layers of a type II van der Waals heterostructure following femtosecond photoexcitation. The UED technique employs ~4 MeV electron pulses to probe a large range of reciprocal space up to ~12 A^{-1}, with a time resolution of ~100 fs. We track the propagation of energy from one layer to the next by measuring the changes in intensities of Bragg peaks. First principles calculations link the measured differential intensities with thermally-activated atomic displacements, providing a sub-nanometer temperature scale. Our results provide insights into the role of ultrafast charge transfer on lattice dynamics, and decouple the vibrational and electronic pathways for energy transfer across a van der Waals interface.

5:25 AM F.EL04.03.03
Insights on the Bulk and Surface Chemistry of the Niobium MAX and MXene Phases from Multinuclear Solid-State NMR Spectroscopy Kent J. Griffith[1,2], Michael Hope[2], Philip Reeves[2], Mark Anayee[3], Yury Gogotsi[3] and Clare Grey[2]; [1]Northwestern University, United States; [2]University of Cambridge, United Kingdom; [3]Drexel University, United States

MXenes, derived from metallic MAX phases, are a class of two-dimensional materials with emerging applications in energy storage, electronics, and catalysis due to their high surface areas and attractive electronic properties. MXene properties are heavily influenced by their surface chemistry but a detailed understanding of the surface functionalization for the niobium MXenes Nb_2CT_x and $Nb_4C_3T_x$ is still lacking. The parent MAX phases, Nb_2AlC and Nb_4AlC_3, exhibit interesting structural and electrical properties but can be sensitive to oxidation. Solid-state NMR allows us to probe the interfacial chemistry, as well as the connectivity using correlation experiments; the phase purity including the presence of amorphous/nanocrystalline phases; and the electronic properties of the MXene and MAX phases with quantitative chemical sensitivity. In this work, we systematically study of the chemistry of Nb MAX and MXenes using solid-state NMR spectroscopy and examine a variety of nuclei (^{1}H, ^{13}C, ^{19}F, ^{27}Al and ^{93}Nb) with a range of techniques (T_1-filtering, QCPMG, MATPASS, HETCOR, TRAPDOR, robot-automated VOCS). Hydroxide and fluoride terminations were identified, found to be intimately mixed, and their chemical shifts compared with other MXenes. In addition to the identification of surface species and their spatial distribution, this multinuclear NMR study demonstrates that diffraction alone is insufficient to characterize the phase composition of MAX and MXene samples as numerous amorphous or nanocrystalline phases were identified including NbC, AlO_6 species, aluminum nitride or oxycarbide, $AlF_3{\times}nH_2O$, Nb metal, and unreacted MAX phase. To the best of our knowledge, this is the first work to examine the metal resonances directly in MXene samples, and the first ^{93}Nb NMR of any MAX phase. Insights from the ^{93}Nb even enabled the previously-elusive assignment of the complex overlapping $^{47/49}Ti$ spectrum of Ti_3AlC_2. The results and methodology presented here provide fundamental insights on MAX and MXene phases and can be used to obtain a more complete picture of MAX and MXene chemistry, to prepare realistic structure models for computational screening, and to guide the analysis of property measurements.

5:35 AM F.EL04.03.04
Double Moiré Superlattices at the 2D/3D Interface—STEM Observations and Electronic Implications Kate Reidy[1], Georgios Varnavides[1,2], Joachim D. Thomsen[1], Abinash Kumar[1], Thang Pham[1], Arthur M. Blackburn[3], Polina Anikeeva[1], Prineha Narang[2], James M. LeBeau[1] and Frances M. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]Harvard

University, United States; [3]University of Victoria, Canada

Following the success of moiré engineering in modulating (opto-)electronic properties of twisted bilayer graphene and graphene/hBN heterostructures, studies have extended the moiré toolbox; from double bilayer, to trilayer graphene, transition metal dichalcogenide (TMDC/TMDC), and hexagonal boron nitride (hBN)-graphene-hBN vdW heterostructures [1]. Moiré engineering has yet to be explored in 'quasi-vdW' systems, such as the interface of a two-dimensional (2D) material and three-dimensional (3D) metal, despite its influence on contact resistance, photo-response, and high-frequency performance [2]. Herein, we report moiré modulation at a 'quasi-vdW' interface between a 3D metal and 2D material, in the model system of 0 ± 0.1^{o} epitaxially aligned Au{111}/MoS_2.

By applying a predictive geometric convolution technique and four-dimensional (4D) scanning transmission electron microscopy (STEM) to epitaxially aligned Au{111}/MoS_2, we demonstrate double moiré periodicity (18 Å and 32 Å) at the 2D/3D interface. 4D STEM allows us to decouple these multiple moirés and image weaker moiré superlattices, otherwise hidden in conventional (S)TEM. Using *ab initio* electronic structure calculations, we find that charge density is modulated with a period of 32 Å, illustrating electronic conductivity and (opto-)electronic modulation via moiré engineering at the 2D/3D interface. With growing potential for tunability in quasi-vdW layers, these results highlight the potential for moiré engineering at the 2D/3D interface, as well as showcasing the growing opportunities for advanced (S)TEM techniques in multiple moiré direct imaging.

5:45 AM F.EL04.03.08
Cleaning and Smoothing the Interfaces of Hexagonal Boron Nitride Encapsulated Monolayer MoS_2 with Contact Mode Atomic Force Microscopy Sihan Chen[1], Jangyup Son[1], Siyuan Huang[1], Kenji Watanabe[2], Takashi Taniguchi[2], Rashid Bashir[1], Arend M. van der Zande[1] and William King[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]National Institute for Materials Science, Japan

The quality of the interfaces is critical for two-dimensional (2D) materials, as atomically thick 2D materials do not have any bulk to screen impurities.[1] For electronic devices based on 2D heterostructures, it is thus vital to have clean and smooth interfaces. Mechanical assembly is the most common and versatile way to assemble 2D heterostructures,[2,3] which often traps contaminants at the interfaces during assembly and does not yield high quality devices. Contact mode atomic force microscopy (AFM) cleaning is a reliable and controllable technique to remove interface contaminants of 2D heterostructures after assembly.[4–6] Reduction of nanometer scale corrugations was surmised to be responsible for improved electrical performance of 2D heterostructures after contact mode AFM cleaning.[5] Direct observation of the flattening of nanometer-scale interfacial roughness would help elucidate how contact mode AFM cleaning improves the electrical performance of 2D heterostructures.
This work reports the reduction of nanometer-scale roughness and improvement of interface qualities of 2D heterostructures, by scanning the heterostructure with an AFM tip in contact mode. The prototypical heterostructure system consists of monolayer MoS_2 encapsulated by top monolayer hBN and bottom multilayer hBN. We detected spatial height fluctuations ~ 1 nm with a lateral dimension of tens of nanometer in bubble-free areas of the heterostructures with AFM, which were minimized by contact mode AFM cleaning. The AFM cleaning process also reduced the photoluminescence (PL) linewidth of monolayer MoS_2, indicating a reduction of interface impurities. The optimal cleaning force for the heterostructure was found to be 70 nN. One MoS_2 field-effect transistor (FET) fabricated on AFM-cleaned heterostructure achieved a high mobility of 73 cm^2/Vs, which can be further improved by passivation with thick hBN or high-k dielectrics for better electrostatic environment. The mobility of four hBN encapsulated monolayer MoS_2 FETs fabricated on as-assembled heterostructure improved from 21±2 cm^2/Vs to 37±6 cm^2/Vs after AFM cleaning. Combining the results from AFM, PL and electrical measurements, we infer that contact mode AFM cleaning is effective in reducing interface disorders and enhancing the mobility of hBN encapsulated monolayer MoS_2. Finally, we anticipate that contact mode AFM cleaning will significantly improve the quality of most mechanically assembled van der Waals heterostructures by cleaning and smoothing their interfaces.

SESSION F.EL04.04: Chemical Vapor Deposition of 2D Materials
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-EL04

5:00 AM F.EL04.04.01
High Yield, Bottom-Up/Top-Down Synthesis of 2D Layered Metal Sulfides, Phosphides and Selenides Using Chemical Vapor Deposition with Applications in Electronics and Electrochemistry Gilbert D. Nessim; Bar Ilan University, Israel

Since the excitement about graphene, a monolayer of graphite, with its 2010 Nobel Prize, there has been extensive research in the synthesis of other non-carbon few/mono-layers exhibiting a variety of bandgaps and semiconducting properties (e.g., n or p type). The main approaches to deposit few/monolayers on a substrate are: (a) bottom-up synthesis from precursors using chemical vapor deposition (CVD) or (b) top-down exfoliation (liquid or mechanical) of bulk layered material. Using a Lego approach of superposing monolayers, we can envisage the fabrication of heterojunctions with original electronic behavior. Here we show a combined bottom-up and top-down approach where (a) we synthesize in one step high yields of bulk layered materials by annealing a metal in the presence of a gas precursor (sulfur, phosphorous, or selenium) using chemical vapor deposition (CVD) and (b) we exfoliate and deposited (dropcast or Langmuir Blodgett) few/mono-layers on a substrate from a sonicated mixture of our material in a specific solvent. It is interesting to note that, besides the structure being 2D layered, the properties of the nanomaterials synthesized slightly differ from the materials with the same stoichiometry synthesized using conventional chemical methods (e.g., solvothermal).
In this talk, we will discuss the chemical synthesis, the very extensive characterizations, and the lessons we learned in making multiple metal sulfides (Cu-S, Ag-S, Ni-S), metal phosphides (Ni-P, Cu-P), and metal selenides (Ag-Se, Cu-Se, W-Se). We will see how we integrated these new materials into electrochemical devices. We will also explore how to deposit large mono/few layers of these materials using techniques such as dropcasting or Langmuir-Blodgett and to connect them to circuits using focused ion beam (FIB) to test their electrical properties with the goal build heterojunctions.

5:10 AM F.EL04.04.02
Precursor Vapor Pressure Control Strategies on the APCVD Growth of Molybdenum Disulfide Guodong Meng, Feihong Wu, Jinan Xie, Changling Wang, Chengye Dong and Yonghong Cheng; Xi'an Jiaotong University, China

Molybdenum disulfide (MoS_2) is known as promising 2D material with a tunable band-gap which is an ideal for optoelectronic devices. Uniform, crystalline and atomic layers of MoS_2 can be produced by the chemical vapor deposition method. The commonly used MoS_2 CVD system is a system with the substrate facing down toward the molybdenum source. A new kind of CVD system which loads and protects the molybdenum source with a separate quartz tube in order to avoid poisoning of molybdenum trioxide has been designed in recent years. Here we report and compare the strategies of precursor vapor pressure control under this two typical MoS_2 preparation systems. In order to obtain high crystalline MoS_2, we studied the heating temperature of the precursor, the flow rate of the carrier gas, the horizontal distance and the vertical distance between the molybdenum source and the substrate during the growth of MoS_2 in this two different preparation systems. The results indicate the heating temperature of the precursor has the greatest influence on the growth of MoS_2. The lower heating temperature of the precursor contributes to lower growth rate, which makes the thickness of MoS_2 is easily controlled. When the heating temperature is more than 650 °C, the thickness and morphology of MoS_2 differs under the two preparation systems. Nevertheless, the flow rate of carrier gas has little influence on growth of MoS_2, but proper carrier gas flow rate can

prevent precursor poisoning. The horizontal distance and the vertical distance between the molybdenum source and the substrate affect the vapor concentration of the molybdenum source and the nucleation density of MoS_2 during the growth of MoS_2.

5:20 AM F.EL04.04.03
Correlation Between Surface Processes and Reaction Kinetics for Predictive Growth of Monolayer MoS_2 Ankit Rao, Kranthi Kumar V, Shashwat Rathkanthiwar and Srinivasan Raghavan; Indian Institute of Science, India

Modeling of physico-chemical processes such as adsorption-desorption equilibrium, adatom diffusion and attachment are required to correlate the change in supersaturation to the growth kinetics on the surface. We demonstrate an approach to predictively control the grain size and nucleation density of monolayer MoS_2 by employing such correlation via modeling the reaction kinetics in a true CVD system. The adatom concentration, on which this supersaturation depends, on the growth surface, is governed by the reaction kinetics of the precursor and the concentration gradients across the boundary layer at the growth surface. The varied dependencies of the rate of nucleation and edge growth rate on supersaturation and surface kinetics have been exploited to reduce nucleation density from 10^7 to 10^3 cm^{-2} and simultaneously increasing the growth rates of the edges to a significant value of 3.3 μm/s. We show that to obtain large grain sizes in small time frames, we identify the physico-chemical windows in which the nucleation kinetics are suppressed but those which govern the growth of edges are enhanced. As in the case of graphene, we observe from the analysis of the rate of nucleations that with an increase in temperature, the availability of adatoms on the growth surface is reduced which in turn results in control of nucleation rate and hence a decrease in nucleation density. We thus simulate the dependence of pressure and temperature on the degree of such pre-reactions to determine the concentration gradients for three substrates placed at different lengths across the reactor tube so as to determine the effect of reaction kinetics on nucleation density. Mass transfer calculations were performed by using the combined convection-diffusion solver. Owing to the vapor phase reactions close to the inlet, the initial precursor concentration was found to reduce from $6x10^{-3}$ to about $2.5x10^{-3}$ for all the cases within about 2 cm from the inlet. The simulations indicate that despite the vapor phase reactions, in the considered pressure and temperature range, the $Mo(CO)_6$ precursor concentration at substrates placed across the length of the tube varies only by a factor of 2. This is not expected to alter the nucleation density significantly. This is in accordance with the experimental results. The simulation results thus rule out the impact of vapor phase reactions on the observed variations in nucleation density (and grain size) with temperature, pressure, and flow rates. Thus we show that the nucleation density of MoS_2 domains in a CVD process can be controlled in a predictive manner by tuning the supersaturation and surface kinetics.

5:30 AM F.EL04.04.04
CVD Growth of Monolayer N-Doped WSe_2 from Solid State Inorganic Precursors Mauro Och[1], Giulia Z. Zemignani[1], Kostantinos Anastasiou[2], Pawel Palczynski[1], Evgeny Alexeev[3], Alexander Tartakovskii[3], Saverio Russo[2] and Cecilia Mattevi[1]; [1]Imperial College London, United Kingdom; [2]University of Exeter, United Kingdom; [3]The University of Sheffield, United Kingdom

Doping is fundamental to tune the properties of 2D transition metal dichalcogenides for their future integration in the CMOS architecture, hence achieving substitutional doping during growth is of paramount importance. N-type monolayer WSe_2 is often exfoliated from bulk crystals and a procedure to directly dope the material is yet to be established. Here, we demonstrate the synthesis of monolayer n-WSe_2 via CVD starting from tungstic acid (H_2WO_4) and zinc selenide (ZnSe). We achieved large WSe_2 triangular monolayer flakes, which exhibit n-type of transport which is attribute to donor states due to the incorporation of Zn ions in the lattice. The doping is very stable and the material exhibits good electron mobilities reaching the highest value at 50 $cm^2V^{-1}s^{-1}$. The substitutional doping has been confirmed via atomic probe tomography (APT), showing Zn inclusions into the individual WSe_2 layers. Our material is of high crystal quality characterized by a sharp room temperature photoluminescence (PL) assessed by the PL spectra evolution from 10 K to room temperature that shows the contribution of neutral and defect-bound excitons, a signal so far reported only in mechanically exfoliated material.

5:40 AM F.EL04.04.05
Universal Approach Towards 2D Van der Waals Heterostructures of Metal Chalcogenides from Molecular Building Blocks Veronika Brune, Lasse Jurgensen, Michael Wilhelm, Michael Frank and Sanjay Mathur; University of Cologne, Germany

Layered materials beyond omnipresent graphene such as chalcogenide-based materials that possess tunable and defined crystallographic structures and elemental compositions offer a broad portfolio of potential applications. The lacking control of large scale and homogeneous formation of 2D layered materials MX_2 (X = S, Se) in commercial formation processes motivated us to develop a unique synthetic approach to layered 2D materials. Complete characterization of synthesized

complexes enabled their controlled decomposition to desired materials.
Herein we report a uniform synthesis of molecular building blocks to form stable precursor classes [M(SEtN(Me)EtS)$_x$] (M = Mo^{IV}, W^{IV}, Ti^{IV}, Zr^{IV}, Hf^{IV}, Sn^{IV}, x = 2; M = Ge^{II}, Sn^{II}, Pb^{II}, x = 1), which can be decomposed to layered 2D van der Waal heterostructures.
Following a simple synthetic protocol, the reaction of tridentate $(HSEt)_2NMe$ donor ligand with suitable metal compounds resulted in (air)stable molecular precursors, which were isolated and characterized by NMR, XRPD and single crystal analysis. Thermal decomposition experiments of synthesized metal precursors where analyzed by TG-DTA measurements and the formation of desired MS_2 and MS (W, Mo, Ti, Sn, Pb) materials was confirmed by XRPD analysis. SEM, XRD and TEM analysis of CVD deposited molecular precursors confirmed the formation of homogeneous crystalline layered sulfur based heterostructures. The number of deposited MX_2 layers was calculated from a combination of TEM and AFM measurements. Moreover, prepared precursors were suitable for wet chemical syntheses as demonstrated via microwave assisted decomposition which resulted in homogeneous spherical SnS_2 particles.
These molecular building blocks provide an extraordinary synthetic approach to a unique molecular precursor class, which reliably delivered chalcogenide-based *van der Waals* heterostructures of metal chalcogenide 2D materials.

5:50 AM F.EL04.04.06
Direct Synthesis of Bilayer MoS_2 Nanoribbons with Sub-10nm Width Xufan Li[1], Raymond Unocic[2], Emmanuel Okogbue[1] and Avetik Harutyunyan[1]; [1]Honda Research Institute USA Inc., United States; [2]Oak Ridge National Laboratory, United States

Nanoribbons of atomically thin transition metal dichalcogenides (TMDs) provide an additional space confinement in the two-dimensional plane and a more prominent edge effect compared to two-dimensional (2D) sheets, which have a potential to show even more unprecedented properties according to theoretical predictions. Etching from 2D sheets through lithography has realized TMD nanoribbons with a width down to ~30 nm. However, contamination introduced by lithography process can alter or even diminish their properties. Therefore, direct, lithography-free synthesis of atomically thin TMD nanoribbons are highly desired. In this work, we demonstrate for the first time a direct growth of MoS_2 bilayer nanoribbons with a width down to less than 10 nm and a length up to 300 μm through a chemical vapor deposition method using nickel clusters as nucleation seeds. These sub-10 nm bilayer nanoribbons allow us to study not only the quantum confinement and edge effect but also the effect of a second layer on the electronic structures as well as electrical and optical properties of the nanoribbons. Nickel nanoparticle that terminates the tip of each bilayer nanoribbon, serves as a nucleation seed, defines the width, and drives the tip growth mechanism. More insights of the growth mechanism are provided based on XPS, XRD, AES (Auger electron spectroscopy), SEM, and STEM studies. The synthesis method has been successfully applied on a variety of substrates including SiO_2/Si, sapphire, and mica. Our synthesis method introduces a new family of TMD nanoribbons i.e. bilayer nanoribbons, which opens an avenue for discovery of new phenomena and properties.

6:00 AM F.EL04.04.08
High Temperature CVD Growth of Crystalline Hexagonal Boron Nitride Anushka Bansal, Maria Hilse, Benjamin Huet, Roman Engel-Herbert and Joan Redwing; The Pennsylvania State University, United States

Hexagonal Boron Nitride (hBN) is a 2D, III-nitride wide bandgap semiconductor that has a structure very similar to graphene. Due to its extraordinary physical properties, such as high resistivity, high thermal conductivity, stability in air up to 1000°C and large bandgap (E_g ~ 5.9 eV), hBN appears to be a promising material for emerging applications, including deep UV (DUV) optoelectronics, single photon emitters and neutron detectors. There is also significant interest in monolayer and few-layer hBN as an encapsulating layer for 2D devices based on graphene and transition metal dichalcogenides.
While high quality hBN bulk crystals are available for exfoliation, the size of the crystals is limited, consequently there is continued interest in the epitaxial growth of large area hBN films on sapphire using chemical vapor deposition (CVD). However, high quality hBN film growth typically requires high growth temperatures (1100°C-1500°C). It has been reported that this temperature range alters the sapphire surface under ultra-high vacuum (UHV) conditions. In case of chemical vapor deposition (CVD), the presence of hydrogen in the growth ambient is expected to also modify the sapphire surface. However, its impact on hBN growth has not yet been explored.
In this work, we studied the growth of crystalline and epitaxial hBN in a vertical cold wall MOCVD reactor using diborane (B_2H_6) and ammonia (NH_3) as precursors for B and N, respectively using H_2 as a carrier gas. The growths were performed on substrates with different plane directions (C-plane v/s A-plane) at a growth temperature of 1350°C under a pressure of 50 Torr. Sequential pulsing of the B_2H_6 (2 sec) and NH_3 (1 sec) precursors using N/B ratio of ~4000 resulted in a growth rate of ~300 nm/hr due to reduction in the extent of parasitic gas phase reactions. Continuous thin films of hBN were obtained on C-plane as well as A-plane sapphire along with wrinkles due to thermal expansion coefficient (CTE) difference between sapphire and hBN. The E_{2g} Raman active mode of hBN was observed at 1368.2 cm^{-1} with a FWHM of 24.6 cm^{-1} on C-plane

sapphire. Residual compressive stress due to CTE mismatch between film and the substrate (wrinkles) along with other inhomogeneities in the film (such as substrate's surface roughness) could be one of the possible reasons for the red shift in the Raman peak position (from bulk crystal Raman peak position at 1365cm^{-1}) and a broader FWHM. Therefore, the film was transferred on to Si/SiO_2 substrate using PMMA based transfer technique to release residual stress. After film transfer, Raman peak position was measured to be 1365 cm^{-1} with a FWHM of 18.5 cm^{-1} (FWHM of the best quality bulk crystal obtained is ~7cm^{-1}). Also, pre-growth H_2 annealing of C-plane sapphire at the growth temperature alters the surface lattice parameter as confirmed by RHEED and is believed to induce a chemical change as well. RHEED pattern of the obtained hBN film suggests rotationally oriented, crystalline hBN film with $[]_{h\text{-}BN}||\ []_{sapphire}$ epitaxial relation. However, for hBN on A-plane sapphire, wrinkle density was higher compared to C-plane sapphire. Also, E_{2g} mode was observed ta 1366.4 cm^{-1} (corresponding well with AFM results showing higher wrinkle density indicating lesser residual stress in the film) with a FWHM of 24.8 cm^{-1}. The cause is still unknown; however, further studies are underway to provide additional insights into the role of crystallographic symmetry and surface preparation to form highly crystalline hBN films on sapphire.

Large-Area $PtTe_2$/Silicon Heterojunction Devices with Ultrafast Photodetection and Enhanced Photovoltaics by Water Droplet Integration Mashiyat Sumaiya Shawkat[1,1], Tanvir Ahmed Chowdhury[1], Hee-Suk Chung[2], Shahid Sattar[3], Tae-Jun Ko[1], Shawn Putnam[1], J. Andreas Larsson[3] and Yeonwoong Jung[1,1,1]; [1]University of Central Florida, United States; [2]Korea Basic Science Institute, Korea (the Republic of); [3]Luleå University of Technology, Sweden

Recently, interests in a family of noble metals-based 2D crystals are on the rise exploiting their superior electrical properties beyond conventional 2D transition metal dichalcogenides (TMDs). 2D platinum (Pt) ditelluride ($PtTe_2$) layers are particularly promising due to their unique band structure and topological nature as well as remarkably high conductivity (>10^6 S/m), surpassing most of previously explored 2D TMD layers. Such intrinsic superiority can be leveraged to practical applications by integrating them with matured 3D semiconductors, which has remained largely unexplored. In this report, we explored $PtTe_2$/silicon hetero-junction devices and unveiled their electrical and opto-electrical applications. We directly grew a large-area (> cm^2) highly metallic 2D $PtTe_2$ layers on doped silicon wafers via a low-temperature chemical vapor deposition (CVD) process, achieving high-quality 2D/3D hetero-interfaces. The integrated devices incorporating the $PtTe_2$/silicon vertical junctions exhibit excellent Schottky transport characteristics such as high rectification ratio (~ 10^5), small ideality factor (~ 1.9), and Schottky barrier height of 0.67 eV. These devices present strong photovoltaic properties and photo-responsiveness despite their large (0.5 cm^2) lateral junction area, i.e., a well-balanced attribute of high photo-detectivity (>10^{13} Jones) and short photo-response time (~ 1 μs), significantly outperforming most of the previously explored 2D/3D or 2D layers-based devices. Furthermore, we identified that the CVD 2D $PtTe_2$ layers exhibit unusually strong hydrophobicity which has been utilized to further improve the device photovoltaic performances; i.e., ~ 300 % and ~ 200 % increase of short circuit current density and power conversion efficiency have been achieved respectively upon an integration of water droplet. Underlying principles for the Schottky junction characteristics, as well as the water-assisted performance enhancement will be discussed.

6:20 AM F.EL04.04.10

The (Mostly) Unwelcome Guest in 2D Chalcogenides—Native Oxidation Rates and the Effects of Oxygen During Processing MoS_2, TiS_2, and $Zr(S,Se)_2$ Seong Soon Jo[1], Yifei Li[1], Akshay Singh[2], Liqiu Yang[3], Subodh C. Tiwari[3], Sungwook Hong[4], Aravind Krishnamoorthy[3], Maria Sales[5], Sean Oliver[6], Patrick Vora[6], Stephen McDonnell[5], Priya Vashishta[3], Rajiv Kalia[3], Aiichiro Nakano[3] and Rafael Jaramillo[1]; [1]Massachusetts Institute of Technology, United States; [2]Indian Institute of Science, India; [3]University of Southern California, United States; [4]California State University, Los Angeles, United States; [5]University of Virginia, United States; [6]George Mason University, United States

A thorough understanding of the properties of native oxides and the role of oxygen during processing is essential for designing semiconductor devices. This is no less true for nanomaterials than it is for legacy semiconductors such as silicon, for which control of the native oxide was a seminal achievement of 20th century materials science. Being a very hard anion, oxygen bonds very differently to transition metals than do the chalcogens. Trace oxygen in a transition metal dichalcogenide (TMD) has a substantial impact on material processing and properties, much more so than for instance trace selenium in a sulfide. Since oxygen is all around us, even in our high-vacuum chambers, it is essential to understand and control the effects of oxygen on processing 2D materials. Here we report three studies of the effect of oxygen on processing TMDs.
We find that lowering trace oxygen concentration in the reactor makes it possible to lower the processing temperature for large-area TiS_2 films, made by reacting Ti thin films with H_2S gas. We quantify how lowering oxygen concentration enables faster metal sulfurization at lower temperatures (down to 500 °C), leading to thin films that are smooth and homogeneous. In contrast, we find the opposite trend for MoS_2: *adding* trace oxygen enables lower processing temperatures (down to 375

°C) for large-area MoS_2 films, made by sulfurizing Mo thin films. We understand these contrasting effects in the light of particulars of Ti-O and Mo-O bonds, including molecular dynamics (MD) simulations that suggest that oxygen is a catalyst for Mo-S bond formation.
We also report a quantitative study of the rate of native oxidation of pristine TMD surfaces. Layered transition metal dichalcogenides nominally have inert, fully-passivated surfaces, but it is well-known that this is an oversimplification and that many TMDs oxidize readily. MoS_2 surfaces remain pristine for over a year in laboratory ambient conditions, without a trace of oxide formation. In contrast, $Zr(S,Se)_2$ alloys oxidize rapidly, with the native oxide growing at a rate up to 0.5 Å/min. MD simulations reveal the kinetic mechanisms that limit native oxide growth for MoS_2 and promote it for $Zr(S,Se)_2$, despite oxide formation in ambient conditions being thermodynamically-favorable in all cases.
Our results provide quantitative detail and atomistic understanding of the role of oxygen during TMD synthesis and processing, and may be broadly useful to ongoing efforts at film synthesis and device integration.

Late News: Synthesis of 2D GaS Films on Versatile Substrates for High-Performance Electronic and Optoelectronic Devices Yang Lu[1] and Jamie Warner[2]; [1]University of Oxford, United Kingdom; [2]The University of Texas at Austin, United States

A chemical vapor deposition method is developed for uniform and continuous gallium(II) sulfide (GaS) films on SiO_2 featuring both thickness-controlled (one to four layers), as well as defect-controlled (defective $GaS_{0.87}$ and stoichiometric GaS). We identify stoichiometry and concentration as two key elements in the growth mechanism. The 2D GaS films show sensitive layer-dependent Raman and optoelectronic properties. Furthermore, an enhanced stability of the stoichiometric GaS is demonstrated under laser and strong UV light, and by controlling defects in GaS, the photoresponse range can be changed from vis-to-UV to UV-discriminating. The stoichiometric GaS is suitable for large-scale, UV-sensitive, high-performance photodetector arrays for information encoding under large vis-light noise, with short response time (<66 ms), excellent UV photoresponsivity (4.7 A W–1 for trilayer GaS), and 26-times increase of signal-to-noise ratio compared with small-bandgap 2D semiconductors. A defect-induced band further appears within the bandgap of $GaS_{0.87}$, which can tune the band alignment of bilayer GaS-WS_2 from type-I heterojunction to type-II heterojunction.
We further synthesized GaS crystals on various substrates including sapphire, Si and other 2D materials such as graphene and MoS_2. The morphology of various GaS crystals is influenced by different surface properties. By comprehensive characterizations from atomic-scale structures to large-scale device performances in 2D semiconductors, the study shows that both layer-controlled defective $GaS_{0.87}$ and stoichiometric GaS prove to be promising platforms for study of novel phenomena and new applications.

Machine Learning-Enabled Design of Point Defects in 2D Materials for Quantum and Neuromorphic Information Processing Nathan Frey[1], Deji Akinwande[2], Deep M. Jariwala[1] and Vivek Shenoy[1]; [1]University of Pennsylvania, United States; [2]The University of Texas at Austin, United States

Engineered point defects in two-dimensional (2D) materials offer an attractive platform for solid-state devices that exploit tailored opto-electronic, quantum emission, and resistive properties. Naturally occurring defects are also unavoidably important contributors to material properties and performance. The immense variety and complexity of possible defects makes it challenging to experimentally control, probe, or understand atomic-scale defect-property relationships. Here, we develop an approach based on deep transfer learning, machine learning, and first-principles calculations to rapidly predict key properties of point defects in 2D materials. Properties including band gap and bulk formation energy are predicted for over

4,000 2D materials using deep transfer learning. 10,000 dopant, vacancy, divacancy, and antisite defect structures are generated in 150 wide band-gap materials and more than 1,000 defect band structures are computed *via* first-principles methods. We use physics-informed featurization to generate a minimal description of defect structures and present a general picture of defects across materials systems. We identify over 100 promising, unexplored dopant defect structures in layered metal chalcogenides, hexagonal nitrides, and metal halides including GeS, h-AlN, and MgI_2. These defects have low formation energies and host material band-gaps calculated to be greater than 2 eV. We also find ten optimal substitutional defects for nonvolatile resistive switching in atomically thin memristor devices, where metal dopants substitute for chalcogen atoms in materials including WSe_2 and $MoTe_2$. Au and Ag substitutions in WTe_2- and $MoTe_2$-based devices are predicted to have switching voltages as low as 110 meV. These defect structures are prime candidates for quantum emission, resistive switching, and neuromorphic computing.

5:10 AM F.EL04.05.02
Site-Selectively Generated Defects as Highly Scalable Quantum Emitters in Encapsulated Monolayer MoS_2 Julian Klein[1,2], Lukas Sigl[1], Alexander Hötger[1], Samuel Gyger[3], Katija Barthelmi[1], Matthias Florian[4], Alexander Kerelsky[5], Elmar Mitterreiter[1], Christoph Kastl[1], Sergio Rey[1], Takashi Taniguchi[6], Kenji Watanabe[6], Frank Jahnke[4], Valery Zwiller[3], Klaus D. Jöns[3], Abhay Pasupathy[5], Frances M. Ross[2], Kai Müller[1], Ursula Wurstbauer[7], Jonathan Finley[1] and A.W. Holleitner[1]; [1]Technical University of Munich, Germany; [2]Massachusetts Institute of Technology, United States; [3]KTH Royal Institute of Technology, Department of Applied Physics, Albanova University Centre, Sweden; [4]University of Bremen, Germany; [5]Columbia University, United States; [6]National Institute for Materials Science, Japan; [7]University of Münster, Germany

Two-dimensional materials offer a wide range of perspectives for hosting functional and highly localized zero-dimensional states, e.g. vacancy defects, that offer great potential for nano-photonic applications [1]. The site-selective generation of such defects and the fundamental understanding of their optical and electronic properties are of key importance for integrated quantum photonic devices.
In this talk, we will demonstrate the highly local formation of individual single-photon sources in a monolayer MoS_2 van der Waals heterostructure [2,3]. Individual defects that act as our single-photon emitters are created by He-ion irradiation. Irradiation after encapsulation of the MoS_2 with hBN reveals spectrally narrow and spatially localized spectral lines that exhibit anti-bunched emission at the defect characteristic energy of ~1.75 eV (194 meV redshifted from 2D exciton). The emission is highly homogeneous and background-free due to the encapsulation [4]. We investigate these individual single-photon emitters spectroscopically using photoluminescence excitation spectroscopy and temperature-dependent measurements. The line shape reveals a strong asymmetry resembling the interaction with LA/TA phonons. Applying the independent boson model to our emission lines, we find that the emitters are spatially localized to a length scale of 2 nm. We attribute the emission to atomistic defects induced by the He-ion irradiation and discuss their microscopic origin in the light of scanning tunneling microscopy measurements [5,6]. Moreover, we further demonstrate spatial integration and electrical control of single-photon sources in field-switchable van der Waals devices. Our work firmly establishes 2D materials as a highly scalable material platform for integrated quantum photonics.

Elimination of Defect States in 2D Transition Metal Dichalcogenides via Doped Organic/Transition Metal Oxide Mixtures Xiaheng Huang, Zidong Li, Xiao Liu, Jize Hou, Jongchan Kim, Stephen R. Forrest and Parag B. Deotare; University of Michigan, United States

Due to intrinsic defects, transition metal dichalcogenides (TMD) monolayers have low (< 0.1%) photoluminescence quantum yield (PLQY), hindering their potential for optoelectronic device applications. Here, we report a passivation method of monolayer TMD using organic/transition metal oxide (TMO) mixtures with laser soaking. A 10 nm mixed layer of 3,3',5,5'-Tetra[(m-pyridyl)-phen-3-yl]biphenyl (BP4mPy) and MoO_3 is vacuum deposited onto a MoS_2 monolayer, which is followed by laser soaking for tens of minutes in ambient. For 1:4 vol% BP4mPy:MoO_3, the passivated MoS_2 monolayer shows up to 250 times enhancement in PL intensity as compared to exfoliated MoS_2. The PLQY reaches ~ 5 % at excitation power

density < 10 W/cm^2 and rolls off as power density increases, reaching 1 % at 10^3 W/cm^2. These values are comparable to those achieved by recently reported superacid-treated[1] samples with PLQY reaching 3 % at 10 W/cm^2 and 1 % at 10^2 W/cm^2. In addition, the passivated MoS_2 is stable in air, vacuum, and solvents (e.g. acetone, isopropanol). Using low temperature PL and transient spectroscopy, we find that the mid-gap defect states of MoS_2 are eliminated by passivation, concomitant with a decrease of exciton-exciton annihilation.

Mechanisms of passivation are studied by varying the photon energy of the soaking laser, and as a function of the structures: 5 nm BP4mPy/*d* nm MoO_3/MoS_2, where *d* is varied from 3 to 12nm. The effectiveness of the passivation is found to be determined by the polaron-pair generation at the BP4mPy/MoO_3 interface and polaron-diffusion efficiency from the interface to MoS_2. This passivation method has been generalized to other organic/TMO capping layers, where organic molecules serve as the electron donor while TMO as the acceptor. It is also applicable to passivating other sulfur-based TMDs (e.g. WS_2), offering a potential platform for next generation 2D device applications.

MoS_2 Defect Insights Using Raman Spectroscopy Kirstin E. Schauble, Ryan Grady and Eric Pop; Stanford University, United States

Two-dimensional (2D) semiconductors, such as MoS_2, are promising for electronics due to their good mobility in ultrathin channels. However, current synthesis methods result in defective films which hinder their electrical performance and can influence doping and reactivity. Therefore, it is important to have a quick and nondestructive method to analyze defect densities in MoS_2.
Past studies used transmission electron microscopy [1] or scanning tunneling microscopy [2] to probe MoS_2 defects, but these methods are time consuming, destructive, and cannot be applied to large-area films. On the other hand, Raman spectroscopy has been used to probe graphene defects, particularly through the D-peak [3]. A similar Raman feature exists in MoS_2 as the LA(M) peak, however this only appears at very large defect densities (>10^{13} cm^{-2}) [4].
Here, we use Raman spectroscopy for rapid, large-area analysis of MoS_2 defect densities in the range of interest for electronic applications. We use a simple Raman peak fitting procedure as well as the phonon confinement (RWL) model [4-6] to compare disorder in monolayer MoS_2 prepared by exfoliation, chemical vapor deposition (CVD), and atomic layer deposition (ALD). Importantly, we uncover a correlation between Raman-based defect metrics and electrical mobility of MoS_2, for the first time.
Non-resonant MoS_2 Raman spectra (532 nm laser) typically have two peaks, E' and A_1'. However, the E' peak is comprised of two optical phonon modes (LO and TO) which almost overlap at the Gamma point. Thus, additional information on defects can be gained by fitting two E' peaks, including the E' shoulder. We use this approach and observe subtle changes in the Raman spectra of MoS_2 prepared by different methods, i.e. peak broadening, shifting, and increased E' peak shoulder intensity, which correlate with increased defect densities [4,6]. Based on these, we find that exfoliated monolayer MoS_2 is the least defective, followed by CVD-grown, and ALD-grown MoS_2 is the most defective material.
To quantitatively understand how defects change the MoS_2 Raman spectra, we use the RWL model [4-6], which posits that defects spatially confine Gamma point phonons, broadening their k-space participation and thus broadening the Raman peak. Non-Gamma point phonons which participate depend on the phonon dispersion, and a steeper dispersion near the Gamma point causes increased Raman peak broadening and asymmetry due to defects. Here we used a fit to the MoS_2 phonon dispersion based on [7].
By comparing Raman data across various MoS_2 samples with the RWL model, we find that as the defect density increases, the E' peak (with LO and TO modes) shifts and asymmetrically broadens. Fitting this model to Raman data from various MoS_2 sources, we can estimate the defect density in each sample and relate it to the relative E' peak positions and intensities. Importantly, we correlate these changes in Raman features with electrical mobility data for various samples from our lab and from the literature, providing a rapid evaluation of the quality of a 2D semiconductor film. This is an important advance, which allows us to distinguish between samples with, e.g. 10 and 30 cm^2/V/s mobility using Raman analysis, without the need for extensive fabrication and electrical measurements. Our approach could also be extended to other 2D semiconductors, in particular WSe_2, which also has a steep phonon dispersion near the Gamma point.

Single versus Dual Ion Conductors for Electric Double Layer Gating of Two-Dimensional Materials Ke Xu[1], Aaron Woeppel[2], Jierui Liang[1], Azimkhan Kozhakhmetov[3], Shubham Sukumar Awate[1], Joshua Robinson[3] and Susan Fullerton[1]; [1]University of Pittsburgh, United States; [2]Purdue University, United States; [3]The Pennsylvania State University, United States

Electric double layer (EDL) gating using a single-ion conductor is compared to a dual-ion conductor using both finite element modeling and experimentally on two-dimensional (2D) crystals based field effect transistors (FETs). A modified version of the Nernst-Planck Poisson (mNPP) equations are used to calculate the ion density per unit area in a parallel plate capacitor geometry with a bulk ion concentration $215 \leq c_{bulk} \leq 1650$ mol/m^3. With electrodes of equal size at a 2 V potential difference, the EDL ion density of the single-ion conductor is ~ 7 x 10^{13} ions/cm^2, which is approximately 50% of the ion density induced in the dual-ion conductor. However, this difference is reduced to 8% when the electrode at which the cationic EDL forms is 10 times smaller than the anionic electrode. Thus, for a FET gated by a single-ion conductor, it is especially important to have a large gate-to-channel size ratio to achieve strong ion doping. I will also show that the numerical modeling results can be approximated by a simple analysis of capacitors in series, where the EDLs are modeled as capacitors with thickness estimated by the sum of the Debye screening length and the Stern Layer. The modeled ion densities are validated by Hall-effect measurements on graphene FETs gated by a polyethylene oxide (PEO)-based single-ion conductor. The sheet carrier density (n_S), which is reported for the first time for a single-ion conductor, is ~ 2 x 10^{13} cm^{-2} at $V_g = 2$ V, which is 3.5 times smaller than the predicted value, and on the same order of magnitude as the n_s measured for a PEO-based dual-ion conductor on the same graphene. Our results suggest single-ion conductor-gated 2D FETs can achieve n_S up to 10^{14} cm^{-2}, which is theoretically predicted to be able to induce sufficient strain required to achieve the semiconducting *2H* to metallic *1T* phase transition in $MoTe_2$. Therefore, in the last part I will discuss the ongoing work focused on the fabrication of single-ion conductor-gated $MoTe_2$ FETs with suspended channels, and the in-situ characterization of the phase transition induced by the strain via the bending of single-ion conductor under an applied field.

Ion-Locking in Solid Polymer Electrolytes for Reconfigurable Gateless Electrostatic Doping Jierui Liang, Ke Xu, Swati Arora, Jennifer Laaser and Susan Fullerton; University of Pittsburgh, United States

Electrostatic doping by ions relies on the formation of an electric double layer (EDL) at the electrolyte/channel interface where the image charges induced by the ions serve as dopants in the channel. Electrostatic doping can induce sheet carrier densities in two-dimensional (2D) crystals exceeding 10^{14} cm^{-2} without altering the intrinsic bandgap, and the doping is reconfigurable between *p*- and *n*-type or *p-n/n-p* junctions by redistributing ions under the field. However, in conventional electrolytes such as ionic liquids/gels, a gate voltage must be continuously applied to hold the ions in place and therefore set the doping state. What would be useful is a “gateless” electrostatic doping wherein the doping could be programmed by ions and then locked into position via a trigger until the ions could be unlocked and reconfigured again on demand. Herein, we report a newly developed doubly polymerizable ionic liquid (DPIL) that can perform ion-locking by a chemical trigger to achieve the gateless electrostatic doping. The structure of DPIL is similar to the ionic liquid, [EMIM][TFSI], but with polymerizable functional groups on both charged species to perform ion-locking. Before polymerization, the DPIL monomers behave as a typical electrolyte with mobile ions that can be drifted by an applied field to form EDLs. To lock the ions, and therefore the EDL into place, either UV or thermal initiated polymerization is used. Once locked, the electric field is removed

and EDL does not dissipate. Here, ion locking to create a gateless, lateral *p-n* junction is demonstrated on graphene.[1] The junction is set by an applied field and DPIL is polymerized to lock the doping; the junction is measured at room temperature. The results are compared to a common locking approach: thermally quenching a polyethylene oxide-based electrolyte to a temperature below the glass transition temperature (T_g) and then measuring the junction at low temperature. Both approaches require only the source/drain terminals to create the junction, and a gate is not required to maintain the doping after ion-locking. Backgated transfer characteristics of both approaches show two current minima – the signature of a *p-n* junction in graphene. We have also made progress towards reconfigurable doping (i.e., locking and unlocking) by incorporating thermally-labile linkers into DPIL to allow ions to be released again after polymerization.[2]

5:20 AM F.EL04.06.03
Near-Unity Molecular Doping Efficiency in Monolayer MoS_2 Milad Yarali[1,1], Yiren Zhong[1,1], Serrae N. Reed[1,1], Juefan Wang[2], Kanchan A. Ulman[2], David Charboneau[1], Julia B. Curley[1], David Hynek[1,1], Joshua V. Pondick[1,1], Sajad Yazdani[1,1], Nilay Hazari[1], Su Ying Quek[2,2], Hailiang Wang[1,1] and Judy Cha[1,1]; [1]Yale University, United States; [2]National University of Singapore, Singapore

Surface functionalization with organic electron donors (OEDs) is an effective doping strategy for two-dimensional (2D) materials, which can achieve doping levels beyond those possible with conventional electric field gating. While the effectiveness of surface functionalization has been demonstrated in many 2D systems, the doping efficiencies of OEDs have largely been unmeasured, which is in stark contrast to their precision syntheses and tailored redox potentials. Here, using monolayer MoS_2 as a model system and an organic reductant based on 4,4'-bipyridine (DMAP-OED) as a strong organic dopant, we establish that the doping efficiency of DMAP-OED to MoS_2 is in the range of 0.63 to 1.26 electrons per molecule. We also achieve the highest doping level to date in monolayer MoS_2 with a carrier density of $5.8 \pm 1.9 \times 10^{13}$ cm^{-2} by surface functionalization with DMAP-OED at the maximum functionalization conditions. This is four times greater than the previous best system based on benzyl viologen, demonstrating that DMAP-OED is a stronger dopant than benzyl viologen. The measured range of the doping efficiency is in good agreement with the values predicted from first-principles calculations. We show that multiple factors, such as reduction potential, size, and binding mode of the dopant molecule, as well as interactions between the molecules and 2D materials and among the molecules themselves play an important role when considering the design of strong molecular dopants. The ability to dope MoS_2 beyond its degenerate limit *via* an organic super electron donor provides opportunities to access correlated electronic phases, such as superconductivity at the degenerate level, and offers an alternative to ionic gating and lithium intercalation for carrier density control, which may produce unwanted electrochemical reactions. Our work provides a basis for the rational design of OEDs for high-level doping of 2D materials.

5:30 AM F.EL04.06.04
Molecular Dopant Dependent Charged Impurity Scattering in Charge-Transfer-Doped WSe_2 Jae-Keun Kim[1], jung-hoon Lee[2], Kyungjune Cho[1], Keehoon Kang[1] and Takhee Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Transition metal dichalcogenides (TMDCs) has attracted great attention as a promising semiconductor of next generation nanoelectronics due to unique properties such as atomically flat nature and tunable band gap property. To utilize TMDCs for complementary logic circuit and various homo/heterjuction devices, controlling of the conductivity and the carrier type is necessary. In order to modulate carrier concentration and carrier type, surface charge transfer doping (SCTD) on TMDCs using functionalized organic molecules has been extensively studied. However, the molecular dopant could limit the electrical performance of TMDCs like in graphene [1] leading to charged impurity scattering. In this regard, a thorough understanding of the effect of SCTD on the charge transport of TMDCs is essential.
In this presentation, we report the effect of surface charge transfer doping on the transport properties of tungsten diselenide (WSe_2) by using three types of p-type molecular dopants, 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (denoted as F_4-TCNQ), molybdenum tris(1,2-bis(trifluoromethyl)ethane-1,2-dithiolene) (denoted as $Mo(tfd\text{-}COCF)_3$), and Tris(4-bromophenyl)ammoniumyl hexachloroantimonate (denoted as magic blue). These strong molecular acceptors have different

electron affinities, and thus the doping strength among the molecular dopants vary significantly, which we characterized with WSe_2 field-effect transistors (FETs). In particular, we measured four-point probe mobility at variable temperature from 10 K to 300 K to investigate the doping effect on the intrinsic charge transport of WSe_2. Comparing to pristine WSe_2, the mobility of molecular doped WSe_2 FETs is significantly reduced at low temperature regime. This result implies that the dopants can induce impurity scattering in the transport of WSe_2 FETs. It is found that magic blue molecule induces the least impurity scattering in WSe_2 FETs among the three molecular dopants. This study can help developing suitable molecular dopants for controlling the electrical properties of TMDC devices by understanding dopant-induced effects on the charge transport.

Structure and Properties of Ni-Doped MoS_2 from DFT—Phase Diagrams, Raman Spectra, Defect States and Solid Lubrication Enrique Guerrero, Rijan Karkee and David A. Strubbe; University of California, Merced, United States

Doping of MoS_2 can introduce novel functionality in terms of electronic, optical, magnetic, or mechanical properties. Experimental resolution of the doped structures have been challenging and often inconclusive, showing an important role for theory. In this work we study Ni-doped MoS_2, motivated specifically by its exploration as a solid lubricant in the low-temperature and low-pressure environment in space, where liquid lubricants fail [MR Vazirisereshk, A Martini, DA Strubbe, and MZ Baykara, Lubricants 7, 57 (2019)]. Some preliminary studies suggest that doping with transition metals (especially Ni) can improve tribology performance by reducing friction and wear, but the structure and mechanisms remain unclear. We use density functional theory (DFT) calculations to determine the structure and properties of Ni-doped MoS_2 in bulk and monolayer form, in various polytypes and doping levels. We consider formation energies for different sites for Mo or S substitution, intercalation, or adsorption, to create a phase diagram in chemical potential space to inform synthesis efforts. Our calculations identify structural changes on doping and which are the most stable structures. Stable Ni-doped MoS_2 phases and cases where phase segregation is favorable are identified. We compute infrared and Raman spectra to enable experimental identification of the doped structures coming from various growth methods. We additionally calculate elastic properties and potential energy for sliding to connect to atomic-force microscopy friction experiments, and use our DFT data to parametrize classical force fields for larger-scale reactive molecular dynamics simulations that can directly address friction and wear on larger length and time scales.

5:50 AM F.EL04.06.07
Preferred Distribution of Dopant Atoms in an Anisotropic Transition Metal Dichalcogenide Amin Azizi[1,1], Mehmet Dogan[1,2], Jeffrey Cain[1,1,2], Alessandro Varieschi[1], Marvin L. Cohen[1,2] and Alex Zettl[1,1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Doping provides a key scheme for tuning materials' functional properties. The atomic-scale control of the position, distribution, and concentration of dopants is crucially important in engineering the material's behavior. Two-dimensional (2D) crystals provide an extremely rich materials platform to study the behaviors of dopant atoms in different lattices and their impacts on material's properties. While there has been remarkable progress in the synthesis and atomic-scale characterization of doped 2D transition metal dichalcogenides (TMDs), most studies have focused on isotropic TMDs with a hexagonal structure. However, anisotropic TMD material systems with a 1T' structure offer a more versatile platform to study the behaviors of dopant atoms. For example, while there is only one atomic site for metal atoms in hexagonal TMDs with the 1H structure, there are two different atomic sites for metal atoms in anisotropic TMDs with the 1T' structure. Here, we dope an anisotropic TMD crystal and probe individual and coupled dopant atoms in its lattice using aberration-corrected scanning transmission electron microscopy (STEM) with sub-Ångstrom resolution. Statistical analyses on the atomically-resolved images reveal the preference of dopant atoms for specific atomic sites. Using density functional theory calculations, we develop a model to describe the preferred distribution of atomic species.

Two-Dimensional As_xP_{1-x} Alloys—Structural and Thermoelectric Properties Jacek B. Jasinski, Bhupendra Karki, Manthila Rajapakse and Gamini Sumanasekera; University of Louisville, United States

In recent years, van der Waals layered materials, especially their two-dimensional (2D) forms (monolayers, bilayers, and few-layers), have attracted significant attention as novel high-performance structures for a variety of applications, including thermoelectric devices, e.g. structures that are based on efficient conversion between heat and electricity. Thermoelectric properties and the performance of different 2D materials, such as SnSe, Bi_2Te_3, and MoS_2, have been studied extensively. Owing to its unique properties, such as high carrier mobility (1000 $cm^2(Vs)^{-1}$ at room temperature), a tunable thickens-

dependent bandgap (0.3–2.0 eV), a large Seebeck coefficient (335 μV K^{-1} at room temperature), and a strong in-plane anisotropy, black phosphorus (BP) and its 2D form, phosphorene, are among the most prospective thermoelectric materials. Recent investigations have indicated that the thermoelectric properties of BP can be further enhanced by alloying or doping. For example, a very high *ZT* value of 6.0 has been predicted by first-principle calculations in black phosphorous with 1/4 of its P atoms substituted with Sb atoms. Here, motivated by these works, we have synthesized a series of As_xP_{1-x} alloys and conducted a comparative study of their structural and thermoelectric properties. Raman measurements of these samples show the presence of 3 types of atomic vibrational modes arising from As-As bonding (< 270 cm^{-1}), As-P bonding (270 cm^{-1} - 350 cm^{-1}), and P-P bonding (> 350 cm^{-1}), respectively. For a wide range of As concentration, these materials are found to crystallize in the orthorhombic puckered structure and are alloy analogs of BP. Furthermore, it is found that the crystal structure of these As_xP_{1-x} alloys expands and their vibrational modes red-shift systematically with the increase of As. These changes are accompanied by the systematic changes of the electrical transport properties, especially the thermoelectric power. Temperature-dependent transport measurements show that, at room temperature, the samples with lower and intermediate As concertation exhibit very high thermopower (as high as 803 μV/K for x = 0.2 compared to 323 μV/K for BP) and high power factor (as high as 317 $\mu Wm^{-1}K^{-2}$ for x = 0.5 compared to 22 $\mu Wm^{-1}K^{-2}$ for BP). Overall, the study suggests that the thermoelectric properties of BP can be greatly improved by alloying, resulting in comparable or even better performance than some of the reported outstanding thermoelectric materials. Additional benefits of As_xP_{1-x} alloys include enhanced durability and higher resistance against degradation than those of BP. Finally, their unique in-plane anisotropy provides an opportunity for decoupling thermal and electronic transport pathways and therefore further enhancing thermoelectric properties.

SESSION F.EL04.07: Exploring 2D Crystal Phase Transitions

F-EL04

5:00 AM F.EL04.07.01
Temperature-Dependent Raman Scattering and X-Ray Diffraction Study of Phase Transitions in Layered Multiferroic $CuCrP_2S_6$ Michael A. Susner[1,2], Rahul Rao[1], Anthony Pelton[1,2], Michael V. McLeod[1,3] and Benji Maruyama[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States; [3]University of Dayton Research Institute, United States

Functional van der Waals layered materials, which exhibit interesting phenomena such as magnetism and ferroelectricity, have been proposed for use in next-generation nanoscale devices and sensors. Metal thiophosphates are an interesting class of 2D van der Waals gapped materials that contain a common structural framework where altering the cation composition can induce different types of ferroic ordering, including ferroelectricity and magnetism. making this family arguably the 2D equivalent od complex oxides.The compound $CuCrP_2S_6$ is a promising 2D material that evinces *multiferroic* behavior where the Cu^{+} and Cr^{+3} cations are responsible for antiferroelectric and antiferromagnetic ordering, respectively, which are theoretically predicted to couple. In this study, we use X-ray diffraction and Raman spectroscopy to map out these phase transitions in the range 70-400 K. The antiferroelectric phase transition is complex and shows a gradual transition to complete antipolar order with an intermediate quasi-antipolar step. X-ray diffraction studies reveal evidence for negative thermal expansion across the antipolar phase transition around 140 K. This is accompanied by a drastic reduction in rotational and translational mode frequencies of the anion groups in $CuCrP_2S_6$. Our temperature-dependent structural data provides an important reference for subsequent research into this promising 2D multiferroic material.

Active Learning of Fast Bayesian Mapped Gaussian Processes—Application to 2D to 3D Structural Phase Transition of Stanene Yu Xie, Jonathan Vandermause, Lixin Sun, Andrea Cepellotti and Boris Kozinsky; Harvard University, United States

Understanding metastability and phase transitions of 2D materials requires long and large-scalemolecular dynamics simulations, but this is hindered by lack of accurate force fields capable ofdescribing the vast variety of configurations and phases. Machine learning teachniques are attractivefor developing force field models because these powerful function-fitting schemes are capable ofreaching first principles accuracy at a small fraction of computational cost. Gaussian process (GP)regression is one promising technique among them, whose remarkable competitive advantage is thebuilt-in uncertainty quantification based on Bayesian posterior inference, which can be used tomonitor the quality of model predictions. A

current limitation of existing GP force fields is that theprediction cost grows linearly with the size of the training data set, making accurate GP predictionsslow. In this work, we exploit the special structure of the kernel function to construct a mapping ofthe trained Gaussian process model, including both forces and their uncertainty predictions, ontoa spline functions of low-dimensional structural features. This method extends previous proposalsof mapping only the forces by incorporating uncertainty at constant scaling cost, accelerating theactive learning workflow for training of Bayesian force fields. To demonstrate the capabilities of thismethod, we construct a force field for 2D stanene and perform large scale dynamics simulation ofits structural evolution as a function of termperature. We discover an unusual phase transformationmechanism of stanene, where the 2D metastable structure distorts, buckles and transforms into 3Dtin or a liquid phase depending on the temperature. By monitoring the uncertainty of the predictionwe are able to systematically improve the force field during the simulation, demonstrating a pathto autonomous learning of fast models for studying phase transformations of complex systems

5:20 AM F.EL04.07.05
Late News: Metal to Semiconductor Transition in MoTe2(1-x)S2x Ternary Alloys Florence A. Nugera, Adrian Popescu, Lilia M. Woods and Humberto R. Gutierrez; University of South Florida, United States

MoTe2 has received much attention due to its unique physical properties that make it good candidate for spintronics, thermoelectric and piezoelectric applications. MoTe2 is stable in both the 2H and 1T` phase. In general, the 1T`phase displays metallic behavior, making MoTe2 also interesting candidate for in-plane interconnects when combined with 2D semiconductors. In this study, we successfully synthesize large-area few-layers MoTe2 using a simple tellurization CVD process. Subsequently, the as-grown transition metal ditelluride was chemically modified using an in situ laser-assisted method recently developed in our group. The entire process takes place within a home-made mini chamber with an optical quartz window, where the samples are exposed to a laser beam in the presence of a controlled environment rich in different chalcogen atoms. For an optimized set of parameters (e.g. exposure time and laser power), the tellurium atoms are replaced by sulfur atoms. The chemical exchange process is monitored in real time via Raman spectroscopy. The site-selective replacement of the chalcogen atoms generate metal-semiconductor heterojunctions. 2D field effect transistors were fabricated to study the electrical response of these lateral heterojunctions. Additionally, we performed first-principle calculations for different chalcogen compositions in the ternary system MoTe2(1-x)S2x and found that the band structure evolves with increasing sulfur composition revealing a systematic transition from metal to semiconductor.

SESSION F.EL04.08: Fundamental Properties of 2D Materials—Computational Studies

5:00 AM F.EL04.08.02
The Role of Li Intercalation Played in the Structural Transition from Layered Black Phosphorene to Layered Blue Phosphorene—A First Principle Study Md Rajib khan K. Musa[1], Congyan Zhang[1], Manthila C. Rajapakse[1], Jacek B. Jasinski[2], Gamini Sumanasekera[1,2] and Ming Yu[1]; [1]University of Louisville, United States; [2]Conn Center for Renewable Energy Research, University of Louisville, United States

Blue phosphorene, a new allotrope of 2D phosphorus material, has been theoretically predicted to be energetically as stable as black phosphorene with energy difference less than 2meV. It has a wide fundamental bandgap (> 2 eV) compared to black phosphorene, tunable gap depending on the number of layers, semiconducting-semimetal transition under strain, possible high carrier mobility, higher in-plane rigidity, and superconductivity with metal intercalation, which would become a worthy contender in the emerging field of post-graphene 2D electronics, such as photodetectors, transistors, and other novel devices. The next task is to synthesize the newly predicted blue phosphorene and to utilize its unique properties in the next generation of nanolithography devices. However, it is a big challenge to simply exfoliate blue phosphorene from its bulk counterpart since blue phosphorus can only exist at high pressure (>5GPa). Alternatively, recent efforts by epitaxial growth method have produced a single layer of blue phosphorus, but it strongly depends on the surface structures of Au, Al. and Te substrates. Therefore, it is extremely desirable if we can develop a new pathway to produce freestanding blue phosphorene. Here, we proposed a novel kinetic pathway to grow layered blue phosphorene from layered black phosphorene via Li intercalation, based on first principle study. This study points out that Li atoms could play as ‘catalysts’ to drive P atoms in the ‘reactive region’ undergoing a bond-breaking process and lead to a local structural transformation from orthorhombic lattice to an assembly of parallel narrow nanoribbons with rhombohedra-like symmetry. After delithiation, these nanoribbons are self-

mended and a layered blue phosphorene is formed. The interlayer distance of the obtained blue phosphorene layers was given by ~ 3.56 Å, indicating a monolayer blue phosphorene could be obtained by mechanical exfoliation. This theoretical study not only reveals the novel transition mechanism from layered black phosphorene to layered blue phosphorene induced by Li interaction, but also provides a fundamental guidance for synthesizing blue phosphorene.

Why Do 2D Semiconductors Generally Have Low Electron Mobility? Yuanyue Liu; The University of Texas at Austin, United States

Atomically-thin (2D) semiconductors have shown great potential as the fundamental building blocks for next-generation electronics. However, all the 2D semiconductors that have been experimentally made so far have room-temperature electron mobility lower than that of bulk silicon. Although materials-specific explanations have been made [1,2], the "universality" of the low mobility is not well understood. Here, by using first-principles calculations and re-formulating the transport equations, we show that the universally low mobility of 2D semiconductors originates from the large “density of scatterings”, which is intrinsic to 2D system. The “density of scatterings” characterizes the number of phonons that can interact with the electrons, and can be fully determined from the electron and phonon band structures without knowledge of electron-phonon coupling strength. Our work reveals the underlying physics limiting the electron mobility of 2D semiconductors, and offers a descriptor to quickly assess the mobility.[3]

Pre-Equilibrium Effects in 2D Materials Under Particle Radiation Alina Kononov and Andre Schleife; University of Illinois at Urbana-Champ, United States

Ion beams in high-resolution imaging and patterning techniques can be used efficiently to manipulate and characterize 2D materials. Achieving higher precision control of the structure and properties necessitates a detailed understanding of the excited electron dynamics occurring in the material in response to the irradiation. Unfortunately, most existing knowledge concerning an energetic ion’s interaction with a material is limited to bulk. While many real-life radiation effects, such as electron emission, inherently involve surface processes also for thick materials, the case is particularly compelling for ion-irradiated 2D materials: Their myriad potential applications oftentimes rely on precise control of defects that can be achieved with ion irradiation. In this context, first-principles simulations are an ideal tool to characterize the elusive fundamental physics of ion-irradiated surfaces and inform ion beam microscopy and patterning techniques for 2D materials.

Here we discuss our recent application of real-time time-dependent density functional theory simulations to two examples: (i) As an ion approaches and traverses a surface, it is expected to exchange charge with the material and transition into a steady-state. We model this pre-equilibrium behavior for protons with 0.5 - 1.5 atomic units of velocity impacting few-layer aluminum sheets. This allows us to interpret an enhancement of energy deposition in the sheet, observed from our simulation results, as being tied to surface plasmons and we derive electron escape depths with important implications for optimization of focused ion beam techniques. (ii) We study energy transfer, charge induced, and electrons emitted for monolayer and trilayer graphene as H^{+}, He^{2+}, Si^{4+}, Si^{12+}, and Xe^{8+} ions with velocities of 0.5 - 4.6 au traverse the material. In particular, we study the emerging excited charge dynamics and its dependence on projectile velocity, trajectory, species, and charge as well as graphene thickness, with important implications for defect formation through particle radiation.

5:30 AM F.EL04.08.06
Unveiling Oxidation Mechanism of Bulk ZrS_2 and MoS_2 Liqiu Yang[1], Subodh C. Tiwari[1], Seong Soon Jo[2], Sungwook Hong[3], Ankit Mishra[1], Aravind Krishnamoorthy[1], Rajiv Kalia[1], Aiichiro Nakano[1], Rafael Jaramillo[2] and Priya Vashishta[1]; [1]University of Southern California, United States; [2]Massachusetts Institute of Technology, United States; [3]California State University, Los Angeles, United States

Transition metal dichalcogenides (TMDC) are known to show great potential for next-generation electric and optoelectronic

devices. In TMDC family, ZrS_2 has shown a superior electrical properties and chemical catalytic properties. However, native oxidation remains a major issue to improve its long-term stability and thus an active area of research. Here, we develop first-principles informed reactive force field for Zr/O/S and perform reactive molecular dynamics simulations to study oxidation of ZrS_2 and MoS_2 to elucidate the reaction mechanisms of oxidation process. Our results show a significantly larger oxidation rate for ZrS_2 in comparison with MoS_2. We find that the oxidation pathway of bulk ZrS_2 involves adsorption of oxygen on ZrS_2 surface, followed by amorphization and oxygen transport into bulk, leading to a continuous oxidation. In contrast, bulk MoS_2 remains inert due to the absence of oxygen transport into bulk. Our results show a valuable insight into the atomistic-scale mechanisms of native oxide formation and provide guidance for processing devices based on MoS_2 and ZrS_2.

This work was supported as part of the Computational Materials Sciences Program funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, under Award Number DE-SC0014607. Computations were performed at the Argonne Leadership Computing facility under the DOE INCITE and Aurora Early Science programs and at the Center for High Performance Computing of the University of Southern California.

5:40 AM F.EL04.08.07
Late News: Atlas of 2D Metals Epitaxial to SiC—Gapping Conditions and Alloying Rules Yuanxi Wang and Vincent Crespi; The Pennsylvania State University, United States

Although common in the periodic table, monoelemental metals appear severely under-represented in known families of 2D materials. Their recent realization in air-stable 2D form (e.g. Ga, In, and Sn), epitaxial to SiC and capped by graphene [1], suggests an immense chemical space of possible 2D metals and alloys that could expand the physics of 2D metals beyond what is known for graphene and Nb/Ta chalcogenides, including unusual nonlinear optical response [2] and 2D superconductivity with doped-semiconductor characters. Here we present a first-principles computational survey predicting the favorabilities of *all* metals in the periodic table in intercalating graphene/SiC. All experimentally known metal intercalant structures agree with predicted 2D metal ground states. This stability survey not only reveals conspicuous trends related to metal cohesive energies and metal-silicon bonding, but also identifies special groups of metals stabilized by opening a bandgap. We discuss conditions required for gapping, including electron counts and in-plane mirror symmetry breaking. From this gapping stabilization, alloying rules unique to 2D metals are derived.

5:50 AM F.EL04.08.08
Late News: Datamining for Substrate Materials Joshua T. Paul[1,2], Alice Galdi[3,3] and Richard G. Hennig[1]; [1]University of Florida, United States; [2]Northwestern University, United States; [3]Cornell University, United States

The design of 2D materials and thin-film devices requires the ability to grow high-quality films consistently and systematically. The selection of substrates is critical to this goal, as a poor match will result in undesired defects and other difficulties during synthesis. To systematically identify potential substrate materials, we apply a topological algorithm and data mining approach to the Materials Project database in search of low-energy surfaces that can act as substrates. Inspired by the recent high-throughput searches for exfoliable 2D materials, we develop a topological algorithm to cleave bonds in fully periodic crystals. If the bond cleaving generates a surface, we isolate the cleaved monolayer and calculate the energy needed to break these bonds. This algorithm is applied to all metastable crystals in the MaterialsProject database with five or fewer atoms in the primitive cell, identifying 4,703 unique surfaces across 2,136 crystals. We compare the cleavage energy to commonly used substrates to identify over 3,000 surfaces with cleavage energy below (0001) AlN. We follow by characterizing trends between cleavage energy and the precursor phase bandgap. We summarize the breadth of materials using the precursor bandgaps and lattice parameters of cleaved surfaces, establishing a computational substrate database. We test the applicability of this database by searching for epitaxial matches to (100) $BaSnO_3$, identifying several matches including (001) Rb_2NiO_2, (001) NiO, and (001) CaSe. We finalize by looking forward to ways to improve the computational prediction of thin-film and substrate interactions. We make this data freely available at MaterialsWeb.org and the software used to cleave the surfaces available in the open-source software package MPInterfaces.

Synthesis of Two-Dimensional Janus Crystals and Their Superlattices Mohammed Yasir Sayyad, Ying Qin and Sefaattin (Sef) Tongay; Arizona State University, United States

Two dimensional (2D) Janus Transition Metal Dichalcogenides (TMDs) are a new class of atomically thin polar materials. In these materials, the top and the bottom atomic layer are made of different chalcogen atoms. To date, several theoretical studies have shown that a broken mirror symmetry induces a colossal electrical field in these materials, which leads to unusual quantum properties. Despite these new properties, the current knowledge in their synthesis is limited only through two independent studies; both works rely on high-temperature processing techniques and are specific to only one type of 2D Janus material - MoSSe. Therefore, there is an urgent need for the development of a new synthesis method to (1) Extend the library of Janus class materials. (2) Improve the quality of 2D crystals. (3) Enable the synthesis of Janus heterostructures. The central hypothesis in this work is that the processing temperature of 2D Janus synthesis can be significantly lowered down to room temperatures by using reactive hydrogen and sulfur radicals while stripping off selenium atoms from the 2D surface. To test this hypothesis, a series of controlled growth studies were performed, and several complementary characterization techniques were used to establish a process–structure-property relationship. The results show that the newly proposed technique, namely Selective Epitaxy and Atomic Replacement (SEAR) is effective in reducing the growth temperature down to ambient conditions. The proposed technique benefits in achieving highly crystalline 2D Janus layers with an excellent optical response. Further studies herein show that this technique can form highly sophisticated lateral and vertical heterostructures of 2D Janus layers. Overall results establish an entirely new growth technique for 2D Janus layers, which pave ways for the realization of exciting quantum effects in these materials such as Skyrmion formation, 2D ferromagnetic ordering, topological superconductivity, and Majorana Zero Modes.

5:10 AM F.EL04.10.02
Abnormal van der Waals Interlayer Coupling Tailored through Janus MoSSe Kunyan Zhang[1], Yunfan Guo[2], Qingqing Ji[2], Shiang Fang[3], Efthimios Kaxiras[4], Jing Kong[2] and Shengxi Huang[1]; [1]The Pennsylvania State University, United States; [2]Massachusetts Institute of Technology, United States; [3]Rutgers University, United States; [4]Harvard University, United States

Janus transition metal dichalcogenide (TMD) differs from conventional TMDs by its out-of-plane mirror asymmetry and intrinsic dipole moment. The dipole moment of Janus TMD monolayer, MoSSe as an example, affects the interlayer coupling of their van der Waals heterostructures (HSs). Here, we present the unexpected interfacial interactions of Janus MoS_2/MoSSe HS by direct synthesis and twist stacking using low-frequency Raman spectroscopy. The interlayer coupling strength of Janus HS with 2H and 3R stackings is found to be strongly enhanced compared with their pristine MoS_2 counterparts through the linear chain model and density functional theory (DFT) calculations. Both experimental and DFT results indicate that the enhancement is attributed to the reduced interlayer distance due to the intrinsic dipole moment and the compressive strain of Janus MoSSe. On the other hand, low-frequency Raman modes of twisted MoS_2/MoSSe heterobilayers exhibit characteristic dependence on the twisting angles that the shear and breathing modes are both observable only at high-symmetry angles. All these spectroscopic features along with DFT calculations serve as a fingerprint of the strong interlayer coupling in Janus HSs and indicate the potential in tuning the interlayer coupling strength through Janus heterostacking.

5:20 AM F.EL04.10.04
2D Layered MOFs—The Response of a Flexible Platform to Dynamics of Confined Water Farnaz A. Shakib, Mohammad Reza Momeni Taheri, Yuliang Shi, Zeyu Zhang and Yen-Jui Chen; New Jersey Institute of Technology, United States

Conductive layered metal-organic frameworks (MOFs) are a new family of 2D materials which offer electrical conductivity in addition to the other known fascinating properties of MOFs including permanent porosity and high surface area. Making progress towards application of these materials as field effect transistors, semiconductors and supercapacitors depends on a deep understanding of the structural, electronic and dynamical behavior of 2D MOFs at the atomistic level. Here, we answer to the open question of the structural stability of 2D MOFs subject to humidity with emphasis on $Co_3(HHTP)_2$ and $Cu_3(HHTP)_2$, HHTP=2,3,6,7,10,11-hexahydroxytriphenylene, which show stark structural differences in aqueous solution. *Static* electronic structure methods are too perfect for reflecting the flexible nature of these layered materials

while *ab initio* molecular dynamics (AIMD) simulations are too expensive for providing a reliable picture of the complex dynamics in these systems. To tame the flexible and ever-changing layered structures of 2D MOFs, we develop *ab initio* parametrized force fields (AIFF) that allow large-scale/long-time simulations of the dynamics of both dry and hydrated MOFs. Our molecular dynamics simulations reproduces the structural properties of both MOFs as well as selective hydrolysis of metal nodes in hydrated $Co_3(HHTP)_2$ vs. intact metal nodes in hydrated $Cu_3(HHTP)_2$, in agreement with experimental reports. Our developed AIFFs reveal that the reason behind this behavior is the presence of \textit{intrinsic defect sites} in dry $Co_3(HHTP)_2$. Quantum mechanical calculations on cluster models cut from crystal structures confirm the higher tendency of Co^{2+} for coordination to water molecules compared to Cu^{2+} which prefers HHTP linkers. Our multi-faceted strategy paves the way toward simulation of realistic MOF-based materials and their interface with confined water molecules which is especially relevant to designing more robust water stable materials with desired properties and applications.

5:30 AM F.EL04.10.05
A Study on Electronic Properties of 2D MOFs Affected by Structural Deformations Zeyu Zhang and Farnaz A. Shakib; New Jersey Institute of Technology, United States

Introduction of a highly stable metal organic framework (MOF) in the late 90s has inspired a wide range of interest in these porous structures. Their high surface area and permanent porosity has stimulated a spectrum of applications for gas adsorption/storage, water treatment, heterogeneous catalysis, and even defunctionalization of chemical warfare agents. Synthesis of conductive 2D layered MOFs, where extended π-π conjugation creates possible intra- and inter-layer charge transfer path, opened another venue of potential applications for these intriguing materials. Tuning electronic properties of 2D MOFs for any specific application such as supercapacitors, field-effect transistors and electronically-induced chemical sensors can be a complicated challenge due to the flexibility of the layered structure that is composed of weak van der Waals interactions. The continuous strive for unravelling the electronic characteristics of 2D MOFs is most illustrated in the ongoing researches on $Ni_3(HITP)_2$, HITP= 2,3,6,7,10,11-hexaiminotriphenylene, which since its synthesis in 2014 has been the subject of a continuous debate on being a metallic or semiconductor material. This debate arise from the fact that most theoretical studies and experimental deductions neglect the flexibility and structural dynamics of 2D MOFs, the two characteristics which should be fully addressed before trying to tune their electronic properties for any specific applications. Here, we employ a range of theoretical tools to elucidate different structural aspects of 2D MOFs and their individual effect on the electronic properties and overall conductivity of the material. By obtaining the 1x1x1 $Ni_3(HITP)_2$ initial cell from experimental results, we construct a 2x2x2 unit cell and optimize it with periodic electronic structure calculation to get the most stable coordination geometry for metal site. According to this optimization, we develop an *ab initio* force field (AIFF) based on the most accurate quantum chemical calculations. Classical molecular dynamics based on the developed AIFF elucidate different structural deformations in specific environments. Then, we apply *ab initio* molecular dynamics (AIMD) to mimic same structural dynamics individually and determine their effects on electronic properties with subsequent periodic electronic structure calculations. Taking advantage of a combination of theoretical and computational tools, we create a general methodology to understand the electronic properties of 2D MOFs at an atomistic level.

5:40 AM F.EL04.10.06
Effect of BN Nanosheets on Mechanical and Thermal Properties of Polyethylene Nanocomposites Md Golam Rasul[1], Alper Kiziltas[2], Reza Shahbazian-Yassar[1] and Babak Arfaei[2]; [1]University of Illinois at Chicago, United States; [2]Ford Motor Company, United States

Hexagonal boron nitride (BN) is an excellent 2D nanomaterial due to possessing with impressive mechanical property (e.g. Young's modulus ~1 TPa), thermal stability up to 800 ºC, high thermal conductivity (600 W/m-K), and electrically insulative properties (band gap ~5.97 eV) (Boldrin *et al.*, 2011). These make BN a suitable reinforcement filler for the application of electrically insulating but thermally conductive polymer composite materials. While polymer nanocomposite offers a wide range of application including packaging to the automotive due to its exceptional low cost and lightweights with improved performances, one of the main challenges is the weak interfacial molecular interaction between reinforcement fillers and polymer matrix, affecting nanocomposite properties (Wang *et al.*, 2014).
In this work, we report a novel method to functionalize BNs by coupling agent silane (3-aminopropyltriethoxy) in order to assess the role of silane functional groups at the interface of polyethylene (PE) and BNs. We studied the effect of non-modified (pBN), and silane modified BNs (sBN) on the melt-extruded PE-BN composite performances by evaluating mechanical and thermal properties. While, both pBN and sBN nanomaterials enhance PE-BN nanocomposite performances, sBN have comparatively higher molecular interaction between PE matrix and BN fillers, resulting a significant improvement to the nanocomposite performances when compared with pBN composites. In comparison with PE materials, addition of 5 wt. % BN increases tensile modulus of elasticity by 37.4 and 42.2 %, tensile strength by 14.5 and 26.9 %, flexural modulus

of elasticity by 24 and 30.5 %, and storage modulus by 80 and 90.6 % for pBN and sBN nanocomposites, respectively. In addition to the mechanical reinforcement, thermal properties were also evaluated for PE-BN nanocomposites. While thermal stability of PE-pBN and PE-sBN nanocomposites was comparable, coefficient of thermal expansion was decreased by 11.7 and 20.3 % at 5 wt. % pBN and sBN loading, respectively. These results confirm enhanced molecular interaction of BN fillers with PE polymer matrix at the interface, affecting mechanical and thermal properties of the nanocomposites. The enhanced interfacial molecular interaction further reduced phonon scattering, resulting an increased thermal conductivity (14% increment for sBN composites when compared with pBN). However, low thermal stability of silane molecules makes it less attractive for limiting PE-BN nanocomposite thermal degradation. With 5 wt.% BN loading, PE-pBN nanocomposites show 4 ^{o}C increase in maximum degradation temperature while PE-sBN is increased by 2 ^{o}C. These polymer nanocomposites with enhanced mechanical and thermal properties can be an excellent choice for application in insulation materials, particularly for cables in automotive vehicles.

"Valley Noise" and Rydberg Excitons in Monolayer Semiconductors—Insights from (Really) High Magnetic Fields Scott Crooker; National High Magnetic Field Lab, United States

Much of the current interest in atomically-thin transition metal dichalcogenide (TMD) semiconductors such as MoS_2 and WSe_2 is driven by the physics of coupled spin & valley degrees of freedom and the potential for new spin- and valley-based devices. This talk will discuss recent optical studies that probe the valley-related physics of electrons, holes, and excitons in monolayer TMD semiconductors.

In a first study [1,2], we measure the polarized magneto-absorption spectra of high-quality exfoliated TMD monolayers in very large magnetic fields to 91 tesla, which allows to follow the diamagnetic shifts of not only the 1*s* ground state of the neutral exciton but also its excited 2*s*, 3*s*, ..., *ns* Rydberg states. The energies and diamagnetic shifts provide a direct determination of the effective (reduced) exciton masses and also the dielectric properties of these monolayer semiconductors – fundamental material parameters that until now were available only from theoretical calculations. Moreover, we also measure other important material properties, including exciton binding energies, exciton radii, and free-particle bandgaps. These results provide essential and quantitative parameters for the rational design of opto-electronic van der Waals heterostructures incorporating 2D semiconductor monolayers.

In a second study, we introduce an entirely passive, noise-based approach for exploring intrinsic valley dynamics in monolayer TMD semiconductors [3]. Under conditions of strict thermal equilibrium, we use optical Faraday rotation to "listen" to the thermodynamic fluctuations of the valley polarization in a Fermi sea of resident electrons or holes, due to their spontaneous scattering between the *K* and *K'*. Frequency spectra of this valley noise reveal narrow Lorentzian lineshapes and therefore very long intrinsic valley relaxation, especially for holes (~microseconds). These results provide quantitative measurements of intrinsic valley dynamics, free from any external perturbation, pumping, or excitation.

Isotropic and Anisotropic Polaritons in van der Waals Materials Qiaoliang Bao and Qingdong Ou; Monash University, Australia

Polaritons, hybrid light-matter excitations, enable nanoscale control of light. Particularly large polariton field confinement and long lifetimes can be found in graphene and van der Waals materials, opening new avenues for low-loss photonic

applications. Here, we present our recent progress in the discovery on engineering of these nanoscale polaritons in 2D materials [1,2]. First, plasmon polaritons arising from graphene and topological insulators were investigated in graphene/Bi_2Te_3, topological insulator Bi_2Te_3, graphene nanoribbon and 3D graphene using either spectroscopic or real space imaging techniques [3-6]. We show how the plasmonic coupling happens in two Dirac materials, how high-order plasmonic modes are observed in 3D graphene structure, how multiple plasmonic modes at sub-wavelength are achieved in graphene nanoribbon and how edge chirality controls the plasmonic shift.
We would also like to highlight our progress on the observation of anisotropic and ultra-low-loss polariton propagation along the surface of natural vdW material α-MoO_3 [7]. We visualized and verified phonon polaritons with elliptic and hyperbolic in-plane dispersion, which have been theoretically predicted but never experimentally observed in natural materials before. To better utilize the low-loss directional polaritons, we developed a chemical intercalation method to reversibly control and switch the phonon polaritons while maintaining their long lifetimes [8]. Combined with photolithography, spatially controlled polariton switching was achieved with various in-plane heterostructure configurations and patterns. Most recently, we show how the hyperbolic polaritons in α-MoO_3 thin slabs were delicately manipulated by controlling the interlayer twist angle [9]. We experimentally observed tunable topological transitions from open (hyperbolic) to closed (elliptical) dispersion contours in twisted α-MoO_3 bilayers at a photonic magic twist angle. The theoretical analysis showed these transitions of in-plane hyperbolic polaritons are controlled by a topological quantity. At the transitions, the photonic dispersion of the resulting topological polaritons flattens, exhibiting low-loss tunable polariton canalization and diffractionless propagation.
In summary, biaxial van der Waals semiconductors like α-MoO_3[7, 9] and V_2O_5[10] represent an emerging family of material supporting exotic polaritonic behaviors and these natural-born hyperbolic materials offer an unprecedented platform for controlling the flow of energy at the nanoscale.

5:30 AM *F.EL04.11.03
Nanophotonics with Low-Dimensional Excitonic Materials Deep M. Jariwala; University of Pennsylvania, United States

The isolation of a growing number of two-dimensional (2D) materials has inspired worldwide efforts to study their fundamental physical properties and integrate distinct 2D materials into van der Waals (vdW) heterostructures.[1-2] While the few atoms thick structure of 2D semiconductors naturally makes their electronic structure quantum confined, it also has profound implications on their optical properties.[3-4] Further being 2D in nature it also presents opportunities for engineering them into 0D and 1D quantum confined structures.[5] My talk will discuss our group's more recent work on optical phenomena and photonic devices made from 2D semiconductors. I will present how 1D nanostructuring of excitonic 2D semiconductors into nanophotonic dielectric gratings can enable exploration of new regimes of light-matter confinement including formation of hybrid exciton-plasmon-polariton states.[6] I will extend this discussion of light-matter interaction to excitonic/dielectric superlattices which are scalable over large areas. I will extend this concept to other excitonic materials and show dynamic tunability of their optical properties. If time permits, I will also discuss new approaches and methods for nanostructuring 2D semiconductors down to ~5 nm lateral dimensions with superior control of crystallinity and structure.[7] I will conclude by giving a broad perspective on future prospects of 2D materials from fundamental science to applications.

Tailoring B-Exciton Emission in a Mixed Dimensional MoS_2:$AgPO_3$ Nanoheterojunctions Abdus S. Sarkar[1], Emmanuel Stratakis[1,2], Ioannis Konidakis[1], Ioanna Demeridou[1,2], Efthymis Serpetzoglou[1,2] and George Kioseoglou[2]; [1]Foundation for Research and Technology Hellas, Greece; [2]University of Crete, Greece

Tailoring the photoluminescence (PL) in two dimensional (2D) transition metal dichalcogenide (TMDs) using external factors is one of the remarkable interest for its use in emerging valleytronics, nanophotonic and optoelectronic applications.[1,2] Significant effort have been devoted to enhance or manipulate the excitonic emission in a monolayer MoS_2. However, it has limited to the nanoscale fundamental studies for nanoelectronics and photonics applications. Here, we will

talk about a novel van der Waal nano- hybrid/heterojunctions system fabricated with a non-lithographic process to manipulate the PL emission, which is composed of a few layer MoS_2 integrated into a transparent semiconducting silver metaphosphate glass matrix. Successful isolation and formation of heterojunction revealed the preservation of phase integrity and the crystallinity. The heterojunctions demonstrated exotic intrinsic A- and B- excitonic peak emission. More interestingly we are able to tailor a dominant B- excitonic emission over A exitonic emission. A significant 6-fold enhancement in PL spectrum (van der Waals hetrojunctions) over a control sample was recorded (Figure 1).[3] Furthermore, exciton plasmon coupling was under taken to demonstrate the enhancement in B-excitonic emission of the van der Waals nanoheterojunctions. Finally, an ultrafast time-resolved spectroscopy interpreted the plasmon-enhanced electron transfer that takes place in Ag nanoparticles-MoS_2 nanoheterojunctions is behind the enhancement of the excitonic emission. No doubt, the efficient coupling of exciton-plasmon and tunability of B- excitonic emission pave great attention in emerging valleytronic and light emitting devices working with B excitons.

Observation of Polaronic Trions in $MoS_2/SrTiO_3$ Heterostructures Soumya Sarkar, Maxim Trushin, Sinu Mathew, Sreetosh Goswami, Shaffiue Adam and T. Venky Venkatesan; National University of Singapore, Singapore

The reduced electrical screening in two-dimensional (2D) materials provides an ideal platform for realization of exotic quasiparticles, that are robust and whose functionalities can be exploited for future electronic, optoelectronic and valleytronic applications. Recent examples include an interlayer exciton, where an electron from one layer binds with a hole from another, and a Holstein polaron, formed by an electron dressed by a sea of phonons. Here, we report a new quasiparticle, 'polaronic trion' in a heterostructure of $MoS_2/SrTiO_3$. This emerges as the Fröhlich bound state of the trion in the atomically thin monolayer of MoS_2 and the very unique low energy soft phonon mode ($\leq$ 7 meV, which is temperature and field tunable) in the quantum paraelectric substrate $SrTiO_3$ (STO), arising below its structural antiferrodistortive (AFD) phase transition temperature. This dressing of the trion with soft phonons manifests in an anomalous temperature dependence of photoluminescence emission leading to a huge enhancement of the trion binding energy (~70 meV). The soft phonons in STO are sensitive to electric field, which enables field control of the interfacial trion-phonon coupling and resultant polaronic trion binding energy. Lastly, these results suggest evidence of Rotational Frohlich Coupling a result of the counter intuitive interplay between the rotational axis of the MoS_2 trion and STO phonon mode. Polaronic trions could provide a platform to realize quasiparticle based tunable optoelectronic applications driven by many body effects.

Dispersion-Free Estimation of Color and Spectrum of Visible Light Using 2D Materials and Machine Learning Davoud Hejazi, Sarah Ostadabbas and Swastik Kar; Northeastern University, United States

Recognizing color is a primary means of object identification – both in biological and non-biological systems. In the latter case, i.e. conventional photodetection or imaging, arbitrary color-identification is not an inherent function. On one hand, a color-camera can disperse incident light into its red, green and blue (RGB) components (using filters) and merely record the voltage-response the RGB-filter-covered detectors in a 0-255 scale. However, either a classification algorithm or a human observer of the regenerated image is needed to recognize the color. For pure machine-based color recognition, the set of recorded RGB responses can be used to estimate the nearest color of the incident light without the observer's mediation. Spectral estimation on the other hand, usually carried out using dispersion-based spectrometers, is the process of breaking the incident light into its wavelength components via diffraction-grating and finding the intensity at each wavelength. These two types of tools, camera and spectrometers, however, cannot be used interchangeably and each have their limitations. We report

on a dispersion-free 2D materials-based and machine learning-enabled color and spectrum-estimator, that can mimic the color-estimation ability of the eye by learning to perceive new colors, as well as spectral estimation capability in the spectral range of 350 nm – 800 nm. This technique, where we use optical transmittance of a few transition-metal-dichalcogenide (TMD)-based thin-film filters -present an alternative for the estimation problem, and can reduce the manufacturing costs and the design complexities of the conventional color-estimation and spectrum-estimation tools, and also introduce the learning capacity to the estimator.
Through a comprehensive simulation scheme that led to the selection of an ideal set of filters, we have shown the importance of excitonic features of the transmittance curves in the estimation problem, and have designed and fabricated the thin-film filters based on outcome of these simulations. We have also studied the efficacy of various machine learning algorithms and identified the key advantages and limitations of each algorithm for color and spectrum estimation. Finally, by modeling the temporal drift of spectral transmittance of the filters over the period of one year, we have shown that it is possible to overcome the drift-induced inaccuracies over extended times.

Isotropic, Stronger Light Absorption in Atomically Thin Materials by Geometry Design Jong-Hoon Kang, Myungjae Lee, Fauzia Mujid and Jiwoong Park; The University of Chicago, United States

Two-dimensional (2D) materials are promising candidates for optoelectronics. Previous studies have shown that light absorption in 2D materials can be enhanced by generating multilayers using layer-by-layer stacking or integration with cavity resonators. However, these approaches have critical limitations as they may lead to optical properties that differ from the intrinsic properties of monolayers and they are still governed by the anisotropic thin film absorption with little control over light with different polarizations and incident angles. Here, we show that adding three-dimensional (3D) textures with controlled geometry to 2D materials, demonstrated with monolayers of transition metal dichalcogenides (TMDs), is a powerful solution to these challenges. For this, monolayer TMDs (MoS_2, WS_2, and WSe_2) were conformally grown on surfaces with nanoscale half-spherical textures, producing wafer-scale optical films with distinct geometry at different length scales: globally they behave as an optically flat substrate, whereas they possess isotropic bubble-like surfaces at the sub-wavelength limit. Spectrally-resolved, angle- and polarization-dependent absorption and reflection measurements confirm that all our TMD films with 3D textures have enhanced absorption for all visible wavelengths with a more pronounced enhancement for higher incident angles and p-polarization that flat optical films do not absorb strongly. This suggests that our TMD monolayers provide flat optoelectronic films with enhanced and isotropic light absorption, which can be precisely predicted by the geometric design of the surface texture parametrized by the aspect ratio of the domes in our experiment. This approach will advance the development of integrated optoelectronic circuitry with customizable light absorption.

6:25 AM F.EL04.11.08
Bulk Transition Metal Dichalcogenides for Integrated Photonics Haonan Ling, Renjie Li and Artur Davoyan; University of California, Los Angeles, United States

Transition metal dichalcogenide materials (TMDCs) are an emerging type of van der Waals semiconductors that possess unique electronic and optical properties[1,2] making them promising candidates for future photonic devices. Previous studies focused on monolayer/few layer structures, while, at the same time, properties of bulk materials and their applications have received little attention. Here we study theoretically light interaction with and propagation in bulk TMDCs materials. We show that owing to their high refractive index[3], TMDCs may pave the way to a new generation of optical components with higher light confinement and smaller footprint, when compared to traditional Si and III/V photonic devices.
We begin our analysis with a study of light guiding in a simple planar waveguide made of bulk TMDCs (MoS_2, $MoSe_2$, WS_2 and WSe_2) and conventional semiconductors (Si, InP and GaAs). In our analysis we focus on the near-infrared and telecom frequencies, that is, below the band gap of the semiconductors, where materials are transparent. By analyzing the dispersion and mode properties of such waveguides, we find that the waveguide footprint may be reduced almost twice when compared to counterparts made of Si. Next we extended our analysis to other waveguide structures, including ridge, rib and slot waveguides. We show that deeply subwavelength and highly confined light guiding is possible in waveguides made out of TMDCs. These findings may pave the way to novel subwavelength optical devices based on TMDC materials.
We further discuss light interaction with photonic crystals made of TMDC materials. Specifically, we have designed and analyzed a 2D photonic crystal slab with a cavity in it. We find that the size of such a cavity can be made significantly smaller (~30%) than that for a comparable Si or GaAs structures, while demonstrating higher resonator quality factor. Small device size and significant concentration of electromagnetic field have profound implications for quantum and nonlinear optics. Specifically, as we show, such cavities demonstrate a threefold enhancement of Purcell factor when compared to analogous Si resonators. We then demonstrate that strong optical confinement in a small volume leads to a strong light-materials interaction and can be utilized to create more energy efficient active devices, such as modulators. In particular, we

demonstrate that two-fold reduction in both cross-sectional area and switching energy consumption are possible with TMDC structures.
Finally we discuss a potential roadmap for integrated photonics based on TMDC structures. We show that owing to an enhanced light-materials interaction in TMDC nanostructures novel opportunities for highly integrated and energy efficient photonic devices emerge.

6:35 AM F.EL04.11.09
Anisotropic MoS2 Nanoscale Patterns for Light Interaction by Design Christian Martella[1], Andrea Camellini[2], Mukul Bhatnagar[3], Marina Caterina Giordano[3], Carlo Mennucci[3], Pinaka Pani Tummala[1], Debasree Chowdhury[3], Andrea Mazzanti[2], Margherita Zavelani Rossi[2,1], Giuseppe Della Valle[2,1], Francesco Buatier de Mongeot[3], Alessio Lamperti[1] and Alessandro Molle[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Politecnico di Milano, Italy; [3]Università degli Studi di Genova, Italy

Two-dimensional flat MoS_2 retains an outstanding interest as active material to manipulate light via modulation or harvesting, owing to its thickness dependent optical response. Starting from this background, MoS_2 layers nanostructured in anisotropic layouts gain an extra-control of the optical characteristics enabling fabrication of novel metasurfaces or flat-optic configurations for light harvesting [1]. Here we illustrate two possible methodologies to reduce ultra-thin MoS_2 to different anisotropic structural fashions. One consists of rippling MoS_2 by means of pattern-assisted chemical vapour deposition [2]. This way, we prove MoS_2 can be continuously grown on a one-directional pre-patterned substrate by means of chemical vapor deposition or sulfurization schemes therein mimicking the anisotropic shape feature [3]. This results in a strongly dichroic optical response that is concomitant with an anisotropic strain redistribution in the MoS_2 layer (revealed by 2D Raman mapping and Kelvin-probe force microscopy) [2] and with a peculiar exciton dynamics (revealed by transient optical spectroscopy) [4]. As an alternative, a second layout is based on physically separated MoS_2 stripes with nanoscale thickness (few nm) produced by sulfurization of a Mo ribbon-like pattern prefabricated by laser interference lithography. Spatial confinement in the stripe pattern results in an enhanced ultrabroadband amplification of the optical absorption throughout the visible spectrum following a guided-mode anomaly. This layout is also presented as a suitable platform where to engineer hybrid plasmonic systems as, for instance, coming from the interplay of MoS_2 nanostripes and Au nanoparticles. Overall, we show that MoS_2 (and expectedly other 2D transistion metal dichalcogenides with similar features) is strikingly suitable to anisotropy design expanding the edges of light-matter interactions with potential in applications for optical modulation, large-area flat optics, and light harvesting.

Study of Transmission Properties of Distorted 1T ReS_2 Based Type-II van der Waals Heterostructures Dipankar Saha and Saurabh Lodha; Indian Institute of Technology Bombay, India

For the last few years we have been witnessing significant progress in micro and nano photonics due to successful fabrication of atomically thin optoelectronic devices based on two-dimensional (2D) layered materials and their vertical stacks [1-5]. Considering near infrared (NIR)/short-wave infrared (SWIR) photodetection, we find a theoretical study reported in [6] which describes various possible combinations of group-6 and group-7 monolayer TMDs. Among different combinations of type-II van der Waals (vdW) heterointerfaces, owing to efficient generation, separation, and collection of charge carriers, it has been found that both ReS_2/WSe_2 and $ReS_2/MoSe_2$ emerge as potentially promising candidates for the next generation ultrathin optoelectronic devices [6].
However, the analysis of electronic transmission through ReS_2/WSe_2 and $ReS_2/MoSe_2$ heterostructures is required for further insights on their conductance at near-equilibrium. In this work, employing density functional theory (DFT) and nonequilibrium Green's function (NEGF) combination, we have computed zero bias transmission spectra of the two-port devices with monolayer ReS_2/monolayer WSe_2 and monolayer ReS_2/monolayer $MoSe_2$ channels. In order to conduct first-

principles based DFT calculations, we have utilized the "QuantumATK" software package [7].
For a small energy range (-2 eV to 2 eV) near the Fermi level, we find that the electronic transmission through $ReS_2/MoSe_2$ heterointerface is slightly better than that in ReS_2/WSe_2. Besides, the near-direct bandgap and superior optical absorption of the constituent $MoSe_2$ layer are the other key features which make $ReS_2/MoSe_2$ heterostructure suitable for NIR/SWIR photodetection [6]. However, the electronic structure calculations reveal that the larger band offset values at the interface can ensure better separation of charge carriers for ReS_2/WSe_2 vertical stack.

Optics in Crystalline Atomically-Thin Films—Nonlinear and Nonlocal Phenomena Alvaro Rodriguez Echarri[1], Joel Cox[2,3] and Javier Garcia de Abajo[1,4]; [1]ICFO - The institute of Photonic Sciences, Spain; [2]Center for Nano Optics, University of Southern Denmark, Denmark; [3]Danish Institute for Advanced Study, University of Southern Denmark, Denmark; [4]ICREA – Institució Catalana de Recerca i Estudis Avançats, Spain

Crystalline metallic films are attracting significant attention within the nanophotonics community as a material platform for plasmonics that offers light concentration and manipulation on extreme subwavelength scales with lower intrinsic losses than for plasmons in amorphous metal films. Recent advances in nanotechnology now enable the fabrication of such crystalline films with nanometer-scale thickness, down to the level of only several atomic monolayers, further boosting plasmon confinement for the miniaturization of next-generation electronic and photonic devices. However, in very thin crystalline metallic films, quantum mechanical effects play a non-negligible role in the dynamics of electrons and their interaction with external electromagnetic fields, manifesting in the spectral features associated with its linear optical response that depend on film thickness and crystallographic orientation. These effects are anticipated to become even more significant when dealing with nonlinear optical phenomena, which necessitate intense optical fields that access additional transitions among quantized electronic states.
Here we reveal quantum and finite-size effects in the nonlinear optical response associated with plasmons supported by few-atom-thick crystalline noble metal films. In particular, we employ a quantum-mechanical description that captures the main features in the electronic band structure associated with the various crystal facets of noble metals to simulate their nonlinear optical response by extending the random-phase approximation to higher orders. Our results demonstrate strong signatures of film thickness and crystallographic orientation in the linear plasmonic response that are amplified in nonlinear optical processes such as harmonic generation and two-photon absorption, with additional effects attributed to surface states, electron spill out, and the directional band gap associated with bulk atomic-layer corrugation. These findings are of key importance in the characterization of atomically-thin crystalline films and their applications for nonlinear plasmonic nanophotonic devices.

7:05 AM F.EL04.11.12
Exfoliated $CrPS_4$ with Promising Photoconductivity Adam K. Budniak[1], Niall A. Killilea[2], Szymon J. Zelewski[3], Mykhailo Sytnyk[2], Yaron Kauffmann[1], Yaron Amouyal[1], Robert Kudrawiec[3], Wolfgang Heiss[2] and Efrat Lifshitz[1]; [1]Technion--Israel Institute of Technology, Israel; [2]Friedrich-Alexander Universitat Erlangen-Nurnberg, Germany; [3]Wroclaw University of Science and Technology, Poland

Layered semiconductors attract significant attention due to their diverse physical properties controlled by their composition and the number of stacked layers. Herein, large crystals of the ternary layered semiconductor chromium thiophosphate ($CrPS_4$) are prepared by a vapor transport synthesis. Optical properties are determined using photoconduction, absorption, photoreflectance, and photoacoustic spectroscopy exposing the semiconducting properties of the material. A simple, one-step protocol for mechanical exfoliation onto transmission electron microscope grid is developed [1,2] and multiple layers are

characterized by advanced electron microscopy methods, including atomic resolution elemental mapping confirming the structure by directly showing the positions of the columns of different elements' atoms. $CrPS_4$ is also liquid exfoliated and in combination with colloidal graphene, an ink-jet printed photodetector is created. This all-printed graphene/$CrPS_4$/graphene heterostructure detector demonstrates specific detectivity of 8.3×10^8 (D*). This study shows a potential application of both bulk crystal as well as individual flakes of $CrPS_4$ as active components in light detection, when introduced as ink printable moieties with a large benefit for manufacturing [1].

Charge Carrier Relaxation Dynamics and Phonon Coupling in Layered Bismuth Halide Semiconductors Lissa Eyre[1], Tahmida Huq[2], Lana C. Lee[2], Robert Hoye[3], Hannah Joyce[2] and Felix Deschler[1]; [1]Technical University Munich, Germany; [2]University of Cambridge, United Kingdom; [3]Imperial College London, United Kingdom

A promising class of lead-free semiconductors for photovoltaic applications include the bismuth halides, such as bismuth iodide [1], bismuth oxyiodide [2] and the double perovskite Cs2AgBiBr6 [3]. Although these materials have been predicted to exhibit defect tolerance, as seen in lead-halide perovskites, and already display improved stabilities and long charge carrier lifetimes, the power conversion efficiencies of the corresponding devices have not reached the level of lead-based perovskites. Potential reasons for this are explored, for example, the disconnected nature of the bismuth halide octahedra in the crystal structure, which limits carrier mobility, and the lower levels of absorption due to indirect bandgaps.
Phonons have been shown to play a crucial role in carrier transport and hot carrier cooling in the lead halides [4], and there are many reports of strong carrier-phonon coupling, especially in low-dimensional morphologies [5]. The effect of phonons is expected to be even greater in the bismuth based perovskites due to their indirect bandgaps, as carriers will emit phonons to cool to the band extrema separated in momentum space from the excitation point, as well as to recombine. The combined effects of quantum confinement and coupling to phonons could allow carriers to overcome this distance in momentum space. The relative rates of these processes are vital for device efficiency, therefore we probe the early-time excited states in many bismuth halide semiconductors using transient absorption, Raman and photoluminescence spectroscopy. Overall, this work indicates that bismuth-based materials have the potential to be used in efficient optoelectronic devices, but there is a need to account for the effects of strong carrier-phonon coupling and localisation of electronic states on carrier scattering rates. We therefore present charge carrier-lattice interaction strength as an important design criterion for efficient next-generation solar cells.

Coupling between Light and 2D Polaritons—Fundamental Limits and How to Overcome Them Eduardo Brioso Dias[1] and F. Javier Garcia de Abajo[1,2]; [1]ICFO–The Institute of Photonic Sciences, Spain; [2]ICREA - Institució Catalana de Recerca i Estudis Avançats, Spain

Polaritons in 2D materials have been extensively studied over the past decade due to their fundamental interest and as a

platform for applications in telecommunications and sensing [1]. The wavelength of these polaritons is generally small compared to that of a photon of the same frequency [2], making them very attractive to manipulate light at deep-subwavelength distances. However, it simultaneously introduces a challenge in the coupling between propagation light and plasmonic modes, since the momentum mismatch between the two makes the in/out-coupling of this process intrinsically weak [2].

In this work, we address some fundamental limits in the coupling of radiation to 2D polaritons [3]. We study the scattering properties of 0D and 1D scatterers over a 2D or finite-thickness layer and quantify the coupling of light-to-polaritons cross-section for this process as a function of the scatterer effective polarizability. We find a generalization of the optical theorem to 2D polaritons, which allows us to determine the maximum possible value of their effective polarizability, which is remarkably independent of material. We present our results in the form of simple and rigorous analytical expressions, delivering an exact quantitative measure of photon-to/from-polariton coupling and polariton-to-polariton scattering. To that end, we first introduce a universal characterization of 2D SPs and their associated optical fields in terms of a single parameter – the ratio of their wavelength λ_p to the film thickness – regardless of the physical nature of the material's response. This allows us to determine the efficiency of different optical scattering channels involving incident light and polaritons, expressed in terms of universal light−polariton coupling strengths and fundamental limits to the scatterer polarizability. We write the result as a universal curve that is applicable to any layer thickness in the electrostatic approximation. Additionally, this result leads to a maximum light-to-polariton coupling cross-section which we explore, particularly by directly comparing the coupling efficiency of 0D and 1D scatterers and finding that the latter are up to 100 times more efficient than the former. We formulate our results for both 0D and 1D scatterers, including material edges, and present them in simple closed-form expressions. We finally propose coupling light to plasmons using a graphene edge as a configuration which maximizes the coupling efficiency, and address the case of scatterers with intrinsic losses to propose an optimum distance between the surface and the scatterer which maximizes the efficiency.

We find the maximum possible photon-to-polariton cross section to be of the order of λ_p^3/λ_0 and λ_p^2/λ_0 for point and line scatterers, respectively (λ_0 is the light wavelength). For graphene, the limits to in-coupling are quantified by the maximum possible ratio between the numbers of generated plasmons and incident photons $N_{plasmon}/N_{photon} \sim \alpha^3$ and α^2 for point and line scatterers, where $\alpha \approx 1/137$ is the fine structure constant. Besides their fundamental interest, our results provide useful tools for the design of optical devices involving the in/out-coupling of propagating light and 2D SPs.

7:35 AM F.EL04.11.15
Late News: Interlayer Excitons in Bilayer MoS2 Shivangi Shree[1], Ioannis Paradisanos[1], Nadine Leisgang[2], Antony George[3], Lukas Sponfeldner[2], Cedric Robert[1], Kenji Watanabe[4], Takashi Taniguchi[4], Richard J. Warburton[2], Andrey Turchanin[3], Xavier Marie[1], Iann C. Gerber[1] and Bernhard Urbaszek[1]; [1]CNRS LPCNO INSA-CNRS-UPS, France; [2]University of Basel, Switzerland; [3]Institute of Physical Chemistry, Friedrich Schiller University, Germany; [4]National Institute for Materials Science, Japan

Transition metal dichalcogenides (TMDs) are ideal for exploring fundamental physics and applied optics as they are semiconductors with a direct bandgap in the monolayer limit. Chemical vapor deposition (CVD) allows growing wafer scale thin films of TMDs. The improved optical quality of MoS_2 monolayers with a reduced transition linewidth below 5 meV at low temperature (T = 4 K) by reducing dielectric disorder allows combining CVD grown MoS_2 monolayers to form multilayers to access new functionalities [1,2].

We examine the correlation between the stacking order and the interlayer coupling of valence states in high quality MoS_2 as grown CVD bilayers and artificially stacked bilayers from CVD monolayers. We show that hole delocalization over the bilayer in 2H stacking is
allowed and results in strong interlayer exciton absorption and also in a larger A-B exciton separation as compared to 3R bilayers, where both holes and electrons are confined to the individual layers [2,3]. Comparing white light reflectivity spectra for 2H and 3R stacking allows extracting an interlayer coupling energy of about 50 meV. Obtaining very similar results for as-grown and artificially stacked bilayers is promising for assembling large area van der Waals structures with CVD material, using inter layer exciton formation and A-B exciton separation as indicators for interlayer coupling [2].

In bilayer MoS_2 the interlayer exciton has an out-of-plane static electric dipole. We show that as a result the interlayer exciton transition energies are widely tunable in applied electric fields, which is impossible for excitons in monolayers.

We show tuning over 120 meV of interlayer excitons with a high oscillator strength in bilayer MoS_2 due to the quantum-confined Stark effect [4]. We optically probed the interaction between intra- and interlayer excitons as they were energetically tuned into resonance. Interlayer excitons interact strongly with intralayer B excitons, as demonstrated by a clear avoided crossing, whereas the interaction with intralayer A excitons is substantially weaker. Our observations are supported by density functional theory (DFT) calculations, which include excitonic effects.

7:45 AM F.EL04.11.16
Late News: Two-Dimensional Material-Based Nanocomposites for Photocatalytic Environmental and Energy Applications Qingzhe Zhang, Mohamed Chaker and Dongling Ma; INRS, Canada

Following the graphene breakthrough, many other 2D materials have been discovered and extensively studied due to their exceptional physicochemical properties arising from the unique layered structure. Therein, 2D graphitic carbon nitride (g-C_3N_4) nanosheet has attracted dramatically increasing attention as a photocatalyst because of its nontoxicity, low cost, high stability and large surface, etc. However, g-C_3N_4 is still suffering from fast recombination of photo-induced charge carriers and insufficiently broad photoresponse range.[1-2] Herein, we will present some of our recent development in efficient and broadband 2D g-C_3N_4 nanosheet-based photocatalysts. One example is about our synthesized nanocomposites based on plasmonic Au nanoparticles (NPs) and in-situ synthesized lanthanide-doped $NaYF_4$ on g-C_3N_4. It showed enhanced ultraviolet (UV)-, visible- and near infrared (NIR)-light photocatalytic activity in the degradation of organic pollutants.[3] The used Au and rare-earth metals in this work are still expensive. To utilize solar energy more efficiently and cost-effectively, a 0D/2D heterojunction based on NIR-responsive quantum dots loaded g-C_3N_4 nanosheets was constructed, which showed a record NIR photocatalytic activity in wastewater treatment.[4] The use of heavy-metal based QDs constitutes a big concern in the environmental application. To utilize solar energy more environmentally-friendly, a completely metal-free 2D/2D heterojunction of black phosphorus (BP)/g-C_3N_4 was synthesized.[5] The 2D/2D heterojunction showed high activity and long-term stability in solar H_2 evolution. It is noteworthy that we developed an innovative, “organic ice”-assisted exfoliation method,[6] which led to the high-yield and high-quality few-layer BP with largely reduced energy inputs and processing time. In addition to yielding novel and interesting materials and properties, the current work also provides physical insights that can contribute to the future development of broadband photocatalysts and their applications in energy and environmental areas.

5:00 AM *F.EL04.12.01
What Governs the “Efficiency“ of Liquid Phase Exfoliation of Layered Crystals? Claudia Backes; Heidelberg University, Germany

Liquid phase exfoliation has become an important top down production technique giving access to large quantities of nanosheets in colloidal dispersion. Importantly, this is a highly versatile technique that can be applied to numerous layered materials from graphite to transition metal dichalcogenides, h-BN, III-VI semiconductors, hydroxides etc. All materials can be exfoliated in a similar way using aqueous surfactant or suitable solvents as stabilisers. Nanosheets in dispersion are extremely polydisperse with broad lateral size and thickness distributions. To narrow size and thickness distributions, liquid cascade centrifugation has proven to be a powerful tool for efficient size selection yielding nanosheet dispersions with well-defined dimensions.
Building on these established methodologies of exfoliation and size selection, it became possible in recent years to adress some fundamental questions regarding the exfoliation process, such as: In which way is the yield, nanosheet size and layer number dependent on the liquid medium? What is a good descriptor for the exfoliation efficiency and what does it depend on? What is the role of defects? In this talk, these fundamental questions will be addressed and a picture of the current understanding will be drawn.

5:15 AM F.EL04.12.03
Crystal Phase Engineering in Ternary $W_xMo_{1-x}Se_2$ Colloidal Nanoflowers for Efficient Catalytic Hydrogen Reduction Maria S. Sokolikova, Gang Cheng, Mauro Och, Pawel Palczynski and Cecilia Mattevi; Imperial College London, United Kingdom

Layered transition metal dichalcogenides (TMDs) exhibit a rich diversity of structural polymorphs defined by the coordination symmetry of transition metal atoms.[1] Tailoring the lattice symmetry within individual TMD layers enables disparate electronic properties ranging from semiconducting (2H phase) to metallic and semimetallic (1T/1T' phases) for the same material composition. The metastable 1T/1T' polymorphs are generally obtained by destabilisation of the thermodynamically stable 2H phase, for instance, via electron transfer. The metastable 1T/1T' phases are particularly appealing for the heterogeneous catalysis as they demonstrate higher electrical conductivity and higher density of catalytically active sites compared to the semiconducting 2H counterparts.[2] Yet to date, obtaining the metastable 1T/1T' phases of high purity and in measurable quantities remains challenging. In our previous work, we demonstrated a successful colloidal synthesis of the 1T' phase of WSe_2.[3] Here, we report on how the designed colloidal approach can be expanded to synthesise $W_xMo_{1-x}Se_2$ (x = 0-1) nanostructures. Although colloidal $MoSe_2$ nanoflowers are attained in the 2H phase, alloying with tungsten, which under the same synthesis conditions forms the 1T' phase of WSe_2, allowed us to stabilise the 1T' phase in the ternary $W_xMo_{1-x}Se_2$ nanostructures. Moreover, the $W_xMo_{1-x}Se_2$ nanostructures display tunable 1T'/2H crystal phase ratio that depends on their chemical composition. A set of the $W_xMo_{1-x}Se_2$ (x = 0-1) working electrodes was tested for the catalytic hydrogen evolution reaction (HER). The ternary 1T'/2H $W_xMo_{1-x}Se_2$ (x ~0.5) nanoflowers demonstrate an enhanced catalytic activity and faster reaction kinetics compared to either the pristine 2H $MoSe_2$ or the 1T' WSe_2 nanoflowers. We suggest that the presence of the metastable 1T' phase in the ternary $W_xMo_{1-x}Se_2$ (x ~0.5) nanoflowers may cause the observed improvement in the catalytic performance.

5:25 AM F.EL04.12.04
Exfoliation and Deposition of 2D Phosphorene Nanosheets via Bipolar Electrochemistry for High-Performance Capacitive Energy Storage Applications Amin Rabiei Baboukani[1], Iman Khakpour[1], Vadym Drozd[2] and Chunlei Wang[1]; [1]Florida International University, United States; [2]Center for the Study of Matter at Extreme Conditions (CeSMEC), United States

Black phosphorus (BP), which was discovered by Bridgman back in 1914, has recaptured attention due to its promising physical and chemical properties. BP is the thermodynamically stable allotrope of phosphorous under ambient conditions. It is a layered material that can be exfoliated into a monolayer two-dimensional (2D) material similar to graphene. As a rising star in 2D materials, few-layer phosphorene is considered a strong competitor against other 2D materials and can be applied in an increasing number of fields such as energy storage and biomedical devices. To realize its real properties, the wide application of phosphorene nanosheets depends on the development and optimization of exfoliation methods. Fabricating BP with a high level of quality, uniformity, and producibility is of crucial importance for its large-scale application. Among

various top-down and bottom-up exfoliation methods, electrochemical exfoliation has emerged as an attractive approach for exfoliating 2D materials with high quality and high yields. However, they are multi-step and time-consuming procedures, and thus less attractive for practical applications. It is, therefore, necessary to develop alternative techniques that can fabricate and deposit phosphorene nanosheets on substrates in a facile, single-step, scalable, and eco-friendly manner for energy storage devices. In this study, we propose a novel and straightforward two-in-one process to exfoliate bulk BP into phosphorene nanosheets in DI water, which are then dragged electrophoretically to be deposited on a conductive substrate. The procedure is based on the mechanism of bipolar electrochemistry (BPE), which is based on applying a sufficiently high voltage to generate electrochemical reactions between two feeding electrodes and a conductive bipolar electrode placed wirelessly between them. The difference in the electric potential between the solution and the bipolar electrode drive redox reactions on the cathodic and anodic poles of the bipolar electrode. Due to the concept of BPE, in general, the induced voltage on the two poles of bulk BP depends on the applied voltage, length of the BP electrode, and distance between the two feeding electrodes. After 24 hours of BPE, bulk BP did not show any noticeable change; however, obvious deposition of a thin film on the feeding electrodes of the bipolar cell can be observed. The exfoliated-and-deposited BP nanosheets were characterized with different microscopic and spectroscopic techniques (SEM, Raman, XPS, and HR-TEM analysis), revealing thin layers of 2D phosphorene with the orthorhombic crystal structure and lateral dimensions up to a few hundreds of nanometers. SEM images showed the high-quality 2D morphology of phosphorene nanosheets on the feeding electrodes. TEM images confirmed that the crystal structure of BP appears to be not affected by the bipolar exfoliation, which confirms a low defect concentration in the produced phosphorene nanosheets. Owing to the 2D structure of the exfoliated-and deposited phosphorene, the electrochemical performance of the phosphorene nanosheets was evaluated for capacitive energy storage application in a two-electrode symmetric configuration (EIS, CV, and GCD). The deposited 2D phosphorene nanosheets delivered high specific capacitance of 11 mF cm^{-2} at the scan rate of 2 mV s^{-1} and specific capacitance of 8.57, 7.62, 6.66, 5.0, 4.65, 4.01, 3.32, and 2.86 mF cm^{-2} at the scan rate of 5, 10, 20, 50, 100, 200, 500, and 1000 mV s^{-1}, respectively, which is superior than most of the 2D materials-based devices such as MXene, 2D MnO_2, graphene or graphene oxide. This non-toxic, straightforward, and inexpensive novel method could be applied for other 2D materials for energy storage and biomedical application. In this conference, detailed novel bipolar exfoliation and deposition of phosphorene nanosheets and its electrochemical characterization will be presented.

SESSION F.EL04.13/F.MT06.03: Joint Session: Quantum Phenomena in Atomically Thin Materials

F-EL04

5:00 AM *F.EL04.13/F.MT06.03.01
Interlayer Excitons in van der Waals Heterostructures Philip Kim; Harvard University, United States

A pair of electron and hole across the interface of semiconductor heterostructure can form a bound quantum state of the interlayer exciton. In a coupled interface between atomically thin van der Waals layers (vdW), the Coulomb interaction of the interlayer exciton increases further. In this presentation, we will discuss observing interlayer exciton formation in semiconducting transition metal dichalcogenide (TMDC) layers. Unlike conventional semiconductor heterostructures, charge transport in of the devices is found to critically depend on the interlayer charge transport, electron-hole recombination process mediated by tunneling across the interface. We demonstrate the enhanced electronic, optoelectronic performances in the vdW heterostructures, tuned by applying gate voltages, suggesting that these a few atom thick interfaces may provide a fundamental platform to realize novel physical phenomena. Furthermore, complete experimental control of density, displacement and magnetic fields in our graphene double layer system enables us to explore the rich phase diagram of several superfluid exciton phases with the different internal quantum degrees of freedom.

5:15 AM *F.EL04.13/F.MT06.03.02
Tunable Quantum Transport High Mobility 2D Materials Jeanie Lau; The Ohio State University, United States

One of the most alluring features of 2D materials is their tunability, as their carrier density, effect mass, band gap, and electronic phases can be tuned in situ by external parameters such as electric field, magnetic field and strain. Here we will present transport studies of high quality 2D materials. For instance, we demonstrate large tunable SOC and zero-field spin-splitting in atomically thin InSe with unprecedented mobility. From beating patterns in quantum oscillations, we establish

that the SOC parameter *a* is thickness-dependent; it can be continuously modulated over a large range by an out-of-plane electric field, achieving zero-field splitting tunable between 0 and 20 meV. Surprisingly, *a* could be enhanced by an order of magnitude in some devices, suggesting that SOC can be further manipulated by variations in interlayer spacing induced by stacking and/or electrostatic compression. Our work highlights the extraordinary tunability of SOC in 2D materials, which can be harnessed for *in operando* spintronic and topological devices and applications.

5:30 AM *F.EL04.13/F.MT06.03.03
Electron Interactions in 2D Materials—Correlated Multi-Particle Excitations and Optical Field Driven ARPES Steven G. Louie[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Many-electron interaction effects dominate many spectroscopic properties of reduced-dimensional systems, leading often to manifestation of novel phenomena not seen in the bulk. In this talk, I present some of our recent work on electron interaction effects in atomically thin quasi 2D materials: (1) strongly bounded correlated multi-particle excitations, such as trions and bi-excitons, in quasi 1D and 2D materials; (2) giant excitonic effects in shift currents, a nonlinear optical phenomenon, in non-centrosymmetric quasi 2D semiconductors; and (3) excitons and band renormalization in optical field driven angle-resolved photoemission spectroscopy (ARPES). Studies of these novel phenomena are made possible because of newly developed theoretical methods which incorporate higher-order many-electron correlation effects from first principles, using an interacting Green's function approach.

5:45 AM *F.EL04.13/F.MT06.03.04
Quantum Anomalous Hall Effect in Intrinsic Magnetic Topological Insulator $MnBi_2Te_4$ Yuanbo Zhang; Fudan University, China

In a magnetic topological insulator, nontrivial band topology conspires with magnetic order to produce exotic states of matter that are best exemplified by quantum anomalous Hall (QAH) insulators and axion insulators. Up till now, such magnetic topological insulators are obtained by doping topological insulators with magnetic atoms. The random magnetic dopants, however, inevitably introduce disorders that hinder further exploration of topological quantum effects in the material. We resolve this dilemma by probing quantum transport in $MnBi_2Te_4$ thin flake—a topological insulator with intrinsic magnetic order. In this layered van der Waals crystal, the ferromagnetic layers couple anti-parallel to each other, so bulk $MnBi_2Te_4$ is an antiferromagnet. Atomically thin $MnBi_2Te_4$, however, becomes ferromagnetic when the sample has odd number of septuple layers (a septuple layer represents a single structural unit in the out-of-plane direction). We observe zero-field QAH effect in a five-septuple-layer specimen; an external magnetic field further enhance the QAH quantization by forcing all layers to align ferromagnetically. $MnBi_2Te_4$ therefore becomes the first intrinsic magnetic topological insulator exhibiting QAH effect.

6:00 AM *F.EL04.13/F.MT06.03.05
THz-Driven Irreversible Topological Phase Transition in Monolayer $MoTe_2$ Keith A. Nelson; Massachusetts Institute of Technology, United States

The availability of intense tabletop terahertz-frequency pulses and simple field-enhancement structures that enable peak electric fields of tens of MV/cm have ked to demonstrations of highly nonlinear THz-induced responses from a wide variety of materials. THz-driven electronic, magnetic, and structural phase transitions and domain switching have illustrated novel possibilities for control over collective properties and dynamics. In experiments on single-layer and few-layer $MoTe_2$, we have found that irradiation with just one sufficiently strong THz pulse induces an irreversible phase transition [1]. The initial, noncentrosymmetric 2H phase disappears, as shown by the disappearance of characteristic Raman lines and second harmonic generation. After further THz irradiation, the topological insulator phase appears, revealed by its distinct Raman spectrum. Single-shot measurements of the $MoTe_2$ evolution as a function of time after THz irradiation reveal complex dynamics over many-picosecond time scales. Theoretical calculations show that the transition is induced through THz-induced liberation of carriers which stabilize the new phase and reduce the energy barrier between the two phases. The result illustrates the prospects for THz control over complex multiphase landscapes in quantum materials.

6:15 AM *F.EL04.13/F.MT06.03.06

Conformal, Area-Specific and Switchable Graphene Nanowrinkles Teri W. Odom; Northwestern University, United States

Selective patterning and functionalization of graphene can produce spatially-defined properties. Buckling or wrinkling of graphene on polymeric substrates enables a direct approach to tune the physical properties without lithographic steps, and the resulting curvature of the wrinkles can control local chemical reactivity. However, most buckling methods have been limited by the range of wavelength tunability, only global control of the wrinkled patterns, and delamination and cracks in the graphene. This talk will describe a scalable approach to achieve area-specific reactivity and patterning of conformal graphene wrinkles. We will discuss how a fluoropolymer layer sandwiched between graphene and different polymer substrates can facilitate crack-free and switchable graphene nanostructures. Such patterned areas with different curvatures show different reactivities based on a plasma fluorination reaction. Our approach for large-area, fine control over graphene wrinkle topographies has prospects for other two-dimensional electronic materials and optoelectronics and plasmonics applications.

SESSION F.EL04.14: Scalable 2D Materials Synthesis
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-EL04

5:00 AM F.EL04.14.01
Scalable Synthesis of Few-Layered 2D Tungsten Di-Selenide (2H-WSe_2) Nanosheets Directly Grown on Tungsten (W) Foil Using Ambient Pressure Chemical Vapor Deposition for Reversible Li-Ion Storage Rajashree Konar[1], Rosy Sharma[1], Ilana Perelshtein[1], Eti Teblum[1], Madina Telkhozhayeva[1], Maria Tkachev[1], Jonathan J. Richter[1], Elti Cattaruzza[2], Andrea P. Charmet[2], Paolo Stoppa[2], Malachi Noked[1] and Gilbert D. Nessim[1]; [1]Bar Ilan University, Israel; [2]Ca'Foscari University of Venice, Italy

Sustainable energy storage devices demand new materials for energy storage systems which alleviate their cost and increase longevity. A prominent energy storage technology for modern applications is Lithium-ion batteries. In this regard, two-dimensional (2D) materials attracted substantial and considerable attention due to their unique properties and abundant potential in various applications, including batteries[1]. Controllable synthesis of 2D materials with high quality and better efficiency is essential for their large scale applications, such as their functions as electrode material in batteries. The methods for synthesis of two-dimensional materials include exfoliation, solvothermal, and chemical vapor deposition (CVD) routes, among which, CVD offers better quality, efficiency, and consistency. In this perspective, the family of 2D transition metal di-chalcogenides (TMDCs) gained significant attention for their ability to store metal ions such as Li, Na, and Mg. TMDCs of group 6 transition metals (MX_2 where M = Mo, W, and X = S, Se, Te) have a lamellar structure (space group $P6_3/mmc$) similar to graphite but with larger interlayer spacing. Tungsten di-chalcogenides are significant here because of the larger size of W that provides a further alteration of the 2D structure and has been successfully utilized for various applications such as photodetectors, field-effect transistors (FETs), etc. The typical group 6 TMDC lattice structure show W atoms confined in a trigonal prismatic coordination sphere neighbored to Se atoms. Because of its very high density (~9.32 g cm^{-3}), WSe_2 also has a high volumetric capacity thereby proving it as a prospective LiB electrode material[2].
Our work focuses on a facile synthesis of 2H-WSe_2 on W foil in the ambient-pressure chemical vapor deposition system using only Argon as carrier gas during the reaction. Extensive characterization of the bulk and exfoliated material confirm that the as-synthesized 2H-WSe_2 is layered (i.e. 2D). XRD (X-Ray Diffraction) confirms the phase while HRSEM (High-Resolution Scanning Electron Microscopy), HRTEM (High-Resolution Scanning Electron Microscopy), and AFM (Atomic Force Microscopy) clarifies morphology of the material. FIB-SEM (Focused-Ion Beam Scanning Electron Microscopy) estimates the depth of the 2H-WSe_2 formation on W foil around 5-8 μm and Raman/UV-Vis measurements prove the quality of the exfoliated 2H-WSe_2. The redox processes of Lithium-ion Battery (LiB) studies show an increase in capacity until 500 cycles. On prolonged cycling the discharge capacity till the 50th cycle at 250 mA/g the material shows a stable capacity of 550 mAh/g. These observations indicate exfoliated 2H-WSe_2 has promising applications as LiB electrode material.

Facile and Scalable Ambient Pressure Chemical Vapor Deposition-Assisted Synthesis of Layered Silver Selenide (β-Ag_2Se) on Ag Foil as an Oxygen Reduction Catalyst in Alkaline Medium Rajashree Konar[1], Suparna Das[1], Eti Teblum[1], Arindam Modak[2], Ilana Perelshtein[1], Jonathan J. Richter[1], Alex Schechter[2] and Gilbert D. Nessim[1]; [1]Bar Ilan University, Israel; [2]Ariel University, Israel

To alleviate the adverse impacts of utilizing fossil fuel reserves on the environment (global warming, greenhouse emissions), extensive research is being devoted to the development of alternative/renewable energy systems, which include: photovoltaics, fuel cells, batteries, etc. Among them, fuel cells are an excellent solution for energy conversion, where, proton exchange membrane (PEM) fuel cells have a wide variety of applications. Some of these applications are being portable systems, automotive, etc., where an important reaction occurring at the cathode is the oxygen reduction reaction (ORR). At the current stage in fuel cell technology, platinum (Pt)-based materials are the most practical catalysts[1], which, undoubtedly are the prime choice as the cathode catalyst for the electro-reduction of oxygen but Pt-based catalysts are expensive. To reduce such costs in commercially viable fuel cells, extensive research is focused on developing alternative catalysts. Silver-based catalysts show a comparatively high thermodynamic stability and excellent catalytic activity over a wide pH range. The TMCs (O, S, Se, and among them especially Se-based chalcogenides) have attracted significant attention since the work on selenium-based cluster compounds. Selenium-based metal-rich TMCs catalysts exhibit good electrocatalytic activity which is mainly attributed to Se because it helps to improve the electronic structure of the metal by preventing the electrochemical oxidation of metals in most transition metal chalcogenides, as seen for the cases of cobalt selenide and ruthenium selenide. Here, we present a high yield, industrially scalable, and the first-time report on the synthesis of silver selenide from silver foil and selenium powder using a two furnace atmospheric pressure-chemical vapor deposition (AP-CVD) system. We grew low temperature, LT-β-Ag_2Se on Ag foil in the AP-CVD system using thermal annealing and leading to a hollow fern-like morphology material, and its first-ever reported application as an ORR cathode catalyst. The exfoliated β-Ag_2Se is characterized using XRD, EDS, HRTEM, AFM, and HRSEM, to determine its stoichiometry and its hollow layered fern-like morphology. Differential scanning calorimetry (DSC) further confirms that the final product is the low-temperature phase β-Ag_2Se. Electrochemical oxygen reduction reaction (ORR) of exfoliated β-Ag_2Se exhibits sharp oxygen reduction current with an onset potential of 0.88 V/RHE under alkaline condition, indicating oxygen reduction property of β-Ag_2Se. The large value of limiting current (3 mA cm^{-2}) as well as small Tafel slope (68.5 mV dec^{-1}) corroborates β-Ag_2Se as a superior layered transition metal chalcogenide cathode material suitable for such energy-related applications (typically fuel cells and/or metal-air batteries).

Cm^2-Scale Synthesis of $MoTe_2$ Thin Films with Layer Control David Hynek[1,1], Raviat M. Singhania[2], Shiyu Xu[1,1], Benjamin Davis[2], Lei Wang[1], Milad Yarali[1,1], Joshua Pondick[1,1], John Woods[1,1], Nick C. Strandwitz[2] and Judy Cha[1,1]; [1]Yale University, United States; [2]Lehigh University, United States

2D transition metal dichalcogenide $MoTe_2$ has recently gained much attention due to its wide-ranging electronic states including the 2H semiconducting state and 1T′ semimetallic state at room temperature, and the T_d Weyl semimetallic state and superconductivity at low temperatures. Due to small energy differences between the polymorphs, phase transition between distinct electronic states can be achieved easily, making $MoTe_2$ a model system for fundamental studies of phase transformation and structure-property relationship as well as for potential applications such as low-power, non-volatile phase-change memory. Currently however, large-scale synthesis of high-crystalline $MoTe_2$ thin films with precise thickness control is largely lacking.

Here, we demonstrate cm^2-scale synthesis of 2H-$MoTe_2$ thin films with layer control down to a monolayer and grain size that spans several microns. Layer precision is achieved by controlling the initial thickness of the precursor MoO_x thin films, which are deposited on sapphire and SiO_2 substrates by atomic layer deposition (ALD) and subsequently converted to $MoTe_2$ through annealing in a tellurium-rich atmosphere. During the reactions, it is found that the precursor-substrate interface is critical in determining the uniformity in thickness and grain size of the resulting $MoTe_2$ films: Robust, uniform film growth is achieved on sapphire down to a monolayer of $MoTe_2$ while incomplete conversion and island growth of $MoTe_2$ is observed on SiO_2. Surface characterization of the $MoTe_2$ films using atomic force microscopy indicates that the $MoTe_2$ films converted on sapphire are uniform in its thickness to within one layer thickness variation. Furthermore, using

dark-field transmission electron microscopy, we show that the films are highly crystalline with grains spanning over tens of microns. Thus, we show that by precisely controlling the number of ALD cycles for the precursor MoO_X films on sapphire, we can achieve $MoTe_2$ thin films with thickness control.
The synthesis strategy we present decouples the layer control from the variabilities of growth conditions, creating a robust growth method that is applicable to other transition metal dichalcogenides. Our $MoTe_2$ films thus enable systematic studies of layer-dependent properties of $MoTe_2$ and other transition metal dichalcogenides.

Orientation-Controlled Growth of Wafer Scale WSe_2 by Metalorganic Chemical Vapor Deposition Haoyue Zhu, Tanushree Choudhury, Benjamin Huet, Nicholas Trainor, Saiphaneendra Bachu, Danielle R. Hickey, Nasim Alem and Joan Redwing; The Pennsylvania State University, United States

Two-dimensional (2D) transition metal dichalcogenides (TMDCs) with desired properties are ideal candidates for novel applications as 3D integrated devices on Si CMOS, sensors, and optoelectronics.[1–4] Due to the low yield of mechanical exfoliation, metalorganic chemical vapor deposition (CVD) has emerged one of the most promising approaches to synthesize WSe_2 monolayers because of its ability to tightly control source concentrations and scale to wafer size. In order to achieve single crystals monolayers, however, the orientation of domains must be controlled at the nucleation stage so that they grow laterally and coalesce without the formation of high angle or inversion domain boundaries.

In this study, we demonstrate the orientation-controlled growth of WSe_2 on 2” diameter c-plane sapphire by metalorganic chemical vapor deposition (MOCVD) in a cold-wall reactor. We used a multi-step growth protocol to independently control the WSe_2 nucleation density and domain lateral growth.[5] By controlling the growth temperature and ratio of H_2Se and $W(CO)_6$, the WSe_2 triangular domains grow epitaxially on the sapphire substrate with >85% of the domains exhibiting a preferred crystallographic direction after 5 minutes of growth. With continued lateral growth time up to 30 minutes, the WSe_2 monolayer becomes fully coalesced with a low surface coverage (2%) of bilayer domains. Dark-field TEM combined with high resolution imaging of WSe_2 removed from the sapphire substrate, demonstrates that the films are nearly single crystal with a low density of inversion domain boundaries. Low temperature (4K) photoluminescence of the WSe_2 monolayer transferred to oxidized silicon reveals emission peaks associated with biexcitons, negative trions, and neutral excitons for which the peak width ranges from 8 to 11 meV. The results demonstrate the potential of MOCVD to produce wafer-scale epitaxial TMD monolayers with structural and optical properties approaching that of single crystal exfoliated flakes.

5:40 AM F.EL04.14.06
Monolayer Half-van der Waals Heavy Metals Enabled by Confinement Heteroepitaxy Alexander Vera[1], Siavash Rajabpour[1], Timothy Bowen[1], Boyang Zheng[1], Wilson Yanez Parreno[1], Hesham El-Sherif[2], Chaoxing Liu[1], Nabil M. Bassim[2], Nitin Samarth[1], Vincent Crespi[1] and Joshua Robinson[1]; [1]The Pennsylvania State University, United States; [2]McMaster University, Canada

Due to relativistic effects, heavy metals (Pb, Bi, etc.) demonstrate strong spin orbit coupling (SOC) effects, making them promising elemental precursors to broken spin degeneracy and non-trivial topology. Atomically thin heavy metal layers exhibit large Rashba effects, translating to large spin Hall angles suitable for spin pumping, memory, and other spintronic applications. Atomically thin lead (Pb) in particular may support superconductivity along with non-trivial topology,

potentially serving as a route to exotic superconducting states. However, typical synthesis techniques do not provide a platform for scalable, stackable, and air-stable 2D metals, necessary for *ex-situ* device work. To answer this challenge, we demonstrate the synthesis of an air-stable 1ML-Pb with strong (~500meV) spin splitting within a graphene/silicon-carbide interface through confinement heteroepitaxy. We expect this material to exhibit a large spin Hall angle suitable for spintronic applications.

5:50 AM F.EL04.14.07
Growth of Large Edge Length WS_2 for Photodetector Applications Mohd Samim Reza, Parvez Akhtar, Sandeep Kumar, Henam Sylvia Devi and Madhusudan Singh; IIT Delhi, India

Tungsten disulfide (WS_2) has a tunable bandgap predicted to go from its measured value of 1.3 eV (indirect) in bulk to 2.1 eV (direct) in monolayer form, and is thus of potential interest for photodetectors. In this work, we report an atmospheric pressure chemical vapor deposition (APCVD) approach to synthesize large domain size WS_2 on SiO_2 (University Wafers) substrates, using a custom-designed and locally fabricated 12-zone horizontal split furnace (Quazar Technologies) and solid phase precursors: tungsten trioxide (WO_3) and elemental sulfur (S). A series of experiments were carried out at temperatures between 900-1100 °C and in the presence of a carrier gas (Ar) flow (0-400 sccm). Thermal coupling between neighboring heating zones for precursors were controlled using tuned distances between precursor boats. At optimized conditions, growths of monolayer (edge size~ 63 μ m), multilayer spiral and pyramidal structural WS_2 were observed on the substrate. Raman measurements were carried out with a laser source (Horiba Labram, 514 nm, 1mW) and spot size of 4 μ m. In-plane (E^1_{2g}) and out-of-plane mode (A_{1g}) peaks at 352/cm and 420/cm confirmed monolayer growth. In other samples, bilayer and multilayer WS_2 growth was observed with Raman shifts 353/cm, 420/cm and 354/cm,421/cm. Field emission scanning electron microscopy (FEI Quanta 200 F SEM, 10 kV) and optical imaging (Olympus BX53M) confirms locally uniform growth of sharp edged WS_2, with some visible upstream dependence of edge sizes (variation from 10 μ m to 60 μ m). Multilayer growth and non-coincidental triangles are observed at the center of the substrate with large edge sizes exceeding 60 μ m. Use of vapor trapping techniques increases area coverage, though growth is then primarily multilayer, consistent with expectations from precursor supply limits during synthesis. Work is continuing towards our aim of achieving large edge size monolayer WS_2 suitable for photodetector applications.

6:00 AM F.EL04.14.08
Chemical Kinetics and Mechanisms for the Synthesis of 2D Polymers via Irreversible Solution-Phase Reactions Ge Zhang, Yuwen Zeng and Michael Strano; Massachusetts Institute of Technology, United States

Novel organic two-dimensional materials synthesized from polymerization of molecular units have recently attracted much attention, due to their versatile and exotic chemical, mechanical, electronic and magnetic properties. However, large scale and facile synthesis of 2D polymers in homogeneous solution, albeit common for conventional linear polymers, remains challenging despite rapid progress in this field. Previously, two-dimensional, covalently bonded polymers have been made by: reversible crystallization under hydrothermal conditions, templated growth on flat surfaces or interfaces, and polymerization after non-covalent assembly. These methods are relatively slow and hard to scale up. In comparison, irreversible reactions in a homogeneous solution phase is attractive due to its potential to synthesize large quantities of chemically stable product. Unfortunately, such reactions are more likely to produce amorphous 3D structures rather than 2D polymers. The lack of restriction on bond rotation can turn a 2D polymer into 3D, and those defects are permanent due to the irreversibility of reaction. Moreover, a 3D polymer grows much faster than a 2D polymer with the same size.

In this work, we propose and compare two possible mechanisms for making two-dimensional polymers from irreversible reactions in solution phase: the autocatalysis effect, and the bond-planarity effect. Autocatalysis could be achieved by self-templated growth on the surface of as-formed 2D molecules, which increases the rates of 2D growth; while bond-planarity would limit the bond rotation and therefore reduce the probability of 3D growth. By modelling the reaction networks as systems of differential equations, we are able to calculate the reaction time, the size distribution function of the product, and the yield of 2D polymer. The autocatalysis and bond planarity effects are parametrized by two factors: $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$, respectively.

The results show that both mechanisms can significantly increase the size and yield of 2D polymer, and suppress the formation of 3D product. Without the aid of either effect, the average size of 2D polymer will be minuscule (<10), and the yield is negligible. In contrast, when either of the two effect is strong enough ($\beta>10^4$ and $\gamma>10^3$), a yield close to unity and a much larger average size (>100) could be achieved for 2D polymer. We find that bond-planarity effect would limit the bond rotation and therefore restore the behaviour of 2D polymerization confined to a plane. On the other hand, autocatalysis could dramatically increase the rates of 2D growth, which leads to sizes even bigger than the ideal 2D polymerization without competition from 3D growth. We also study the combined effect of both mechanisms, and obtain further enhancement in the

average size (>1000) and near-unity yield, indicating a potential synergy between the two factors.
Our calculation show for the first time from theory, the feasibility of producing two-dimensional polymers from irreversible polymerization in solution. The framework is independent of the detailed pathways of reactions and structures/functionalities of molecules, hence the results are expected to be general and applicable for all types of 2D polymerization process that happen irreversibly in solution. Latest experimental work from our group has successfully demonstrated the synthesis of mechanically strong 2D polymer from irreversible polymerization in solution, via the bond-planarity mechanism, which provides validation for our calculation.

6:10 AM F.EL04.14.09
An Irreversible Route to an Ultra-Strong Two-Dimensional Polymer Yuwen Zeng, Ge Zhang and Michael Strano; Massachusetts Institute of Technology, United States

Polymers that extend covalently in two dimensions have attracted recent attention as a means of combining the mechanical strength and in-plane energy conduction of layered nanomaterials with the low densities, synthetic processability, and organic composition of their one-dimensional counterparts. Efforts to date have proven successful in forms that do not allow that full realization of these properties, such as polymerization at flat interfaces or fixation of monomers in immobilized 2D lattices. A frequently employed synthetic route is to introduce microscopic reversibility, at the cost of bond stability, to achieve 2D crystals after extensive error corrections. Herein we demonstrate a synthetic route to 2D irreversible polycondensation directly in the solution phase, resulting in covalently bonded 2D polymer platelets that are chemically stable, acid-soluble, and allowed to be further fabricated into highly oriented thin films and membranes. The resulting films of 30-nm thickness exhibit exceptional film strength at 2.52 GPa as well as a highly oriented nature, demonstrated by polarized in-plane photoluminescence study. This synthetic route provides new opportunities to 2D polymers with applications to composite materials and molecular sieving membranes.

Large-Area Growth of 2D Layered Materials—Chalcogenides, Oxides and Halides Kibum Kang; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The 2D layered materials are the potential components in next-generation semiconductor devices and quantum devices. For the integration of 2D layered materials into such functional devices, it is necessary to develop a high-quality large-area growth process.
In this talk, I will introduce the MOCVD growth of 2D layered materials, including transition metal dichalcogenides, metal oxides, and metal halides. Furthermore, I will discuss the MOCVD grown 2D layered materials and their heterostructures that could potentially be utilized in a single-photon source for quantum devices.

6:35 AM *F.EL04.14.11
Electronics with Nobel Metal Dichalcogenides Applications Georg Düsberg; Universität der Bundeswehr München, Germany

Two-dimensional materials such as transition metal dichalcogenides (TMDs) are intensively investigated because of their potential applications in future electronics. So far mainly group six (Mo/W) TMDs have been investigated, which show thickness depend electronic and optical properties. Metal-to-semiconductor transitions, high mobilities, and high potential for various sensing applications, now raised interest to the group 10 (Pt/Pd) TMDs or Nobel Metal Dichalcogenides (NMDs).
In this presentation, the low temperature synthesis of various TMDs by thermally assisted conversion (TAC) is presented. [1] The composition and morphology of the resulting large-scale layers are investigated by a multitude of characterization techniques including Raman spectroscopy, [2] AFM and X-ray photoelectron spectroscopy (XPS). In particular, the low temperature TAC synthesis PtSe2 potentially allows back end of line (BEOL) integration compatible with silicon technology. The effects of growth on the underlying substrates or investigated by TOF-SIMS and transmission electron microscopy. Further, as pre-pattered structures can be grown by the TAC, which allows to fabricate electronic devices using standard micro-fabrication technology. [3] PtSe2 has shown potential for a range of novel electronics devices. Examples for high performance chemical sensors, [1] IR-photodetectors[4] and MEMS[5] devices based on PtSe2 will be presented.

Tailoring 2D Chalcogenide Interfaces for Heterostructure Growth and Device Optimization Lincoln J. Lauhon; Northwestern University, United States

Understanding and control of surfaces and interfaces is necessary to exploit the potential of 2D metal chalcogenides in electronics and optical devices. The ubiquity and scalability of vapor-phase processing in particular provides a wealth of opportunities, from the growth of van der Waals heterostructures to the chemical tailoring of interfaces to optimize device performance, including devices made from "composite" 2D materials such as those printed from inks. This talk will describe research to leverage interfaces for devices via two routes: atomic layer deposition (ALD) of metal oxides to modify dichalcogenide properties and pulsed chemical vapor deposition of ferroelectric monochalcogenides. In prior work, tuning of ALD oxide stoichiometry was shown to tune the Fermi level of MoS_2. [1] More recently, in situ monitoring of MoS_2 and $MoSe_2$ transistor performance during deposition of an oxide dielectric enabled the disentangling of changes in carrier concentration and mobility during the alternating dosing of the metal-organic precursor and oxidant.[2] Intriguingly, we find a substantial enhancement in field effect mobility with sub-monolayer coverage. Variable temperature transport measurements indicate that charged impurity scattering is reduced by screening even prior to formation of a complete dielectric, pointing to the importance of seeding conditions in maximizing mobility. Vapor deposition processes also provide scalable routes to van der Waals heterostructures whose properties can be engineered by band-offsets and dimensionality. Building on prior work demonstrating low-temperature epitaxy of SnS on MoS_2[3], a range of processing conditions were explored to understand how SnS film morphology is influenced by substrates including amorphous SiO_2, mica, MoS_2, and hexagonal boron nitride (hBN). Control over film thickness and morphology is particularly important to harness the in-plane ferroelectricity of SnS for devices. Large area monolayer regions are readily achieved on MoS_2 substrates by targeting temperatures and purge times that enhance selective growth at edges. Due to the relative inertness of the vdW surface of hBN, modified surface preparation and pulsing schemes are necessary to favor lateral growth of SnS, and monolayers growth is more challenging. However, isolated islands of epitaxial SnS on hBN are relatively easy to achieve, providing a path towards highly scaled memristive devices based on ferroelectric switching.

[1] Chem. Mater. 2018, 30, 3628. [2] ACS Appl. Electron. Mater. 2020, 2, 1273. [3] ACS Appl. Mater. Interfaces 2019, 43, 40543.

5:15 AM F.EL04.15.02
Atomic Layer Deposition of Al Doped MoS_2—A *p*-Type 2D Semiconductor with Tunable Carrier Density and Control Over the Doping Profile Vincent Vandalon[1], Marcel Verheijen[1,2], Erwin Kessels[1] and Ageeth Bol[1]; [1]Eindhoven University of Technology, Netherlands; [2]Eurofins Material Science, Netherlands

Two-dimensional layered transition metal dichalcogenides (TMD) such as MoS_2 and WS_2 are of interest for nanoelectronics because of their promising electronic characteristics and their predictable properties even in the few- and monolayer regime. The merits of TMDs for transistor applications have already been demonstrated by fabrication of field-effect transistors (FET) mainly using intrinsic MoS_2. However, doped variants of these TMDS are essential for the fabrication of high-performance devices and the realization of advanced transistors concepts. To allow adoption in actual device fabrication workflows, both the doped and the undoped material has to be fabricated with scalable synthesis methods. So far, it has proven difficult to synthesize doped TMDs with good control over the carrier density. Consequently, control over the doping profile is even farther out of reach.
Here we present a synthesis method for Al doped MoS_2 based on plasma-enhanced atomic-layer deposition (ALD) with good control over both the carrier density and doping profile. Using this method *p*-type doped MoS_2 was deposited with an precisely tunable carrier density between 10^{17} and 10^{21} cm^{-3}. The Al dopant was introduced using an ALD supercycle concept which consisted of N MoS_2 ALD cycles followed by 1 AlS_x ALD cycle. With this approach the Al concentration is controlled simply by varying the N parameter and the supercycle can be repeated as often as needed to deposit the desired film thickness. Both the doped and undoped films showed virtually no N, C, and O impurities and the Mo:S ratio was not

impacted by the Al incorporation. The films were crystalline and showed the typical 2D layered structure, even at high Al concentration, as observed with cross-section transmission electron microscopy (TEM) imaging. This, combined with the minimal impact of the Al doping on the mobility, suggests that the introduction of Al does not disrupt the layered nature of the TMD and it acts like a well behaved dopant.
The excellent control over the doping profile of this approach was demonstrated in a combined TEM and energy-dispersive X-ray spectroscopy (EDX) study. A stack of 5 alternatingly doped and undoped regions, each 10 nm thick, was synthesized for characterization. The crystal structure was not interrupted by the transition between doped and undoped regions. On the other hand, the Al concentration showed a sharp transition between the doped and undoped regions, demonstrating the control over the doping profile.
To conclude, *p*-type doped MoS_2 was synthesized with a widely tunable carrier density and good control over the doping profile. Compatibility with large-scale fabrication was ensured by the conformallity, uniformity, and the sub-nm thickness control inherent of ALD. This approach is therefore of interest for the fabrication of nanoelectronics based on doped MoS_2. Moreover, *p*-type doped TMDs are of interest in other fields including photovoltaics and catalysis.

5:25 AM F.EL04.15.03
From Mono- to Multilayers: Adjustable Layer Thickness of Hexagonal Boron Nitride Thin Films by Atomic Layer Deposition (ALD) Rene Weißing, Daniel Stadler, David Graf, Heechae Choi and Sanjay Mathur; University of Cologne, Germany

Hexagonal boron nitride (h-BN) with its atomically flat structure, excellent stability and large band gap energy (~ 6 eV) is an ideal insulator for 2D electronics and an outstanding material for the growth and encapsulation of transition metal dichalcogenides (TMdCs). Fabrication of h-BN thin films is dominated by exfoliation of multi-layer or bulk crystals and chemical vapor deposition (CVD) via thermal decomposition and surface nucleation of single-source precursors such as amino boranes and borazine. While mechanical exfoliation and chemical transfer procedures typically deliver h-BN flakes of several tens of micrometers that come along with significant interfacial impurities, a precise thickness control in the Ångström region by CVD grown thin films is hardly achievable. ALD, a vapor phase deposition technique based on self-limiting gas-surface reactions, is the ideal choice for a precise thickness control and high uniformity over areas in the centimeter regions. Therefore, we have developed ALD processes based on DFT calculations regarding the kinetics of film formation to grow h-BN layers in the centimeter region with a precise thickness control relevant for electronic applications. The synthetic access was achieved by two complementary half-reactions of B and N precursors with respect to adsorption energy calculation for each decomposition reaction step confirmed by mass spectroscopy. In addition to an insight into the growth mechanism, parameter-dependent layer thickness optimization was obtained.

3D Printed Networks of 2D Nanosheets for On-Chip Supercapacitors Apostolos Panagiotopoulos, Stefano Tagliaferri, Maria S. Sokolikova and Cecilia Mattevi; Imperial College London, United Kingdom

Miniaturization over three-dimensions is very attractive for future on-chip technologies where efficiencies need to be optimized over millimetre sized areas. This is a new challenge, as device fabrication is mainly developed to achieve planar-geometries. Direct Ink Writing is a cost-effective, industrially scalable route that brings the possibility of making electrodes and energy storage devices in a three-dimensional geometry.
Here, we demonstrate 3D printed supercapacitors from highly concentrated, water-based inks. The active materials are atomically thin sheets of transition metal dichalcogenides, either exfoliated from bulk or obtained via direct synthesis in solution. To ensure rapid prototyping as well as streamlined manufacturing, we formulated viscoelastic slurries with tailored rheological properties allowing printability and mechanical integrity of the printed structures in various resolutions.
The printed architectures, from woodpile and serpentine structures to interdigitated electrodes, are extended over a few mm in three-dimensions and present structural integrity with as low as 100microns sized struts. Following electrode optimisation via thermal annealing, we formed high-surface area mechanically robust networks of 2D nanosheets. They combine electrochemical surface controlled kinetic processes to deliver high amounts of energy, in short bursts, to power electronics as standalone or in conjunction with other energy conversion/storage devices

5:45 AM F.EL04.15.08
Towards the Rational Design of Printed 2D Materials Zhehao Zhu, Joon-Seok Kim and Lincoln J. Lauhon; Northwestern University, United States

The formulation of inks based on 2D materials could provide new functional behaviors to printed electronics while retaining

scalable manufacturing processes. Recent advances in solution-based exfoliation have demonstrated that the electronic properties of single semiconducting 2D nanosheets can be preserved during ink processing, but there remain several challenges to the production of thin film transistors based on printed 2D materials. In addition to minimizing interface resistance and preserving bulk-like mobilities, the microstructure of the composite material must be optimized. To rationally guide the development of 2D inks and related processing, we integrated device modeling with electrical and scanning probe characterization of transistors with "composite" 2D channels. Experiments and finite element modeling were guided by a gate-dependent resistor network model that quantifies performance trade-offs determined by nanosheet thickness, degree of overlap, and interface resistivity. We measured the electrical characteristics of model MoS_2/MoS_2 homojunctions created by mechanical exfoliation to validate model parameters. Kelvin probe force microscopy (KPFM) was used to measure the surface potential profiles in transistor channels as a function of applied bias conditions and morphological characteristics such as sheet thickness. Finite element device simulations, using parameters derived from experiments, were used to interpret both the experiments and trends observed in the resistor network model. We find that screening of the upper portions of overlapping nanosheets produces current crowding at junctions between the edge of one nanosheet and the basal plane of another. Reducing the nanosheet thickness (i.e. the number of layers) distributes the current over larger areas and facilitates efficient charge transfer, increasing the effective mobility and on/off ratio, providing further motivation to develop exfoliation schemes that preserve intrinsic monolayer properties. Detailed analysis of potential drops measured in KPFM provides indirect evidence that weakly screened trapped charges at edge states further limit charge transfer, suggesting that passivation and/or functionalization schemes targeting the edges of nanosheets could greatly improve transistor performance.

Late News: Rapid Time-Resolved Laser Crystallization and Patterning of 2D Quantum Materials on Flexible Substrates Zabihollah Ahmadi, Parvin Fathi-Hafshejani, Emre Kayali, Majid Beidaghi and Masoud Mahjouri-Samani; Auburn University, United States

Rapid direct writing of geometrically complex patterns of two dimensional (2D) quantum materials is critical for applications in a variety of areas, including flexible and wearable electronics and sensors. However, the available synthesis methods (e.g., CVD, MOCVD, MBE) are neither capable of direct writing nor possible to integrate onto flexible substrates due to high growth temperatures. Here, we demonstrate a rapid laser-based crystallization and complex patterning of 2D quantum materials (MoS_2, WS_2) on flexible substrates. A thin layer of solid-state stoichiometric amorphous 2D film is first pulsed laser deposited onto the flexible substrates – e.g., polydimethylsiloxane (PDMS) and polyethylene terephthalate (PET) - followed by a time-resolved infrared laser crystallization to controllably couple a precise amount of energy to locally heat and crystallize the amorphous 2D materials. The influence of pulse duration, frequency, and the number of pulses on the crystallization of 2D materials is investigated, and the spectroscopy and structural investigations verify the quality of crystallized 2D materials on the flexible substrates. Moreover, ultrathin 2D devices on stretchable PDMS substrate are fabricated, and their electrical characteristics under tensile strains and stretching cycles are measured. This novel method opens up a new opportunity for the future 2D materials-based wearable, transparent, and flexible optoelectronic and photonic devices.

Mr. Zabihollah Ahmadi is currently a Ph.D. student in the Department of Electrical and Computer Engineering (ECE) at Auburn University (AU). His research in the Laser-Assisted Science and Engineering (LASE), Lab under the supervision of Prof. Mahjouri-Samani, focuses on developing novel laser-based approaches for the synthesis and processing of 2D quantum materials and heterostructures on the flexible platform for optoelectronic and photonic applications.

Enabling 2D Heterostructure Development with Atomic Resolution Imaging—Studies of Twist Reconstruction and Degradation Sarah J. Haigh, David Hopkinson, Nick Clark, Astrid Weston and Yichao Zou; University of Manchester, United Kingdom

2D materials and their heterostructures provide an exciting playground for pioneering science. In this talk I will demonstrate how atomic resolution scanning transmission electron microscopy (STEM) imaging and analysis is being used to support the

advancement of these systems.

For example, I will discuss new results revealing the structural relaxation that occurs when two transition metal dichalcogenide (TMDC) monolayers are misoriented by a small twist (rotation angle). Many high profile experimental measurements of the exciting physics present in twisted TMDCs have necessarily neglected the potential for local structural relaxation. We have used atomic resolution STEM to reveal that TMDCs bilayers twisted to a small angle, less than ~3 degrees, reconstruct into energetically favourable stacking domains separated by a network of stacking faults, and that this behaviour is more complex than is observed in graphene [1]. For crystal alignments close to 3R stacking, we find that a tessellated pattern of mirror reflected triangular 3R domains while for alignments close to 2H stacking, stable 2H domains dominate, with nuclei of an earlier unnoticed metastable phase limited to ~ 5nm in size. This appears as a kagome-like pattern at twist angles less than 1 degree, transitioning to a hexagonal array of screw dislocations separating large-area 2H domains as the twist angle approaches 0 degrees. Tunneling spectroscopy measurements reveals that such reconstruction creates strong piezoelectric textures and pseudo-magnetic fields, opening new avenues for engineering of 2D material properties on the nanometre scale [1].

As the range of 2D materials increases rapidly, many of those with the most the promising magnetic or optoelectronic properties are found to be unstable in air or moisture, which makes fabrication challenging and hampers their use. Even relatively stable 2D crystals like MoSe2 and WSe2 are found to have perfect interfaces only when processed in an inert environment [2]. These materials can be stabilised to ambient conditions by encapsulating with stable 2D layers, such as graphene and hexagonal boron nitride. [3] For example, we have applied the encapsulation approach to study the presence and behaviour of point and extended defects in the 2D monochalcogenides, GaSe and InSe which are of interest due to their relatively high electron mobilities, strong second harmonic generation and quasi-direct bandgap when reduced to the monolayer limit.[4] Nonetheless the properties of InSe and GaSe crystals often degrade on exposure to air, light, and/or moisture, thought to be the result of oxidation induced defects. We have used atomic resolution STEM together with electron energy loss spectroscopy (EELS) and energy dispersive X-ray spectroscopy to characterise individual point and extended defects in InSe and GaSe [5]. We observe that both materials contain multiple point and extended defects, even when exfoliated in argon and encapsulated in graphene. Point vacancies are observed to be healable under the electron beam, while extended defects and stacking faults have symmetries not found in bulk samples and which could be used to tune the properties of 2D post-transition-metal monochalcogenide materials for optoelectronic applications. We also demonstrate the nanopatterning of black phosphous using electron beam lithography via etching protocols developed in the STEM [6], and recent work revealing oxidation induce improvement of superconductivity in few layer TaS2 [7].

Twistronic Structures and Moire Superlattices in Homo- & Heterobilayers of Transition Metal Dichalcogenides Vladimir Falko; University of Manchester, United Kingdom

We apply a multiscale modelling approach to study moiré superlattice in twisted homo- and heterobilayers of transition metal dichalcogenides (TMD), taking into account the interlayer hybridisation of the electronic orbital and lattice reconstruction due to stacking-dependent adhesion. First of all, we develop DFT-parametrized interpolation formulae for interlayer adhesion energies of $MoSe_2$, WSe_2, MoS_2, and WS_2 with both parallel and antiparallel orientation of their unit cells and arbitrary offset of the honeycomb lattices in the adjacent layers. Then, we combine those interpolation formulae with elasticity theory and analyze the bilayer lattice relaxation into mesoscale domain structures. We find that 3R and 2H stacking domains develop for, respectively, bilayers with parallel (P) and antiparallel (AP) orientation of the monolayer unit cells, separated by a network of dislocations, for twist angles $\theta < \theta_P \sim 2.5$ and $\theta < \theta_{AP} \sim 1$. Such lattice reconstruction has been verified by STEM imaging. We also show that the triangular domain structures of P-oriented homobilayers would manifest itself in local tunnelling characteristics of marginally twisted. For AP bilayer, we show that the deformation of the lattices around domain walls (which resemble twist dislocations oriented along the planes of in bulk 2H crystals) generate piezo-electric charges, reaching local density up to $\pm 0.5 \times 10^{12} e/cm^2$ at the junctions of the honeycomb domain wall network. Finally, we use DFT

modelling of bandstructure of bilayers with various stacking configurations and interlayer distances to develop and parametrise interpolation formulae for the interlayer hoping between the layers for the relevant parts of the Brillouin zone, and, then, establish the electronic structure of the bilayeracross the moire supercell, taking into account the piezolectric potentials.

Interplay Between Intra- and Inter-Layer Interactions in Stacked Two-Dimensional Crystals Young-Woo Son; Korea Institution for Advanced Study, Korea (the Republic of)

Interlayer interactions in stacked 2D crystals are one of key ingredients in exhibiting their qualitative distinct physical properties, differing from their single layer physics [1]. For example, a well-known 2D quantum spin Hall insulating transition metal dichalcogenide (TMDC) can show either topological Weyl metallic phase or trivial one depending on a minute stacking order difference [1,2]. Recent advances in fabricating stacked 2D crystals enable us to perform controlled studies on interesting electronic, magnetic and topological properties in low dimensional heterostructures. In this talk, I will first discuss interplay between intralayer correlation, interlayer interaction, and magnetism in layered materials [3-5]. To understand magnetic properties, I will introduce a new computationally efficient method to calculate various correlation effects in layered materials [3]. Another interesting examples revealing intriguing interlayer interactions will be discussed for graphene bilayer systems [6,7] and TMDCs [8]. For a graphene bilayer system with a rotation angle of 30 degrees, it is shown that a quasicrystalline order through a perfect incommensurate interlayer interaction shows localized 12 fold resonant states with fractal scaling [6]. For a bilayer MoS2 system, I will demonstrate a intrinsic coupling between strain and shear in the system that can alter its low energy Raman modes, thereby providing a way to obtain its almost all fundamental mechanical constants through light-matter interactions.

Surface and Strain Control of 2D Materials—From Fundamental Properties to Nanomanufacturing Joel W. Ager[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

In the monolayer limit transition metal dichalcogenides (TMDs) such as MoS_2 and WS_2 have direct bandgaps, leading to significant interest in the use of these materials for opto-electronic applications. Their internal photoluminescence (PL) quantum efficiency (QE) is a sensitive measure of their quality. While some III-V thin films and II-VI quantum dot structures can achieve near-unity values of this metric, most semiconductor materials have QEs which are much smaller. We have discovered that treatment of sulfur-based TMDs with an organic superacid dissolved in a non-polar solvent suppresses non-radiative recombination at low pump powers, leading to near 100% QE. [1]. Similar, near-unity, QE values can be achieved via electrostatic gating by lowering the Fermi level to near mid-gap to suppress the formation of non-radiative trions [2]. Tuning of band parameters with strain is a common motif in semiconductor devices. Chemical vapor deposition of some monolayer TMDs on thermal expansion coefficient mismatched substrates can induce strains on the order of 1%, in spite of the weak van der Waals interaction [3]. Larger strains can be envisioned: Au grows epitaxially on MoS_2 with a predicted mismatch strain of 10% [4]. Further, the strain is predicted to be confined to the monolayer in contact with the Au, while other layers in the structure remain unstrained. This effect weakens the bonding between the top layer and the bulk [5], which enables exfoliation of large areas of monolayer material with defined patterns [6,7]. Further optimization of this nano-manufacturing process has improved the yield to nearly 50% and has led to the ability to form defined TMD heterostructures [8].

Charge Carrier Funneling and Radiative Trion Production in Nano-Pillar Strained MoS2 Mounika Vutukuru[1], Zhuofa Chen[1], Hossein Ardekani[2], Zhangcheng Yao[1], Kenan Gundogdu[2] and Anna Swan[1]; [1]Boston University, United States; [2]North Carolina State University, United States

We investigate the strain-driven localization of electrons and enhanced photoluminescence (PL) response of trions and excitons in monolayer MoS_2 strained by SiO_2 nanopillars. Using spatially resolved PL and Raman mapping, we observe the well-recognized red shift in the PL and Raman on the apex of the pillars due to the strain response, together with an overall 6-fold increase in the PL intensity and an increased fraction of radiative trions. The increased trion fraction in the strained areas is attributed to more efficient electron strain-funneling than exciton funneling, which increases the trion production relative to the A excitons. The large overall PL intensity increase on the pillars is due to a combination of interference enhancements and charge and exciton funneling. Using time-resolved PL, we also study radiative lifetimes of excitons and charge carriers to explore the effect of strain on the intrinsic radiative lifetime of each species which leads to increased production of trions on the strained site . The results demonstrate that strain-induced local energy minima affect diffusion of excitons and free charge carriers differently, as in the case of non-uniformly strained WS_2 [1]. Our results show that strain control could be used in addition to the electric field, as part of the toolbox for quasiparticle manipulation in 2D systems.

The Role of Bubble Geometry and Thickness on Luminescence Properties of 2D Multilayers Haeyeon Lee, Frances M. Ross and Silvija Gradečak; Massauchsetts Institute of Technology, United States

In-plane and out-of-plane deformation of 2D materials, especially of van der Waals (vdW) heterostructures, occurs readily during the fabrication process and it modifies their optical and electronic properties. Bubbles that form between layers in vdW heterostructures have been viewed as an inconvenience, with research focusing on how to avoid them during fabrication. On the other hand, practical applications of bubbles have been recently reported including quantum dot-like emitters and single photon emitters. Therefore, understanding mechanical properties of bubbles is necessary to manipulate their geometry and optoelectronic properties. Bubbles formed by monolayers are found to exhibit universal shape and aspect ratio depending on the elastic stiffness of each monolayer. However, studies on bubbles formed by multilayers have not been established yet due to non-negligible bending modulus and unconventional lubricant interfaces.
Here, we present that the geometry of bubbles formed by hexagonal boron nitride (hBN) multilayers is strongly correlated to the thickness of multilayers, which enables us to manipulate the aspect ratio of bubbles by the thickness. Since the bending rigidity of 2D multilayers is no more negligible as in the case of monolayers, two phenomena in multilayer bubbles are observed, which are distinct to monolayer bubble with fixed aspect ratio: the aspect ratio of multilayer bubble (1) decreases with the thickness of multilayer and (2) increases with the radius of bubbles. In addition, significant enhancement of luminescence is observed by cathodoluminescence from the bubbles in ultraviolet region owing to a large band gap nature of hBN. Moreover, Fabry-Perot interference is created where the pattern largely depends on the geometry of bubbles. We believe that optical properties and/or strain could be efficiently manipulated by designing the geometry of multilayer bubbles with desirable thickness.

6:20 AM F.EL04.16.07
Coherent Lattice Wobbling and Dynamic Breaking of Friedel's Law Observed in Layered Gallium Telluride by Ultrafast Electron Diffraction Qingkai Qian[1], Xiaozhe Shen[2], Duan Luo[2], X.J. Wang[2] and Shengxi Huang[1]; [1]The Pennsylvania State University, United States; [2]SLAC National Accelerator Laboratory, United States

The inspection of Friedel's law in ultrafast electron diffraction (UED) is important to gain a comprehensive understanding of material atomic structure and its dynamic response. Here, monoclinic gallium telluride (GaTe), as a low-symmetry, layered crystal in contrast to many other 2D materials, is investigated by mega-electron-volt UED. Strong out-of-phase oscillations of Bragg peak intensities are observed for Friedel pairs, which has dynamically violated the Friedel's law. As evidenced by the preserved mirror symmetry and supported by both kinematic and dynamic scattering simulations, the intensity oscillations are provoked by the lowest-order longitudinal acoustic breathing phonon. Our results provide a generalized understanding of Friedel's law in UED, and demonstrate that by designed misalignment of surface normal and primitive lattice vectors, coherent lattice wobbling and effective shear strain can be generated in crystal films by laser pulse excitation, which is otherwise hard to achieve and can be further utilized to dynamically tune and switch material properties.

6:30 AM F.EL04.16.09
Late News: Interplay Between Direct and Indirect Exciton in Strained Monolayers of Transition Metal Dichalcogenides Navendu Mondal[1], Yuri Gartstein[1], Masoud Mahjouri-Samani[2] and Anton Malko[1]; [1]The University of Texas at Dallas, United States; [2]Auburn University, United States

Owing to the spatial and dielectric confinement, monolayers of transition metal dichalcogenides (TMDs) undergo strong many-body Columbic interactions yielding into large binding energies for the exciton (>0.1 eV) and higher order exciton-complexes compared to the conventional semiconductors. However, local environments experienced by these tightly bound excitons often drive the optoelectronic properties of these TMDs. These TMDs often exhibit low photoluminescence quantum yield (PLQY) and short intrinsic radiative lifetime due to the presence of large impurities, defects and efficient phonon assisted non-radiative Auger recombination processes. Currently researchers in the community are exploring various routes to modulate the bandgaps and tailor optoelectronic properties of these TMDs to make them more suitable for the real device applications.
In this context, an interesting avenue continuously evolving in this field is that modulation of the bandgap (even upto 0.5 eV) of these semiconductors by inducing strain (tensile & compressive).This has understood by means of controlling the mechanical stress on those monolayers and studies in this line are largely limited within the PL properties and dynamics. While the effects of strain on the fate of those excitons (in ultrashort timescale) including excitonic many-body events remains less unexplored.
To unravel the effect of stress on those excitons and their dynamics, we first study the excitonic properties of high-quality monolayer MoS2, WS_2 & WSe2 (grown by laser-assisted evaporation technique; analogous to CVD-method) samples both under substrate and suspended condition employing ultrafast optical (namely transient absorption, TA) spectroscopy as a major tool. Optical characterization data reveals that these as-synthesized monolayer flakes in fused silica substrates possess highly red-shifted absorption/PL w.r.t. the typical excitonic position. This characteristic low-band-gap signature is attributed to the effect of strain that presumably arises from the thermal expansion coefficient mismatch between the TMDs and substrate. It is quite common to observe this sort of unavoidable strain on TMDs during the CVD growth process. This is further corroborated when the strains were released from those monolayers by means of exfoliating them from the as-grown substrate. These suspended monolayer samples exhibit an enhanced PL intensity and the abs./PL position shifts back near to the typical excitonic position. TA spectroscopic measurement (for a representative case of WS2 in fused silica) reveals that under low-excitation density, sharp excitonic bleach signal (~ 640 nm) decays quickly within 200 ps, consistent with earlier reports. Interestingly, under higher excitation density, even though spectral features remain similar, but the overall TA signal becomes long-lived and hardly decays within 2000 ps. This slowing down signature at higher exciton density is found to be similar for MoS2 and WSe2 as well. This observation contrasts with the typically observed faster bleach recovery dynamics (due to exciton-exciton annihilation events) at higher excitation fluence for large no of semiconductors including TMDs. This slow dynamic is anticipated as a typical signature of strain induced formation of indirect exciton. As the intervalley scattering dominates at higher exciton density, large number of direct excitons quickly scatter into the other-valley (indirect) and thus contribution of the long-lived TA signal increases. This is further evident from the TA measurements of suspended (strain-reduced) samples in which slowing down effect of the TA signal (at higher exciton density) is relatively suppressed. This interesting finding of controlling the population of direct and indirect excitons by means of optical excitation will open exciting areas in potential optoelectronic applications.

Imaging Carrier Inhomogeneities in Active 2D Material Devices Samuel Berweger; National Institute of Standards and Technology, United States

Scanning microwave microscopy (SMM, often called scanning microwave impedance microscopy, sMIM) is a scanning probe implementation that can directly probe free carriers with nanometer spatial resolution using tip-localized GHz fields. With the subsurface sensitivity inherent to near-field techniques and the ability to measure electrically isolated systems, SMM is well-suited for studying electronic inhomogeneities in 2D semiconducting materials and their devices. We begin by highlighting SMM measurements of photogenerated free carriers in transition metal dichalcogenide lateral heterostructures.

We then focus on the application of SMM to studying ambipolar field effect transistors of 2D films of the 1D van der Waals material tellurium (tellurene). Tellurene can be solution processed, exhibits high bipolar mobilities, and is stable under ambient conditions, which makes it an attractive alternative to conventional 2D semiconductors. We combine SMM with a differential implementation to image spatial variations in conductivity as well as the associated carrier type as a function of the applied backgate voltage in tellurene devices. We reveal spatial inhomogeneities in carrier type and conductivity and show that the measured backgate-dependent device conduction minimum in fact arises from the simultaneous coexistence of n-type and p-type regions in an overall minimum conductivity configuration. We further show that the spatial inhomogeneities in conductivity and carrier type in four-terminal devices results in differing transport characteristics between different terminals across the same device in well-defined backgate-controlled p-type and n-type conduction channels. While these results highlight the challenges facing the reproducible fabrication of 2D material devices, the possibilities of solution-based doping and deterministic weighting of multiple inputs into the same device hold future promise.

5:15 AM F.EL04.17.02
Long Continuous Electroluminescence in All 2D van der Waals Vertical Heterostructure Devices Linlin Hou[1], Qianyang Zhang[1], Viktoryia Shautsova[1] and Jamie Warner[2]; [1]University of Oxford, United Kingdom; [2]The University of Texas at Austin, United States

2D materials can be assembled into various vertical heterostructure stacks to emit strong electroluminescence. However, until now, most work has been done using mechanical exfoliated materials, with little insights gained into the operation mechanisms when using synthetically grown crystals by chemical vapour deposition (CVD). In particular, the operation lifetime/duration of electroluminescence and subsequent failure mechanisms are poorly understood, mainly due to lack of abundance in device numbers that can shed statistical significance into the ensemble response. Here, we demonstrate that all 2D vertical layered heterostructures (Gr:hBN:WS2:hBN:Gr) using CVD grown materials can generate strong red electroluminescence (EL). Here, graphene acts as a transparent electrode, WS2 works as an ultrathin photo-active material, and h-BN serves as a tunnelling barrier for carrier injection. Tens of the devices are produced across a single chip, with the success rate of working devices over 90%. EL starts to be detected at bias values of ~5 V, with a bright red EL dot located at the junction area. Continuous operation of the devices generate EL for more than 2 hours without significant degradation of WS2 under high bias. Further investigation on breakdown tests reveal that the dominant reason for the device failure is local heating accumulation on top-graphene electrodes. This study provides a viable way for wafer-scale fabrication of high performance 2D LED arrays for ultra-thin and flexible optoelectronic devices and detailed insights about the mechanisms of failure and operation limits of EL devices made with CVD grown 2D materials within ambient conditions.

5:25 AM F.EL04.17.04
Monolayer/Multilayer Homojunctions in Transition Metal Dichalcogenides Enhance Photoinduced Charge Generation in Heterostructures with Carbon Nanotubes Dana Kern, Hanyu Zhang, Zhaodong Li and Jeffrey L. Blackburn; National Renewable Energy Laboratory, United States

Increasing the lifetimes and yields of photoexcited charge carriers in quantum-confined heterostructures is an important goal for realizing efficient next-generation energy conversion and storage devices. One-dimensional single-walled carbon nanotubes (SWCNTs) and two-dimensional transition metal dichalcogenides (TMDCs) are fascinating materials classes with possible applications in photovoltaic and photoelectrochemical technologies. However, the photophysics in heterostructures containing these materials are not well understood. Here, we explore a model Type-II heterojunction with (6,5)-SWCNTs as the electron donor and MoS_2 as the acceptor, where the energy level offsets at these interfaces provide a promising strategy to separate charge and overcome the ultrafast decay of tightly bound excitons that are inherent to these materials. We find that the TMDC microstructure affects the charge photogeneration pathways in MoS_2/SWCNT heterojunctions, where a small fraction of multilayer islands in monolayer MoS_2 leads to longer-lived charge carriers and higher carrier yields, despite the emergence of a defect-associated spectral signature. We combine transient absorption spectroscopy with time-resolved

microwave photoconductivity to explore the interplay between defect states and the generation of mobile carriers. Global fitting of our transient absorption spectra enables us to separately analyze exciton, charge, and defect evolution on the MoS_2 and SWCNT layers, and microwave photoconductivity distinguishes between free and trapped charge. Our comparisons between multilayer-containing and monolayer-only MoS_2/SWCNT heterostructures provide valuable insight for understanding the impact of local TMDC thickness variations on charge generation pathways.

5:35 AM F.EL04.17.05
Electron-Phonon Coupling Enhances Thermal Boundary Conductance of 2D-3D Interfaces Arnab K. Majee, Cameron Foss and Zlatan Aksamija; University of Massachusetts Amherst, United States

Devices made of two-dimensional (2D) van der Waals (vdW) materials, including graphene, transition metal dichalcogenides (TMDs, e.g. MoS_2, $MoSe_2$, WeS_2 etc.) and beyond-graphene materials (e.g. phosphorene, silicene, germanene, etc.), hold tremendous potential for next-generation nanoelectronics applications. The prospect of vertically stacking[1]--both homogeneous and heterogeneous--vdW materials has opened numerous avenues to engineer them for superior device performance. However, practical realization of electronic devices made of 2D vdW materials is limited by the inefficient thermal dissipation from the 2D material to the substrate. The high interface thermal resistance can cause unreliable performance and even lead to device failure. Significant research interests have been invested towards improving the electronic properties such as mobility, subthreshold slope, etc.,[2-4] but heat dissipation has received less attention.
Heat removal in 2D field-effect transistors is mainly cross-plane through the substrate, owing to the small thermal healing length[5] and large lateral/vertical aspect ratio.[6] Heat dissipated by electrons is carried from the 2D material to the substrate via flexural out-of-plane lattice vibrations (ZA phonons) and the efficiency of heat transfer is quantified by thermal boundary conductance (TBC). Our previous studies suggest that the TBC of graphene and MoS_2 monolayers on various substrates can be improved by encapsulation.[6] However, encapsulation is not a viable alternative to improve TBC in optoelectronic devices. A recent study demonstrated lowering of in-plane thermal conductivity of 2D materials via phonon-electron interactions, opening a new avenue to modulate heat transfer by electrostatic gating;[7] however, the impact of electron-phonon coupling on cross-plane heat transfer through the 2D-substrate interface is not yet fully understood.
Here we demonstrate the role of phonon-electron scattering as a tool to tune TBC of 2DvdW materials on SiO_2 substrate. We calculate the electronic bandstructures and phonon dispersions of 2D materials from first principles Density Functional Theory using the QUANTUM ESPRESSO package.[8] Then we compute phonon-electron rates () from Fermi's Golden rule. is combined with the anharmonic phonon rates in our thermal model[9] to obtain TBC of the 2D-3D interface. We found that TBCs of MoS_2 and $MoSe_2$ are improved by 21.4% and 23.6%, respectively, when the carrier density is varied from 10^{10} cm^{-2} to 10^{14} cm^{-2} at 300K. On the other hand, WS_2 and WSe_2 show a weaker dependence on phonon-electron coupling with an improvement of 2.4% and 5.4%, respectively, which is due to dominant phonon-phonon scattering in these materials. The maximum enhancement in TBC due to phonon-electron coupling is obtained for TMDs composed of transition metals with smaller atomic mass and heavier chalcogen atoms. We also found that TMDs with smaller effective masses exhibit better TBC. From a fundamental perspective, we found that in all these 2D materials TBC is limited by the rate at which ZA phonons are replenished in the monolayer and not by the rate at which they scatter with the substrate. This study provides a novel tool to dynamically tune TBC by gating.

Exciton Transport under Periodic Potential in TMD Heterostructures Zidong Li[1], Xiaobo Lu[2], Darwin Cordovilla Leon[1], Zhengyang Lyu[1], Jize Hou[1], Yanzhao Lu[1], Austin Kaczmarek[1], Takashi Taniguchi[3], Kenji Watanabe[3], Liuyan Zhao[2], Li Yang[2] and Parag B. Deotare[1,1]; [1]University of Michigan, United States; [2]Washington University in St. Louis, United States; [3]National Institute for Materials Science, Japan

In this work, we unravel the mechanism that affects exciton transport in a periodic potential created by stacking two lattice mismatched transition metal dichalcogenide (TMD) monolayers. The confined periodic excitonic states (moiré excitons[1–3]) in the heterostructure creates a diffusion barrier that impacts the energy transport and dynamics of interlayer excitons (electron and hole spatially separated in different monolayers).
We experimentally quantify the diffusion barrier experienced by interlayer excitons in both R-type and H-type, h-BN encapsulated MoSe2/WSe2 heterostructures. We further support the observations with density functional theory (DFT) simulations and a three-level model that represents the exciton dynamics at various temperatures. By measuring the diffusion

of interlayer excitons at various bath temperatures, we observe that the effective diffusivity of excitons can be significantly lower than their intrinsic diffusivity in the absence of the periodic potential. In fact, at low temperatures, most of the excitons remain immobile, ceasing exciton transport completely. We conclude that the strong localization of interlayer excitons at low temperature and the temperature activated Arrhenius type of diffusivity are inherent to the deep periodic potentials arising from the moiré superlattice. Based on the temperature dependent diffusivity and lifetime of interlayer excitons, we extracted the moiré potential of 20±4 meV for the H-type (54 degree twisted angle) heterostructure and 34±3 meV for the R-type heterostructure (5 degree twisted angle).
We believe the results will significantly advance the understanding of exciton transport in van der Waals heterostructures and will aid in the design of room-temperature efficient excitonic devices that leverage the various regimes of diffusivity based on twisted angle.

Thermal Boundary Conductance of Buckled Group IV,V, and III-V Two-Dimensional Materials Cameron Foss and Zlatan Aksamija; University of Massachusetts Amherst, United States

In the last decade, entire families of novel two-dimensional (2D) materials have been theoretically predicted and subsequently synthesized. The combination of their ultrathin geometry, environmental sensitivity, and mechanical robustness make 2D materials an exciting framework from which improved device performance and novel functionalities can be realized. While much of the attention on 2D materials focused on their electronic, magnetic, and optical properties, heat dissipation in these materials remains a major concern for their future implementation. The primary pathway for heat removal in 2D-based devices is the thermal pathway from the 2D layer to its underlying 3D substrate. Since 2D-3D interfaces are governed by weak van der Waals interactions, the interface thermal pathways can be one to two orders of magnitude more resistive than 3D-3D covalently bonded interface counterparts. Therefore, developing solutions to boost 2D-3D thermal boundary conductance (TBC) and identifying 2D material properties that favor interface thermal transport are critical to the future implementation of 2D-based devices.
The TBC between graphene, boron nitride (BN), and transitional metal dichalcogenides on several substrates have been studied rigorously. However, more recently synthesized 2D materials such as buckled group IV, V, and III-V 2D materials have not been investigated. Previously [2D Mater. 6 (2019) 025019] we have shown that 2D-3D TBC depends strongly on the overlap of available phonon modes in the long-wavelength regime and found selection criteria for choosing the best substrate for TBC. Here we turn our focus to 2D material features and report theoretical predictions of TBC for silicene, blue phosphorene, black phosphorene, and boron arsenide (BAs) on SiO_2 (with comparisons to graphene and BN). Our TBC model is driven by ab initio phonon dispersions and takes into account the two mechanisms that govern TBC: (i) an external resistance between ZA phonons in the 2D layer and the substrate which depopulates the ZA phonon population of the 2D layer and (ii) an internal resistance between ZA phonons and other thermal energy carriers which replenishes the ZA phonon population. Weak internal scattering can lead to a large internal resistance which effectively reduces the overall TBC. However, encapsulation has been shown to increase the internal scattering of ZA phonons effectively reducing the internal resistance and increasing the overall TBC [Adv. Mater. 30 (2018) 1801629].
We predict the external TBC, which is an upper bound on the effective TBC, of 2D/SiO_2 of (a) graphene, (b) BN, (c) blue phosphorene, (d) black phosphorene, (e) silicene, and (f) BAs interfaces without encapsulation to be (a) 20, (b) 32, (c) 70, (d) 80, (e) 100, and (f) 130 $MW.m^{-2}.K^{-1}$, respectively. On the other hand, the effective TBC values are approximately 50% ((a) 54%, (b) 52.5%, (c) 45%, (d) 51.6%, (e) 48%, and (f) 50.3%, respectively) of the external TBC because of additional internal resistance due to a slow repopulation of ZA phonons. However, upon encapsulation, which increases the damping and repopulation of ZA phonons, nearly half ((a) 26%, (b) 25.7%, (c) 21%, (d) 26%, (e) 20.1%, and (f) 16.6%) of those losses are regained at room temperature. Furthermore, the effective TBC of encapsulated samples shows a far weaker temperature dependence than the uncoated counterparts which is most significant at low temperatures where a near order of magnitude increase in the total TBC for temperatures below 50 K is seen for some cases. We also see that the TBC can vary over nearly an order of magnitude depending on the phonon bandwidth of the ZA branch. Our results help highlight the role of encapsulation on the temperature dependence of TBC and we find that 2D materials with narrower ZA branch bandwidths correlate strongly to high TBC.

Vibrational Properties of Black Phosphorous under Intercalation and High-Pressure—An *In Situ* Study Manthila C. Rajapakse, Rajib Musa, Usman Abu, Bhupendra Karki, Ming Yu, Gamini Sumanasekera and Jacek B. Jasinski; University of Louisville, United States

This work reports a systematic study of electrochemical Li intercalation and high-pressure studies of black phosphorous (BP). In-situ Raman spectroscopy is used to analyze the time evolution of vibrational modes of BP under lithiation during galvanostatic discharge in a dedicated electrochemical cell. At a constant current, discharge time accounts for the number of Li ions transferred to BP cathode, hence providing good control over the composition of LixP compound. Black phosphorous has three fundamental vibrational modes. The study shows that all three fundamental vibrational modes, A1g, B2g and A2g red-shift as a result of lithiation and in-plane modes (B2g and A2g) are red-shifting about 1.6 times more than out-of-plane mode A1g. The results also indicate the structural expansion measured using electron diffraction of ex-situ lithiated samples. Further analysis using optical and electron microscopy shows also that the intercalation of BP is highly anisotropic, where channels along the zigzag direction are found to be the easy direction for intercalation. The diffusion along these channels also leads to a formation of weakly connected nanoribbons, which could be used as an alternative route to fabricate phosphorene nanoribbons. X-ray diffraction on intercalated samples indicates a reduction of thickness as lithiation weakens interlayer bonding, thus resulting in a partial exfoliation of BP flakes. The experimental results show a random filling of Li atoms between BP layers rather than a periodic filling assumed in the first principle calculations based on density function theory which explains the discrepancy between the theoretical and experimental Raman peak positions. Furthermore, studying vibrational modes of BP under high-pressure is important and adds to the knowledge on mechanical properties and strain engineering in this material which could also lead to a structural phase transition towards blue phosphorous, as predicted by first principle calculations. A diamond anvil cell (DAC) is used to apply high pressure (up to ≈15 GPa) on BP. In this method, sample is stressed against two transparent diamond anvils via a liquid pressure transfer medium. Transparency of the diamond anvils allow in-situ Raman spectroscopy to monitor changes in phonon modes under pressure. High-pressure in-situ experiments are underway on both pristine and Li intercalated BP samples, also with a systematic study on the effect of different pressure media to study the possible structural phase changes of this intriguing material under high-pressure.

Modifying Energetic Disorder and Hot Exciton Dynamics Through Cation Modification in Excitonic 2D Hybrid Perovskites Daniel B. Straus[1,2], Sebastian Hurtado Parra[2], Natasha Iotov[2], Michael R. Gau[2], Qinghua Zhao[2], Patrick J. Carroll[2], James M. Kikkawa[2] and Cherie Kagan[2]; [1]Princeton University, United States; [2]University of Pennsylvania, United States

We report a family of two-dimensional hybrid perovskites (2DHPs) based on phenethylammonium lead iodide ($(PEA)_2PbI_4$) that exhibit complex cation-dependent optical properties. By replacing the 4-position (*para*) H on the phenyl moiety of the phenethylammonium cation with F, Cl, CH_3, or Br, we increase the length of the cation but leave the cross-sectional area unchanged, resulting in structurally similar PbI_4^{2-} frameworks with increasing interlayer spacing. Longer cations result in broader, blue-shifted excitonic absorption spectra with reduced or eliminated structure, indicating greater energetic disorder. Photoluminescence spectra are largely invariant and insensitive to cation length, suggesting polaron formation stabilizes a structural and electronic minimum. Temperature-dependent linewidth analysis reveals excitons couple to a vibration on the organic framework that is weakly sensitive to these cation substitutions, and Raman spectra and electronic structure calculations support the presence of such a cationic mode. Despite carriers being confined to the inorganic framework, the length of the organic cation alters the optical and electronic properties of 2DHPs.

If instead we replace the 2-position (*ortho*) H with F, Cl, or Br, we increase the cation's cross-sectional area. Unlike the 4-position substitutions, these single-atom substitutions substantially change the observable number of and spacing between discrete resonances in the excitonic absorption and PL spectra and drastically increase the amount of hot exciton PL that violates Kasha's rule by over an order of magnitude. To fit the progressively larger cations, the inorganic framework distorts and is strained, reducing the Pb-I-Pb bond angles and increasing the 2DHP band gap. Correlation between the 2DHP structure and steady-state and time-resolved spectra suggests the complex structure of resonances arises from one or two manifolds of states, depending on the 2DHP Pb-I-Pb bond angle (as)symmetry, and the resonances within a manifold are

regularly spaced with an energy separation that decreases as the mass of the cation increases. The uniform separation between resonances and the dynamics that show excitons can only relax to the next-lowest state are consistent with a vibronic progression caused by a vibrational mode on the cation. These results demonstrate that simple changes to the cation can be used to tailor the properties and dynamics of the confined excitons without directly modifying the inorganic framework.

Radiation Hardness of Atomically Thin Proton Irradiated Monolayer MoS_2 Burcu Ozden; Penn State Abington, United States

We live in an era where space tourism finally becomes a reality. Space tourism is expected to become a large industry within the next decade along with the more and more private sector companies promoting it. These ambitious goals can only be achieved through the development of technologies, which are resilient to damage due to high, persistent fluxes of ionizing radiation in the extreme space environment. In this regard, two-dimensional materials (2DMs) have attracted great attention in the electrical device research for space applications due to potential use as a replacement of traditional semiconductors substrates for next-generation electronic devices and circuits. Studying the effects of proton irradiation on MoS_2 can help us to understand the response of optoelectronic devices fabricated from these materials operating in radiation hard environments such as space radiation environment, high-altitude flights, military aircraft, satellites, nuclear reactors, and particle accelerators. In this research, proton irradiation-induced effects on monolayer MoS_2 were studied by emulating a certain space radiation environment using a relatively low energies (150 and 590keV) proton beam with the same fluence of 1×10^{12} protons/cm^2. The pristine and irradiated monolayer MoS2 samples were characterized by comparing the phenomenological changes in the optical and morphological properties. The crystal quality was examined with x-ray diffraction (XRD) analysis and micro-Raman spectroscopy. The possible effects on defects/ traps were probed using photoluminescence (PL) spectroscopy. The surface compositional analysis was performed via x-ray photoelectron spectroscopy (XPS), and surface morphology was inspected using atomic force microscopy (AFM), scanning electron microscopy (SEM), and transmission electron microscopy (TEM). The MoS_2 material grown with the facilitation of sodium bromide by the chemical vapor deposition shows the negligible change in optical and morphological characteristics after the irradiation. Our results open the way for the use of robust and reliable MoS_2 based devices in space environments.

Fluoric Self-Assembled Monolayer (FSAM) for Enhancing the Electrical Properties of Graphene on Arbitrary Substrates Shih-Ming He, Hsin-Yin Lin and Ching Yuan Su; National Central University, Taiwan

Charge scattering, impurities, wrinkles, and polymer residues among the substrate decline the electrical properties, such as carrier mobility and n-/p-type doping, has been a challenge for graphene-based electronic devices. Self-assembled monolayers (SAMs) have been widely used to tailoring the electronic structure of substrate-supported graphene due to the effective modifications such as the extremely flatten surface or dipole at the interface. Also, the fluoric self-assembly monolayer (FSAM) used to promoting the electrical properties due to the hydrophobic so that it can eliminate the residue of water molecules between the substrate and graphene during the transferring process. In this study, the trichloro(1H,1H,2H,2H-perfluorooctyl)silane (FDTS) was selected as the precursor followed by the formation of the FSAM layers through the dip-coating and spin-coating methods on arbitrary substrates such as Si, SiO_2/Si, PET, and glass. As the result, it was found out that the surface roughness of the FSAM/SiO_2 substrate significantly reduce from 2.96 to 0.29 nm with the optimized condition by dip-coating, on which the graphene mobility measured from Hall measurement increases about 1.77 times from 894.6 cm^2/Vs to 1588cm^2/Vs; the calculated mobility of graphene/FSAM with a top-gated field effect transistor (FET) is about 15 times higher than that of device without SAM-modified substrate. The increased mobility is mainly due to the lower surface roughness and dipole effect when graphene on FSAM layer, which is observed on other versatile substrates. The dipole at the interface of graphene or other 2D(MoS_2 and WSe_2) and FSAM layer were comprehensively studied, where it allows for altering the carrier transport properties especially in FETs. This method provides a new strategy through the substrate modification to enhancing the electrical performance on graphene or 2D-based FETs, which could pave a way toward next-generation high-performance nanoelectronics.

Ice Templated and Directed Assembly to Construct 3D Boron Nitride and Graphene Oxide Nanosheet Topological Networks for Property Enhancement Sanju Gupta[1,2]; [1]CCNY, United States; [2]Western Kentucky University, United States

Inspired by the nano/microscale hierarchical structure, topological network and precise inorganic/organic interfaces, we fabricated artificial ‘nacre-like’ papers and aerogels based on noncovalent functionalized boron nitride nanosheets (NF-BNNSs) and varying poly(vinyl alcohol) (PVA) concentration via vacuum-assisted self-assembly and freeze-drying (or ice-templating) techniques. The electron microscopy showed an ordered ‘brick-and-mortar’ arrangement of NF-BNNSs and PVA paper and aerogels, in which the long-chain PVA molecules act as the bridge to link NF-BNNSs via hydrogen bonds. Likewise, due to the need for heat removal in modern electronic devices, polymer composites with high thermal conductivity have drawn much attention. However, the traditional method to enhance polymers' thermal conductivity by random addition of nanofillers usually creates composites with not only limited thermal conductivity but also other detrimental effects due to a large amount of fillers required. Here, novel polymer composites are prepared by first constructing 3D boron nitride nanosheets (3D-BNNS) network using an ice-templated approach with varying BNNS sheets concentration and then infiltrating them with epoxy matrix. The thermal and mechanical properties of resulting free-standing nacre-like papers, aerogels and composites are investigated. They elucidated high glass transition temperature, low interfacial thermal resistance, or high thermal conductivity with relatively low BNNS loading thus revealing their superiority as flexible substrates. These results demonstrate that this approach opens a new avenue for the design and preparation of polymer composites with high thermal conductivity useful in advanced electronic packaging techniques, namely, thermal interface materials, underfill materials, and molding compounds.

F.EL04.19.02
Development of New Nanofiltration Membranes Using 2D Nanomaterials Natalia Garcia Domenech[1,2], Yurii Goun'ko[1,2] and Finn Purcell-Milton[1,2]; [1]Trinity College Dublin, Ireland; [2]BiOrbic Bioeconomy Research Centre, Ireland

Nanofiltraton has gained much attention in recent years due to its possible applications as a highly efficient and low-energy usage separation and purification technology[1,2]. Moreover, nanofiltration has shown to be potentially superior and more cost-effective than other filtration techniques. Nanofiltration was initially adapted for wastewater treatment, but has been implemented by other industries, such as the pharmaceutical and the food industries, where the standard for high quality products and stringent safety requirements necessitate further and more specialised separation approaches[1,3].
The main aim of this project was to use inorganic 2D nanomaterials in order to develop new membranes for nanofiltration applications, in particular, boron nitride (BN). In this project, BN was exfoliated by liquid assisted exfoliation and the membranes were prepared by vacuum filtration using hydrophilic polytretrafluoroethylene as template. Boron nitride was also partially oxidised before exfoliation proving new chemically functionalised BN materials. All membranes were tested using different dyes and calculating the rejection of each one. Almost 100% rejection rates have been achieved for optimised BN membranes demonstrating the superb nanofiltration performance for selected dyes. The new membranes are to be used for the separation of D- and L- lactic acid and various mono- and disaccharides from agricultural residues.

Raman Studies of a Natural van der Waals Heterostructure Viviane Z. Costa[1], Addison Miller[1], Sam Vaziri[2], Shirin Jamil[1], Andrew Ichimura[1], Eric Pop[2,2,2] and Akm Newaz[1]; [1]San Francisco State University, United States; [2]Stanford University, United States

Van der Waals heterostructures comprised of two-dimensional (2D) materials offer a platform to obtain materials by design with unique electronic properties. Until recently, these van der Waals heterostructures (vdWH) materials were synthesized in

the laboratory by vertically stacking different atomically thin materials, which often leads to stacks with the presence of fabrication defects and air contaminants between layers. Franckeite is a naturally occurring vdWH comprised of two distinct alternately stacked semiconducting layers. Because it is naturally heterostructured, it enables the study of a complex layered system without the presence of fabrication defects, and where the crystal orientation between layers has been preserved. Unlike other layered sulfide-based 2D materials, Franckeite is a grained-textured layered solid composed of few-millimeters flakes in random orientation. For this reason, mechanical exfoliation of thin flakes with uniform and large surface area for optical characterization and transfer techniques is especially challenging, leading to a knowledge gap of the fundamental properties of Franckeite. Raman spectroscopy is a widely and powerful method to characterize and study the fundamental properties of molecules in 2D crystals. All of the power that Raman spectroscopy provides in characterizing 2D materials stems from a large and well-established literature on the Raman signature of these crystals, which is lacking for Franckeite. In this work, we performed an extensive micro-Raman spectroscopy study of Franckeite. At room temperature, Raman spectroscopy data were acquired for a large sample size of flakes with thickness ranging from 6 to 100 nm prepared by mechanical exfoliation on SiO_2 substrates. The Raman signature of Franckeite is detected for flakes thicker than 10 nm. We observed that the position of all Raman peaks is independent of sample thickness. As expected, signal intensity is enhanced for flakes prepared on ultra-flat gold (Au) substrates (root-mean-square (rms) surface roughness < 0.2 nm), but different Raman modes undergo different rates of enhancements when comparing flakes of the same thickness on SiO_2 and Au. Raman data was acquired for excitation sources of both 532 and 633 nm of wavelength. Comparison data plots indicate resonance-enhanced Raman scattering with 633 nm of excitation, confirmed by additional absorption measurements. Temperature-dependent data was acquired from room temperature to 225 °C. All Raman modes present redshift with increasing temperature, suggesting that the chemical bond length of Franckeite increases with increasing temperature, and therefore the bond's vibrational force constant decreases. Moreover, we observed new low-frequency shearing and breathing modes in the Raman spectra. These low-frequency vibrational modes of Franckeite can provide a broader understanding of interlayer vibrational modes in 2D crystals, and especially in van der Waals heterostructures.

Measuring Thermal Expansion Coefficient of Monolayer Molybdenum Disulfide Using Micro-Raman Spectroscopy Lenan Zhang, Zhengmao Lu, Youngsup Song, Lin Zhao, Bikram Bhatia, Kevin Bagnall and Evelyn Wang; Massachusetts Institute of Technology, United States

Atomically thin two-dimensional (2D) molybdenum disulfide (MoS_2) is highly attractive due to its unique properties and promising applications in nanoscale electronics. Characterization of thermal expansion coefficient (TEC) of 2D MoS_2 is ubiquitous for reducing the thermal mismatch and improving the thermal management of MoS_2-based devices. However, measuring the TEC of 2D MoS_2 is particularly challenging owing to its nanoscale thickness, microscale area and optical transparency properties. As a result, the thermal expansion on 2D MoS_2 still extensively relies on simulation. In this work, we report a pure experimental approach to characterize the TEC of monolayer MoS_2 using micro-Raman spectroscopy. We analyzed the stress and temperature dependent phonon frequency of monolayer MoS_2 using the perturbation theory and symmetry analysis. To decouple the effect of thermal stress on phonon frequency shift, monolayer MoS_2 flakes were transferred on fused silica, pure copper and micro-hole patterned thermal oxide substrates. We characterized the temperature coefficients on three substrates through the temperature-dependent Raman measurement. The in-plane TEC of monolayer MoS_2 was then extracted by comparing these coefficients. The resulting in-plane TECs were $(7.6\pm0.9)\times10^{-6}$ 1/K and $(7.4\pm0.5)\times10^{-6}$ 1/K, which were independently obtained from two different phonon modes of MoS_2 and in reasonable agreement with previous first-principle reported values. This work provides accurate measurement on the TEC of monolayer MoS_2. Additionally, the general experimental approach can be widely applied to study many other 2D materials or thin films in a simple way.

F.EL04.19.06

Luminescence Properties of Hexagonal Boron Nitride Powders Probed by Deep UV Photoluminescence Spectroscopy Nikesh Maharjan and Mim Nakarmi; Brooklyn College and The Graduate Center of CUNY, United States

Hexagonal boron nitride (h-BN) is an ultrawide (~ 6.0 eV) semiconductor that has potential applications for developing

electronic, optoelectronic and nanophotonic devices including source of ultraviolet emitters. A key issue in these applications is understanding the effect of impurities, especially carbon and oxygen on its properties. Deep UV photoluminescence spectroscopy was employed for optical characterization of irregular-shaped h-BN crystal powders. Fourth harmonic laser (195 nm) generated from the Ti: sapphire laser was used for optical excitation in the experiments. The luminescence properties are investigated by annealing the sample at different temperatures under different conditions. The deep UV photoluminescence spectra from h-BN samples annealed at 700 ^{o}C in ambient air reveals a strong phonon-assisted band-edge emissions along with a sharp atomic-like emission line at 4.09 eV, and its phonon replicas at 3.89 and 3.69 eV. In addition to these peaks, sharp multi-phonon peaks are observed adjacent to them. The PL spectra of the sample shows the broadening of the main peaks as the annealing temperature exceeds 900 ^{o}C. We will present our findings of atomic-like features that could have potential applications as quantum sources in UV regions for quantum information technologies.

F.EL04.19.08
Quantification of Surface Reactivity and Step-Selective Etching Chemistry on Single-Crystal BiOI Julia Martin, Roy Stoflet, Alexander Carl, Katarina Himmelberger and Ronald L. Grimm; Worcester Polytechnic Institute, United States

We synthesized single-crystal BiOI via vapor transport, subjected the resulting crystals to a series of surface treatments, and quantified the resulting chemical states and electronic properties. Vapor transport methods included both physical vapor transport from single-source BiOI, as well as chemical vapor transport from Bi_2O_3 + BiI_3 and from Bi + I_2 + Bi_2O_3. Surface treatments included tape cleaving, rinsing in water, sonication in acetone, an aqueous HF etch, and a sequential HF etch with subsequent sonication in acetone. X-ray diffraction, XRD, and X-ray photoelectron spectroscopy, XPS, probed the resulting bulk crystalline species and interfacial chemical states, respectively. In comparison with overlayer models of idealized oxide-terminated or iodide-terminated BiOI, angle-resolved XPS elucidated surface terminations as a function of each treatment. Ultraviolet photoelectron spectroscopy, UPS, established work-function and Fermi-level energies for each treatment. Data reveal that HF etching yields interfacial BiI_3 at BiOI steps that is subsequently removed with acetone sonication. UPS establishes n-type behavior for the vapor-transport-synthesized BiOI, and surface work function and Fermi level shifts for each chemical treatment under study. We discuss the implications for processing BiOI nanofilms for PV and photocatalysis applications.

F.EL04.19.09
Impact of Salt and Solvent Identity on the Deposition of a Cobalt Crown Ether Phthalocyanine Monolayer Electrolyte Huiran Wang, Shubham Sukumar Awate and Susan Fullerton; University of Pittsburgh, United States

A monolayer electrolyte, developed by our group, has been used to demonstrate a solid-state nonvolatile two-dimensional (2D) crystal memory based on an electric-double-layer (EDL) gated field effect transistor. (Nano Lett., 19, 8911, 2019) The monolayer electrolyte consists of cobalt crown ether phthalocyanine (CoCrPc), with four crown ethers that can solvate one lithium ion each. By simply drop-casting and annealing, CoCrPc forms a flat and ordered array on 2D crystals including graphene and WSe_2. The key mechanism of the nonvolatile memory is the toggling of lithium ions up and down through the cavity of crown ether (i.e., away from or nearby the channel). This toggling is accomplished by an applied electric field to overcome the diffusion barrier for ion movement. Our previous experimental work focused on one combination of materials: CoCrPc with 15-crown 5-ether (15C5), $LiClO_4$, and ethanol as the solvent for the salt. However, additional material combinations should result in varying diffusion barriers, thereby offering a path to tune the voltage required to toggle the ions. In this study, we investigate CoCrPc with 15C5 combined with two kinds of salts, LiCl and LiI, and three solvents: anhydrous acetone, acetonitrile, and nitromethane. LiCl and LiI were chosen to isolate the impact of anion identity (Cl vs. I vs. ClO_4) on the quality of the monolayer, and the three solvents were chosen for their reported tendency to promote ion-crown complexation. Monolayer quality is evaluated by measuring the thickness and surface roughness with atomic force microscopy (AFM) after deposition on 2D crystals in a water and oxygen-free glovebox. This study establishes the design rules for monolayer electrolyte deposition on 2D crystals, which can be used to engineer devices with multiple diffusion barriers in monolayer electrolyte random-access memory (MERAM). This work is supported by the NSF under Grant # NSF-DMR-EPM CAREER: 1847808.

Monolayer Xene Films Synthesized by Molecular-Beam Epitaxy Kaylyn Holmes, Ruizhe Kang, Qi Song, Charles Brooks, Jennifer E. Hoffman and Julia Mundy; Harvard University, United States

Single element atomic monolayer honeycomb lattice films (also called “Xene” films) are a quickly-growing topic in condensed matter physics and materials science. In contrast to graphene, Xene films from higher *Z* elements such as

bismuthene (from bismuth) and stanene (from tin) are predicted to exhibit quantum spin Hall effects at temperatures closer to room temperature due to their larger topological band gaps, making them more useful for potential applications in next generation electronics. Although these two Xene films have strong theoretical and computational evidence supporting their candidacy for higher temperature quantum spin Hall effects and topologically protected edge states, they are both very difficult to produce because hexagonal unit cells are unstable configurations for the crystallization of these elements. Here, we present our work on using molecular-beam epitaxy (MBE) to synthesize monolayers and thin layers of bismuthene.

2D Nanostructured Tetrasilicates with Cr(II) and Cr(II)/Fe(II) in Square Planar Coordination—Preparation and Magnetic Properties Harshani Rathnaweera and Tina Salguero; University of Georgia, United States

The chromium-containing alkaline earth metal tetrasilicates, $ACrSi_4O_{10}$ (A= Ca, Sr, and Ba), are noteworthy as examples of rare, high spin Cr(II) in square-planar coordination complexes in chromium oxide-crystal chemistry. Though the synthesis of $ACrSi_4O_{10}$ has been known in the literature for several decades, much of the chemistry surrounding $ACrSi_4O_{10}$ formation remains unknown. In this contribution, we describe magnetic properties of all $ACrSi_4O_{10}$ phases prepared through improved synthetic routes as well as the subsequent nanostructuring of them into nanosheets by exfoliation. For flux-based routes, we utilize a metal envelope made from folded Cr foil to maintain a low oxygen fugacity in the reaction environment to avoid the formation of highly oxidized Cr species. We further extend the chemistry of $BaCrSi_4O_{10}$ to include mixed metal centers, specifically Cr(II) and Fe(II). The incorporation of mixed metal centers in $ABSi_4O_{10}$ phase is new territory in metal tetrasilicate chemistry, and this is the first example of transition metal substitution in any of the known $ABSi_4O_{10}$ systems (B = Cu, Fe, Cr). We find that the targeted stoichiometry of $Ba(Cr,Fe)Si_4O_{10}$ crystals yields an experimentally-determined composition with up to a ~40% incorporation of Fe(II), which appears to constitute the maximum incorporation of Fe(II) into $BaCrSi_4O_{10}$. Interestingly, $Ba(Cr,Fe)Si_4O_{10}$ crystals show a different magnetic infrastructure due to the interaction of antiferromagnetic Cr(II) and ferromagnetic Fe(II) centers in a single lattice. In this paper, we characterize the magnetic properties of $Ba(Cr,Fe)Si_4O_{10}$ crystals and nanosheets using Mössbauer and EPR spectroscopies.

Fabrication of Large-Area MoS_2 Nanosheets by Salt-Assisted Mechanical Milling Process and Chemical Exfoliation in Cosolvent Hsiang-Chun Yu and Tsung-Eong Hsieh; National Chiao Tung University, Taiwan

Salt-assisted mechanical milling and chemical exfoliation in cosolvent were adopted to prepare the large-area MoS_2 nanosheets with a few layers in thickness. First, the MoS_2 powder was blend with salt, *e.g.*, potassium chloride (KCl), calcium chloride ($CaCl_2$) or sodium carbonate (Na_2CO_3), and sent to a ball mill containing zirconia beads with 1 cm in diameter. The milling process was carried out at 300 rpm for 2 hrs so as to generate numerous dangling bonds at the edges of MoS_2. The dangling bonds would react with the salt to form the functionalized groups which may induce the electrical repulsion for the dispersion of MoS_2 in subsequent chemical exfoliation process. The functionalized MoS_2 powder was added in a centrifuge tube containing the cosolvent comprised of water and alcohol at the weight ratio of 1:1. After the ultrasonic vibration for 30 mins at room temperature, the MoS_2 nanosheets with thickness of 1-2 nm could be obtained *via* the centrifugation of solution. Most studies of chemical exfoliation reported the MoS_2 nanosheets with the lateral size smaller than 1 μm. However, our study observed the MoS_2 nanosheets which average area of 12×5.6 μm^2 using Na_2CO_3 and average area of 14×6 μm^2 using KCl. Presently, the MoS_2 FET devices containing the large-area MoS_2 nanosheets are prepared and their electrical properties are measured.

An Exfoliation of Mixed Dimensional van der Waals Organic/WS_2 Heterojunctions Ink for Emerging Electronics Abdus S. Sarkar[1,2] and Suman Kalyan Pal[1]; [1]Indian Institute of Technology Mandi, India; [2]Foundation For Research and Technology Hellas, Greece

Since, the isolation of single layer graphene, a great attention has been paid to integrate distinct emerging beyond graphene 2D materials into van der Waals (vdW) heterostructures. The emerging 2D transition metal dichalcogenides (TMDCs), such as semiconducting (2H-phase) tungsten sulfide (WS_2) and their mixed dimensional heterojunctions have drawn most vibrant areas of nanoscience/photonic research because of fascinating optical and electrical properties in their low dimensional interface. [1-3] However, most of the preparation (chemical) methods do not preserve the semiconductive properties of WS_2. Here, we have prepared a novel mixed dimensional 2D semiconductor p-n heterojunction of few layer WS_2, which is exfoliated in the presence of an organic semiconductor (OS) and characterized by various experimental techniques. Our results revealed that the few hundred nanometer size, few layer (4-5 layers) thick WS_2 sheets are grafted with OS. Hexagonal pattern in HR-TEM image intimate the preservation of 2H-phase WS_2. Significant changed in the electrical behavior in the p-

n nanoheterojunctions are presented. The insight spectroscopic analysis indicated the possible hybrid optoelectronic applications. Furthermore, the heterojunction dispersion WS_2 sheets are quite stable with prior little aggregation after 180 days.

Mechanisms of Molybdenum Trioxide Sulfurization in the Growth of Two-Dimensional Molybdenum Disulfide Joshua Maurer, Thierry Tsafack and Stephen F. Bartolucci; US Army CCDC AC, United States

Powder vaporization is a common method for the generation of large-area, single-crystal, two-dimensional molybdenum disulfide. While commonly employed as a growth method, the fundamental molecular mechanisms are not well understood. Recent ab initio analyses have shown that molybdenum oxysulfide rings play a key role in the sulfurization of molybdenum trioxide from elemental sulfur. Here, we present the utilization of molecular dynamics simulations with a reactive force field and ab initio calculations to elucidate the reaction pathway of sulfur with molybdenum trioxide. The molecular dynamics simulations demonstrated that for all sulfur allotropes the reaction pathway could be reduced to that of disulfur, trisulfur, or a combination of the two, and that molybdenum trioxide can catalyze the decomposition of larger sulfur allotropes. Ab initio calculations were used to illuminate the intermediates and transition states in the reaction pathways for disulfur and trisulfur. Analysis of the temperature dependence of the transition state energies show that the maximum reaction rates occur between 1000 and 1100 K, which corresponds with commonly reported experimental growth temperatures for molybdenum disulfide.

Influence of Solvent Properties on the Morphology of Ultra-Thin Tin Monoxide Nanomaterials for Next-Generation Energy Storage Applications Seán Kavanagh[1,2,3], Sonia Jaskaniec[3], João Coelho[3], Sean Ryan[3] and Valeria Nicolosi[3]; [1]Imperial College London, United Kingdom; [2]University College London, United Kingdom; [3]Trinity College Dublin, Ireland

Two-dimensional (2D) nanomaterials, especially those with controlled size and shape, have attracted significant attention over the last decade, due to their enhanced performance in comparison to their bulk counterparts.[1–3] One such chemical compound is tin monoxide (SnO), whose layered crystal structure renders it amenable to the fabrication of 2D architectures. SnO has demonstrated promising performance in many relevant applications, including thin-film transistors,[4–6]photocatalysis,[7] gas sensing[8] and, primarily, energy storage - as next-generation battery anode materials.[9–11] However, the synthesis of SnO nanomaterials with controlled morphology still poses a considerable challenge in the field.[9,12–17] In this work, we provide a comprehensive study of the complex relationship between wet chemistry synthesis conditions and resulting nanoparticle morphology. The solvent nature is observed to strongly influence the kinetics of nucleation and crystal growth in solution, and thus the final morphological and electrochemical properties.

Extensive characterization of the precipitate nanomaterial has been performed, including scanning electron microscopy (SEM), high-resolution transmission electron microscopy (HRTEM), selected area electron diffraction (SAED), x-ray diffraction (XRD) and thermogravimetric analysis (TGA), in order to comprehensively describe the solvent-morphology dependence. Furthermore, high-level electronic structure theory, including dispersion corrections to account for Van der Waal's effects, were employed to augment our understanding of the underlying chemical mechanisms. Using supercell calculations, electronic vacuum alignment and surface energies were determined, allowing the prediction of the thermodynamically-favored crystal shape (Wulff construction) and surface-weighted work function, important parameters for battery performance. Finally, the synthesized nanomaterials were tested as battery materials, illustrating the impact of particle morphology on electrochemical performance.

Our results reveal promising pathways to the controlled synthesis of nanomaterials with tailored morphologies for enhanced performance in specific applications.

Effect of Aliovalent Doping on Epitaxial Growth, Structure and Properties of Triple-Layered Ruddlesden-Popper Phase Lanthanum Nickelate Akifumi Matsuda[1], Tomoaki Oga[1], Shohei Hisatomi[1], Nobuo Tsuchimine[2], Satoru Kaneko[3,1] and Mamoru Yoshimoto[1]; [1]Tokyo Institute of Technology, Japan; [2]Toshima Manufacturing Co., Ltd., Japan; [3]Kanagawa Institute of Industrial Science and Technology, Japan

Ruddlesden-Popper phase lanthanum nickelates ($La_{n+1}Ni_nO_{3n+1}$) with two-dimensional perovskite structure have attracted interests for their electronic properties related to the structure and mixed valence Ni-ions [1]. These two-dimensional perovskites are also expected as precursors to develop infinite-layer nickelate superconductors such as Sr-doped $NdNiO_3$ [2]. Development of epitaxial thin films of lanthanum nickelate with multilayered structure and modifying their structure, electronic state, and properties according to interfacial strain and substitutional doping would contribute to develop further understanding and application of their solid-state physics. There are some reports of triple-layered $La_4Ni_3O_{10}$ for its metal-insulator-transition due to oxygen deficiency and possible application to such as SOFCs and gas sensors [1,3]. However, aliovalent doping in $La_4Ni_3O_{10}$ epitaxial thin films similar to La_2NiO_4 and $La_3Ni_2O_7$ still requires further researches to explain its effect on structure and properties [4,5]. In this study, effect of aliovalent dopants substituting La^{3+} in triple-layered $La_4Ni_3O_{10}$ on its epitaxial growth as well as on the structure and electric properties of the thin films was investigated.
The lanthanum nickelate thin films were prepared by pulsed laser deposition technique equipped with a KrF excimer laser (λ=248 nm, d=20 ns, and E~1.0 J/cm^2). The films were deposited on atomically stepped $SrTiO_3$ and $NdGaO_3$ single crystal substrates at 700–750°C in O_2 atmosphere (10 Pa) using sintered targets of $La_4Ni_3O_{10}$ doped with Hf and Sn. The thin films were then thermally treated at ~950°C for 2 hours in high-purity O_2 atmosphere (1 atm, 200 sccm) to modify the crystal phases and the valence of Ni-ions. X-ray diffraction results indicated epitaxy of $La_4Ni_3O_{10}$ (001) thin films after annealing in O_2, while epitaxial growth of La_2NiO_4 (100) was observed for the as-grown films. The formation of La_2O_3 buffer layer at the interface was suggested to have contribution on the epitaxy of $La_4Ni_3O_{10}$ phase. The Hf and Sn-doped $La_4Ni_3O_{10}$ (001) thin films with thickness of ~100 nm demonstrated low resistivity of ~5 mΩcm at room-temperature measured by a 4-probe DC method. Further detailed structural analyses of the lanthanum nickelate thin films, and the effect of the aliovalent doping on the electronic property related to the structure would also be discussed.

Thermoelectric Effect of Conductive Polymer Films from Functionalized Graphene Byeonggwan Kim, Cheolhyun Cho and Eunkyoung Kim; Yonsei University, Korea (the Republic of)

Thermoelectric effects in conductive polymers (CPs) have received significant attention owing to its high electrical conductivity, high Seebeck coefficient, and low thermal conductivity. Among the CPs, poly(3,4-ethylenedioxythiophene) (PEDOT) is a notable material by taking advantage of solution processability, high degree of crystallinity, and bipolaronic network. We prepared a PEDOT grafted graphene film by solution casting polymerization using surface functionalized graphenes, to provide thermoelectric PEDOT on graphene (PEOG) film. The PEOG showed a high degree of crystallinity,

which enhanced both electrical conductivity and Seebeck coefficient. Taking advantage of graphene functionality, TE properties were modulated via several external stimuli. This result reinforced the application potential of CP-based TE materials in a multifunctional energy conversion.

A Novel Approach to Synthesize 2D Materials by Direct Heating of Bulk Sources and Detailed Photoluminescence Study in Comparison to Most Popular Synthesis Techniques Davoud Hejazi, Renda Tan and Swastik Kar; Northeastern University, United States

Semiconducting 2D materials are becoming more and more attractive for various optoelectronics and sensing applications; however, synthesis of high-quality 2D materials for lab-scale research is not often practical for many research laboratories, since the synthesis process often requires reactors, carrier gases, or furnaces of various levels of complexities. A simple method of growing various types of 2D materials or their combined structures (i.e. heterostructure, alloys etc.) that is easy to set up and run can further accelerate 2D research. We report on a new synthesis technique, finding that single and multilayered 2D materials of various types can be easily fabricated by direct thermal evaporation of bulk sources under an inert atmosphere. This is in stark contrast with conventional vapor-phase techniques which require chemical reactions of precursors, and a flow of one or more inert carrier gases, thereby substantially reducing the cost and complexities involved. In this study, sources of target nanomaterials are taken in their commercial bulk form, reduced to a powder for convenience and placed on a clean container in close proximity of the target substrate inside an inert environment, then heated to a range of high temperature values and held at those temperatures for material-specific durations. The nanomaterials evaporate from the source and deposit directly on the substrate in the form of well-formed crystals that can be evaluated for quality or modified for basic research or proof-of-concept applications. This synthesis methodology is much simpler than the other synthesis techniques such as CVD, MBE, ME, etc. We present detailed analysis (AFM, optical images, Raman, photoluminescence) of the various types of 2D materials and structures possible through direct, mixed, and sequential evaporation of bulk powders.
By studying the photoluminescence (PL) spectra of the 2D materials fabricated with this method and comparing them with the PL spectra of the 2D materials synthesized by other methods, found in the literature, we show that the quality of these samples, observable in FWHM of the A-exciton, is comparable with the samples grown with the best synthesis techniques. Furthermore, by detailed analysis of the PL spectra of these samples, we observe metrology-dependent variations in quantum properties of these crystals, where the relative distance of the A-exciton and A^--trion becomes smaller for the specific crystals with high PL intensity, which appear to have wrinkles that may have originated from spacial confinement, induced by seed in the nucleation cite.

F.EL04.19.24

Enhanced Charge Separation with Insulator Mediation in Vertically Stacked InSe/GeS Heterostructures Christy Roshini Paul Inbaraj[1,2,3], Roshan Jesus Mathew[1,2], Raman Sankar[2], Chih-Hao Lee[1] and Yang-Fang Chen[3]; [1]National Tsing Hua University, Taiwan; [2]Academia Sinica, Taiwan; [3]National Taiwan University, Taiwan

Modulating the physical properties of two-dimensional materials by stacking different layers to form vertical heterostructures gives rise to the new exciting phenomenon. In this work, we developed a method to improve charge separation in the type-II band aligned heterostructures (InSe/GeS) by using thin dielectric spacers (h-BN). The optical transitions at the junctions exhibit quenched emission without h-BN layers indicating indirect recombination due to the strong interlayer coupling. However, the InSe/GeS heterojunction with h-BN layers in-between exhibits strongly enhanced emission granting an additional degree of freedom to modulate the optical property. The photoresponse of the heterostructures showing enhanced photocurrent density for InSe/h-BN/GeS device by refraining interlayer charge recombination backs up the argument. Thus, the improved charge separation with h-BN mediation demonstrates a higher photoresponsivity and detectivity in the order of 10^2 A W^{-1} and 10^{14} Jones, respectively. Furthermore, the high electron detection is evident from the photogain estimated in the order of 10^3. In addition, the negative short-circuit current reveals the photovoltaic effect of the device. Therefore, our semiconductor-insulator-semiconductor (InSe/h-BN/GeS) device structure will be a promising candidate for future optoelectronics.

F.EL04.19.25

Surface Characterization of Atomic Layer Deposited Molybdenum Oxide Films Using High Sensitivity Low Energy Ion Scattering Raivat Singhania[1], Benjamin Davis[1], David Hynek[2], Judy Cha[2] and Nick C. Strandwitz[1]; [1]Lehigh University, United States; [2]Yale University, United States

Transition metal dichalcogenides (TMDC), such as $MoTe_2$, are a promising new class of materials with wide ranging

applications in the computing, optics, and photovoltaic industries. The deposition quality of these films has a drastic effect on overall film properties, and therefore device performance. In particular, achieving uniform and reproducible nucleation is important for creation of single monolayer films. However, islanding often occurs during film growth in which isolated regions of the film form initially, creating a discontinuous film and/or non-uniform film thickness, both of which are undesirable. We have investigated the uniformity and thickness control of molybdenum oxide films that are deposited via atomic layer deposition (ALD) and are precursors to $MoTe_2$ TMDCs. High-sensitivity low energy ion spectroscopy (HS-LEIS) was used to assess surface coverage and islanding of a variety of film MoO_x films ranging in thickness from 0.2 nm to over 7 nm. HS-LEIS is used for this purpose due to its ability to selectively detect and differentiate between atoms in the outermost atomic layer and subsurface atoms. Absence of a signal from the substrate indicated that uniform nucleation and coverage of the surface with MoO_x occurred at film thicknesses of approximately 0.5 nm. Ongoing research is focused on using Monte-Carlo simulations to predict LEIS spectra, which would allow for more quantitative analysis of nucleation and film growth. Quantitative analysis of nucleation and film growth is of great importance for next generation electronics that rely on layers that are only one or several atomic layers in thickness.

F.EL04.19.26

Air Stable 2D Halide Perovskite/Transition Metal Dichalcogenide Heterostructures for Improved Optoelectronics Abin Varghese[1,2], Yuefeng Yin[1], Saurabh Lodha[2] and Nikhil Medhekar[1]; [1]Monash University, Australia; [2]Indian Institute of Technology Bombay, India

Low-dimensional materials such as monolayer transition metal dichalcogenides (TMD) and two-dimensional (2D) perovskites have demonstrated enormous potential for optoelectronic applications.[1,2] TMDs have been explored for fast, high-responsivity photodetection owing to their sizeable bandgaps and high optical absorption coefficients, but their photovoltaic efficiency is quite low.[3] On the other hand, 2D Ruddlesden-Popper phase hybrid organic-inorganic perovskites have exhibited encouraging solar cell power conversion efficiencies and better ambient stability compared to the typical 3D perovskites.[4] However, the major challenges in realizing 2D perovskite based photovoltaic devices are its vulnerability to oxygen/humidity, large exciton binding energy, as well as poor optical absorption in the visible wavelengths.[2] In this work, using first-principles calculations, we propose a new strategy of employing TMD/2D perovskite heterostructures for optoelectronic applications to mitigate the intrinsic drawbacks of using TMD or 2D perovskite independently. These heterostructures formed via van der Waals (vdW) interaction between the constituents could be custom-designed for specific applications.

We show that the stacking of air stable TMDs like MoS_2 on top of the 2D perovskite (e.g., BA_2PbBr_4, BA is Butylammonium) could lead to improved ambient stability in addition to novel properties of the heterojunction. The calculated electronic band structure of the MoS_2/ BA_2PbBr_4 heterostructure shows a type-II band alignment with good charge separation at the heterojunction. The effective bandgap at the heterointerface is ~ 0.8 eV, much lower than the intrinsic bandgaps of BA_2PbBr_4 (~ 3 eV) and monolayer MoS_2 (1.9 eV).[1,4] Also, the calculated fermi level alignments of MoS_2 and BA_2PbBr_4 show that the TMD can function as a selective electron transport layer resulting in improved solar cell performance with enhanced air stability. On the other hand, selenide based WSe_2/BA_2PbBr_4 heterointerface demonstrates a type-I alignment with a comparatively higher hetero-bandgap at ~ 1.5 eV, useful for light emitting applications at visible wavelengths.

In summary, this study explores the properties of TMD/2D perovskite heterostructures and provides new insights towards realizing high-performance next-generation optoelectronic devices. The high tensile strength of TMDs and molecular softness provided by the large organic chains could further enable the use of these heterostructures for flexible solar cells or light emitting devices.

Magnetic Properties in Correlated 2D van der Waals Metal Phosphosulfides Due to Suppression of Antiferromagnetic Ordering Nitish Mathur[1], Fengmei Wang[1,2], Aurora Janes[1], Peng He[2], Xueli Zheng[3], Tofik A. Shifa[2], Peng Yu[2], J.R. Schmidt[1], Jun He[2] and Song Jin[1]; [1]University of Wisconsin--Madison, United States; [2]CAS Center for Excellence in Nanoscience, CAS Key Laboratory of Nanosystem and Hierarchical Fabrication, National Center for Nanoscience and Technology, China; [3]Stanford University, United States

Two-dimensional (2D) van der Waals (vdW) materials offer a versatile platform to explore their potential applications in electronic, photonic, and spintronic devices. Among them, the family of vdW layered metal phosphosulfides (MPS_3, M = Ni, Fe, Co, Mn, etc.) show intriguing electronic physics, potential magnetic properties, and electrocatalysis applications. Recently, it has been reported that a strong long-range coupling between the electronic and magnetic structures results from super-exchange mechanism in 2D vdW $NiPS_3$ antiferromagnet (AFM). In this work, we demonstrate a new chemical route for suppression of AFM ordering in $NiPS_3$ system. Composition-tunable $Ni_{1-x}Co_xPS_3$ ($0 \leq x < 0.50$) few-layered nanosheets (NSs) are successfully synthesized. Significantly, obvious suppression of AFM ordering below Néel temperature (T_N ~ 143-155 K) in magnetic susceptibility measurements were observed in $Ni_{1-x}Co_xPS_3$ NSs, which contrast with the magnetic properties observed in bulk single crystals of $Ni_{1-x}Co_xPS_3$. These findings provide a new direction for disruption of AFM long range ordering and opens a new window of opportunities for investigation of correlated physics and magnetism in 2D materials systems.

F.EL04.19.29
High-Performance Ideal PN Photodidoe Using Directly Grown CVD Heterostructure Jieun Kim and Woo Jong Yu; Sungkyunkwan University, Korea (the Republic of)

As silicon-based field effect transistors (FET) face miniaturization limitations, various two-dimensional (2D) material-based FETs are promising for next-generation electronic and optoelectronic devices. These days, not only study to produce high performance 2D-FETs, but also to implement integrated circuits with 2D materials has been reported. In terms of integrated circuits, PN junction is essential for complementary circuit. To fabricate 2D PN junction, usually transferring and stacking with exfoliated flakes has been used. Even if the flakes electronic quality is good, it needs trained skills and is time consuming. In addition, it is hard to ensure interface quality and has residue problems which deteriorate device performances.

In this paper, we report the direct growth of PN heterostrucutures with transition metal dichalcogenide (Nb doped $WSe_2/MoSe_2$) on SiO_2/Si substrates with chemical vapor deposition (CVD) method with one mixed solution source. To confirm the composition and structural properties of our as-grown heterojunction sample Raman, PL, XPS and AFM analysis is done. At inner and outer domain, obviously different center Raman and PL peaks are observed. The niobium (Nb) doping signal also confimed by Raman peaks and XPS peaks. In AFM height profile data, inner and outer height show no difference which represents lateral heterostructure. To obtain electronic properties at inner, outer and junction region, multi electrodes are evaporated. At junction, current rectification behavior is shown as a PN diode with 1.3 ildeality factor which is close to ideal ideality factor of 1. Also the current level between P (Nb doped WSe_2) and N ($MoSe_2$) domain is simillar. Under lasers illumination, optoelectronic characteristic is shown. Several properties such as built-in potential across the junciton, type-II band alignment of the materials (WSe_2 and $MoSe_2$), low lattice mismatch and atomically sharp interface from directly growth mechanism, allow high advantages in optoelectronic devices. Additionally, the niobium acceptor dopants allow wide range of absorption wavelength from ultraviolet (UV) to near infrared (NIR) which overcomes the limitation of the TMD photodetectors. Additionally, back gated PN photodiode can effectively suppress dark current through gate voltage modulation, thus realizing very high detectivity.

Thus, our direct grown Nb doped $WSe_2/MoSe_2$ PN heterostructure photodiode shows outstanding optoelectronic performances, such as high detectivities (10^{15} *Jones*), I_{light}/I_{dark} (10^5) under $V_{DS} = 0$ V. Our approach of direct grown PN heterostructure photodiode allows fabricate high quality and easy integrated optoelectronic 2D atomic layer devices.

Two-Dimensional ZnO Nanoplates Grown on r-plane Oriented Al_2O_3 and Their Photocatalytic Properties Shota Sakurai and Junghyun Cho; Binghamton University, The State University of New York, United States

Two-dimensional (2-D) nanomaterials have recently received considerable attention with their unique characteristics, which were not seen in their bulk and 1-D nanomaterials. Zinc oxide (ZnO) is chemically stable, non-toxic, and available at low cost, which makes it into one of the most intriguing materials. Since the surface is surrounded largely by basal c-planes, 2-D ZnO nanomaterials have the good potential for tailoring the functional properties through adjusting their surface morphologies. To achieve the growth of such 2-D ZnO nanoplatelets, the growth direction must be along the a-axis, while suppressing the growth along the c-axis. This growth is challenging because the growth along the c-axis is energetically favorable. To control the growth direction, a seed layer plays a significant role. r-plane (1-102) aluminum oxide (Al_2O_3) can serve as a good seed layer for 2-D ZnO growth as the lattice mismatch between r-plane Al_2O_3 and a-plane ZnO is only 1.53% along ZnO [0001] and Al_2O_3 [2-201] directions. In this study, we prepared r-plane oriented Al_2O_3 on Si (111) substrate as a seed layer by spin coating followed by annealing at high temperatures. r-plane Al_2O_3 also has an epitaxial relationship with Si (111). 2-D ZnO nanoplates were then grown on the seed layer by the hydrothermal method. The c-plane of ZnO nanoplates

contains a high concentration of the surface defects and is off-stoichiometric; therefore, the thinner the nanoplate is, the more it is influenced by the defects on the c-plane. It makes these 2-D nanoplates very attractive as an effective photocatalytic surface for the degradation of organic contaminants. As a result, the templated growth of the 2-D ZnO nanoplates shows the great potential to form functional surfaces that can be very sensitive to external stimuli such as light and environment by controlling the concentration and type of defects. Photoluminescence (PL) and Raman spectra are used to characterize defect characteristics of various nanoplate morphologies. This presentation highlights current research progresses made for the control of the defect population, size, aspect ratio, and packing density of the ZnO nanoplates at various conditions and the effect of the resulting morphologies of the nanoplates on their photocatalytic properties.

F.EL04.19.33

Resonance Raman Signatures of Atomically-Thin Black Phosphorus Nannan Mao[1,1], Xi Ling[2], Liangbo Liang[3], William Tisdale[1] and Jing Kong[1]; [1]Massachusetts Institute of Technology, United States; [2]Boston University, United States; [3]Oak Ridge National Laboratory, Oak Ridge, United States

Black phosphorus (BP) is an elemental two-dimensional semiconductor with quantized electronic structure, high mobility and tightly bonded exciton. Especially, due to the quantum confinement in the out-of-plane direction and significant interlayer interaction, BP has direct band gap for all thicknesses that is highly tunable from visible region to mid-infrared region. Besides, the conduction band and valence band in phosphorene split into quantized subbands, which constitute a series of thickness-dependent interband electronic transitions. These pronounced subband transitions, evidenced by sharp thickness-dependent absorption peaks in the visible region and infrared region, give rise to strong coupling with photons and phonons in few-layer BP. Here we investigated the electron-photon and electron-phonon coupling in few-layer BP samples by resonance Raman spectroscopy. Firstly, we observed Raman splitting effect in atomically thin-BP, and the origin of this phenomenon will be revealed. Secondly, based on the collective interlayer vibration modes, the accurate interlayer interaction of BP was measured in experiment. Thirdly, A_g^1 mode shows much smaller resonance effect than A_g^2 mode when the incident polarization is along armchair direction of BP, which can be explained by the symmetry-dependent electron-phonon coupling. These investigations give direct evidence of the significant interlayer interaction and deep insights into fundamental electron-photon and electron-phonon coupling in atomically-thin BP.

Raman Scattering of Electrocatalytic 2D MoS_2 Nanosheets in Water Splitting Kit Sze, Mikel Tucker, Saroj Pramanik and Yucheng Lan; Morgan State University, United States

Molybdenum disulfide (MoS_2) is one of the most promising hydrogen-evolution-reaction (HER) electrocatalysts to replace noble metals in water splitting. Raman scattering is one non-destructive, efficient, and mature technique to characterize renewable energy materials. Here, the 2D MoS_2 nanosheets with various crystallinity are prepared and their electrocatalytic behaviors are *in-situ* investigated by Raman scattering under varied electric fields and temperatures. The results would enlighten the electrocatalytic mechanism of MoS_2 nanosheets and help us to improve its HER activities over the Pt catalyst.

The Thermal Oxidation of Hexagonal Boron Nitride Single Crystals—Dry and Ambient Air Compared Neelam Khan[1], Michael B. Katz[2], Albert Davydov[2] and James H. Edgar[3]; [1]Georgia Gwinnett College, United States; [2]National Institute of Standards and Technology, United States; [3]Kansas State University, United States

Hexagonal boron nitride (hBN), a layered van-der-Waals material, is employed as a template and an insulator to improve the performance of devices made from graphene and other two-dimensional (2D) materials. Moreover, due to its oxidation resistance, it is used to protect 2D materials devices from the environment through encapsulation. This study aims to understand the ultimate protective qualities of hBN layers at high temperatures in dry vs. ambient air. Single crystals of hBN were thermally oxidized at different temperatures ranging from 800 °C to 1100 °C for different durations, from 20 min to 100 min. Atomic force microscopy analysis revealed surface pits of about 50-100 nm in width, and 1-2 nm in depth, for the layers exposed to 900 °C for 20 minutes in dry air. Increasing the temperature and duration did not significantly change the surface pit sizes, in contrast to the thermal oxidation in ambient air, where longer oxidation times and higher temperatures, produced larger etch pits. Having no effect of thermal oxidation as a function of temperature and duration in dry air could be due to formation of the surface oxide layer, which slows down the etching process. Complimentary transmission electron microscopy will be employed to compare the extent of surface oxidation in ambient versus dry air and to study the origin and morphology of the surface pit formation.

F.EL04.19.36

Late News: Efficient Electron Doping of Monolayer MoS2 by Salt-Crown Ether Treatment Hiroto Ogura[1], Yoshiyuki Nonoguchi[2], Toshifumi Irisawa[3], Takahiko Endo[1], Hong En Lim[1], Yusuke Nakanishi[1] and Yasumitsu Miyata[1]; [1]Tokyo Metropolitan University, Japan; [2]Nara Institute of Science and Technology, Japan; [3]AIST, Japan

Atomic layers of transition metal dichalcogenides (TMDCs) have attracted much attention because of their unique two-dimensional structure and high electrical performance. For electronics applications, it is essential to develop a sophisticated way to control their carrier density of materials. So far, carrier control of TMDCs is achieved via surface charge transfer by using chemical doping. To further improve doping concentration, it is highly desired to find any stable and efficient dopants for TMDCs. Recently, Nonoguchi et al. have reported the electron doping of carbon nanotubes using a series of ordinary salts with crown ethers. In this study, we have applied this technique to monolayer MoS_2 and investigated the transport and optical properties of such chemically-doped MoS_2.
Monolayer MoS_2 films were grown on SiO_2/Si substrates by using chemical vapor deposition method. Electron doping was conducted by spin coating of butanol solution of KOH and benzo-18-crown-6. The doping process changes the transfer curves of MoS_2 field-effect transistors (FETs) from a typical n-type semiconducting state to metallic one in air. We also found photoluminescence quenching and peak shift in the A'_1 Raman mode for doped MoS2. These results indicate that the salt-based doping provides an effective way for the electron doping of MoS_2. In the presentation, the details of transport and optical properties will be discussed.

F.EL04.19.37

Late News: Few-Layered Two-Dimensional Ruddlesen-Pooper Organic-Inorganic Hybrid Perovskite Magnets Ki-Yeon Kim[1], Garam Park[1], Jaehun Cho[2], Joonwoo Kim[2], June-Seo Kim[2], Jinyong Jung[2], Kwonjin Park[2] and In-Hwan Oh[1]; [1]KAERI, Korea (the Republic of); [2]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Atomically thin two-dimensional (2D) Van der Waals (vdw) magnets have received extensive attention due to their interesting magnetic phenomena inherent to low-dimensional magnetism such as Berezinskii-Kosterlitz-Thouless transition in 2D XY models and Mermin-Wagner Theorem. However, it is not until 2017 that the first 2D ferromagnetic magnets such as $Cr_2Ge_2Te_6$ and CrI_3 were experimentally realized via mechanical exfoliation method using Scotch tape. Since then, although a number of potential 2D vdw magnets have been theoretically predicted a very limited number of atomically thin or few-layered 2D vdw magnets still have been experimentally available. Specifically, since 1960's, 2D Ruddlesden-Popper organic-inorganic halide perovskites (RH-OIHP) have been considered as the ideal model closest to 2D Heisenberg model. Recent theoretical calculation using first principle density functional theory shows that the cleavage energy of $(R\text{-}NH_3)_2CuCl_4$ (R = a monovalent organic moiety such as C_nH_{2n+1} or $C_6H_5C_2H_4$) is smaller by a factor of 2-2.5 than that of graphite (0.36 J/m^2). It means that 2D RP-OIHP monolayer by mechanical exfoliation from bulk crystals would be experimentally feasible. However, until now, there has not been successful report on fabrication of atomically thin or few-layered 2D RP-OIHP thin films with intrinsic magnetism at all. We will demonstrate the few-layered 2D OIHP magnets via solvent engineering based on spin coating technique.

F.EL04.19.38

Late News: First-Principles Study of Interaction of O3 with Silicene Lokanath Patra[1], Geeta Sachdeva[1], Ravindra Pandey[1] and Shashi Karna[2]; [1]Michigan Technological University, United States; [2]CCDC Army Research Laboratory, Weapons, and Materials Research Directorate, United States

Silicene, an analogous silicon counterpart of graphene with unique physical properties, has attracted a great deal of attention. Its interaction with environmental molecules, e.g ozone needs to be investigated thoroughly as it has a great role to play for silicon-based technology at the nanoscale. In this study, we study the interaction of O, O_2, and O_3 with silicene using density functional theory. We find that O, being more electronegative than Si, draws electrons from the Si-Si bond. Consequently, it is chemisorbed at the bridge site forming an epoxide like Si-O-Si configuration with a binding energy of 5.76 eV. On the other hand, O_2 and O_3 interacting with silicene dissociate at the surface, in contrast to what has been reported for graphene. Moreover, the dissociation process is spontaneous and exothermic without any energy barrier leading to the formation of Si-O bonds at the surface.

F.EL04.19.39

Late News: Mild Condition Synthesis of Nanosized Bismuth Vanadate and Polyoxometalates Composite Boon Chong Ong, Teik Thye Lim and Zhili Dong; Nanyang Technological University, Singapore

Nanosized materials often possess unique characteristics compared to their bulk counterpart and are useful in various

applications. Bismuth vanadate (BiVO4), a type of mixed-metal oxide, gains popularity in the field of catalysis reaction, especially the light-induced related process. They are active towards visible light irradiation and able to stimulate a catalytic reaction, for example, the water oxidation process. However, the main drawback of BiVO4 is the photogenerated electron-hole pairs tend to recombine in a very short period, which negatively impacts their catalytic performance. Coupling metal oxide with other materials is often regarded as one of the promising methods to alter their properties and improve catalytic performance. In the field of catalysis, polyoxometalates (POMs) have a distinctive property to act as electron and hole scavengers, which can retard the recombination of photogenerated electron-hole pairs effectively. They belong to a large class of nanosized metal-oxygen anion complexes of early transition elements with tunable structure, their properties greatly influence by the type of metals present in their structure. In this experiment, all the materials were synthesized in mild condition, without the use of strong base and acid. By avoiding a harsh environment, the complexity in the synthesis process can be reduced and are safer. A nanocomposite of BiVO4 and cobalt-based POMs is produced to integrate the excellent properties of both materials for the application in photochemical water oxidation. Characterization tests are performed, such as field emission scanning electron microscopy (FESEM) to study the shape and size of composites materials, X-ray diffraction (XRD) for confirming the crystal lattice structure and Fourier-transform infrared spectroscopy to identify the types of chemical bonds. A sheet-like behavior of BiVO4 can be noticed from the FESEM analysis. The synthesized BiVO4 is in a monoclinic phase as confirmed by the XRD result, in which intense peaks are noticed for (130) and (040) planes, while the POMs produced are in the triclinic phase. It is believed that the BiVO4/POMs composite is able to improve the photocatalytic water oxidation reaction.
Keywords: Bismuth Vanadate, Nanomaterials, Polyoxometalate, Mild condition

F.EL04.19.40
Late News: Optical Absorbance in Multilayer Two-Dimensional Materials—Graphene and Antimonene Geeta Sachdeva[1], Ashok Kumar[1], Ravindra Pandey[1] and Shashi Karna[2]; [1]Michigan Technological University, United States; [2]CCDC Army Research Laboratory, United States

Antimonene, one of the group V elemental monolayers, has attracted intensive interest due to their intriguing optical properties. Considering the case of atomically-flat antimonene for which directional bonding between Sb atoms appears to be analogous to C-C bonds in graphene, we present its optical absorption properties from near IR to visible spectral regime. The results based on density functional theory predict that absorbance in multilayer antimonene is equivalent to or higher than that calculated for multilayer graphene. Specifically, the IR absorption in antimonene is significantly higher with a prominent peak at about 4 mm associated with the dipole-allowed interband transitions. Moreover, a strong dependence of absorbance on topology is predicted for both antimonene and graphene which can be attributed to the subtle variations in their stacking-dependent band structures. Our results suggest the possibility of multilayer antimonene coating be realized as effective optical limiting material in the IR region for optoelectronic materials.

F.EL04.19.41
Late News: Impact of Partial Reduction on Electrical Properties in Graphene Oxide Films Akiko Ohata[1], Francisco Romero[2] and Noel Rodriguez[2]; [1]Institute of Astronautical Science, Japan; [2]Granada university, Spain

Graphene-based composite materials and nanostructures have been intensively studied in terms of unique electrical properties and a wide spectrum of applications. Among them, reduced graphene oxide(rGO) has attractive advantages of flexibility, electrical and thermal conductivity, and low-cost production. We have already reported memristive properties in rGO films partially reduced by the laser irradiation to graphene oxide(GO). However, the resistance switching mechanism has not been fully understood. In this study, by electrically characterizing the transition region from GO to the laser-irradiated rGO, a possible mechanism for the memristive properties is discussed.
Reduced GO film preparation: The GO films prepared by drop-casting commercially available GO colloid (4mg/mL) on PET film were placed on a 3D-shaker at room temperature until the water was fully evaporated. A PC-driven 405nm laser (scan speed 3 min/cm2) was used for the photothermal reduction of GO films with a rectangular shape(~1.5mm width).
Electrical characterization: GO films were initially non-conductive, while it became conductive with the laser-power increase. Interestingly, when GO films were reduced at the threshold laser-power for GO reduction, memristive properties were clearly observed. Around this region, on/off ratio was rather sharp (digital change) and large (maximum ratio was nearly 12). In addition, hysteric I-V characteristics (continuous change) were also detected. In this study, we mainly discuss the continuous hysteresis observed in the transition region between laser-irradiated and non-irradiated GO films.
The electrical measurements were performed by two-probe measurement. The probe-head was made of tungsten carbide with r = 25μm. The probe distance was 1 mm and the probe weight was fixed at 50g. The current was monitored by a source-measure unit. Two probes were set in parallel to the laser-irradiated side region.
Two-probe resistance systematically changes from 6M ohm to 3kohm, as the probes were approached from off region to

laser-irradiated one. Furthermore, the continuous hysteresis was observed, which means the resistance changed from the high(Rup) to low states(Rdown) by increasing and decreasing the applied voltage. At the distance of 1mm from the laser-reduced parts, Rup/Rdown, i.e., (resistance when applied voltage increases)/(resistance when applied voltage decreases after increasing) is quite large(very large hysteresis). Around or on the laser reduced GO area, Rup even becomes smaller than Rdown.
As the mechanism of electrical conduction in rGO films, the hopping conduction between highly conductive sp2 domains has been proposed. The sp2 domain created by the laser irradiation are electrically connected by the hopping conduction in fully reduced area. When the current increases by applying voltage, the carrier trapping that can be the potential barrier for the transport could occur. It can cause the increase in the resistance, resulting in Rup/Rdown <1. On the other hand, at the area with the short distance (0.5~1mm) from the laser-irradiated GO, as the remained sp2 domains due to the imperfect reduced graphene oxide could be critically connected, small current still flows and large continuous hysteresis is observed. As conduction paths cannot respond to the applied voltage instantaneously, Rup could be larger than Rdown by the voltage sweeping.
Summary: We systematically investigated the electrical transport in partially-reduced GO films by changing the distance from the laser-reduced area. We characterized electrical properties in the partially reduced area between GO to rGO and found the continuous hysteresis. Our results show that GO film can be a resistor with memory function by laser assisted reduction; an inexpensive and simple method. The memory effect is basically originated from graphene and oxygen-containing functional groups bonded to carbon. Therefore, this type of resistor can be scaled down to the atomic level.

SESSION F.LP05.01: Live Poster Session: Electronics and Optics (F.EL04 and F.EL05)

Ice Templated and Directed Assembly to Construct 3D Boron Nitride and Graphene Oxide Nanosheet Topological Networks for Property Enhancement Sanju Gupta[1,2]; [1]CCNY, United States; [2]Western Kentucky University, United States

Inspired by the nano/microscale hierarchical structure, topological network and precise inorganic/organic interfaces, we fabricated artificial ‘nacre-like’ papers and aerogels based on noncovalent functionalized boron nitride nanosheets (NF-BNNSs) and varying poly(vinyl alcohol) (PVA) concentration via vacuum-assisted self-assembly and freeze-drying (or ice-templating) techniques. The electron microscopy showed an ordered ‘brick-and-mortar’ arrangement of NF-BNNSs and PVA paper and aerogels, in which the long-chain PVA molecules act as the bridge to link NF-BNNSs via hydrogen bonds. Likewise, due to the need for heat removal in modern electronic devices, polymer composites with high thermal conductivity have drawn much attention. However, the traditional method to enhance polymers' thermal conductivity by random addition of nanofillers usually creates composites with not only limited thermal conductivity but also other detrimental effects due to a large amount of fillers required. Here, novel polymer composites are prepared by first constructing 3D boron nitride nanosheets (3D-BNNS) network using an ice-templated approach with varying BNNS sheets concentration and then infiltrating them with epoxy matrix. The thermal and mechanical properties of resulting free-standing nacre-like papers, aerogels and composites are investigated. They elucidated high glass transition temperature, low interfacial thermal resistance, or high thermal conductivity with relatively low BNNS loading thus revealing their superiority as flexible substrates. These results demonstrate that this approach opens a new avenue for the design and preparation of polymer composites with high thermal conductivity useful in advanced electronic packaging techniques, namely, thermal interface materials, underfill materials, and molding compounds.

F.EL04.19.02
Development of New Nanofiltration Membranes Using 2D Nanomaterials Natalia Garcia Domenech[1,2], Yurii Goun'ko[1,2] and Finn Purcell-Milton[1,2]; [1]Trinity College Dublin, Ireland; [2]BiOrbic Bioeconomy Research Centre, Ireland

Nanofiltraton has gained much attention in recent years due to its possible applications as a highly efficient and low-energy usage separation and purification technology[1,2]. Moreover, nanofiltration has shown to be potentially superior and more cost-effective than other filtration techniques. Nanofiltration was initially adapted for wastewater treatment, but has been

implemented by other industries, such as the pharmaceutical and the food industries, where the standard for high quality products and stringent safety requirements necessitate further and more specialised separation approaches[1,3].
The main aim of this project was to use inorganic 2D nanomaterials in order to develop new membranes for nanofiltration applications, in particular, boron nitride (BN). In this project, BN was exfoliated by liquid assisted exfoliation and the membranes were prepared by vacuum filtration using hydrophilic polytretrafluoroethylene as template. Boron nitride was also partially oxidised before exfoliation proving new chemically functionalised BN materials. All membranes were tested using different dyes and calculating the rejection of each one. Almost 100% rejection rates have been achieved for optimised BN membranes demonstrating the superb nanofiltration performance for selected dyes. The new membranes are to be used for the separation of D- and L- lactic acid and various mono- and disaccharides from agricultural residues.

Raman Studies of a Natural van der Waals Heterostructure Viviane Z. Costa[1], Addison Miller[1], Sam Vaziri[2], Shirin Jamil[1], Andrew Ichimura[1], Eric Pop[2,2,2] and Akm Newaz[1]; [1]San Francisco State University, United States; [2]Stanford University, United States

Van der Waals heterostructures comprised of two-dimensional (2D) materials offer a platform to obtain materials by design with unique electronic properties. Until recently, these van der Waals heterostructures (vdWH) materials were synthesized in the laboratory by vertically stacking different atomically thin materials, which often leads to stacks with the presence of fabrication defects and air contaminants between layers. Franckeite is a naturally occurring vdWH comprised of two distinct alternately stacked semiconducting layers. Because it is naturally heterostructured, it enables the study of a complex layered system without the presence of fabrication defects, and where the crystal orientation between layers has been preserved. Unlike other layered sulfide-based 2D materials, Franckeite is a grained-textured layered solid composed of few-millimeters flakes in random orientation. For this reason, mechanical exfoliation of thin flakes with uniform and large surface area for optical characterization and transfer techniques is especially challenging, leading to a knowledge gap of the fundamental properties of Franckeite. Raman spectroscopy is a widely and powerful method to characterize and study the fundamental properties of molecules in 2D crystals. All of the power that Raman spectroscopy provides in characterizing 2D materials stems from a large and well-established literature on the Raman signature of these crystals, which is lacking for Franckeite. In this work, we performed an extensive micro-Raman spectroscopy study of Franckeite. At room temperature, Raman spectroscopy data were acquired for a large sample size of flakes with thickness ranging from 6 to 100 nm prepared by mechanical exfoliation on SiO_2 substrates. The Raman signature of Franckeite is detected for flakes thicker than 10 nm. We observed that the position of all Raman peaks is independent of sample thickness. As expected, signal intensity is enhanced for flakes prepared on ultra-flat gold (Au) substrates (root-mean-square (rms) surface roughness < 0.2 nm), but different Raman modes undergo different rates of enhancements when comparing flakes of the same thickness on SiO_2 and Au. Raman data was acquired for excitation sources of both 532 and 633 nm of wavelength. Comparison data plots indicate resonance-enhanced Raman scattering with 633 nm of excitation, confirmed by additional absorption measurements. Temperature-dependent data was acquired from room temperature to 225 °C. All Raman modes present redshift with increasing temperature, suggesting that the chemical bond length of Franckeite increases with increasing temperature, and therefore the bond's vibrational force constant decreases. Moreover, we observed new low-frequency shearing and breathing modes in the Raman spectra. These low-frequency vibrational modes of Franckeite can provide a broader understanding of interlayer vibrational modes in 2D crystals, and especially in van der Waals heterostructures.

Measuring Thermal Expansion Coefficient of Monolayer Molybdenum Disulfide Using Micro-Raman Spectroscopy Lenan Zhang, Zhengmao Lu, Youngsup Song, Lin Zhao, Bikram Bhatia, Kevin Bagnall and Evelyn Wang; Massachusetts Institute of Technology, United States

Atomically thin two-dimensional (2D) molybdenum disulfide (MoS_2) is highly attractive due to its unique properties and promising applications in nanoscale electronics. Characterization of thermal expansion coefficient (TEC) of 2D MoS_2 is ubiquitous for reducing the thermal mismatch and improving the thermal management of MoS_2-based devices. However, measuring the TEC of 2D MoS_2 is particularly challenging owing to its nanoscale thickness, microscale area and optical transparency properties. As a result, the thermal expansion on 2D MoS_2 still extensively relies on simulation. In this work, we report a pure experimental approach to characterize the TEC of monolayer MoS_2 using micro-Raman spectroscopy. We analyzed the stress and temperature dependent phonon frequency of monolayer MoS_2 using the perturbation theory and symmetry analysis. To decouple the effect of thermal stress on phonon frequency shift, monolayer MoS_2 flakes were transferred on fused silica, pure copper and micro-hole patterned thermal oxide substrates. We characterized the temperature coefficients on three substrates through the temperature-dependent Raman measurement. The in-plane TEC of monolayer MoS_2 was then extracted by comparing these coefficients. The resulting in-plane TECs were $(7.6\pm0.9)\times10^{-6}$ 1/K and $(7.4\pm0.5)\times10^{-6}$ 1/K, which were independently obtained from two different phonon modes of MoS_2 and in reasonable agreement with previous first-principle reported values. This work provides accurate measurement on the TEC of monolayer MoS_2. Additionally, the general experimental approach can be widely applied to study many other 2D materials or thin films in a simple way.

Luminescence Properties of Hexagonal Boron Nitride Powders Probed by Deep UV Photoluminescence Spectroscopy Nikesh Maharjan and Mim Nakarmi; Brooklyn College and The Graduate Center of CUNY, United States

Hexagonal boron nitride (h-BN) is an ultrawide (~ 6.0 eV) semiconductor that has potential applications for developing electronic, optoelectronic and nanophotonic devices including source of ultraviolet emitters. A key issue in these applications is understanding the effect of impurities, especially carbon and oxygen on its properties. Deep UV photoluminescence spectroscopy was employed for optical characterization of irregular-shaped h-BN crystal powders. Fourth harmonic laser (195 nm) generated from the Ti: sapphire laser was used for optical excitation in the experiments. The luminescence properties are investigated by annealing the sample at different temperatures under different conditions. The deep UV photoluminescence spectra from h-BN samples annealed at 700 ºC in ambient air reveals a strong phonon-assisted band-edge emissions along with a sharp atomic-like emission line at 4.09 eV, and its phonon replicas at 3.89 and 3.69 eV. In addition to these peaks, sharp multi-phonon peaks are observed adjacent to them. The PL spectra of the sample shows the broadening of the main peaks as the annealing temperature exceeds 900 ºC. We will present our findings of atomic-like features that could have potential applications as quantum sources in UV regions for quantum information technologies.

F.EL04.19.08
Quantification of Surface Reactivity and Step-Selective Etching Chemistry on Single-Crystal BiOI Julia Martin, Roy Stoflet, Alexander Carl, Katarina Himmelberger and Ronald L. Grimm; Worcester Polytechnic Institute, United States

We synthesized single-crystal BiOI via vapor transport, subjected the resulting crystals to a series of surface treatments, and quantified the resulting chemical states and electronic properties. Vapor transport methods included both physical vapor transport from single-source BiOI, as well as chemical vapor transport from $Bi_2O_3 + BiI_3$ and from $Bi + I_2 + Bi_2O_3$. Surface treatments included tape cleaving, rinsing in water, sonication in acetone, an aqueous HF etch, and a sequential HF etch with subsequent sonication in acetone. X-ray diffraction, XRD, and X-ray photoelectron spectroscopy, XPS, probed the resulting bulk crystalline species and interfacial chemical states, respectively. In comparison with overlayer models of idealized oxide-terminated or iodide-terminated BiOI, angle-resolved XPS elucidated surface terminations as a function of each treatment. Ultraviolet photoelectron spectroscopy, UPS, established work-function and Fermi-level energies for each treatment. Data reveal that HF etching yields interfacial BiI_3 at BiOI steps that is subsequently removed with acetone sonication. UPS establishes n-type behavior for the vapor-transport-synthesized BiOI, and surface work function and Fermi level shifts for each chemical treatment under study. We discuss the implications for processing BiOI nanofilms for PV and photocatalysis applications.

Impact of Salt and Solvent Identity on the Deposition of a Cobalt Crown Ether Phthalocyanine Monolayer Electrolyte Huiran Wang, Shubham Sukumar Awate and Susan Fullerton; University of Pittsburgh, United States

A monolayer electrolyte, developed by our group, has been used to demonstrate a solid-state nonvolatile two-dimensional (2D) crystal memory based on an electric-double-layer (EDL) gated field effect transistor. (Nano Lett., 19, 8911, 2019) The monolayer electrolyte consists of cobalt crown ether phthalocyanine (CoCrPc), with four crown ethers that can solvate one lithium ion each. By simply drop-casting and annealing, CoCrPc forms a flat and ordered array on 2D crystals including graphene and WSe_2. The key mechanism of the nonvolatile memory is the toggling of lithium ions up and down through the cavity of crown ether (i.e., away from or nearby the channel). This toggling is accomplished by an applied electric field to overcome the diffusion barrier for ion movement. Our previous experimental work focused on one combination of materials: CoCrPc with 15-crown 5-ether (15C5), $LiClO_4$, and ethanol as the solvent for the salt. However, additional material combinations should result in varying diffusion barriers, thereby offering a path to tune the voltage required to toggle the ions. In this study, we investigate CoCrPc with 15C5 combined with two kinds of salts, LiCl and LiI, and three solvents: anhydrous acetone, acetonitrile, and nitromethane. LiCl and LiI were chosen to isolate the impact of anion identity (Cl vs. I vs. ClO_4) on the quality of the monolayer, and the three solvents were chosen for their reported tendency to promote ion-crown complexation. Monolayer quality is evaluated by measuring the thickness and surface roughness with atomic force microscopy (AFM) after deposition on 2D crystals in a water and oxygen-free glovebox. This study establishes the design rules for monolayer electrolyte deposition on 2D crystals, which can be used to engineer devices with multiple diffusion barriers in monolayer electrolyte random-access memory (MERAM). This work is supported by the NSF under Grant # NSF-DMR-EPM CAREER: 1847808.

Monolayer Xene Films Synthesized by Molecular-Beam Epitaxy Kaylyn Holmes, Ruizhe Kang, Qi Song, Charles Brooks, Jennifer E. Hoffman and Julia Mundy; Harvard University, United States

Single element atomic monolayer honeycomb lattice films (also called “Xene” films) are a quickly-growing topic in condensed matter physics and materials science. In contrast to graphene, Xene films from higher *Z* elements such as bismuthene (from bismuth) and stanene (from tin) are predicted to exhibit quantum spin Hall effects at temperatures closer to room temperature due to their larger topological band gaps, making them more useful for potential applications in next generation electronics. Although these two Xene films have strong theoretical and computational evidence supporting their candidacy for higher temperature quantum spin Hall effects and topologically protected edge states, they are both very difficult to produce because hexagonal unit cells are unstable configurations for the crystallization of these elements. Here, we present our work on using molecular-beam epitaxy (MBE) to synthesize monolayers and thin layers of bismuthene.

2D Nanostructured Tetrasilicates with Cr(II) and Cr(II)/Fe(II) in Square Planar Coordination—Preparation and Magnetic Properties Harshani Rathnaweera and Tina Salguero; University of Georgia, United States

The chromium-containing alkaline earth metal tetrasilicates, $ACrSi_4O_{10}$ (A= Ca, Sr, and Ba), are noteworthy as examples of rare, high spin Cr(II) in square-planar coordination complexes in chromium oxide-crystal chemistry. Though the synthesis of $ACrSi_4O_{10}$ has been known in the literature for several decades, much of the chemistry surrounding $ACrSi_4O_{10}$ formation remains unknown. In this contribution, we describe magnetic properties of all $ACrSi_4O_{10}$ phases prepared through improved synthetic routes as well as the subsequent nanostructuring of them into nanosheets by exfoliation. For flux-based routes, we utilize a metal envelope made from folded Cr foil to maintain a low oxygen fugacity in the reaction environment to avoid the formation of highly oxidized Cr species. We further extend the chemistry of $BaCrSi_4O_{10}$ to include mixed metal centers, specifically Cr(II) and Fe(II). The incorporation of mixed metal centers in $ABSi_4O_{10}$ phase is new territory in metal tetrasilicate chemistry, and this is the first example of transition metal substitution in any of the known $ABSi_4O_{10}$ systems (B = Cu, Fe, Cr). We find that the targeted stoichiometry of $Ba(Cr,Fe)Si_4O_{10}$ crystals yields an experimentally-determined composition with up to a ~40% incorporation of Fe(II), which appears to constitute the maximum incorporation of Fe(II) into $BaCrSi_4O_{10}$. Interestingly, $Ba(Cr,Fe)Si_4O_{10}$ crystals show a different magnetic infrastructure due to the interaction of antiferromagnetic Cr(II) and ferromagnetic Fe(II) centers in a single lattice. In this paper, we characterize the magnetic properties of $Ba(Cr,Fe)Si_4O_{10}$ crystals and nanosheets using Mössbauer and EPR spectroscopies.

Fabrication of Large-Area MoS_2 Nanosheets by Salt-Assisted Mechanical Milling Process and Chemical Exfoliation in Cosolvent Hsiang-Chun Yu and Tsung-Eong Hsieh; National Chiao Tung University, Taiwan

Salt-assisted mechanical milling and chemical exfoliation in cosolvent were adopted to prepare the large-area MoS_2 nanosheets with a few layers in thickness. First, the MoS_2 powder was blend with salt, *e.g.*, potassium chloride (KCl),

calcium chloride ($CaCl_2$) or sodium carbonate (Na_2CO_3), and sent to a ball mill containing zirconia beads with 1 cm in diameter. The milling process was carried out at 300 rpm for 2 hrs so as to generate numerous dangling bonds at the edges of MoS_2. The dangling bonds would react with the salt to form the functionalized groups which may induce the electrical repulsion for the dispersion of MoS_2 in subsequent chemical exfoliation process. The functionalized MoS_2 powder was added in a centrifuge tube containing the cosolvent comprised of water and alcohol at the weight ratio of 1:1. After the ultrasonic vibration for 30 mins at room temperature, the MoS_2 nanosheets with thickness of 1-2 nm could be obtained *via* the centrifugation of solution. Most studies of chemical exfoliation reported the MoS_2 nanosheets with the lateral size smaller than 1 μm. However, our study observed the MoS_2 nanosheets which average area of 12×5.6 μm^2 using Na_2CO_3 and average area of 14×6 μm^2 using KCl. Presently, the MoS_2 FET devices containing the large-area MoS_2 nanosheets are prepared and their electrical properties are measured.

An Exfoliation of Mixed Dimensional van der Waals Organic/WS_2 Heterojunctions Ink for Emerging Electronics Abdus S. Sarkar[1,2] and Suman Kalyan Pal[1]; [1]Indian Institute of Technology Mandi, India; [2]Foundation For Research and Technology Hellas, Greece

Since, the isolation of single layer graphene, a great attention has been paid to integrate distinct emerging beyond graphene 2D materials into van der Waals (vdW) heterostructures. The emerging 2D transition metal dichalcogenides (TMDCs), such as semiconducting (2H-phase) tungsten sulfide (WS_2) and their mixed dimensional heterojunctions have drawn most vibrant areas of nanoscience/photonic research because of fascinating optical and electrical properties in their low dimensional interface. [1-3] However, most of the preparation (chemical) methods do not preserve the semiconductive properties of WS_2. Here, we have prepared a novel mixed dimensional 2D semiconductor p-n heterojunction of few layer WS_2, which is exfoliated in the presence of an organic semiconductor (OS) and characterized by various experimental techniques. Our results revealed that the few hundred nanometer size, few layer (4-5 layers) thick WS_2 sheets are grafted with OS. Hexagonal pattern in HR-TEM image intimate the preservation of 2H-phase WS_2. Significant changed in the electrical behavior in the p-n nanoheterojunctions are presented. The insight spectroscopic analysis indicated the possible hybrid optoelectronic applications. Furthermore, the heterojunction dispersion WS_2 sheets are quite stable with prior little aggregation after 180 days.

Mechanisms of Molybdenum Trioxide Sulfurization in the Growth of Two-Dimensional Molybdenum Disulfide Joshua Maurer, Thierry Tsafack and Stephen F. Bartolucci; US Army CCDC AC, United States

Powder vaporization is a common method for the generation of large-area, single-crystal, two-dimensional molybdenum disulfide. While commonly employed as a growth method, the fundamental molecular mechanisms are not well understood. Recent ab initio analyses have shown that molybdenum oxysulfide rings play a key role in the sulfurization of molybdenum trioxide from elemental sulfur. Here, we present the utilization of molecular dynamics simulations with a reactive force field and ab initio calculations to elucidate the reaction pathway of sulfur with molybdenum trioxide. The molecular dynamics simulations demonstrated that for all sulfur allotropes the reaction pathway could be reduced to that of disulfur, trisulfur, or a combination of the two, and that molybdenum trioxide can catalyze the decomposition of larger sulfur allotropes. Ab initio calculations were used to illuminate the intermediates and transition states in the reaction pathways for disulfur and trisulfur. Analysis of the temperature dependence of the transition state energies show that the maximum reaction rates occur between 1000 and 1100 K, which corresponds with commonly reported experimental growth temperatures for molybdenum disulfide.

F.EL04.19.20

Influence of Solvent Properties on the Morphology of Ultra-Thin Tin Monoxide Nanomaterials for Next-Generation Energy Storage Applications Seán Kavanagh[1,2,3], Sonia Jaskaniec[3], João Coelho[3], Sean Ryan[3] and Valeria Nicolosi[3]; [1]Imperial College London, United Kingdom; [2]University College London, United Kingdom; [3]Trinity College Dublin, Ireland

Two-dimensional (2D) nanomaterials, especially those with controlled size and shape, have attracted significant attention over the last decade, due to their enhanced performance in comparison to their bulk counterparts.[1–3] One such chemical

compound is tin monoxide (SnO), whose layered crystal structure renders it amenable to the fabrication of 2D architectures. SnO has demonstrated promising performance in many relevant applications, including thin-film transistors,[4–6]photocatalysis,[7] gas sensing[8] and, primarily, energy storage - as next-generation battery anode materials.[9–11] However, the synthesis of SnO nanomaterials with controlled morphology still poses a considerable challenge in the field.[9,12–17] In this work, we provide a comprehensive study of the complex relationship between wet chemistry synthesis conditions and resulting nanoparticle morphology. The solvent nature is observed to strongly influence the kinetics of nucleation and crystal growth in solution, and thus the final morphological and electrochemical properties.
Extensive characterization of the precipitate nanomaterial has been performed, including scanning electron microscopy (SEM), high-resolution transmission electron microscopy (HRTEM), selected area electron diffraction (SAED), x-ray diffraction (XRD) and thermogravimetric analysis (TGA), in order to comprehensively describe the solvent-morphology dependence. Furthermore, high-level electronic structure theory, including dispersion corrections to account for Van der Waal's effects, were employed to augment our understanding of the underlying chemical mechanisms. Using supercell calculations, electronic vacuum alignment and surface energies were determined, allowing the prediction of the thermodynamically-favored crystal shape (Wulff construction) and surface-weighted work function, important parameters for battery performance. Finally, the synthesized nanomaterials were tested as battery materials, illustrating the impact of particle morphology on electrochemical performance.
Our results reveal promising pathways to the controlled synthesis of nanomaterials with tailored morphologies for enhanced performance in specific applications.

Effect of Aliovalent Doping on Epitaxial Growth, Structure and Properties of Triple-Layered Ruddlesden-Popper Phase Lanthanum Nickelate

Akifumi Matsuda[1], Tomoaki Oga[1], Shohei Hisatomi[1], Nobuo Tsuchimine[2], Satoru Kaneko[3,1] and Mamoru Yoshimoto[1]; [1]Tokyo Institute of Technology, Japan; [2]Toshima Manufacturing Co., Ltd., Japan; [3]Kanagawa Institute of Industrial Science and Technology, Japan

Ruddlesden-Popper phase lanthanum nickelates ($La_{n+1}Ni_nO_{3n+1}$) with two-dimensional perovskite structure have attracted interests for their electronic properties related to the structure and mixed valence Ni-ions [1]. These two-dimensional perovskites are also expected as precursors to develop infinite-layer nickelate superconductors such as Sr-doped $NdNiO_3$ [2]. Development of epitaxial thin films of lanthanum nickelate with multilayered structure and modifying their structure, electronic state, and properties according to interfacial strain and substitutional doping would contribute to develop further understanding and application of their solid-state physics. There are some reports of triple-layered $La_4Ni_3O_{10}$ for its metal-insulator-transition due to oxygen deficiency and possible application to such as SOFCs and gas sensors [1,3]. However, aliovalent doping in $La_4Ni_3O_{10}$ epitaxial thin films similar to La_2NiO_4 and $La_3Ni_2O_7$ still requires further researches to explain its effect on structure and properties [4,5]. In this study, effect of aliovalent dopants substituting La^{3+} in triple-layered $La_4Ni_3O_{10}$ on its epitaxial growth as well as on the structure and electric properties of the thin films was investigated.

The lanthanum nickelate thin films were prepared by pulsed laser deposition technique equipped with a KrF excimer laser (λ=248 nm, d=20 ns, and E~1.0 J/cm^2). The films were deposited on atomically stepped $SrTiO_3$ and $NdGaO_3$ single crystal substrates at 700–750°C in O_2 atmosphere (10 Pa) using sintered targets of $La_4Ni_3O_{10}$ doped with Hf and Sn. The thin films were then thermally treated at ~950°C for 2 hours in high-purity O_2 atmosphere (1 atm, 200 sccm) to modify the crystal phases and the valence of Ni-ions. X-ray diffraction results indicated epitaxy of $La_4Ni_3O_{10}$ (001) thin films after annealing in O_2, while epitaxial growth of La_2NiO_4 (100) was observed for the as-grown films. The formation of La_2O_3 buffer layer at the interface was suggested to have contribution on the epitaxy of $La_4Ni_3O_{10}$ phase. The Hf and Sn-doped $La_4Ni_3O_{10}$ (001) thin films with thickness of ~100 nm demonstrated low resistivity of ~5 mΩcm at room-temperature measured by a 4-probe DC method. Further detailed structural analyses of the lanthanum nickelate thin films, and the effect of the aliovalent doping on the electronic property related to the structure would also be discussed.

Thermoelectric Effect of Conductive Polymer Films from Functionalized Graphene Byeonggwan Kim, Cheolhyun Cho and Eunkyoung Kim; Yonsei University, Korea (the Republic of)

Thermoelectric effects in conductive polymers (CPs) have received significant attention owing to its high electrical conductivity, high Seebeck coefficient, and low thermal conductivity. Among the CPs, poly(3,4-ethylenedioxythiophene) (PEDOT) is a notable material by taking advantage of solution processability, high degree of crystallinity, and bipolaronic network. We prepared a PEDOT grafted graphene film by solution casting polymerization using surface functionalized graphenes, to provide thermoelectric PEDOT on graphene (PEOG) film. The PEOG showed a high degree of crystallinity, which enhanced both electrical conductivity and Seebeck coefficient. Taking advantage of graphene functionality, TE properties were modulated via several external stimuli. This result reinforced the application potential of CP-based TE materials in a multifunctional energy conversion.

F.EL04.19.23
A Novel Approach to Synthesize 2D Materials by Direct Heating of Bulk Sources and Detailed Photoluminescence Study in Comparison to Most Popular Synthesis Techniques Davoud Hejazi, Renda Tan and Swastik Kar; Northeastern University, United States

Semiconducting 2D materials are becoming more and more attractive for various optoelectronics and sensing applications; however, synthesis of high-quality 2D materials for lab-scale research is not often practical for many research laboratories, since the synthesis process often requires reactors, carrier gases, or furnaces of various levels of complexities. A simple method of growing various types of 2D materials or their combined structures (i.e. heterostructure, alloys etc.) that is easy to set up and run can further accelerate 2D research. We report on a new synthesis technique, finding that single and multilayered 2D materials of various types can be easily fabricated by direct thermal evaporation of bulk sources under an inert atmosphere. This is in stark contrast with conventional vapor-phase techniques which require chemical reactions of precursors, and a flow of one or more inert carrier gases, thereby substantially reducing the cost and complexities involved. In this study, sources of target nanomaterials are taken in their commercial bulk form, reduced to a powder for convenience and placed on a clean container in close proximity of the target substrate inside an inert environment, then heated to a range of high temperature values and held at those temperatures for material-specific durations. The nanomaterials evaporate from the source and deposit directly on the substrate in the form of well-formed crystals that can be evaluated for quality or modified for basic research or proof-of-concept applications. This synthesis methodology is much simpler than the other synthesis techniques such as CVD, MBE, ME, etc. We present detailed analysis (AFM, optical images, Raman, photoluminescence) of the various types of 2D materials and structures possible through direct, mixed, and sequential evaporation of bulk powders.
By studying the photoluminescence (PL) spectra of the 2D materials fabricated with this method and comparing them with the PL spectra of the 2D materials synthesized by other methods, found in the literature, we show that the quality of these samples, observable in FWHM of the A-exciton, is comparable with the samples grown with the best synthesis techniques. Furthermore, by detailed analysis of the PL spectra of these samples, we observe metrology-dependent variations in quantum properties of these crystals, where the relative distance of the A-exciton and A^--trion becomes smaller for the specific crystals with high PL intensity, which appear to have wrinkles that may have originated from spacial confinement, induced by seed in the nucleation cite.

F.EL04.19.24

Enhanced Charge Separation with Insulator Mediation in Vertically Stacked InSe/GeS Heterostructures Christy Roshini Paul Inbaraj[1,2,3], Roshan Jesus Mathew[1,2], Raman Sankar[2], Chih-Hao Lee[1] and Yang-Fang Chen[3]; [1]National Tsing Hua University, Taiwan; [2]Academia Sinica, Taiwan; [3]National Taiwan University, Taiwan

Modulating the physical properties of two-dimensional materials by stacking different layers to form vertical heterostructures gives rise to the new exciting phenomenon. In this work, we developed a method to improve charge separation in the type-II band aligned heterostructures (InSe/GeS) by using thin dielectric spacers (h-BN). The optical transitions at the junctions exhibit quenched emission without h-BN layers indicating indirect recombination due to the strong interlayer coupling. However, the InSe/GeS heterojunction with h-BN layers in-between exhibits strongly enhanced emission granting an additional degree of freedom to modulate the optical property. The photoresponse of the heterostructures showing enhanced photocurrent density for InSe/h-BN/GeS device by refraining interlayer charge recombination backs up the argument. Thus, the improved charge separation with h-BN mediation demonstrates a higher photoresponsivity and detectivity in the order of 10^2 A W^{-1} and 10^{14} Jones, respectively. Furthermore, the high electron detection is evident from the photogain estimated in the order of 10^3. In addition, the negative short-circuit current reveals the photovoltaic effect of the device. Therefore, our semiconductor-insulator-semiconductor (InSe/h-BN/GeS) device structure will be a promising candidate for future optoelectronics.

F.EL04.19.25

Surface Characterization of Atomic Layer Deposited Molybdenum Oxide Films Using High Sensitivity Low Energy Ion Scattering Raivat Singhania[1], Benjamin Davis[1], David Hynek[2], Judy Cha[2] and Nick C. Strandwitz[1]; [1]Lehigh University, United States; [2]Yale University, United States

Transition metal dichalcogenides (TMDC), such as $MoTe_2$, are a promising new class of materials with wide ranging applications in the computing, optics, and photovoltaic industries. The deposition quality of these films has a drastic effect on overall film properties, and therefore device performance. In particular, achieving uniform and reproducible nucleation is important for creation of single monolayer films. However, islanding often occurs during film growth in which isolated regions of the film form initially, creating a discontinuous film and/or non-uniform film thickness, both of which are undesirable. We have investigated the uniformity and thickness control of molybdenum oxide films that are deposited via atomic layer deposition (ALD) and are precursors to $MoTe_2$ TMDCs. High-sensitivity low energy ion spectroscopy (HS-LEIS) was used to assess surface coverage and islanding of a variety of film MoO_x films ranging in thickness from 0.2 nm to over 7 nm. HS-LEIS is used for this purpose due to its ability to selectively detect and differentiate between atoms in the outermost atomic layer and subsurface atoms. Absence of a signal from the substrate indicated that uniform nucleation and coverage of the surface with MoO_x occurred at film thicknesses of approximately 0.5 nm. Ongoing research is focused on using Monte-Carlo simulations to predict LEIS spectra, which would allow for more quantitative analysis of nucleation and film growth. Quantitative analysis of nucleation and film growth is of great importance for next generation electronics that rely on layers that are only one or several atomic layers in thickness.

F.EL04.19.26

Air Stable 2D Halide Perovskite/Transition Metal Dichalcogenide Heterostructures for Improved Optoelectronics Abin Varghese[1,2], Yuefeng Yin[1], Saurabh Lodha[2] and Nikhil Medhekar[1]; [1]Monash University, Australia; [2]Indian Institute of Technology Bombay, India

Low-dimensional materials such as monolayer transition metal dichalcogenides (TMD) and two-dimensional (2D) perovskites have demonstrated enormous potential for optoelectronic applications.[1,2] TMDs have been explored for fast, high-responsivity photodetection owing to their sizeable bandgaps and high optical absorption coefficients, but their photovoltaic efficiency is quite low.[3] On the other hand, 2D Ruddlesden-Popper phase hybrid organic-inorganic perovskites have exhibited encouraging solar cell power conversion efficiencies and better ambient stability compared to the typical 3D perovskites.[4] However, the major challenges in realizing 2D perovskite based photovoltaic devices are its vulnerability to oxygen/humidity, large exciton binding energy, as well as poor optical absorption in the visible wavelengths.[2] In this work, using first-principles calculations, we propose a new strategy of employing TMD/2D perovskite heterostructures for optoelectronic applications to mitigate the intrinsic drawbacks of using TMD or 2D perovskite independently. These heterostructures formed via van der Waals (vdW) interaction between the constituents could be custom-designed for specific applications.

We show that the stacking of air stable TMDs like MoS_2 on top of the 2D perovskite (e.g., BA_2PbBr_4, BA is Butylammonium) could lead to improved ambient stability in addition to novel properties of the heterojunction. The

calculated electronic band structure of the MoS_2/ BA_2PbBr_4 heterostructure shows a type-II band alignment with good charge separation at the heterojunction. The effective bandgap at the heterointerface is ~ 0.8 eV, much lower than the intrinsic bandgaps of BA_2PbBr_4 (~ 3 eV) and monolayer MoS_2 (1.9 eV).[1,4] Also, the calculated fermi level alignments of MoS_2 and BA_2PbBr_4 show that the TMD can function as a selective electron transport layer resulting in improved solar cell performance with enhanced air stability. On the other hand, selenide based WSe_2/BA_2PbBr_4 heterointerface demonstrates a type-I alignment with a comparatively higher hetero-bandgap at ~ 1.5 eV, useful for light emitting applications at visible wavelengths.

In summary, this study explores the properties of TMD/2D perovskite heterostructures and provides new insights towards realizing high-performance next-generation optoelectronic devices. The high tensile strength of TMDs and molecular softness provided by the large organic chains could further enable the use of these heterostructures for flexible solar cells or light emitting devices.

Magnetic Properties in Correlated 2D van der Waals Metal Phosphosulfides Due to Suppression of Antiferromagnetic Ordering Nitish Mathur[1], Fengmei Wang[1,2], Aurora Janes[1], Peng He[2], Xueli Zheng[3], Tofik A. Shifa[2], Peng Yu[2], J.R. Schmidt[1], Jun He[2] and Song Jin[1]; [1]University of Wisconsin--Madison, United States; [2]CAS Center for Excellence in Nanoscience, CAS Key Laboratory of Nanosystem and Hierarchical Fabrication, National Center for Nanoscience and Technology, China; [3]Stanford University, United States

Two-dimensional (2D) van der Waals (vdW) materials offer a versatile platform to explore their potential applications in electronic, photonic, and spintronic devices. Among them, the family of vdW layered metal phosphosulfides (MPS_3, M = Ni, Fe, Co, Mn, etc.) show intriguing electronic physics, potential magnetic properties, and electrocatalysis applications. Recently, it has been reported that a strong long-range coupling between the electronic and magnetic structures results from super-exchange mechanism in 2D vdW $NiPS_3$ antiferromagnet (AFM). In this work, we demonstrate a new chemical route for suppression of AFM ordering in $NiPS_3$ system. Composition-tunable $Ni_{1-x}Co_xPS_3$ ($0 \leq x < 0.50$) few-layered nanosheets (NSs) are successfully synthesized. Significantly, obvious suppression of AFM ordering below Néel temperature (T_N ~ 143-155 K) in magnetic susceptibility measurements were observed in $Ni_{1-x}Co_xPS_3$ NSs, which contrast with the magnetic properties observed in bulk single crystals of $Ni_{1-x}Co_xPS_3$. These findings provide a new direction for disruption of AFM long range ordering and opens a new window of opportunities for investigation of correlated physics and magnetism in 2D materials systems.

High-Performance Ideal PN Photodidoe Using Directly Grown CVD Heterostructure Jieun Kim and Woo Jong Yu; Sungkyunkwan University, Korea (the Republic of)

As silicon-based field effect transistors (FET) face miniaturization limitations, various two-dimensional (2D) material-based FETs are promising for next-generation electronic and optoelectronic devices. These days, not only study to produce high performance 2D-FETs, but also to implement integrated circuits with 2D materials has been reported. In terms of integrated circuits, PN junction is essential for complementary circuit. To fabricate 2D PN junction, usually transferring and stacking with exfoliated flakes has been used. Even if the flakes electronic quality is good, it needs trained skills and is time consuming. In addition, it is hard to ensure interface quality and has residue problems which deteriorate device performances.

In this paper, we report the direct growth of PN heterostrucutures with transition metal dichalcogenide (Nb doped WSe_2/$MoSe_2$) on SiO_2/Si substrates with chemical vapor deposition (CVD) method with one mixed solution source. To confirm the composition and structural properties of our as-grown heterojunction sample Raman, PL, XPS and AFM analysis is done. At inner and outer domain, obviously different center Raman and PL peaks are observed. The niobium (Nb) doping signal also confimed by Raman peaks and XPS peaks. In AFM height profile data, inner and outer height show no difference which represents lateral heterostructure. To obtain electronic properties at inner, outer and junction region, multi electrodes are evaporated. At junction, current rectification behavior is shown as a PN diode with 1.3 ildeality factor which is close to ideal ideality factor of 1. Also the current level between P (Nb doped WSe_2) and N ($MoSe_2$) domain is simillar. Under lasers illumination, optoelectronic characteristic is shown. Several properties such as built-in potential across the junciton, type-II

band alignment of the materials (WSe_2 and $MoSe_2$), low lattice mismatch and atomically sharp interface from directly growth mechanism, allow high advantages in optoelectronic devices. Additionally, the niobium acceptor dopants allow wide range of absorption wavelength from ultraviolet (UV) to near infrared (NIR) which overcomes the limitation of the TMD photodetectors. Additionally, back gated PN photodiode can effectively suppress dark current through gate voltage modulation, thus realizing very high detectivity.

Thus, our direct grown Nb doped $WSe_2/MoSe_2$ PN heterostructure photodiode shows outstanding optoelectronic performances, such as high detectivities (10^{15} *Jones*), I_{light}/I_{dark} (10^5) under $V_{DS} = 0$ V. Our approach of direct grown PN heterostructure photodiode allows fabricate high quality and easy integrated optoelectronic 2D atomic layer devices.

Two-Dimensional ZnO Nanoplates Grown on r-plane Oriented Al_2O_3 and Their Photocatalytic Properties Shota Sakurai and Junghyun Cho; Binghamton University, The State University of New York, United States

Two-dimensional (2-D) nanomaterials have recently received considerable attention with their unique characteristics, which were not seen in their bulk and 1-D nanomaterials. Zinc oxide (ZnO) is chemically stable, non-toxic, and available at low cost, which makes it into one of the most intriguing materials. Since the surface is surrounded largely by basal c-planes, 2-D ZnO nanomaterials have the good potential for tailoring the functional properties through adjusting their surface morphologies. To achieve the growth of such 2-D ZnO nanoplatelets, the growth direction must be along the a-axis, while suppressing the growth along the c-axis. This growth is challenging because the growth along the c-axis is energetically favorable. To control the growth direction, a seed layer plays a significant role. r-plane (1-102) aluminum oxide (Al_2O_3) can serve as a good seed layer for 2-D ZnO growth as the lattice mismatch between r-plane Al_2O_3 and a-plane ZnO is only 1.53% along ZnO [0001] and Al_2O_3 [2-201] directions. In this study, we prepared r-plane oriented Al_2O_3 on Si (111) substrate as a seed layer by spin coating followed by annealing at high temperatures. r-plane Al_2O_3 also has an epitaxial relationship with Si (111). 2-D ZnO nanoplates were then grown on the seed layer by the hydrothermal method. The c-plane of ZnO nanoplates contains a high concentration of the surface defects and is off-stoichiometric; therefore, the thinner the nanoplate is, the more it is influenced by the defects on the c-plane. It makes these 2-D nanoplates very attractive as an effective photocatalytic surface for the degradation of organic contaminants. As a result, the templated growth of the 2-D ZnO nanoplates shows the great potential to form functional surfaces that can be very sensitive to external stimuli such as light and environment by controlling the concentration and type of defects. Photoluminescence (PL) and Raman spectra are used to characterize defect characteristics of various nanoplate morphologies. This presentation highlights current research progresses made for the control of the defect population, size, aspect ratio, and packing density of the ZnO nanoplates at various conditions and the effect of the resulting morphologies of the nanoplates on their photocatalytic properties.

Resonance Raman Signatures of Atomically-Thin Black Phosphorus Nannan Mao[1,1], Xi Ling[2], Liangbo Liang[3], William Tisdale[1] and Jing Kong[1]; [1]Massachusetts Institute of Technology, United States; [2]Boston University, United States; [3]Oak Ridge National Laboratory, Oak Ridge, United States

Black phosphorus (BP) is an elemental two-dimensional semiconductor with quantized electronic structure, high mobility and tightly bonded exciton. Especially, due to the quantum confinement in the out-of-plane direction and significant interlayer interaction, BP has direct band gap for all thicknesses that is highly tunable from visible region to mid-infrared region. Besides, the conduction band and valence band in phosphorene split into quantized subbands, which constitute a series of thickness-dependent interband electronic transitions. These pronounced subband transitions, evidenced by sharp thickness-dependent absorption peaks in the visible region and infrared region, give rise to strong coupling with photons and phonons in few-layer BP. Here we investigated the electron-photon and electron-phonon coupling in few-layer BP samples by resonance Raman spectroscopy. Firstly, we observed Raman splitting effect in atomically thin-BP, and the origin of this phenomenon will be revealed. Secondly, based on the collective interlayer vibration modes, the accurate interlayer interaction of BP was measured in experiment. Thirdly, A_g^1 mode shows much smaller resonance effect than A_g^2 mode when the incident polarization is along armchair direction of BP, which can be explained by the symmetry-dependent electron-phonon coupling. These investigations give direct evidence of the significant interlayer interaction and deep insights into fundamental electron-photon and electron-phonon coupling in atomically-thin BP.

Raman Scattering of Electrocatalytic 2D MoS_2 Nanosheets in Water Splitting Kit Sze, Mikel Tucker, Saroj Pramanik and Yucheng Lan; Morgan State University, United States

Molybdenum disulfide (MoS_2) is one of the most promising hydrogen-evolution-reaction (HER) electrocatalysts to replace noble metals in water splitting. Raman scattering is one non-destructive, efficient, and mature technique to characterize renewable energy materials. Here, the 2D MoS_2 nanosheets with various crystallinity are prepared and their electrocatalytic behaviors are *in-situ* investigated by Raman scattering under varied electric fields and temperatures. The results would enlighten the electrocatalytic mechanism of MoS_2 nanosheets and help us to improve its HER activities over the Pt catalyst.

The Thermal Oxidation of Hexagonal Boron Nitride Single Crystals—Dry and Ambient Air Compared Neelam Khan[1], Michael B. Katz[2], Albert Davydov[2] and James H. Edgar[3]; [1]Georgia Gwinnett College, United States; [2]National Institute of Standards and Technology, United States; [3]Kansas State University, United States

Hexagonal boron nitride (hBN), a layered van-der-Waals material, is employed as a template and an insulator to improve the performance of devices made from graphene and other two-dimensional (2D) materials. Moreover, due to its oxidation resistance, it is used to protect 2D materials devices from the environment through encapsulation. This study aims to understand the ultimate protective qualities of hBN layers at high temperatures in dry vs. ambient air. Single crystals of hBN were thermally oxidized at different temperatures ranging from 800 °C to 1100 °C for different durations, from 20 min to 100 min. Atomic force microscopy analysis revealed surface pits of about 50-100 nm in width, and 1-2 nm in depth, for the layers exposed to 900 °C for 20 minutes in dry air. Increasing the temperature and duration did not significantly change the surface pit sizes, in contrast to the thermal oxidation in ambient air, where longer oxidation times and higher temperatures, produced larger etch pits. Having no effect of thermal oxidation as a function of temperature and duration in dry air could be due to formation of the surface oxide layer, which slows down the etching process. Complimentary transmission electron microscopy will be employed to compare the extent of surface oxidation in ambient versus dry air and to study the origin and morphology of the surface pit formation.

F.EL04.19.36

Late News: Efficient Electron Doping of Monolayer MoS2 by Salt-Crown Ether Treatment Hiroto Ogura[1], Yoshiyuki Nonoguchi[2], Toshifumi Irisawa[3], Takahiko Endo[1], Hong En Lim[1], Yusuke Nakanishi[1] and Yasumitsu Miyata[1]; [1]Tokyo Metropolitan University, Japan; [2]Nara Institute of Science and Technology, Japan; [3]AIST, Japan

Atomic layers of transition metal dichalcogenides (TMDCs) have attracted much attention because of their unique two-dimensional structure and high electrical performance. For electronics applications, it is essential to develop a sophisticated way to control their carrier density of materials. So far, carrier control of TMDCs is achieved via surface charge transfer by using chemical doping. To further improve doping concentration, it is highly desired to find any stable and efficient dopants for TMDCs. Recently, Nonoguchi et al. have reported the electron doping of carbon nanotubes using a series of ordinary salts with crown ethers. In this study, we have applied this technique to monolayer MoS_2 and investigated the transport and optical properties of such chemically-doped MoS_2.
Monolayer MoS_2 films were grown on SiO_2/Si substrates by using chemical vapor deposition method. Electron doping was conducted by spin coating of butanol solution of KOH and benzo-18-crown-6. The doping process changes the transfer curves of MoS_2 field-effect transistors (FETs) from a typical n-type semiconducting state to metallic one in air. We also found photoluminescence quenching and peak shift in the A'_1 Raman mode for doped MoS2. These results indicate that the salt-based doping provides an effective way for the electron doping of MoS_2. In the presentation, the details of transport and optical properties will be discussed.

F.EL04.19.37

Late News: Few-Layered Two-Dimensional Ruddlesen-Pooper Organic-Inorganic Hybrid Perovskite Magnets Ki-Yeon Kim[1], Garam Park[1], Jaehun Cho[2], Joonwoo Kim[2], June-Seo Kim[2], Jinyong Jung[2], Kwonjin Park[2] and In-Hwan Oh[1]; [1]KAERI, Korea (the Republic of); [2]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Atomically thin two-dimensional (2D) Van der Waals (vdw) magnets have received extensive attention due to their interesting magnetic phenomena inherent to low-dimensional magnetism such as Berezinskii-Kosterlitz-Thouless transition in 2D XY models and Mermin-Wagner Theorem. However, it is not until 2017 that the first 2D ferromagnetic magnets such as $Cr_2Ge_2Te_6$ and CrI_3 were experimentally realized via mechanical exfoliation method using Scotch tape. Since then, although a number of potential 2D vdw magnets have been theoretically predicted a very limited number of atomically thin or few-layered 2D vdw magnets still have been experimentally available. Specifically, since 1960's, 2D Ruddlesden-Popper organic-inorganic halide perovskites (RH-OIHP) have been considered as the ideal model closest to 2D Heisenberg model. Recent theoretical calculation using first principle density functional theory shows that the cleavage energy of (R-

$NH_3)_2CuCl_4$ (R = a monovalent organic moiety such as C_nH_{2n+1} or $C_6H_5C_2H_4$) is smaller by a factor of 2-2.5 than that of graphite (0.36 J/m^2). It means that 2D RP-OIHP monolayer by mechanical exfoliation from bulk crystals would be experimentally feasible. However, until now, there has not been successful report on fabrication of atomically thin or few-layered 2D RP-OIHP thin films with intrinsic magnetism at all. We will demonstrate the few-layered 2D OIHP magnets via solvent engineering based on spin coating technique.

F.EL04.19.38

Late News: First-Principles Study of Interaction of O3 with Silicene Lokanath Patra[1], Geeta Sachdeva[1], Ravindra Pandey[1] and Shashi Karna[2]; [1]Michigan Technological University, United States; [2]CCDC Army Research Laboratory, Weapons, and Materials Research Directorate, United States

Silicene, an analogous silicon counterpart of graphene with unique physical properties, has attracted a great deal of attention. Its interaction with environmental molecules, e.g ozone needs to be investigated thoroughly as it has a great role to play for silicon-based technology at the nanoscale. In this study, we study the interaction of O, O_2, and O_3 with silicene using density functional theory. We find that O, being more electronegative than Si, draws electrons from the Si-Si bond. Consequently, it is chemisorbed at the bridge site forming an epoxide like Si-O-Si configuration with a binding energy of 5.76 eV. On the other hand, O_2 and O_3 interacting with silicene dissociate at the surface, in contrast to what has been reported for graphene. Moreover, the dissociation process is spontaneous and exothermic without any energy barrier leading to the formation of Si-O bonds at the surface.

Late News: Mild Condition Synthesis of Nanosized Bismuth Vanadate and Polyoxometalates Composite Boon Chong Ong, Teik Thye Lim and Zhili Dong; Nanyang Technological University, Singapore

Nanosized materials often possess unique characteristics compared to their bulk counterpart and are useful in various applications. Bismuth vanadate (BiVO4), a type of mixed-metal oxide, gains popularity in the field of catalysis reaction, especially the light-induced related process. They are active towards visible light irradiation and able to stimulate a catalytic reaction, for example, the water oxidation process. However, the main drawback of BiVO4 is the photogenerated electron-hole pairs tend to recombine in a very short period, which negatively impacts their catalytic performance. Coupling metal oxide with other materials is often regarded as one of the promising methods to alter their properties and improve catalytic performance. In the field of catalysis, polyoxometalates (POMs) have a distinctive property to act as electron and hole scavengers, which can retard the recombination of photogenerated electron-hole pairs effectively. They belong to a large class of nanosized metal-oxygen anion complexes of early transition elements with tunable structure, their properties greatly influence by the type of metals present in their structure. In this experiment, all the materials were synthesized in mild condition, without the use of strong base and acid. By avoiding a harsh environment, the complexity in the synthesis process can be reduced and are safer. A nanocomposite of BiVO4 and cobalt-based POMs is produced to integrate the excellent properties of both materials for the application in photochemical water oxidation. Characterization tests are performed, such as field emission scanning electron microscopy (FESEM) to study the shape and size of composites materials, X-ray diffraction (XRD) for confirming the crystal lattice structure and Fourier-transform infrared spectroscopy to identify the types of chemical bonds. A sheet-like behavior of BiVO4 can be noticed from the FESEM analysis. The synthesized BiVO4 is in a monoclinic phase as confirmed by the XRD result, in which intense peaks are noticed for (130) and (040) planes, while the POMs produced are in the triclinic phase. It is believed that the BiVO4/POMs composite is able to improve the photocatalytic water oxidation reaction.

Keywords: Bismuth Vanadate, Nanomaterials, Polyoxometalate, Mild condition

Late News: Optical Absorbance in Multilayer Two-Dimensional Materials—Graphene and Antimonene Geeta Sachdeva[1], Ashok Kumar[1], Ravindra Pandey[1] and Shashi Karna[2]; [1]Michigan Technological University, United States; [2]CCDC Army Research Laboratory, United States

Antimonene, one of the group V elemental monolayers, has attracted intensive interest due to their intriguing optical properties. Considering the case of atomically-flat antimonene for which directional bonding between Sb atoms appears to be analogous to C-C bonds in graphene, we present its optical absorption properties from near IR to visible spectral regime. The results based on density functional theory predict that absorbance in multilayer antimonene is equivalent to or higher than that calculated for multilayer graphene. Specifically, the IR absorption in antimonene is significantly higher with a prominent peak at about 4 mm associated with the dipole-allowed interband transitions. Moreover, a strong dependence of absorbance on topology is predicted for both antimonene and graphene which can be attributed to the subtle variations in their stacking-

dependent band structures. Our results suggest the possibility of multilayer antimonene coating be realized as effective optical limiting material in the IR region for optoelectronic materials.

Late News: Impact of Partial Reduction on Electrical Properties in Graphene Oxide Films Akiko Ohata[1], Francisco Romero[2] and Noel Rodriguez[2]; [1]Institute of Astronautical Science, Japan; [2]Granada university, Spain

Graphene-based composite materials and nanostructures have been intensively studied in terms of unique electrical properties and a wide spectrum of applications. Among them, reduced graphene oxide(rGO) has attractive advantages of flexibility, electrical and thermal conductivity, and low-cost production. We have already reported memristive properties in rGO films partially reduced by the laser irradiation to graphene oxide(GO). However, the resistance switching mechanism has not been fully understood. In this study, by electrically characterizing the transition region from GO to the laser-irradiated rGO, a possible mechanism for the memristive properties is discussed.
Reduced GO film preparation: The GO films prepared by drop-casting commercially available GO colloid (4mg/mL) on PET film were placed on a 3D-shaker at room temperature until the water was fully evaporated. A PC-driven 405nm laser (scan speed 3 min/cm2) was used for the photothermal reduction of GO films with a rectangular shape(~1.5mm width).
Electrical characterization: GO films were initially non-conductive, while it became conductive with the laser-power increase. Interestingly, when GO films were reduced at the threshold laser-power for GO reduction, memristive properties were clearly observed. Around this region, on/off ratio was rather sharp (digital change) and large (maximum ratio was nearly 12). In addition, hysteric I-V characteristics (continuous change) were also detected. In this study, we mainly discuss the continuous hysteresis observed in the transition region between laser-irradiated and non-irradiated GO films.
The electrical measurements were performed by two-probe measurement. The probe-head was made of tungsten carbide with r = 25μm. The probe distance was 1 mm and the probe weight was fixed at 50g. The current was monitored by a source-measure unit. Two probes were set in parallel to the laser-irradiated side region.
Two-probe resistance systematically changes from 6M ohm to 3kohm, as the probes were approached from off region to laser-irradiated one. Furthermore, the continuous hysteresis was observed, which means the resistance changed from the high(Rup) to low states(Rdown) by increasing and decreasing the applied voltage. At the distance of 1mm from the laser-reduced parts, Rup/Rdown, i.e., (resistance when applied voltage increases)/(resistance when applied voltage decreases after increasing) is quite large(very large hysteresis). Around or on the laser reduced GO area, Rup even becomes smaller than Rdown.
As the mechanism of electrical conduction in rGO films, the hopping conduction between highly conductive sp2 domains has been proposed. The sp2 domain created by the laser irradiation are electrically connected by the hopping conduction in fully reduced area. When the current increases by applying voltage, the carrier trapping that can be the potential barrier for the transport could occur. It can cause the increase in the resistance, resulting in Rup/Rdown <1. On the other hand, at the area with the short distance (0.5~1mm) from the laser-irradiated GO, as the remained sp2 domains due to the imperfect reduced graphene oxide could be critically connected, small current still flows and large continuous hysteresis is observed. As conduction paths cannot respond to the applied voltage instantaneously, Rup could be larger than Rdown by the voltage sweeping.
Summary: We systematically investigated the electrical transport in partially-reduced GO films by changing the distance from the laser-reduced area. We characterized electrical properties in the partially reduced area between GO to rGO and found the continuous hysteresis. Our results show that GO film can be a resistor with memory function by laser assisted reduction; an inexpensive and simple method. The memory effect is basically originated from graphene and oxygen-containing functional groups bonded to carbon. Therefore, this type of resistor can be scaled down to the atomic level.

F.EL05.05.01

Photothermal Effect of Porphyrin Compounds for Optical Thermal Insulation Jou Lin[1], Yuan Zhao[2], David Kundrat[1], Mathias Bonmarin[3], John Krupczak[4], Som V. Thomas[1], Mengyao Lyu[1] and Donglu Shi[1]; [1]University of Cincinnati, United States; [2]The Pennsylvania State University, United States; [3]Zurich University of Applied Sciences, Switzerland; [4]Hope College, United States

The photothermal effect has been found in some porphyrin compounds including chlorophyll, chlorophyllin, hemoglobin, and phthalocyanine, all of which share similar structural characteristics. The porphyrin compounds are typically composed of four modified subunits bounded with carbon atoms forming a “ring-like” structure, therefore also known as “porphyrin rings.” Upon white light irradiation, these compounds can selectively observe light in a wide range of frequency from UV to NIR, and convert it to thermal energy. One of the major applications of these porphyrin compounds is in the energy-efficient windows via a newly developed concept of optical thermal insulation (OTI). Most of the thermally insulated windows in cold climate regions are double-paned, sandwiching transparent insulating materials (such as gases), creating additional and

unnecessary volume and weight. Thermal transmittance (U-factor) is proportional to the temperature difference, ΔT, between the center of room and window interior surface. OTI does not rely on any conventional thermal insulating materials or gases, such as air or argon, as often used in conventional double-pane windows, but achieves its effectiveness via photothermally-heated building skins. If a spectral-selective thin film is applied on a window inner surface that exhibits strong UV/NIR absorptions and high visible transmittance, the pronounced photothermal (PT) effect will be photonically-activated to increase the surface temperature, resulting in much reduced heat transfer through the window. In this study, we report recent experimental results on deposition of transparent thin films of porphyrin compounds and show much lowered U-factors via OTI under simulated solar irradiation. Also identified is the operating mechanism of the photothermal effects for different porphyrin compounds.

F.EL05.05.02

Effect of Incident Light Angle on the Photothermal Properties of Iron Oxide and Porphyrin-Based Thin Films for Energy-Efficient Single-Pane Window Applications Mengyao Lyu[1], Jou Lin[1], John Krupczak[2] and Donglu Shi[1]; [1]University of Cincinnati, United States; [2]Hope College, United States

Photothermal experiments of incident light angle dependence were carried out by using solar-simulated light on iron oxides (Fe_3O_4 and Fe_3O_4@$Cu_{2-x}S$) and porphyrin compounds (chlorophyll and chlorophyllin) thin films. All thin films were deposited on glass substrates by spin-coating method with the photothermal materials evenly dispersed in polymethyl methacrylate (PMMA) solutions. The Fe_3O_4 film was found to exhibit a strong absorption peak near the UV region but only with background absorptions in the visible and NIR regions. A broad NIR absorption was observed in the Fe_3O_4@$Cu_{2-x}S$ thin film. Both chlorophyll and chlorophyllin showed pronounced peaks near UV and NIR characterized with the U-shaped spectra, ideal for energy-efficient single-pane window applications that require efficient solar harvest and high transparency. Thermal transmittance through the window can be significantly reduced by decreasing the temperature difference, ΔT, between the window inner surface and the room interior based on a so-called “optical thermal insulation” (OTI) without any intervention medium, such as air/argon. Upon solar irradiation, ΔT is reduced by increasing the inner surface temperature of the window through the photothermal heating of the iron oxide and porphyrin coatings. It is therefore possible to replace double- or triple- panes with single panes based on OTI. As the seasonal changes of sunlight inevitably affect OTI, an incident light angle dependence of the photothermal effect was carried on the oxide (Fe_3O_4 and Fe_3O_4@$Cu_{2-x}S$) and porphyrin (chlorophyll and chlorophyllin) thin films. It was found that their heating curves all reached maximum temperatures at small angles of incidence while that of which considerably reduced at large angles. The angle dependence data provides important references for OTI that the window exposure to the sun is higher at the winter solstice (small angle) and lower in summer (large angle). The enhanced solar harvesting at winter solstice can induce a stronger photothermal effect for effective optical thermal insulation of single-pane windows.

F.EL05.05.03

Reconfigurable Azo-LCN/rGO Bilayers with Tailorable Mechanical and Electrical Properties Woongbi Cho[1], Jisoo Jeon[1], Wonsik Eom[2], Tae Hee Han[2], Dong Gyun Kim[3], Yong Seok Kim[3] and Jeong Jae Wie[1]; [1]Inha university, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of); [3]Korea Research Institute of Chemical Technology, Korea (the Republic of)

Azo-benzene functionalized polymers have tremendously been studied owing to the advantages of battery-free light trigger shape reconfigurable properties. However, the trade-off relationship between mechanical strength and deformability and insulating properties are great limitations of azo-functionalized polymer for shape reconfigurable devices. In this presentation, we introduce bilayered structure of azobenzene functionalized liquid crystalline polymer networks (Azo-LCN) with reduced graphene oxide (rGO) toward drastic enhancement in mechanical and electrical properties without sacrifice of strain responsivity. The Young’s modulus of the Azo-LCN/rGO bilayer increases by 5 times (6.4 GPa) in comparison with the neat Azo-LCN, and the electrical conductivity is recorded to be 340 S/cm. Remarkably, the Azo-LCN/rGO bilayer overcomes the tradeoff relationship between mechanical stiffness and elongational responsivity by mismatch of structural character of each layers. Upon exposure to broadband UV, the bending angle of azo-LCN/rGO bilayer is enhanced in forward and backward bending, respectively 2.4 times (97.5 to 229.5 degree) and 12 times (5.4 to 65.2 degree) compared to the neat Azo-LCN. In addition to in-plane bending, twisting actuation mode is achieved by simply adjusting the cutting angle of the linearly patterned azo-LCN/rGO bilayers. The Azo-LCN/rGO bilayer can also be shape-reconfigurable by thermal stimuli including near infrared (NIR), sunlight and lighter. The photothermal effect is selectively induced on the rGO layer by irradiation of NIR stimuli which drive bending actuation of azo-LCN/rGO bilayer. Then, spatially localized actuation of azo-LCN/rGO bilayer is demonstrated by focused irradiation of solar ray. Finally, a rapid and large actuation is also demonstrated by direct heat energy transfer by operation of a lighter.

F.EL05.05.04

Light-Driven Manipulation of Microdroplet on a GeSbTe Substrate Yuka Takamatsu[1], Eiji Yamamoto[1], Keiko Esashika[1], Masashi Kuwahara[2] and Toshiharu Saiki[1]; [1]Keio University, Japan; [2]Nanoelectronics Research Institute, National Institute of Advanced Industrial Science & Technology, Japan

The phenomena related to droplet migration at the micro-scale is expected to be applied to micro medical robots, new printing technologies, and basic research for the locomotion mechanisms of active matter such as cells or microbial populations. One of the main driving forces of droplet motion is Marangoni flow, which takes place from lower to higher surface tension regions. There are many studies on droplet manipulation based on Marangoni flow by generating surface tension difference under temperature gradient. Since, generally, surface tension decreases with temperature, a droplet moves from higher to lower temperature regions. In this study, we demonstrated light-driven microdroplet formation and transportation in a two-dimensional slit on a $Ge_2Sb_2Te_5$ (GST) substrate. GST as a substrate material is suitable for local laser heating due to its large light absorption and low thermal conductivity. We found an inverse Marangoni effect, which refers to the droplet motion from lower to higher temperature regions. The inverse Marangoni mechanism is more advantageous for droplet manipulation by laser beam positioning.

As a droplet material, polyethylene glycol (PEG) was mixed with toluene at a volume ratio of 7:1 to control the temperature dependence of surface tension of the droplet. The toluene/PEG solution was sandwiched with two coverslips, one of which was coated with GST. Droplet formation and transportation was observed under an inverse optical microscope. A local temperature gradient was induced by focusing subnanosecond pulsed laser (λ=532 nm) onto the GST layer through the microscope objective.

When the interface area between bulk-like toluene/PEG and its vapor was irradiated with the laser spot, many small droplets of toluene/PEG were generated in the vapor side and they merged together at the center of the laser spot to form a single larger droplet. When slightly shifting the laser spot, we found that the droplet immediately moved to follow the spot. The result implies that the droplet moved towards higher temperature region, which direction is opposite to that expected from the conventional Marangoni effect. When the laser was turned off, the droplet spread to its equilibrium diameter. We can control the diameter of droplet simply by changing the laser intensity.
We show possible explanation for the mechanism of inverse Marangoni effect. In the toluene/PEG mixed droplet under laser irradiation, the volume ratio of PEG becomes larger in the higher temperature region because the vapor pressure of PEG is much lower than that of toluene and evaporates more slowly. Also importantly, the surface tension of PEG is larger than that of toluene. Considering these facts, we can expect that the surface tension of droplet in the higher temperature side is larger and thereby Marangoni flow is directed towards the center of laser spot. In order to support this explanation, the same experiment was conducted using pure toluene.
The droplet moved towards the opposite direction with respect to the case of mixed solution. The result can be explained by conventional Marangoni effect. The efficient inverse Marangoni effect we obtained may be also attributed to the significantly low surface energy and its temperature dependence of GST.

F.EL05.05.05

Enhanced Magnetic Actuation of Micropillar Arrays via Anisotropic Stress Distribution Jeong Eun Park[1], Jisoo Jeon[1], Sei Jin Park[2], Sukyoung Won[1], Zahyun Ku[3] and Jeong Jae Wie[1]; [1]Inha University, Korea (the Republic of); [2]Lawrence Livermore National Laboratory, United States; [3]Air Force Research Laboratory, United States

Recently, magnetically reconfigurable micropillar arrays have been documented by aligning magnetic particles within the microstructure. When the orientation axis of magnetic particles is deviated from the external magnetic field axis, micropillars undergo directional twisting and bending deformation according to the alignment of magnetic particles. Previous studies have mostly been focused on cylindrical micropillars, resulting in identical actuation regardless of magnetic field direction. In this presentation, we discuss a strategy of anisotropic stress distribution by employing anisotropic pillar geometry in order to introduce a preferential direction for strain responsivity. Under the linear external magnetic field, the effects of geometric anisotropy on magnetic actuation will be investigated by comparing experimental results with magneto-mechanical simulation for rectangular and triangular micropillars. Furthermore, we will discuss the anisotropic liquid spreading and wetting on magnetically actuated micropillar arrays where the pillars twist and bend.

F.EL05.05.06

Multi-Functional and Transparent 3D Shape-Morphing by Patterned Adhesive Tapes via Photothermal Effects Jae Gyeong Lee, Sukyoung Won, Jeong Eun Park and Jeong Jae Wie; Inha University, Korea (the Republic of)

Construction of 3-dimentional (3D) architectures from 2-dimentional (2D) sheets has recently been drawn a great attention. In particular, printing of black ink hinges on pre-strained polymers provides facile and contactless shape-morphing by selective light absorption via photothermal effects. However, remaining ink hinges obstruct transparency and can cause undesirable over-actuation by thermal conduction to unpatterned regions. In this study, we suggest a facile strategy for formation of transparent non-Euclidean structures from pre-strained polystyrene (PS) sheets by employing adhesive tape. Upon exposure to near infrared (NIR) light, pre-stretched PS below the adhesive tape pattern undergoes relaxation of polymer segment into a random conformation above the glass transition temperature on account of local light absorption. Contraction of patterned areas induces 3D shape morphing and remaining tape patterns can simply be removed on-demand after the construction of the targeted 3D structures. Herein, we employed radial and chiral patterns to generate complex 3D architectures and conjugated the multi-material to endow heterogeneous strain-responsivity for each material in a single curvilinear structure. We will also discuss sequential folding by control of light absorption time with sequential removal of adhesive tapes.

F.EL05.05.07
Optical Properties of Si Doped ta-C Anti-Reflective Coatings for Photovoltaic Applications SangYul Lee[1], Jung-Wan Kim[2] and HoeKun Kim[1]; [1]Korea Aerospace University, Korea (the Republic of); [2]Incheon National University, Korea (the Republic of)

Metal containing carbon nanocomposite coatings (Me doped DLC coatings) which include metal or metal carbide phase embedded in amorphous carbon matrix have attracted a significant attention for the past few decades. The association between the carbon matrix and the encapsulated metallic or metal carbide phase not only improve the overall mechanical properties of the nanocomposite coatings, but also attribute the optical properties by accompanying phase and microstructure changes in the coatings. Recently, it has been shown that DLC based coatings are very promising anti-reflection (AR) and protective coatings for photovoltaic applications due to their high chemical stability, radiation stability and high hardness with the possibility of changing their optical properties. Among the various DLC coating classification, tetrahedral amorphous carbon (ta-C) coatings, which showed high sp3/sp2 fraction over 60%, with extremely high hardness, excellent wear resistance, and better radiation stability have been paid much attention to an alternative anti-reflection protective coating materials. So in this study, various contents of Si metal were doped in the ta-C coating to improve optical properties of the ta-C coatings. Filtered cathodic vacuum arc (FCVA) and sputter hybrid PVD system was conducted to synthesize the metal doped ta-C coating. As increasing of Si content in ta-C coating, microstructure of the coatings changed from a dense featureless amorphous to a columnar “moth-eye” like structure by a formation of rhomb silicon carbide (SiC) phase, and that is especially useful for reducing reflections and increasing transmission between materials by the roll of light absorption. Raman spectroscopy analysis showed that all the coatings had high sp3/sp2 fraction about 63%, and the hardness showed high values of 47.5 GPa. The ta-C coating with 4at.% Si showed improved transmittance (over 93.4%) in the field of ultraviolet, and this value was higher than that of other carbon based coatings. These results indicate that the Si doped ta-C coating could be applied for protective & AR coating for photovoltaic applications.

Late News: Supramolecular Modulation of π-Stacking in Anthracene Crystals—Toward Photoactive Organic Semiconductors Gonzalo Campillo-Alvarado and Ying Diao; University of Illinois at Urbana-Champaign, United States

Organic semiconductors (OSCs) are a rapidly emerging field in molecular electronics. Specifically, single crystals of OSCs have received considerable attention due to unique properties associated with long-range order, absence of grain boundaries, and extremely low defect density [1] leading to a wide range of multi-functional materials (e.g., field-effect transistors, light-emitting diodes, photovoltaics). However, the lack of strategies to control and promote π-stacking in single crystals of OSCs has limited their tunability and application. While covalent modification of OSCs has arguably received the most attention [2], the noncovalent approach (e.g., supramolecular modulation) has been largely unexplored [3].

In this contribution, we introduce of efforts in the use of small molecules (e.g., templates) to promote π-stacking of a pyridyl-containing anthracene through weak non-covalent interactions. Modulation of the geometry of π-stacking in the crystalline solid state is accompanied by changes in the photophysical properties. We envisage the supramolecular control of π-stacking in single crystals of OSCs could lead to rapid developments and diversification of multifunctional crystalline electronics.

Light-Induced Curvature of a Landscape to Drive Mechanics Applications Daniel Duffy, Fan Feng, John Biggins and Mark Warner; University of Cambridge, United Kingdom

Light-driven strains can be large, controlled by colour and polarisation of light, and quickly activated in liquid crystalline solids, both rubbery and glassy.
The challenge for applications is to make the response strong, typically involving stretch rather than bend energies if the distortions are loaded. To achieve stretch in both pull and in push without instabilities, the director needs to be programmed in the solid to change the Gaussian curvature of sheet and shell-like objects.
We make contact with current experiments and suggest new Gaussian-curved evolving landscapes, including those arising from curved fold non-isometric origami objects, for effective applications.

7:43 PM *F.EL05.03.01
Coupling Molecular and Material Photomechanical Response Ruobing Bai, Kevin Korner and Kaushik Bhattacharya; California Institute of Technology, United States

Actuation by light is attractive for a number of reasons: Objects can be actuated from a distance, distinct frequencies can be used to actuate and control distinct modes with minimal interference, and significant power can be transmitted over long distances through corrosion-free, lightweight fiber optic cables. Azobenzene and other molecules that are known to change conformation when exposed to light are the building blocks of photomechanical actuation. An important challenge is how the change of conformation of individual molecules can be harnessed into a robust change of deformation of the material. Approaches range from mean-field entropic coupling as in photoactive nematic elastomers to direct chemical bond coupling

as in molecular crystal to hybrid composite approaches where molecular crystals are embedded an elastic matrix. The mean-field entropic coupling can lead to weak coupling while the stiffness of molecular crystal can inhibit actuation or cause them to shatter on actuation. This talk will present a series of theoretical models to understand various aspects of this molecular to material coupling, illustrate them with experimental observations and discuss how ideas from these studies can be harnessed in real materials and devices.

7:53 PM *F.EL05.02.03
Self-Regulating Photoactive Materials for Actuation Megan T. Valentine; University of California-Santa Barbara, United States

Light is an attractive source of remote control and power: it is non-invasive, wavelength-selective, and provides high spatial and temporal resolution. However, the development of new materials is required to fully exploit these advantages by optimizing light energy transduction pathways and/or the light-mediated modulation of materials properties. In this talk, I will present my group's collaborative efforts to advance the incorporation of donor–acceptor Stenhouse adducts (DASAs) into materials designed for light-driven generation and control of material motion. DASAs present unique advantages for actuation. These highly-absorbing, negatively photochromic molecules have highly tunable reaction kinetics and respond to visible light. We have shown them to be effective photothermal and photochemical agents that can drive the motion of amorphous polymeric materials as well as liquid flows. In particular, through control of DASA reaction kinetics and the applied light field, it is possible create self-regulating flow fields that hold promise for valveless optofluidic devices and soft robotics.

Mechanically Flexible Crystals—Crystal Engineering Malla Reddy Chilla; IISER Kolkata, India

In recent times various intriguing dynamic single crystals that respond to external stimuli such as mechanical stress, heat, light, solvent, humidity, have been reported, but their systematic design remained a challenge. In my talk, I will demonstrate a variety of mechanically reconfigurable and certain other stimuli responsive organic single crystals, where a range of supramolecular weak interactions such as van der Waals (vdW) and π-stacking, play a crucial role in absorbing the internal and external stresses generated.[1-3] I shall present a detailed case study of photomechanical work (i.e. mechanical bending) done by a crystal using visible light mediated photopolymerization chemical reaction, and recovery of the original shape in a reversible manner by a thermal depolymerization reaction.[4] A few other examples covering waveguides and mechanochromic luminescence will be discussed. Our study demonstrated the potential of soft interactions for designing mechanical behaviour of ordered molecular materials, including those from π-conjugated semiconducting systems, which are of paramount importance for achieving flexible smart materials.

Photo-Steered Deformation and Locomotion of Nanocomposite Hydrogels Qing Li Zhu, Zhi Jian Wang, Chen Fei Dai, Qiang Zheng and Zi Liang Wu; Zhejiang University, China

Inspired by the natural activated systems, realization of programmed deformations and locomotion in artificial materials has recently attracted great interest due to their promising applications in biomedical devices, soft robotics, and flexible electronics. Photo-responsive hydrogels are recognized as one ideal material to construct soft actuators and robots owing to their drastic volume change induced by contactless light irradiation with high spatial and temporal resolutions. The challenge is how to construct composite hydrogel with gradient structure and dynamically activate the specific regions of the gel toward

programmed deformation and locomotion. We present here a photolithographic method to fabricate patterned composite hydrogel sheets with heterogeneous structures by embedding the photo-responsive hydrogel in a preformed nonresponsive hydrogel. Under photo irradiation, the swelling/contraction mismatch results in the built-up of internal stress and thus programmed deformations of the composite hydrogel. Furthermore, a moving light beam is imposed on the composite hydrogel to spatiotemporally actuate the gel that shows sophisticated motions, including crawling, walking, and turning. Experimental and simulation results reveal that multigait locomotion is realized by the mutual coordination of shape-morphing and dynamic friction of the gel against a substrate under the spatiotemporal light stimulation. The programmed deformations of motions of photo-responsive hydrogels should be instructive for the development of soft robotics with advanced technologies and versatile applications.

8:23 PM *F.EL05.01.10
Photo-Induced Cooperative Supramolecular Nanosheets Shenqiang Ren; SUNY Buffalo, United States

Photostrictive compounds are promising device materials because of their fundamental photophysical properties and light-induced cooperative behaviors. Although molecular charge-transfer crystals exhibiting light–matter interactions have been successfully deployed in optoelectronics, an air-stable molecular material that couples photons and electrons, achieving photostriction through the coupling of light and mechanical degrees of freedom, has not yet been discovered. Herein, we report a substantial light-induced dilation in a molecular material at room temperature, which is accompanied by simultaneous photocurrent generation. This finding opens avenues for coupling optical, electronic, and mechanical functionalities for possible use in remote wireless photoswitchable devices.

8:33 PM *F.EL05.03.03
Magnifying Photomechanical Actuation Using Mechanical Instabilities Ravi Shankar; University of Pittsburgh, United States

The ability to harness light for photochromic switching that directs mechanical work generation within a macromolecular network is a platform for envisioning photomechanical machines, which are neither encumbered by onboard power sources, nor require microfabricated components and mechanisms. Light offers multiple control knobs for photomechanical regulation, including spatiotemporal modulation of intensity, direction, polarization and chirality. Unfortunately for actuators driven with light, the length over which the photons are attenuated (typically, few micrometers) limits the thickness of the photoactuators. The photomechanical strain generation is via bending, resulting from the gradation in the strains that are generated. Slender structures that respond by bending make for weak actuators. Work content that can be accessed is intrinsically bounded in the characteristically micrometer-scale thickness actuators.

Unusual opportunities emerge when we move beyond flat photoactive geometries, where the patterning of the molecular switches and the graded photomechanical strains conspire to result in non-linear mechanical responses. Snap-through in rod-like structures are one example. Creasing instabilities are another, where the bending of liquid crystalline polymers that are photoresponsive is used to drive non-linear transformations of curved shells, which are confined at their periphery. Torque densities >100 Nm/kg and flexural actuation rates >100 radians/s can be produced. Profiles of these photomechanical actuators places them in a property space that competes favorably with electromechanical systems. A third example is that of photoactuated tape-spring mimicking structures. Here, ms-scale actuation is triggered in shells that switch their principal curvatures, via a snap-through mechanism. Beyond these illustrations, opportunities also exist for utilizing a broader class of latch and torque-inversion mechanisms to magnify actuation by integrating active and passive (structural) materials.

Overall, accessing 3-dimensionally patterned freeform actuators is useful for magnifying photomechanical actuation. Realizing these geometries is simplified by the availability of an additive manufacturing platform, wherein the molecular order can be patterned voxel-by-voxel during the composition of multimaterial architectures. The interplay of magnetically assisted alignment and site-specific photopolymerization is a vehicle for achieving this in an inverted stereolithographic setup. In comparison to say, extrusion-based methods, decoupling the material accretion from the endowment of molecular order is key to expanding the design-space, which can be fabricated.

Magnifying photoactuation in monolithic polymeric structures, which can be scaled from the micrometer to mm-scale form factors holds implications for enabling photomechanical machines. It is possible to envision optically powered and reconfigurable devices in applications ranging from microrobotics, biomedicine and manipulation in environments hostile to electromechanical systems.

8:46 PM *F.EL05.03.04
Characterizing the Photomechanical Response of Materials Peter Palffy-Muhoray, Anastasia Svanidze, Seung-Won Oh, Tianyi Guo and Xiaoyu Zheng; Kent State University, United States

When illuminated, photomechanical materials move and demonstrate forces which cause motion. This response indicates that they have acquired momentum as consequence of photoexcitation. We characterize their response by identifying and quantifying the effectiveness of the physical mechanisms connecting photoexcitation and the mechanical response. We are particularly interested in the details of how photostress results from the exciting flux of photons, whose momentum is negligible compared to what is observed in the response, and how photostresses produced in the bulk are transported to the sample surfaces and do mechanical work. We introduce a simple relation linking a stress in light to the photostress, and propose that elements of the tensor relating these serve as measures of the effectiveness of the different aspects of the photoresponse, both in transforming photon energy to stress and in storing photon energy and making it available for mechanical work. Using this metric, we compare the performance of different classes of photomechanical materials using data from the published literature.

8:56 PM F.EL05.01.04
Hybrid Organic-Inorganic Photoactuators Based on Molecular Crystals Chris Bardeen and Xinning Dong; University of California, Riverside, United States

Crystals organize photoreactive molecules and coordinate their motions, leading to photoinduced deformations like expansion, bending, twisting, peeling and coiling. This class of materials provides a path to photomechanical actuators that can be scaled down to micro- or nanoscale dimensions, but along the way several challenges must be addressed: 1) optimization of the molecular structure to control the rate and mechanism of reversibility (photon versus thermal activation); 2) control of crystal morphology to generate actuating structures with a variety of shapes and sizes; and 3) the hierarchical organization of nano-scale and micro-scale crystals into a macroscopic actuator structure, usually by templated growth and organization. Recent progress in all three areas have led to the development of composite organic-inorganic structures with unprecedented power-to-weight ratios: under light illumination, less than 1 mg of a diarylethene photochrome can move a load weighing more than 100 g. These materials consist of organic photochromic crystals aligned in the pores of various types of inorganic host materials, including Al_2O_3 and SiO_2. The effects of the inorganic matrix material, organic photochromic molecule, and crystal alignment and orientation are all analyzed. The potential of these hybrid materials as practical photoactuators will be assessed.

9:06 PM F.EL05.01.06
Photoinduced Picosecond Nonthermal Amorphization in Sb_2Te_3 Subodh C. Tiwari[1], Rajiv Kalia[1], Aiichiro Nakano[1], Fuyuki Shimojo[2], Priya Vashishta[1] and Paulo Branicio[1]; [1]University of Southern California, United States; [2]Kumamoto University, Japan

Phase change materials are of great interest for low-power high-throughput storage devices and next-generation neuromorphic computing technologies due to their contrasting properties between amorphous and crystalline phases and fast switching rate. Notably, Sb_2Te_3, an archetypical Ge-Sb-Te alloy, displays a fast and energy-efficient crystallization-amorphization cycle, due to its growth-dominated crystallization and low melting point. Here, we demonstrate a new nonthermal amorphization pathway of Sb_2Te_3 which can further reduce time required for amorphization from nanoseconds to picoseconds. We employ non-adiabatic quantum molecular dynamics simulations to investigate the time evolution of Sb_2Te_3 at a constant temperature of 500 K with 2.6%, 5.2%, 7.5%, 10.3%, and 15% photoexcited valence electron-hole carriers. Results reveal picosecond nonthermal amorphization at and above a critical excitation of 7.5% valence electrons. The rapid amorphization originates from an instantaneous charge transfer from Te-*p* orbitals to Sb-*p* orbitals upon photoexcitation. Subsequent evolution of the excited state, within picosecond timescale, indicates a Sb-Te bonding to antibonding transition. Concurrently, Sb-Sb and Te-Te antibonding decreases, leading to the formation of wrong bonds. For 7.5% valence electron photoexcitation or larger, the electronic changes destabilize the crystal structure, leading to large atomic diffusion and loss of long-range order. These results highlight an ultrafast energy-efficient amorphization pathway that could be used to enhance the performance of phase change materials based opto-electronic devices.

This work was supported as part of the Computational Materials Sciences Program funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, under Award Number DE-SC0014607. The simulations were performed at the Argonne Leadership Computing Facility under the DOE INCITE and Aurora Early Science programs and at the Center for High Performance Computing of the University of Southern California.

9:12 PM F.EL05.01.07

Understanding and Control of Giant Opto-Mechanics in Wide-Band Gap Compound Semiconductors Yifei Li[1], Yuying Zhou[2,3], Haowei Xu[1], Alan F. Schwartzman[1], Ju Li[1] and Rafael Jaramillo[1]; [1]Massachusetts Institute of Technology, United States; [2]Shanghai Institute of Applied Physics, Chinese Academy of Science, China; [3]University of Chinese Academy of Sciences, China

The coupling between mechanical and optical properties can be surprisingly large, and has a long history of study. Optical absorption resonances are related to breaking, reforming, and rearranging bonds, on an energy scale of 1 eV/molecule, and it stands to reason that the effects of optical absorption on mechanical properties may be substantial; still these effects continue to surprise, and are often overlooked. Opto-mechanical effects may be especially strong when mediated by optically-active defects that store charge, induce local lattice distortions, and interact with modes of plastic deformation. The connection between defects and opto-mechanics provides a handle for controlling opto-mechanical effects through materials processing, and suggests new applications.

Here we show that the wide-band gap compound semiconductors ZnO, ZnS, and CdS all feature large opto-mechanical coupling that is mediated by point defects. We measure the mechanical properties of sintered and single crystal samples using a nanoindenter equipped with a purpose-built variable wavelength and intensity illumination system. We find that both elasticity and plasticity vary strongly with moderate illumination. For instance, the hardness and stiffness of ZnO can increase by up to 40-80% due to blue illumination of intensity 3 mW/cm^2. The wavelength-dependence shows that band-edge absorption (*e.g*. UV light) has the strongest effect, and the relative size of the effect of sub-band gap illumination varies between samples – a clear sign of defect-mediated processes. We further show that these giant opto-elastic and opto-plastic effects can be tuned by materials processing, and that the processing-dependence can be understood within a framework of point defect equilibrium. We tune point defect concentrations by annealing treatments, and measure composition by direct (inductively-coupled plasma optical emission spectroscopy, ICP-OES) and indirect (X-ray diffraction, XRD) methods. Our composition measurements for ZnO, ZnS and CdS all show that the magnitude of the optomechanical response varies with anion vacancy concentration. This is consistent with the hypothesis that photoconductivity and photoplasticity are positively correlated, and provides a rational guideline for engineering optomechanical response. We use density functional theory (DFT) calculations to interpret our experimental results. DFT suggests that photo-induced charge carriers migrate along strain gradients, and gather around anion vacancies. The high local net charge concentrations ($10^{21} \sim 10^{22}$ cm^{-3}) create pseudo-tensile-strain (~5%), which opposes the compressive strain from the indenter, thereby enhancing the elastic modulus.

We will conclude with an outlook on opto-mechanical effects in wide-band gap semiconductors, and with several proposed, new applications for these still-surprising effects.

9:18 PM F.EL05.01.08

Casimir Heat Transfer and Strong Phonon Coupling Haokun Li, King Yan Fong and Xiang Zhang; University of California, Berkeley, United States

In 1948, Casimir described a bizarre force that acts between neutral objects based on quantum fluctuations of electromagnetic fields. This effect is of both fundamental interest in quantum field theory and practical importance in nanotechnology. Recently, it has been predicted that Casimir force can induce phonon coupling between nearby objects and thus transfer heat across a vacuum gap. Revealing this unique quantum effect experimentally would bring fundamental insights to quantum thermodynamics and practical implications to nanoscale thermal management. Here, we present the first experimental demonstration of the Casimir heat transfer. We use nanomechanical systems to realize strong Casimir phonon coupling and observe the exchange of thermal energy between individual phonon modes. The experimental observation agrees well with our theoretical calculations and is unambiguously distinguished from other effects such as near-field radiation and electrostatic interaction. This experiment opens up new opportunities for studying nanoscale energy transport and quantum thermodynamics.

9:24 PM F.EL05.01.09
Late News: Synthesis of Anthracene-Based Next-Generation Photomechanical Molecular Crystals. Rabih O. Al-Kaysi[1,2], Fei Tong[3] and Chris Bardeen[3]; [1]King Saud bin Abdulaziz University for Health Sciences, Saudi Arabia; [2]King Abdullah International Medical Research Center, Saudi Arabia; [3]University of California, Riverside, United States

Photomechanical organic crystals are fast becoming the next generation smart-materials that can convert light energy into mechanical work. While the majority of these photomechanical crystals are made from diarylethene or azobenzene derivatives our group has focused on the synthesis of anthracene-based compounds that can be grown into photomechanical crystals. These crystals can expand, bend, twist, curl, peel, or jump when exposed to UV or visible light. We will survey the synthetic routes used to make these anthracene derivatives. We will also describe how we made the corresponding photomechanical crystals using different techniques such as solvent annealing inside Anodic Aluminum Oxide (AAO) templates and aqueous surfactant-mediated precipitation technique.
Esterification of 9-Anthracenecarboxylic acid with aliphatic alcohols gives a family of photomechanically active anthracene derivatives. When these derivatives are grown into crystalline nanowires via solvent annealing inside AAO templates, the resulting nanowires expand anisotropically along their long axis when exposed to UV light. The intermolecular [4+4] photocycloaddition between parallel anthracene rings is the driving force behind the crystal expansion. A thoroughly studied molecule is the photomechanical expansion of tert-butyl anthracene-9-carboxylate (**9TBAE**) nanowires by 15% upon irradiation with 365 nm light. Crystalline microribbons grown from the commercially available 9-Anthracenecarboxylic acid (**9AC**) can twist reversibly (T-type) when exposed UV light. The microribbons require several minutes to reset by reversing the thermally unstable [4+4] photocycloaddition. The introduction of substituents on the **9AC** anthracene ring helps expand our toolbox of T-type photomechanical crystals. Multi-step synthesis was used to introduce substituents on different positions of the **9AC** anthracene ring. These substituents (F, Cl, or Br, NO2, CH3, etc.) either suppress or enhance the T-type character of the substituted 9-anthracene carboxylic acid crystals. While the 4-fluoro-9-anthracene carboxylic acid (**4F9AC**) shortened the reset time of the crystal by an order of magnitude, the 10-fluoro-9-anthracene carboxylic acid (**10F9AC**) derivative did the exact opposite. Extending the conjugation of the anthracene ring at the 9-position by attaching propenal using Mizoroki–Heck or Wittig reaction yields the very useful 3-(9-Anthryl)acrolein which was used as a building block for the synthesis of second-generation photomechanical anthracene derivatives. Adding different electron-withdrawing groups to the 3-(9-Anthryl)acrolein aldehyde via Knoevenagel condensation leads to a novel type of photomechanical crystals that are driven by trans/cis photochemistry. These crystals are dominantly P-type. For example, 2-(3-anthracene-9-yl-allylidene)-malononitrile (**9DVAM**) crystals and nanowires exhibit P-type photomechanical response under visible and UV light. When these crystals are grown into microwires from an aqueous surfactant they exhibit continuous photo-induced wiggling-like motion resembling flagella. Block-like microcrystals composed of *cis*-dimethyl-2(3-(anthracene-9-yl)allylidene)malonate (**DMAAM**) can peel off amorphous layers upon UV-light exposure while similar analog derivatives can super expand by transforming from crystalline-to-gel like material under intense green light exposure. The introduction of fluorine on the 9DVAM anthracene ring yields derivatives with P-type photosalient crystals and nanowires that may find future application in light-driven microactuators.
Synthesis of Anthracene-based photomechanical crystals coupled with non-classical crystal growth techniques has shown to be essential for both understanding the basic principles and advancing the field of photomechanical smart-crystals.

11:30 AM INTRODUCTION AND WELCOME

11:33 AM *
Robotic Soft Materials Activated by Photons and Magnetic Fields Samuel I. Stupp; Northwestern University, United States

The development of soft synthetic materials that can emulate living organisms in their capacity to translate in space, change shape, and perform useful tasks with small energy inputs is a great challenge for materials science. Such "robotic soft matter" could be used to assist in productive functions that may range from robotics to smart management of chemical reactions and even communication with cells. This lecture will describe the development of molecularly designed hydrogels that can exhibit mechanical actuation in response to visible light or the combined action of photons and magnetic fields. The materials are created using components such as hybrid bonding polymers, which consist of supramolecular polymers integrated with light responsive covalent polymer networks. Relative to polymer networks, exposure of HBPs to photons results in faster bending and flattening actuation of objects, as well as longer steps during their light-driven crawling motion. In systems containing polymer networks and ferromagnetic nanostructures we have observed fast walking motion of macroscopic objects on surfaces with programmable trajectories and external activation of cargo delivery.

11:42 AM *F.EL05.04.01
Light-Induced Actuation of Hybrid Crystalline/Polymeric Photomechanical Materials Ryan C. Hayward; University of Colorado Boulder, United States

Materials capable of directly converting photon energy into mechanical deformation offer promise in a wide variety of contexts including adaptive optics, remotely operated swimmers, and actuators controlled via lightweight optical cables that resist corrosion and electromagnetic interference. Organic photoswitches offer significant potential in this regard, thanks to their ability to undergo large changes in molecular conformation upon excitation, and their highly tailorable absorption spectra. To date, efforts have focused largely on either crystalline lattices of small photomechanical molecules, which offer the possibility for greater work output due to their high density and well-organized nature, or on polymer matrices containing a modest concentration of photochromes, which generally have superior processability and mechanical properties. We have recently considered two classes of hybrid materials that combine many of the advantages of these disparate approaches. In one case, we have studied the growth of micrometer-scale photomechanical diarylethene crystals within the pores of polymer membranes. For appropriately controlled orientations of the crystals, such materials can exhibit photomechanical work outputs rivalling the best previously reported systems, while enabling facile processing into mechanically robust samples with cm-scale lateral dimensions. In a second case, we have developed a new class of structurally regular addition polymers bearing photoisomerizable azobenzene groups alternating with chain extenders. These materials form semicrystalline solids that exhibit fundamentally interesting temperature- and light-dependent melting and recrystallization behaviors, and that can be processed into aligned films and fibers exhibiting two-way optical shape memory properties.

11:51 AM *F.EL05.02.01
Hydrazone-Based Switches and Functional Materials Ivan Aprahamian; Dartmouth College, United States

For the past few years we have been developing structurally simple, easy to make, modular, and tunable hydrazone-based functional materials (*e.g.*, switches, sensors and fluorophores).[1] This presentation will deal with our recent advances with these systems, with an emphasis on newly developed photochromic compounds[2] that exhibit many interesting properties, including emission ON/OFF toggling in solution (see below) and the solid-state.[3] The integration of these photochromic compounds into liquid crystals[4] and liquid crystalline elastomers[5] will also be discussed.

12:00 PM *F.EL05.04.03
Eliciting Diverse Deformation Modes from a Compositionally Uniform Liquid Crystalline Elastomer Microstructure Shucong Li, Michael M. Lerch and Joanna Aizenberg; Harvard University, United States

The type of deformations and range of motion, which microstructures can undergo, determines their function, be it for soft

robotics, for sensing or for changing properties in optical or metamaterials. While composite, multimaterial architectures allow imprinting of pre-determined deformation behaviors, their fabrication at the microscale is difficult and the deformation modes are fixed once fabricated. Herein, we demonstrate the use of an alternative strategy – the generation of a transient bilayer architecture within microstructures by an external light stimulus, – and a variety of deformation behaviors that the same structure can display as a result. Changing the direction of UV-irradiation of high-aspect-ratio compositionally uniform microstructures fabricated from photoresponsive liquid crystalline elastomers gives access to a wide range of sophisticated deformations such as clockwise and counter-clockwise twisting, light seeking and avoiding, particularly if rotational symmetry is broken. Light intensity is demonstrated to be a further control parameter that allows one to tap into non-monotonic bending motions and combinations of twisting, bending and expansions/contractions. Finally, because the light-generated layered architectures are transient, they adapt and evolve as the deformation proceeds, leading to highly complex, yet controllable, self-regulated deformation behaviors. The described LCE microstructures are rapidly and easily fabricated and they offer exciting opportunities to further explore essential features of their finely controllable deformation abilities for applications in next generation smart materials.

12:09 PM *F.EL05.02.02
New Photochromes for Efficient Transduction of Photonic Energy to Potential Energy for Bond-Breaking and Bond-Making Processes Jeffrey Rack; University of New Mexico, United States

We will describe our latest efforts to create new photochromic compounds based on sulfoxides and sulfoxide mimics. We will also detail our advances in the creation of first row transition metals, where we propose that isomerization is capable of stabilizing of high spin states available for first row transition metal complexes. In addition, we will detail our spectroscopic studies of these new materials, both in solution and in solid state.

Modeling Photo-Mechanical Actuation in Liquid Crystal Polymers Robin L. Selinger[1], Michael Varga[1], Youssef M. Golestani[1] and Sajedeh Afghah[1,2]; [1]Kent State University, United States; [2]Microsoft / OptoFidelity, United States

Liquid crystal polymer networks undergo reversible shape change in response to any stimulus that affects the strength of nematic order. These soft actuators can be fabricated as thin films, surface coatings, or 4D printed solids and have potential applications in soft robotics, biomedical devices, microfluidics, and sensors. Trajectories for shape change are “programmed” by patterning the nematic director when the polymer is cross-linked. Actuation is induced when the strength of nematic order is modulated by stimuli such as a change of temperature or chemical environment; for example, heating induces contraction along the nematic director and expansion in orthogonal directions. The addition of azobenzene derivatives that undergo photo-isomerization produces a soft actuator that flexes like an artificial muscle in response to illumination; if the cis-to-trans thermal relaxation is fast enough, the material can also flex rapidly back toward its original shape when illumination is removed. Such reversible photo-mechanical actuation is a highly attractive option to control a soft robot as it combines both control and power for induced motion without need for tethering or onboard batteries.

Modeling the dynamics of photo-mechanical actuation in these materials is important both to explain the mechanisms behind experimental observations and for device design. To model photo-mechanical actuation at the device scale, we use nonlinear finite element method (FEM) elastodynamics simulation based on a Hamiltonian approach. This method can simulate underdamped motion where momentum plays an important role. The code was developed in-house and implemented in CUDA for execution on a GPU-enabled computer.

We used this approach to model oscillatory mechanical wave motion in a soft robot whose motion was both controlled and powered by light [1]. We use a simplified ray tracing algorithm to determine which parts of the device were illuminated and which in shadow, and used a kinetic model of photo-isomerization/relaxation to describe the time evolution of nematic order. We found that the directionality of light-induced mechanical wave propagation is controlled by a self-shadowing mechanism and periodic pop-through transitions.

We also model a variety of other prototype devices including surface-adhered nematic polymer coatings that transform from flat to complex surface profiles with microchannels, spikes, or dimples recently observed in experiments by Babakhanova et al [2]. Next we model polymer coatings patterned with biomimetic “octopus-like" suckers, designed to grasp and release

nonporous objects on command. Such a device would have the potential to achieve strong, reversible adhesion. Our results demonstrate that actuation geometry produced by a disclination in a nematic polymer is controlled not only by the defect's topological charge and orientation but also by the details of its defect core structure. We compare our modeling results with relevant experiments by collaborators and discuss potential applications.

Photomechanical Effects in Liquid Crystalline Polymer Networks and Elastomers Timothy White; University of Colorado Boulder, United States

Photons have been "put to work" in polymeric materials for more than 50 years. Photogeneration of work has been observed in a range of polymeric materials spanning the continuum from soft elastomers to rigid, high performance materials. Of particular importance is the organization of the polymer chains within the network which can affect magnitude, rate, and directionality of photoinduced deformation. Photomechanical effects in liquid crystalline polymer networks and elastomers are particularly appealing in enabling distinctive conversion of light into work. This presentation will summarize the salient benefits of using light as an actinic stimulus as well as highlight recent developments in this topical area of materials research from our laboratory.

Understanding the Photochemistry of Donor-Acceptor Stenhouse Adducts David Sanchez, Umberto Raucci, Katherine Ferreras and Todd J. Martínez; Stanford University, United States

Donor-acceptor Stenhouse adducts (DASA) are a promising new chromophore for photomechanical applications. We detail studies of the photochemistry of this chromophore, including both the initial light-induced isomerization and the thermal ring-closing reaction. We further provide details on a framework for modeling excited state dynamics under force, combining the ab initio multiple spawning formalism for nonadiabatic dynamics with the force-modified potential energy surface framework developed for ground state mechanochemistry. We discuss the role of external force (either compressive or extensional) on the photodynamics of the DASA chromophore and its implications for the use of DASA chromophores in light-triggered mechanical actuators.

Twist Again—Dynamically and Reversibly Controllable Chirality in Liquid Crystalline Elastomer Microposts Anna C. Balazs[1], James T. Waters[1], Shucong Li[2], Yuxing Yao[2], Michael M. Lerch[2], Michael Aizenberg[2] and Joanna Aizenberg[2]; [1]University of Pittsburgh, United States; [2]Harvard University, United States

Photo-responsive liquid crystalline elastomers (LCEs) constitute ideal actuators for soft robots because their light-induced macroscopic shape changes can be harnessed to perform mechanical work. Conventional LCEs, however, do not typically exhibit complex modes of bending and twisting necessary to perform sophisticated maneuvers. Here, we model LCE microposts encompassing side-chain mesogens oriented along a specific axis characterized by the nematic director, and azo-benzene crosslinkers, which determine the deformations of illuminated posts. On altering the nematic director from 90o to 0o relative to the underlying substrate, the post's bending respectively changes from light-seeking to light-avoiding. Moreover, with the director tilted at 45o, the initially achiral post reversibly twists into a right- or left-handed chiral structure, controlled by the angle of incident light. We exploit this photo-induced chirality to design "chimera" posts (encompassing two regions with distinct director orientations) that exhibit simultaneous bending and twisting, mimicking motions exhibited by the human musculoskeletal system.

Designable, Responsive Non-Linear Optics of Light-Responsive, Spiroypyran-Functionalized Hydrogels Amos Meeks[1], Rebecca Mac[2], Simran Chathanat[2] and Joanna Aizenberg[1]; [1]Harvard University, United States; [2]University of Waterloo, Canada

We demonstrate the potential of spiropyran-functionalized, light-responsive hydrogels to be a promising new platform for nonlinear optical materials. Nonlinear optical behavior in these materials arises from the swelling/deswelling and resulting refractive index changes that occur due to photoisomerization between the hydrophilic ring-open merocyanine isomer and the hydrophobic ring-closed spiropyran isomer. These materials show an unprecedented combination of reversibility, soft easily processed material, low laser powers, and long-range interactions. These long-range interactions are especially promising for potential applications in all-optical computing or sensing. We show that the long-range interactions can be explained by thermal swelling or deswelling of the gel. The presence of a secondary temperature gradient that influences beam behavior leads to novel repulsive long-range interactions, which are not possible in conventional nonlinear optical materials in the absence of external symmetry breaking. Furthermore, the direction and magnitude of a hydrogel's thermal response can be controlled by changing the gel composition, which allows the behavior of single and multiple beams in these gel materials to be rationally designed over a potentially vast design space. We demonstrate this potential by exploring two beam interactions in poly(N-isopropylacrylamide-co-acrylic acid) gels which contract rather than swelling as function of increasing temperature. We observe a lack of long-range interactions in these gels along with behaviors indicative of short-range attractive interactions, such as spiraling and beam fusion. This tunable diversity of behaviors suggests the enormous potential for photoresponsive hydrogels as extremely versatile, rationally designable, soft, nonlinear optical materials.

Light-Fueled Rolling and Jumping of Polymers Jeong Jae Wie, Jisoo Jeon and Jae Gwang Kim; Inha University, Korea (the Republic of)

Light-fueled soft robots have recently demonstrated untethered manipulation of locomotion without the complex mechanical and electrical design principles of conventional robotic systems[1-2]. To achieve photomechanical motility, we photopolymerized light active molecular machines along with reactive liquid crystalline monomers. For energy effective and rapid photomotility, rolling is employed as an in-plane locomotive mode to reduce friction with the substrates in comparison with crawling. In this presentation, we will also discuss design strategy to implement and program jumping motion of liquid crystalline polymers by controlling the molecular alignment for miniaturized yet high-performance untethered soft robots.

Programmable Photothermal Actuation Driven by Visible Light Using Negative Photochromic Donor-Acceptor Stenhouse Adduct (DASA) Polymers Jaejun Lee, Miranda M. Sroda, Younghoon Kwon, Sara El-Arid, Serena Seshadri, Luke F. Gockowski, Elliot W. Hawkes, Megan T. Valentine and Javier Read de Alaniz; University of California, Santa Barbara, United States

The demonstration of tunable actuation performance at a single light intensity by the simple remodeling of material properties advances the field of light responsive materials one step closer to the development of "life-like" actuators. We introduce a novel approach for programmable actuation using negatively photochromic molecular photoswitches, termed donor-acceptor Stenhouse adducts (DASAs), capable of tuning the photothermal actuation amplitude under constant light intensity based on photochemically programed logic. We present a synthetic pathway for chemically attaching DASA conjugates to polymers through Diels-Alder click chemistry. We report a visible light-responsive bilayer actuator that can lift weight against gravity, as well as a simple light-powered crawler, that exploit photothermal energy conversion. Programmable control of the magnitude of actuation is achieved by slowly converting a highly-absorbing DASA photochrome into a non-absorbing form upon irradiation. Our results highlight the promising benefits of high molar

absorptivity, negative photochromism, and broadband visible light absorption of DASAs for programmable actuation.

From Appendage to Crosslinker—Self-Regulation of Spiropyran Isomerizations in Volume-Changing Hydrogels Michael M. Lerch, Amos Meeks, Ankita Shastri, Shucong Li and Joanna Aizenberg; Harvard University, United States

Molecular photoswitches – molecules that can switch between multiple states of differing properties – are useful to impart actuation and changes in optical properties of soft materials. The chemistry of these photoswitches can be conveniently tuned to control the resulting material properties and have found application in soft actuators, non-linear optics, and optical memories. Yet, there is often a mutual interaction between photoswitch and embedding matrix, in which the photoswitch not only determines material functionality, but in turn the embedding matrix influences photoswitching behavior, enabling self-regulated behaviors through feedback loops. Here, we show how such self-regulated behavior arises in spiropyran-functionalized hydrogels and what effects govern this behavior. We are able to disentangle influences of hydrogel chemistry, type of photoswitch attachment, ionic strength, changes in hydrogel volume, and aggregation on the isomer-distribution of the photoswitch. In particular, we find that by changing the spiropyran from appendage to crosslinker, we can not only control feedback in hydrogel swelling behavior, but also control the non-linear optical properties of the hydrogel. These studies directly inform how such feedback loops can be leveraged for the fabrication of evermore sophisticated self-regulated optical materials.

Molecular Engineering of Liquid Crystalline Elastomers to Enhance Phototropic Disruption of Order Tayler Hebner and Timothy White; University of Colorado Boulder, United States

Liquid crystal elastomers (LCEs) can be functionalized with photochromic moieties to sensitize these materials to light exposure. Prior work has demonstrated that phototropic disruption of order via photochemical adjustment of the isomeric state of azobenzene (for example) disrupts the anisotropic chain configurations of the polymer network. The phototropic disruption of order in azobenzene-functionalized LCEs (azo-LCEs) with UV light via *trans-cis* isomerization generates comparatively large strain, exceeding 20%.
Fundamentally, the strength of intermolecular interactions between polymer chains defines the thermotropic response of both low molar mass and polymeric liquid crystal compositions. Here we show that by adjusting the intermolecular interaction by introducing a nontraditional liquid crystalline monomer, light irradiation can induce photomechanical responses in azo-LCE at lower energy inputs to achieve equivalent mechanical output.

Photoresponsive Diarylethene Molecular Crystals for Photoactuators Seiya Kobatake; Osaka City University, Japan

Photochromic compounds undergo a photochemically reversible transformation reaction between two isomers. Such molecules in organic crystals, which are regularly oriented and fixed in the crystal lattice, may be potentially useful for optoelectronic devices. To apply photochromic diarylethene crystals to functional materials in photonics, electronics, mechanics, and medical fields, the materials are required to change large physical property by photoirradiation. We have reported photoinduced crystal shape change of diarylethene crystals.[1] In the photoinduced crystal shape changes, there are contraction/expansion, bending, twisting, and so on,[2] which depend on the crystal structure and the size of the crystal. In this work, we have focused on the photoinduced crystal shape changes of diarylethene crystals depending on the crystal size, irradiation power, irradiation wavelength, irradiation direction with polarized UV light, and the direction of the incident light.

The rod-like crystals composed of the diarylethene derivatives showed the crystal bending away from the incident UV light or toward the incident UV light, depending on the molecular structure or the crystal packing. The bending velocity depended on the crystal thickness, and the curvature change against the crystal thickness was well fitted to Timoshenko's bimetal model.[3] When the irradiation power was changed, the bending velocity was proportional to the power of the UV irradiation, indicating that local strain acts cumulatively due to the structural changes in the individual diarylethene molecule at the initial stage of the photochromic reaction.[4] Moreover, the bending behavior depended on the wavelength of the incident light.[5] When the crystal was irradiated under polarized UV light, the bending speed depended on the polarization angles.[6] A unique mechanical behavior of a molecular crystal was induced by a combination of a photochromic reaction and a reversible single-crystal-to-single-crystal phase transition.[7] The photoinduced reversible crystal twisting of a diarylethene crystal was observed upon alternating irradiation with UV and visible light. The crystal twisting takes place in both a left-handed helix and a right-handed helix. The direction of the twisting depends on the face irradiated with UV light. The control of the photomechanical twisting of a diarylethene crystal was studied from the viewpoint of illumination direction.[8] Changing the UV illumination direction for the crystal resulted in different twisting modes, ranging from helicoid to cylindrical. The control of photomechanical crystal deformation by illumination direction provides a convenient and useful way to generate a variety of photomechanical motions from a single crystal.

Mechanically Flexible Crystals—Crystal Engineering Malla Reddy Chilla; IISER Kolkata, India

In recent times various intriguing dynamic single crystals that respond to external stimuli such as mechanical stress, heat, light, solvent, humidity, have been reported, but their systematic design remained a challenge. In my talk, I will demonstrate a variety of mechanically reconfigurable and certain other stimuli responsive organic single crystals, where a range of supramolecular weak interactions such as van der Waals (vdW) and π-stacking, play a crucial role in absorbing the internal and external stresses generated.[1-3] I shall present a detailed case study of photomechanical work (i.e. mechanical bending) done by a crystal using visible light mediated photopolymerization chemical reaction, and recovery of the original shape in a reversible manner by a thermal depolymerization reaction.[4] A few other examples covering waveguides and mechanochromic luminescence will be discussed. Our study demonstrated the potential of soft interactions for designing mechanical behaviour of ordered molecular materials, including those from π-conjugated semiconducting systems, which are of paramount importance for achieving flexible smart materials.

Converting Light Into Displacement Through Multifunctional Materials Nelson Sepulveda; Michigan State University, United States

Phase-change materials have demonstrated to be capable of the largest energy densities in micrometer-sized actuators. Vanadium dioxide-based devices, for example, have shown energy densities near 1 MJ per cubic meter only within a temperature change of only 10 degrees. Comparable work/volume characteristics can only be obtained using difference thermal expansion mechanisms through temperature changes of hundreds of degrees, or by shape memory alloys. Another intrinsic advantages of using vanadium dioxide in micro-actuators include reversibility and ability to use the material's

hysteretic behavior to program mechanical states. However, even though vanadium dioxide is the solid-solid phase change material with the transition temperature closest to room temperature, micrometer-sized actuators based on this material still suffer from low efficiencies, especially when photothermal actuation is used. Designing vanadium dioxide-based photothermal actuators has typically involved unavoidable trade-offs that hinder the demonstration of ubiquitous devices with high energy density, speed, flexibility, efficiency, sensitivity, and multifunctionality. This talk will show techniques that use carbon nanotube thin films of different chiralities to overcome this low-efficiency issue; which also produced faster devices with increased sensitivity, and the demonstration of wavelength-selective photothermal actuators.

5:45 AM F.EL05.01.04
Hybrid Organic-Inorganic Photoactuators Based on Molecular Crystals Chris Bardeen and Xinning Dong; University of California, Riverside, United States

Crystals organize photoreactive molecules and coordinate their motions, leading to photoinduced deformations like expansion, bending, twisting, peeling and coiling. This class of materials provides a path to photomechanical actuators that can be scaled down to micro- or nanoscale dimensions, but along the way several challenges must be addressed: 1) optimization of the molecular structure to control the rate and mechanism of reversibility (photon versus thermal activation); 2) control of crystal morphology to generate actuating structures with a variety of shapes and sizes; and 3) the hierarchical organization of nano-scale and micro-scale crystals into a macroscopic actuator structure, usually by templated growth and organization. Recent progress in all three areas have led to the development of composite organic-inorganic structures with unprecedented power-to-weight ratios: under light illumination, less than 1 mg of a diarylethene photochrome can move a load weighing more than 100 g. These materials consist of organic photochromic crystals aligned in the pores of various types of inorganic host materials, including Al_2O_3 and SiO_2. The effects of the inorganic matrix material, organic photochromic molecule, and crystal alignment and orientation are all analyzed. The potential of these hybrid materials as practical photoactuators will be assessed.

5:55 AM F.EL05.01.05
Cooperative Reaction Dynamics in Molecular Crystals and Optical Control of the Photomechanical Response Chris Bardeen[1], Rabih Al-Kaysi[2] and Connor J. Easley[1]; [1]University of California, Riverside, United States; [2]King Saud bin Abdulaziz University, Saudi Arabia

In molecular crystals, reaction at one site can influence the reaction probability at other sites. This cooperative photochemistry can lead to interesting and possibly useful phenomena. The fluoro-9-anthracenecarboxylic acids comprise a family of thermally reversible (T-type) photomechanical molecular crystals. Their photomechanical response is driven by a [4+4] photodimerization reaction, while the dimer dissociation determines the reset time. A microscopic fluorescence-recovery-after-photobleaching experiment is used to monitor the kinetics of dimer dissociation and mechanical bending in single crystals. The recovery kinetics depend strongly on the initial concentration of photodimer, slowing down and becoming nonexponential at high dimer concentrations. A new feature in the photomechanical behavior is identified: the ability of a very weak control beam to suppress dimer dissociation after large initial dimer conversions. This phenomenon provides a way to optically control the mechanical response of this photomechanical crystal. To gain physical insight into the origin of the nonexponential recovery curves, the experimental results were analyzed in terms of a standard first-order kinetic model and a nonlinear Finke-Watzky (FW) model, but neither model can reproduce the suppression of the recovery in the presence of a weak holding beam. More sophisticated theoretical treatments that explicitly take spatial heterogeneity into account are probably required to analyze the role of cooperative molecular phenomena in solid-state crystalline reactions and their photomechanical response.

6:05 AM F.EL05.01.06
Photoinduced Picosecond Nonthermal Amorphization in Sb_2Te_3 Subodh C. Tiwari[1], Rajiv Kalia[1], Aiichiro Nakano[1], Fuyuki Shimojo[2], Priya Vashishta[1] and Paulo Branicio[1]; [1]University of Southern California, United States; [2]Kumamoto University, Japan

Phase change materials are of great interest for low-power high-throughput storage devices and next-generation neuromorphic computing technologies due to their contrasting properties between amorphous and crystalline phases and fast switching rate. Notably, Sb_2Te_3, an archetypical Ge-Sb-Te alloy, displays a fast and energy-efficient crystallization-amorphization cycle, due to its growth-dominated crystallization and low melting point. Here, we demonstrate a new

nonthermal amorphization pathway of Sb_2Te_3 which can further reduce time required for amorphization from nanoseconds to picoseconds. We employ non-adiabatic quantum molecular dynamics simulations to investigate the time evolution of Sb_2Te_3 at a constant temperature of 500 K with 2.6%, 5.2%, 7.5%, 10.3%, and 15% photoexcited valence electron-hole carriers. Results reveal picosecond nonthermal amorphization at and above a critical excitation of 7.5% valence electrons. The rapid amorphization originates from an instantaneous charge transfer from Te-*p* orbitals to Sb-*p* orbitals upon photoexcitation. Subsequent evolution of the excited state, within picosecond timescale, indicates a Sb-Te bonding to antibonding transition. Concurrently, Sb-Sb and Te-Te antibonding decreases, leading to the formation of wrong bonds. For 7.5% valence electron photoexcitation or larger, the electronic changes destabilize the crystal structure, leading to large atomic diffusion and loss of long-range order. These results highlight an ultrafast energy-efficient amorphization pathway that could be used to enhance the performance of phase change materials based opto-electronic devices.

This work was supported as part of the Computational Materials Sciences Program funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, under Award Number DE-SC0014607. 6:15 AM F.EL05.01.07

Understanding and Control of Giant Opto-Mechanics in Wide-Band Gap Compound Semiconductors Yifei Li[1], Yuying Zhou[2,3], Haowei Xu[1], Alan F. Schwartzman[1], Ju Li[1] and Rafael Jaramillo[1]; [1]Massachusetts Institute of Technology, United States; [2]Shanghai Institute of Applied Physics, Chinese Academy of Science, China; [3]University of Chinese Academy of Sciences, China

The coupling between mechanical and optical properties can be surprisingly large, and has a long history of study. Optical absorption resonances are related to breaking, reforming, and rearranging bonds, on an energy scale of 1 eV/molecule, and it stands to reason that the effects of optical absorption on mechanical properties may be substantial; still these effects continue to surprise, and are often overlooked. Opto-mechanical effects may be especially strong when mediated by optically-active defects that store charge, induce local lattice distortions, and interact with modes of plastic deformation. The connection between defects and opto-mechanics provides a handle for controlling opto-mechanical effects through materials processing, and suggests new applications.

Here we show that the wide-band gap compound semiconductors ZnO, ZnS, and CdS all feature large opto-mechanical coupling that is mediated by point defects. We measure the mechanical properties of sintered and single crystal samples using a nanoindenter equipped with a purpose-built variable wavelength and intensity illumination system. We find that both elasticity and plasticity vary strongly with moderate illumination. For instance, the hardness and stiffness of ZnO can increase by up to 40-80% due to blue illumination of intensity 3 mW/cm^2. The wavelength-dependence shows that band-edge absorption (*e.g.* UV light) has the strongest effect, and the relative size of the effect of sub-band gap illumination varies between samples – a clear sign of defect-mediated processes. We further show that these giant opto-elastic and opto-plastic effects can be tuned by materials processing, and that the processing-dependence can be understood within a framework of point defect equilibrium. We tune point defect concentrations by annealing treatments, and measure composition by direct (inductively-coupled plasma optical emission spectroscopy, ICP-OES) and indirect (X-ray diffraction, XRD) methods. Our composition measurements for ZnO, ZnS and CdS all show that the magnitude of the optomechanical response varies with anion vacancy concentration. This is consistent with the hypothesis that photoconductivity and photoplasticity are positively correlated, and provides a rational guideline for engineering optomechanical response. We use density functional theory (DFT) calculations to interpret our experimental results. DFT suggests that photo-induced charge carriers migrate along strain gradients, and gather around anion vacancies. The high local net charge concentrations ($10^{21} \sim 10^{22}$ cm^{-3}) create pseudo-tensile-strain (~5%), which opposes the compressive strain from the indenter, thereby enhancing the elastic modulus.

We will conclude with an outlook on opto-mechanical effects in wide-band gap semiconductors, and with several proposed, new applications for these still-surprising effects.

6:25 AM F.EL05.01.08

Casimir Heat Transfer and Strong Phonon Coupling Haokun Li, King Yan Fong and Xiang Zhang; University of California, Berkeley, United States

In 1948, Casimir described a bizarre force that acts between neutral objects based on quantum fluctuations of electromagnetic fields. This effect is of both fundamental interest in quantum field theory and practical importance in nanotechnology. Recently, it has been predicted that Casimir force can induce phonon coupling between nearby objects and thus transfer heat across a vacuum gap. Revealing this unique quantum effect experimentally would bring fundamental insights to quantum

thermodynamics and practical implications to nanoscale thermal management. Here, we present the first experimental demonstration of the Casimir heat transfer. We use nanomechanical systems to realize strong Casimir phonon coupling and observe the exchange of thermal energy between individual phonon modes. The experimental observation agrees well with our theoretical calculations and is unambiguously distinguished from other effects such as near-field radiation and electrostatic interaction. This experiment opens up new opportunities for studying nanoscale energy transport and quantum thermodynamics.

6:35 AM F.EL05.01.09
Late News: Synthesis of Anthracene-Based Next-Generation Photomechanical Molecular Crystals. Rabih O. Al-Kaysi[1,2], Fei Tong[3] and Chris Bardeen[3]; [1]King Saud bin Abdulaziz University for Health Sciences, Saudi Arabia; [2]King Abdullah International Medical Research Center, Saudi Arabia; [3]University of California, Riverside, United States

Photomechanical organic crystals are fast becoming the next generation smart-materials that can convert light energy into mechanical work. While the majority of these photomechanical crystals are made from diarylethene or azobenzene derivatives our group has focused on the synthesis of anthracene-based compounds that can be grown into photomechanical crystals. These crystals can expand, bend, twist, curl, peel, or jump when exposed to UV or visible light. We will survey the synthetic routes used to make these anthracene derivatives. We will also describe how we made the corresponding photomechanical crystals using different techniques such as solvent annealing inside Anodic Aluminum Oxide (AAO) templates and aqueous surfactant-mediated precipitation technique.
Esterification of 9-Anthracenecarboxylic acid with aliphatic alcohols gives a family of photomechanically active anthracene derivatives. When these derivatives are grown into crystalline nanowires via solvent annealing inside AAO templates, the resulting nanowires expand anisotropically along their long axis when exposed to UV light. The intermolecular [4+4] photocycloaddition between parallel anthracene rings is the driving force behind the crystal expansion. A thoroughly studied molecule is the photomechanical expansion of tert-butyl anthracene-9-carboxylate (**9TBAE**) nanowires by 15% upon irradiation with 365 nm light. Crystalline microribbons grown from the commercially available 9-Anthracenecarboxylic acid (**9AC**) can twist reversibly (T-type) when exposed UV light. The microribbons require several minutes to reset by reversing the thermally unstable [4+4] photocycloaddition. The introduction of substituents on the **9AC** anthracene ring helps expand our toolbox of T-type photomechanical crystals. Multi-step synthesis was used to introduce substituents on different positions of the **9AC** anthracene ring. These substituents (F, Cl, or Br, NO2, CH3, etc.) either suppress or enhance the T-type character of the substituted 9-anthracene carboxylic acid crystals. While the 4-fluoro-9-anthracene carboxylic acid (**4F9AC**) shortened the reset time of the crystal by an order of magnitude, the 10-fluoro-9-anthracene carboxylic acid (**10F9AC**) derivative did the exact opposite. Extending the conjugation of the anthracene ring at the 9-position by attaching propenal using Mizoroki–Heck or Wittig reaction yields the very useful 3-(9-Anthryl)acrolein which was used as a building block for the synthesis of second-generation photomechanical anthracene derivatives. Adding different electron-withdrawing groups to the 3-(9-Anthryl)acrolein aldehyde via Knoevenagel condensation leads to a novel type of photomechanical crystals that are driven by trans/cis photochemistry. These crystals are dominantly P-type. For example, 2-(3-anthracene-9-yl-allylidene)-malononitrile (**9DVAM**) crystals and nanowires exhibit P-type photomechanical response under visible and UV light. When these crystals are grown into microwires from an aqueous surfactant they exhibit continuous photo-induced wiggling-like motion resembling flagella. Block-like microcrystals composed of *cis*-dimethyl-2(3-(anthracene-9-yl)allylidene)malonate (**DMAAM**) can peel off amorphous layers upon UV-light exposure while similar analog derivatives can super expand by transforming from crystalline-to-gel like material under intense green light exposure. The introduction of fluorine on the 9DVAM anthracene ring yields derivatives with P-type photosalient crystals and nanowires that may find future application in light-driven microactuators.
Synthesis of Anthracene-based photomechanical crystals coupled with non-classical crystal growth techniques has shown to be essential for both understanding the basic principles and advancing the field of photomechanical smart-crystals.

Photo-Induced Cooperative Supramolecular Nanosheets Shenqiang Ren; SUNY Buffalo, United States

Photostrictive compounds are promising device materials because of their fundamental photophysical properties and light-induced cooperative behaviors. Although molecular charge-transfer crystals exhibiting light–matter interactions have been successfully deployed in optoelectronics, an air-stable molecular material that couples photons and electrons, achieving photostriction through the coupling of light and mechanical degrees of freedom, has not yet been discovered. Herein, we report a substantial light-induced dilation in a molecular material at room temperature, which is accompanied by simultaneous photocurrent generation. This finding opens avenues for coupling optical, electronic, and mechanical functionalities for possible use in remote wireless photoswitchable devices.

Hydrazone-Based Switches and Functional Materials Ivan Aprahamian; Dartmouth College, United States

For the past few years we have been developing structurally simple, easy to make, modular, and tunable hydrazone-based functional materials (*e.g.*, switches, sensors and fluorophores).[1] This presentation will deal with our recent advances with these systems, with an emphasis on newly developed photochromic compounds[2] that exhibit many interesting properties, including emission ON/OFF toggling in solution (see below) and the solid-state.[3] The integration of these photochromic compounds into liquid crystals[4] and liquid crystalline elastomers[5] will also be discussed.

New Photochromes for Efficient Transduction of Photonic Energy to Potential Energy for Bond-Breaking and Bond-Making Processes Jeffrey Rack; University of New Mexico, United States

We will describe our latest efforts to create new photochromic compounds based on sulfoxides and sulfoxide mimics. We will also detail our advances in the creation of first row transition metals, where we propose that isomerization is capable of stabilizing of high spin states available for first row transition metal complexes. In addition, we will detail our spectroscopic studies of these new materials, both in solution and in solid state.

5:30 AM *F.EL05.02.03
Self-Regulating Photoactive Materials for Actuation Megan T. Valentine; University of California-Santa Barbara, United States

Light is an attractive source of remote control and power: it is non-invasive, wavelength-selective, and provides high spatial and temporal resolution. However, the development of new materials is required to fully exploit these advantages by optimizing light energy transduction pathways and/or the light-mediated modulation of materials properties. In this talk, I will present my group's collaborative efforts to advance the incorporation of donor–acceptor Stenhouse adducts (DASAs) into materials designed for light-driven generation and control of material motion. DASAs present unique advantages for actuation. These highly-absorbing, negatively photochromic molecules have highly tunable reaction kinetics and respond to visible light. We have shown them to be effective photothermal and photochemical agents that can drive the motion of amorphous polymeric materials as well as liquid flows. In particular, through control of DASA reaction kinetics and the applied light field, it is possible create self-regulating flow fields that hold promise for valveless optofluidic devices and soft robotics.

5:45 AM *F.EL05.02.04
Light-Activated Molecular Machines That Work at All Scales Nicolas Giuseppone; University of Strasbourg, France

Making molecular machines that can be useful in the macroscopic world is a challenging long-term goal of nanoscience. Inspired by the protein machinery found in biological systems, and based on the theoretical understanding of the physics of motion at the nanoscale, organic chemists have developed a number of molecules that can produce work when triggered by

various external chemical or physical stimuli. In particular, basic molecular switches that commute between at least two thermodynamic minima and more advanced molecular motors that behave as dissipative units working out-of-equilibrium when fueled with external energy have been reported. However, the ultimate challenge of coordinating individual molecular motors in a continuous mechanical process that can have a measurable effect at the macroscale has remained elusive until very recently. We will discuss advances developed by our group on light-activated molecular machines and involving their mechanical coupling within dynamic polymer systems. We will show that it is now possible to amplify their individual motions to achieve macroscopic functions in materials. In particular, we will present a dual-light controlled system operating fully out-of-equilibrium, and in which the integrated motions of two types of mechanically active units can be tuned by modulation of frequencies. Finally, we will discuss the possibility to use similar ideas to get control over mechanotransduction in living cells.

Designable, Responsive Non-Linear Optics of Light-Responsive, Spiroypyran-Functionalized Hydrogels Amos Meeks[1], Rebecca Mac[2], Simran Chathanat[2] and Joanna Aizenberg[1]; [1]Harvard University, United States; [2]University of Waterloo, Canada

We demonstrate the potential of spiropyran-functionalized, light-responsive hydrogels to be a promising new platform for nonlinear optical materials. Nonlinear optical behavior in these materials arises from the swelling/deswelling and resulting refractive index changes that occur due to photoisomerization between the hydrophilic ring-open merocyanine isomer and the hydrophobic ring-closed spiropyran isomer. These materials show an unprecedented combination of reversibility, soft easily processed material, low laser powers, and long-range interactions. These long-range interactions are especially promising for potential applications in all-optical computing or sensing. We show that the long-range interactions can be explained by thermal swelling or deswelling of the gel. The presence of a secondary temperature gradient that influences beam behavior leads to novel repulsive long-range interactions, which are not possible in conventional nonlinear optical materials in the absence of external symmetry breaking. Furthermore, the direction and magnitude of a hydrogel's thermal response can be controlled by changing the gel composition, which allows the behavior of single and multiple beams in these gel materials to be rationally designed over a potentially vast design space. We demonstrate this potential by exploring two beam interactions in poly(N-isopropylacrylamide-co-acrylic acid) gels which contract rather than swelling as function of increasing temperature. We observe a lack of long-range interactions in these gels along with behaviors indicative of short-range attractive interactions, such as spiraling and beam fusion. This tunable diversity of behaviors suggests the enormous potential for photoresponsive hydrogels as extremely versatile, rationally designable, soft, nonlinear optical materials.

6:10 AM F.EL05.02.06

From Appendage to Crosslinker—Self-Regulation of Spiropyran Isomerizations in Volume-Changing Hydrogels Michael M. Lerch, Amos Meeks, Ankita Shastri, Shucong Li and Joanna Aizenberg; Harvard University, United States

Molecular photoswitches – molecules that can switch between multiple states of differing properties – are useful to impart actuation and changes in optical properties of soft materials. The chemistry of these photoswitches can be conveniently tuned to control the resulting material properties and have found application in soft actuators, non-linear optics, and optical memories. Yet, there is often a mutual interaction between photoswitch and embedding matrix, in which the photoswitch not only determines material functionality, but in turn the embedding matrix influences photoswitching behavior, enabling self-regulated behaviors through feedback loops. Here, we show how such self-regulated behavior arises in spiropyran-functionalized hydrogels and what effects govern this behavior. We are able to disentangle influences of hydrogel chemistry, type of photoswitch attachment, ionic strength, changes in hydrogel volume, and aggregation on the isomer-distribution of the photoswitch. In particular, we find that by changing the spiropyran from appendage to crosslinker, we can not only control feedback in hydrogel swelling behavior, but also control the non-linear optical properties of the hydrogel. These studies directly inform how such feedback loops can be leveraged for the fabrication of evermore sophisticated self-regulated optical materials.

5:00 AM *F.EL05.03.01
Coupling Molecular and Material Photomechanical Response Ruobing Bai, Kevin Korner and Kaushik Bhattacharya; California Institute of Technology, United States

Actuation by light is attractive for a number of reasons: Objects can be actuated from a distance, distinct frequencies can be used to actuate and control distinct modes with minimal interference, and significant power can be transmitted over long distances through corrosion-free, lightweight fiber optic cables. Azobenzene and other molecules that are known to change conformation when exposed to light are the building blocks of photomechanical actuation. An important challenge is how the change of conformation of individual molecules can be harnessed into a robust change of deformation of the material. Approaches range from mean-field entropic coupling as in photoactive nematic elastomers to direct chemical bond coupling as in molecular crystal to hybrid composite approaches where molecular crystals are embedded an elastic matrix. The mean-field entropic coupling can lead to weak coupling while the stiffness of molecular crystal can inhibit actuation or cause them to shatter on actuation. This talk will present a series of theoretical models to understand various aspects of this molecular to material coupling, illustrate them with experimental observations and discuss how ideas from these studies can be harnessed in real materials and devices.

5:15 AM *F.EL05.03.02
Modeling Photo-Mechanical Actuation in Liquid Crystal Polymers Robin L. Selinger[1], Michael Varga[1], Youssef M. Golestani[1] and Sajedeh Afghah[1,2]; [1]Kent State University, United States; [2]Microsoft / OptoFidelity, United States

Liquid crystal polymer networks undergo reversible shape change in response to any stimulus that affects the strength of nematic order. These soft actuators can be fabricated as thin films, surface coatings, or 4D printed solids and have potential applications in soft robotics, biomedical devices, microfluidics, and sensors. Trajectories for shape change are “programmed” by patterning the nematic director when the polymer is cross-linked. Actuation is induced when the strength of nematic order is modulated by stimuli such as a change of temperature or chemical environment; for example, heating induces contraction along the nematic director and expansion in orthogonal directions. The addition of azobenzene derivatives that undergo photo-isomerization produces a soft actuator that flexes like an artificial muscle in response to illumination; if the cis-to-trans thermal relaxation is fast enough, the material can also flex rapidly back toward its original shape when illumination is removed. Such reversible photo-mechanical actuation is a highly attractive option to control a soft robot as it combines both control and power for induced motion without need for tethering or onboard batteries.

Modeling the dynamics of photo-mechanical actuation in these materials is important both to explain the mechanisms behind experimental observations and for device design. To model photo-mechanical actuation at the device scale, we use nonlinear finite element method (FEM) elastodynamics simulation based on a Hamiltonian approach. This method can simulate underdamped motion where momentum plays an important role. The code was developed in-house and implemented in CUDA for execution on a GPU-enabled computer.

We used this approach to model oscillatory mechanical wave motion in a soft robot whose motion was both controlled and powered by light [1]. We use a simplified ray tracing algorithm to determine which parts of the device were illuminated and which in shadow, and used a kinetic model of photo-isomerization/relaxation to describe the time evolution of nematic order. We found that the directionality of light-induced mechanical wave propagation is controlled by a self-shadowing mechanism and periodic pop-through transitions.

We also model a variety of other prototype devices including surface-adhered nematic polymer coatings that transform from flat to complex surface profiles with microchannels, spikes, or dimples recently observed in experiments by Babakhanova et al [2]. Next we model polymer coatings patterned with biomimetic “octopus-like" suckers, designed to grasp and release nonporous objects on command. Such a device would have the potential to achieve strong, reversible adhesion. Our results demonstrate that actuation geometry produced by a disclination in a nematic polymer is controlled not only by the defect’s topological charge and orientation but also by the details of its defect core structure. We compare our modeling results with relevant experiments by collaborators and discuss potential applications.

Magnifying Photomechanical Actuation Using Mechanical Instabilities Ravi Shankar; University of Pittsburgh, United States

The ability to harness light for photochromic switching that directs mechanical work generation within a macromolecular network is a platform for envisioning photomechanical machines, which are neither encumbered by onboard power sources, nor require microfabricated components and mechanisms. Light offers multiple control knobs for photomechanical regulation, including spatiotemporal modulation of intensity, direction, polarization and chirality. Unfortunately for actuators driven with light, the length over which the photons are attenuated (typically, few micrometers) limits the thickness of the photoactuators. The photomechanical strain generation is via bending, resulting from the gradation in the strains that are generated. Slender structures that respond by bending make for weak actuators. Work content that can be accessed is intrinsically bounded in the characteristically micrometer-scale thickness actuators.

Unusual opportunities emerge when we move beyond flat photoactive geometries, where the patterning of the molecular switches and the graded photomechanical strains conspire to result in non-linear mechanical responses. Snap-through in rod-like structures are one example. Creasing instabilities are another, where the bending of liquid crystalline polymers that are photoresponsive is used to drive non-linear transformations of curved shells, which are confined at their periphery. Torque densities >100 Nm/kg and flexural actuation rates >100 radians/s can be produced. Profiles of these photomechanical actuators places them in a property space that competes favorably with electromechanical systems. A third example is that of photoactuated tape-spring mimicking structures. Here, ms-scale actuation is triggered in shells that switch their principal curvatures, via a snap-through mechanism. Beyond these illustrations, opportunities also exist for utilizing a broader class of latch and torque-inversion mechanisms to magnify actuation by integrating active and passive (structural) materials.

Overall, accessing 3-dimensionally patterned freeform actuators is useful for magnifying photomechanical actuation. Realizing these geometries is simplified by the availability of an additive manufacturing platform, wherein the molecular order can be patterned voxel-by-voxel during the composition of multimaterial architectures. The interplay of magnetically assisted alignment and site-specific photopolymerization is a vehicle for achieving this in an inverted stereolithographic setup. In comparison to say, extrusion-based methods, decoupling the material accretion from the endowment of molecular order is key to expanding the design-space, which can be fabricated.

Magnifying photoactuation in monolithic polymeric structures, which can be scaled from the micrometer to mm-scale form factors holds implications for enabling photomechanical machines. It is possible to envision optically powered and reconfigurable devices in applications ranging from microrobotics, biomedicine and manipulation in environments hostile to electromechanical systems.

5:45 AM *F.EL05.03.04
Characterizing the Photomechanical Response of Materials Peter Palffy-Muhoray, Anastasia Svanidze, Seung-Won Oh, Tianyi Guo and Xiaoyu Zheng; Kent State University, United States

When illuminated, photomechanical materials move and demonstrate forces which cause motion. This response indicates that they have acquired momentum as consequence of photoexcitation. We characterize their response by identifying and quantifying the effectiveness of the physical mechanisms connecting photoexcitation and the mechanical response. We are particularly interested in the details of how photostress results from the exciting flux of photons, whose momentum is negligible compared to what is observed in the response, and how photostresses produced in the bulk are transported to the sample surfaces and do mechanical work. We introduce a simple relation linking a stress in light to the photostress, and propose that elements of the tensor relating these serve as measures of the effectiveness of the different aspects of the photoresponse, both in transforming photon energy to stress and in storing photon energy and making it available for mechanical work. Using this metric, we compare the performance of different classes of photomechanical materials using data from the published literature.

6:00 AM *F.EL05.03.05
Light-Induced Curvature of a Landscape to Drive Mechanics Applications Daniel Duffy, Fan Feng, John Biggins and Mark Warner; University of Cambridge, United Kingdom

Light-driven strains can be large, controlled by colour and polarisation of light, and quickly activated in liquid crystalline solids, both rubbery and glassy.
The challenge for applications is to make the response strong, typically involving stretch rather than bend energies if the distortions are loaded. To achieve stretch in both pull and in push without instabilities, the director needs to be programmed in the solid to change the Gaussian curvature of sheet and shell-like objects.
We make contact with current experiments and suggest new Gaussian-curved evolving landscapes, including those arising from curved fold non-isometric origami objects, for effective applications.

6:15 AM *F.EL05.03.06
Understanding the Photochemistry of Donor-Acceptor Stenhouse Adducts David Sanchez, Umberto Raucci, Katherine Ferreras and Todd J. Martínez; Stanford University, United States

Donor-acceptor Stenhouse adducts (DASA) are a promising new chromophore for photomechanical applications. We detail studies of the photochemistry of this chromophore, including both the initial light-induced isomerization and the thermal ring-closing reaction. We further provide details on a framework for modeling excited state dynamics under force, combining the ab initio multiple spawning formalism for nonadiabatic dynamics with the force-modified potential energy surface framework developed for ground state mechanochemistry. We discuss the role of external force (either compressive or extensional) on the photodynamics of the DASA chromophore and its implications for the use of DASA chromophores in light-triggered mechanical actuators.

5:00 AM *F.EL05.04.01
Light-Induced Actuation of Hybrid Crystalline/Polymeric Photomechanical Materials Ryan C. Hayward; University of Colorado Boulder, United States

Materials capable of directly converting photon energy into mechanical deformation offer promise in a wide variety of contexts including adaptive optics, remotely operated swimmers, and actuators controlled via lightweight optical cables that resist corrosion and electromagnetic interference. Organic photoswitches offer significant potential in this regard, thanks to their ability to undergo large changes in molecular conformation upon excitation, and their highly tailorable absorption spectra. To date, efforts have focused largely on either crystalline lattices of small photomechanical molecules, which offer the possibility for greater work output due to their high density and well-organized nature, or on polymer matrices containing a modest concentration of photochromes, which generally have superior processability and mechanical properties. We have recently considered two classes of hybrid materials that combine many of the advantages of these disparate approaches. In one case, we have studied the growth of micrometer-scale photomechanical diarylethene crystals within the pores of polymer membranes. For appropriately controlled orientations of the crystals, such materials can exhibit photomechanical work outputs rivalling the best previously reported systems, while enabling facile processing into mechanically robust samples with cm-scale lateral dimensions. In a second case, we have developed a new class of structurally regular addition polymers bearing photoisomerizable azobenzene groups alternating with chain extenders. These materials form semicrystalline solids that exhibit fundamentally interesting temperature- and light-dependent melting and recrystallization behaviors, and that can be processed into aligned films and fibers exhibiting two-way optical shape memory properties.

5:15 AM *F.EL05.04.02
Twist Again—Dynamically and Reversibly Controllable Chirality in Liquid Crystalline Elastomer Microposts Anna C. Balazs[1], James T. Waters[1], Shucong Li[2], Yuxing Yao[2], Michael M. Lerch[2], Michael Aizenberg[2] and Joanna Aizenberg[2]; [1]University of Pittsburgh, United States; [2]Harvard University, United States

Photo-responsive liquid crystalline elastomers (LCEs) constitute ideal actuators for soft robots because their light-induced

macroscopic shape changes can be harnessed to perform mechanical work. Conventional LCEs, however, do not typically exhibit complex modes of bending and twisting necessary to perform sophisticated maneuvers. Here, we model LCE microposts encompassing side-chain mesogens oriented along a specific axis characterized by the nematic director, and azo-benzene crosslinkers, which determine the deformations of illuminated posts. On altering the nematic director from 90o to 0o relative to the underlying substrate, the post's bending respectively changes from light-seeking to light-avoiding. Moreover, with the director tilted at 45o, the initially achiral post reversibly twists into a right- or left-handed chiral structure, controlled by the angle of incident light. We exploit this photo-induced chirality to design "chimera" posts (encompassing two regions with distinct director orientations) that exhibit simultaneous bending and twisting, mimicking motions exhibited by the human musculoskeletal system.

5:30 AM *F.EL05.04.03
Eliciting Diverse Deformation Modes from a Compositionally Uniform Liquid Crystalline Elastomer Microstructure Shucong Li, Michael M. Lerch and Joanna Aizenberg; Harvard University, United States

The type of deformations and range of motion, which microstructures can undergo, determines their function, be it for soft robotics, for sensing or for changing properties in optical or metamaterials. While composite, multimaterial architectures allow imprinting of pre-determined deformation behaviors, their fabrication at the microscale is difficult and the deformation modes are fixed once fabricated. Herein, we demonstrate the use of an alternative strategy – the generation of a transient bilayer architecture within microstructures by an external light stimulus, – and a variety of deformation behaviors that the same structure can display as a result. Changing the direction of UV-irradiation of high-aspect-ratio compositionally uniform microstructures fabricated from photoresponsive liquid crystalline elastomers gives access to a wide range of sophisticated deformations such as clockwise and counter-clockwise twisting, light seeking and avoiding, particularly if rotational symmetry is broken. Light intensity is demonstrated to be a further control parameter that allows one to tap into non-monotonic bending motions and combinations of twisting, bending and expansions/contractions. Finally, because the light-generated layered architectures are transient, they adapt and evolve as the deformation proceeds, leading to highly complex, yet controllable, self-regulated deformation behaviors. The described LCE microstructures are rapidly and easily fabricated and they offer exciting opportunities to further explore essential features of their finely controllable deformation abilities for applications in next generation smart materials.

5:45 AM *F.EL05.04.05
Photomechanical Effects in Liquid Crystalline Polymer Networks and Elastomers Timothy White; University of Colorado Boulder, United States

Photons have been "put to work" in polymeric materials for more than 50 years. Photogeneration of work has been observed in a range of polymeric materials spanning the continuum from soft elastomers to rigid, high performance materials. Of particular importance is the organization of the polymer chains within the network which can affect magnitude, rate, and directionality of photoinduced deformation. Photomechanical effects in liquid crystalline polymer networks and elastomers are particularly appealing in enabling distinctive conversion of light into work. This presentation will summarize the salient benefits of using light as an actinic stimulus as well as highlight recent developments in this topical area of materials research from our laboratory.

6:00 AM *F.EL05.04.06
Photo-Steered Deformation and Locomotion of Nanocomposite Hydrogels Qing Li Zhu, Zhi Jian Wang, Chen Fei Dai, Qiang Zheng and Zi Liang Wu; Zhejiang University, China

Inspired by the natural activated systems, realization of programmed deformations and locomotion in artificial materials has recently attracted great interest due to their promising applications in biomedical devices, soft robotics, and flexible electronics. Photo-responsive hydrogels are recognized as one ideal material to construct soft actuators and robots owing to their drastic volume change induced by contactless light irradiation with high spatial and temporal resolutions. The challenge is how to construct composite hydrogel with gradient structure and dynamically activate the specific regions of the gel toward programmed deformation and locomotion. We present here a photolithographic method to fabricate patterned composite hydrogel sheets with heterogeneous structures by embedding the photo-responsive hydrogel in a preformed nonresponsive hydrogel. Under photo irradiation, the swelling/contraction mismatch results in the built-up of internal stress and thus programmed deformations of the composite hydrogel. Furthermore, a moving light beam is imposed on the composite hydrogel to spatiotemporally actuate the gel that shows sophisticated motions, including crawling, walking, and turning. Experimental and simulation results reveal that multigait locomotion is realized by the mutual coordination of shape-morphing and dynamic friction of the gel against a substrate under the spatiotemporal light stimulation. The programmed

deformations of motions of photo-responsive hydrogels should be instructive for the development of soft robotics with advanced technologies and versatile applications.

6:15 AM F.EL05.04.07
Light-Fueled Rolling and Jumping of Polymers Jeong Jae Wie, Jisoo Jeon and Jae Gwang Kim; Inha University, Korea (the Republic of)

Light-fueled soft robots have recently demonstrated untethered manipulation of locomotion without the complex mechanical and electrical design principles of conventional robotic systems[1-2]. To achieve photomechanical motility, we photopolymerized light active molecular machines along with reactive liquid crystalline monomers. For energy effective and rapid photomotility, rolling is employed as an in-plane locomotive mode to reduce friction with the substrates in comparison with crawling. In this presentation, we will also discuss design strategy to implement and program jumping motion of liquid crystalline polymers by controlling the molecular alignment for miniaturized yet high-performance untethered soft robots.

Programmable Photothermal Actuation Driven by Visible Light Using Negative Photochromic Donor-Acceptor Stenhouse Adduct (DASA) Polymers Jaejun Lee, Miranda M. Sroda, Younghoon Kwon, Sara El-Arid, Serena Seshadri, Luke F. Gockowski, Elliot W. Hawkes, Megan T. Valentine and Javier Read de Alaniz; University of California, Santa Barbara, United States

The demonstration of tunable actuation performance at a single light intensity by the simple remodeling of material properties advances the field of light responsive materials one step closer to the development of “life-like” actuators. We introduce a novel approach for programmable actuation using negatively photochromic molecular photoswitches, termed donor-acceptor Stenhouse adducts (DASAs), capable of tuning the photothermal actuation amplitude under constant light intensity based on photochemically programed logic. We present a synthetic pathway for chemically attaching DASA conjugates to polymers through Diels-Alder click chemistry. We report a visible light-responsive bilayer actuator that can lift weight against gravity, as well as a simple light-powered crawler, that exploit photothermal energy conversion. Programmable control of the magnitude of actuation is achieved by slowly converting a highly-absorbing DASA photochrome into a non-absorbing form upon irradiation. Our results highlight the promising benefits of high molar absorptivity, negative photochromism, and broadband visible light absorption of DASAs for programmable actuation.

6:35 AM F.EL05.04.09
Molecular Engineering of Liquid Crystalline Elastomers to Enhance Phototropic Disruption of Order Tayler Hebner and Timothy White; University of Colorado Boulder, United States

Liquid crystal elastomers (LCEs) can be functionalized with photochromic moieties to sensitize these materials to light exposure. Prior work has demonstrated that phototropic disruption of order via photochemical adjustment of the isomeric state of azobenzene (for example) disrupts the anisotropic chain configurations of the polymer network. The phototropic disruption of order in azobenzene-functionalized LCEs (azo-LCEs) with UV light via *trans-cis* isomerization generates comparatively large strain, exceeding 20%.
Fundamentally, the strength of intermolecular interactions between polymer chains defines the thermotropic response of both low molar mass and polymeric liquid crystal compositions. Here we show that by adjusting the intermolecular interaction by introducing a nontraditional liquid crystalline monomer, light irradiation can induce photomechanical responses in azo-LCE at lower energy inputs to achieve equivalent mechanical output.

Photothermal Effect of Porphyrin Compounds for Optical Thermal Insulation Jou Lin[1], Yuan Zhao[2], David Kundrat[1], Mathias Bonmarin[3], John Krupczak[4], Som V. Thomas[1], Mengyao Lyu[1] and Donglu Shi[1]; [1]University of Cincinnati, United States; [2]The Pennsylvania State University, United States; [3]Zurich University of Applied Sciences, Switzerland; [4]Hope College, United States

The photothermal effect has been found in some porphyrin compounds including chlorophyll, chlorophyllin, hemoglobin, and phthalocyanine, all of which share similar structural characteristics. The porphyrin compounds are typically composed of four modified subunits bounded with carbon atoms forming a "ring-like" structure, therefore also known as "porphyrin rings." Upon white light irradiation, these compounds can selectively observe light in a wide range of frequency from UV to NIR, and convert it to thermal energy. One of the major applications of these porphyrin compounds is in the energy-efficient windows via a newly developed concept of optical thermal insulation (OTI). Most of the thermally insulated windows in cold climate regions are double-paned, sandwiching transparent insulating materials (such as gases), creating additional and unnecessary volume and weight. Thermal transmittance (U-factor) is proportional to the temperature difference, ΔT, between the center of room and window interior surface. OTI does not rely on any conventional thermal insulating materials or gases, such as air or argon, as often used in conventional double-pane windows, but achieves its effectiveness via photothermally-heated building skins. If a spectral-selective thin film is applied on a window inner surface that exhibits strong UV/NIR absorptions and high visible transmittance, the pronounced photothermal (PT) effect will be photonically-activated to increase the surface temperature, resulting in much reduced heat transfer through the window. In this study, we report recent experimental results on deposition of transparent thin films of porphyrin compounds and show much lowered U-factors via OTI under simulated solar irradiation. Also identified is the operating mechanism of the photothermal effects for different porphyrin compounds.

Effect of Incident Light Angle on the Photothermal Properties of Iron Oxide and Porphyrin-Based Thin Films for Energy-Efficient Single-Pane Window Applications Mengyao Lyu[1], Jou Lin[1], John Krupczak[2] and Donglu Shi[1]; [1]University of Cincinnati, United States; [2]Hope College, United States

Photothermal experiments of incident light angle dependence were carried out by using solar-simulated light on iron oxides (Fe_3O_4 and Fe_3O_4@$Cu_{2-x}S$) and porphyrin compounds (chlorophyll and chlorophyllin) thin films. All thin films were deposited on glass substrates by spin-coating method with the photothermal materials evenly dispersed in polymethyl methacrylate (PMMA) solutions. The Fe_3O_4 film was found to exhibit a strong absorption peak near the UV region but only with background absorptions in the visible and NIR regions. A broad NIR absorption was observed in the Fe_3O_4@$Cu_{2-x}S$ thin film. Both chlorophyll and chlorophyllin showed pronounced peaks near UV and NIR characterized with the U-shaped spectra, ideal for energy-efficient single-pane window applications that require efficient solar harvest and high transparency. Thermal transmittance through the window can be significantly reduced by decreasing the temperature difference, ΔT, between the window inner surface and the room interior based on a so-called "optical thermal insulation" (OTI) without any intervention medium, such as air/argon. Upon solar irradiation, ΔT is reduced by increasing the inner surface temperature of the window through the photothermal heating of the iron oxide and porphyrin coatings. It is therefore possible to replace double- or triple- panes with single panes based on OTI. As the seasonal changes of sunlight inevitably affect OTI, an incident light angle dependence of the photothermal effect was carried on the oxide (Fe_3O_4 and Fe_3O_4@$Cu_{2-x}S$) and porphyrin (chlorophyll and chlorophyllin) thin films. It was found that their heating curves all reached maximum temperatures at small angles of incidence while that of which considerably reduced at large angles. The angle dependence data provides important references for OTI that the window exposure to the sun is higher at the winter solstice (small angle) and lower in summer (large angle). The enhanced solar harvesting at winter solstice can induce a stronger photothermal effect for effective optical thermal insulation of single-pane windows.

Reconfigurable Azo-LCN/rGO Bilayers with Tailorable Mechanical and Electrical Properties Woongbi Cho[1], Jisoo Jeon[1], Wonsik Eom[2], Tae Hee Han[2], Dong Gyun Kim[3], Yong Seok Kim[3] and Jeong Jae Wie[1]; [1]Inha university, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of); [3]Korea Research Institute of Chemical Technology, Korea (the Republic of)

Azo-benzene functionalized polymers have tremendously been studied owing to the advantages of battery-free light trigger shape reconfigurable properties. However, the trade-off relationship between mechanical strength and deformability and

insulating properties are great limitations of azo-functionalized polymer for shape reconfigurable devices. In this presentation, we introduce bilayered structure of azobenzene functionalized liquid crystalline polymer networks (Azo-LCN) with reduced graphene oxide (rGO) toward drastic enhancement in mechanical and electrical properties without sacrifice of strain responsivity. The Young's modulus of the Azo-LCN/rGO bilayer increases by 5 times (6.4 GPa) in comparison with the neat Azo-LCN, and the electrical conductivity is recorded to be 340 S/cm. Remarkably, the Azo-LCN/rGO bilayer overcomes the tradeoff relationship between mechanical stiffness and elongational responsivity by mismatch of structural character of each layers. Upon exposure to broadband UV, the bending angle of azo-LCN/rGO bilayer is enhanced in forward and backward bending, respectively 2.4 times (97.5 to 229.5 degree) and 12 times (5.4 to 65.2 degree) compared to the neat Azo-LCN. In addition to in-plane bending, twisting actuation mode is achieved by simply adjusting the cutting angle of the linearly patterned azo-LCN/rGO bilayers. The Azo-LCN/rGO bilayer can also be shape-reconfigurable by thermal stimuli including near infrared (NIR), sunlight and lighter. The photothermal effect is selectively induced on the rGO layer by irradiation of NIR stimuli which drive bending actuation of azo-LCN/rGO bilayer. Then, spatially localized actuation of azo-LCN/rGO bilayer is demonstrated by focused irradiation of solar ray. Finally, a rapid and large actuation is also demonstrated by direct heat energy transfer by operation of a lighter.

F.EL05.05.04

Light-Driven Manipulation of Microdroplet on a GeSbTe Substrate Yuka Takamatsu[1], Eiji Yamamoto[1], Keiko Esashika[1], Masashi Kuwahara[2] and Toshiharu Saiki[1]; [1]Keio University, Japan; [2]Nanoelectronics Research Institute, National Institute of Advanced Industrial Science & Technology, Japan

The phenomena related to droplet migration at the micro-scale is expected to be applied to micro medical robots, new printing technologies, and basic research for the locomotion mechanisms of active matter such as cells or microbial populations. One of the main driving forces of droplet motion is Marangoni flow, which takes place from lower to higher surface tension regions. There are many studies on droplet manipulation based on Marangoni flow by generating surface tension difference under temperature gradient. Since, generally, surface tension decreases with temperature, a droplet moves from higher to lower temperature regions. In this study, we demonstrated light-driven microdroplet formation and transportation in a two-dimensional slit on a $Ge_2Sb_2Te_5$ (GST) substrate. GST as a substrate material is suitable for local laser heating due to its large light absorption and low thermal conductivity. We found an inverse Marangoni effect, which refers to the droplet motion from lower to higher temperature regions. The inverse Marangoni mechanism is more advantageous for droplet manipulation by laser beam positioning.

As a droplet material, polyethylene glycol (PEG) was mixed with toluene at a volume ratio of 7:1 to control the temperature dependence of surface tension of the droplet. The toluene/PEG solution was sandwiched with two coverslips, one of which was coated with GST. Droplet formation and transportation was observed under an inverse optical microscope. A local temperature gradient was induced by focusing subnanosecond pulsed laser (λ=532 nm) onto the GST layer through the microscope objective.

When the interface area between bulk-like toluene/PEG and its vapor was irradiated with the laser spot, many small droplets of toluene/PEG were generated in the vapor side and they merged together at the center of the laser spot to form a single larger droplet. When slightly shifting the laser spot, we found that the droplet immediately moved to follow the spot. The result implies that the droplet moved towards higher temperature region, which direction is opposite to that expected from the conventional Marangoni effect. When the laser was turned off, the droplet spread to its equilibrium diameter. We can control the diameter of droplet simply by changing the laser intensity.
We show possible explanation for the mechanism of inverse Marangoni effect. In the toluene/PEG mixed droplet under laser irradiation, the volume ratio of PEG becomes larger in the higher temperature region because the vapor pressure of PEG is much lower than that of toluene and evaporates more slowly. Also importantly, the surface tension of PEG is larger than that of toluene. Considering these facts, we can expect that the surface tension of droplet in the higher temperature side is larger and thereby Marangoni flow is directed towards the center of laser spot. In order to support this explanation, the same experiment was conducted using pure toluene.
The droplet moved towards the opposite direction with respect to the case of mixed solution. The result can be explained by conventional Marangoni effect. The efficient inverse Marangoni effect we obtained may be also attributed to the significantly low surface energy and its temperature dependence of GST.

F.EL05.05.05

Enhanced Magnetic Actuation of Micropillar Arrays via Anisotropic Stress Distribution Jeong Eun Park[1], Jisoo Jeon[1], Sei Jin Park[2], Sukyoung Won[1], Zahyun Ku[3] and Jeong Jae Wie[1]; [1]Inha University, Korea (the Republic of); [2]Lawrence Livermore National Laboratory, United States; [3]Air Force Research Laboratory, United States

Recently, magnetically reconfigurable micropillar arrays have been documented by aligning magnetic particles within the microstructure. When the orientation axis of magnetic particles is deviated from the external magnetic field axis, micropillars undergo directional twisting and bending deformation according to the alignment of magnetic particles. Previous studies have mostly been focused on cylindrical micropillars, resulting in identical actuation regardless of magnetic field direction. In this presentation, we discuss a strategy of anisotropic stress distribution by employing anisotropic pillar geometry in order to introduce a preferential direction for strain responsivity. Under the linear external magnetic field, the effects of geometric anisotropy on magnetic actuation will be investigated by comparing experimental results with magneto-mechanical simulation for rectangular and triangular micropillars. Furthermore, we will discuss the anisotropic liquid spreading and wetting on magnetically actuated micropillar arrays where the pillars twist and bend.

F.EL05.05.06
Multi-Functional and Transparent 3D Shape-Morphing by Patterned Adhesive Tapes via Photothermal Effects Jae Gyeong Lee, Sukyoung Won, Jeong Eun Park and Jeong Jae Wie; Inha University, Korea (the Republic of)

Construction of 3-dimentional (3D) architectures from 2-dimentional (2D) sheets has recently been drawn a great attention. In particular, printing of black ink hinges on pre-strained polymers provides facile and contactless shape-morphing by selective light absorption via photothermal effects. However, remaining ink hinges obstruct transparency and can cause undesirable over-actuation by thermal conduction to unpatterned regions. In this study, we suggest a facile strategy for formation of transparent non-Euclidean structures from pre-strained polystyrene (PS) sheets by employing adhesive tape. Upon exposure to near infrared (NIR) light, pre-stretched PS below the adhesive tape pattern undergoes relaxation of polymer segment into a random conformation above the glass transition temperature on account of local light absorption. Contraction of patterned areas induces 3D shape morphing and remaining tape patterns can simply be removed on-demand after the construction of the targeted 3D structures. Herein, we employed radial and chiral patterns to generate complex 3D architectures and conjugated the multi-material to endow heterogeneous strain-responsivity for each material in a single curvilinear structure. We will also discuss sequential folding by control of light absorption time with sequential removal of adhesive tapes.

F.EL05.05.07
Optical Properties of Si Doped ta-C Anti-Reflective Coatings for Photovoltaic Applications SangYul Lee[1], Jung-Wan Kim[2] and HoeKun Kim[1]; [1]Korea Aerospace University, Korea (the Republic of); [2]Incheon National University, Korea (the Republic of)

Metal containing carbon nanocomposite coatings (Me doped DLC coatings) which include metal or metal carbide phase embedded in amorphous carbon matrix have attracted a significant attention for the past few decades. The association between the carbon matrix and the encapsulated metallic or metal carbide phase not only improve the overall mechanical properties of the nanocomposite coatings, but also attribute the optical properties by accompanying phase and microstructure changes in the coatings. Recently, it has been shown that DLC based coatings are very promising anti-reflection (AR) and protective coatings for photovoltaic applications due to their high chemical stability, radiation stability and high hardness with the possibility of changing their optical properties. Among the various DLC coating classification, tetrahedral amorphous carbon (ta-C) coatings, which showed high sp3/sp2 fraction over 60%, with extremely high hardness, excellent wear resistance, and better radiation stability have been paid much attention to an alternative anti-reflection protective coating materials. So in this study, various contents of Si metal were doped in the ta-C coating to improve optical properties of the ta-C coatings. Filtered cathodic vacuum arc (FCVA) and sputter hybrid PVD system was conducted to synthesize the metal doped ta-C coating. As increasing of Si content in ta-C coating, microstructure of the coatings changed from a dense featureless amorphous to a columnar “moth-eye” like structure by a formation of rhomb silicon carbide (SiC) phase, and that is especially useful for reducing reflections and increasing transmission between materials by the roll of light absorption. Raman spectroscopy analysis showed that all the coatings had high sp3/sp2 fraction about 63%, and the hardness showed high values of 47.5 GPa. The ta-C coating with 4at.% Si showed improved transmittance (over 93.4%) in the field of ultraviolet, and this value was higher than that of other carbon based coatings. These results indicate that the Si doped ta-C coating could be applied for protective & AR coating for photovoltaic applications.

F.EL05.05.08
Late News: Supramolecular Modulation of π-Stacking in Anthracene Crystals—Toward Photoactive Organic Semiconductors Gonzalo Campillo-Alvarado and Ying Diao; University of Illinois at Urbana-Champaign, United States

Organic semiconductors (OSCs) are a rapidly emerging field in molecular electronics. Specifically, single crystals of OSCs

have received considerable attention due to unique properties associated with long-range order, absence of grain boundaries, and extremely low defect density [1] leading to a wide range of multi-functional materials (e.g., field-effect transistors, light-emitting diodes, photovoltaics). However, the lack of strategies to control and promote π-stacking in single crystals of OSCs has limited their tunability and application. While covalent modification of OSCs has arguably received the most attention [2], the noncovalent approach (e.g., supramolecular modulation) has been largely unexplored [3].

In this contribution, we introduce of efforts in the use of small molecules (e.g., templates) to promote π-stacking of a pyridyl-containing anthracene through weak non-covalent interactions. Modulation of the geometry of π-stacking in the crystalline solid state is accompanied by changes in the photophysical properties. We envisage the supramolecular control of π-stacking in single crystals of OSCs could lead to rapid developments and diversification of multifunctional crystalline electronics.

SESSION Tutorial F.EL06: Research Methods and Best Practices to Study and Optimize Contacts and Interfaces
Session Chairs: Robert Hoye, Thomas Kirchartz and Sebastian Siol
Sunday Morning, November 29, 2020
F.EL06

8:00 AM *
Fabrication, Processing and Characterization of Interfacial Layers for Optoelectronic Devices Robert Hoye; Imperial College London, United Kingdom

The instructor will cover growth of oxide charge transport layers by chemical- and physical-based methods for photovoltaics and light-emitting diodes; characterization and mitigation of loss processes at interfaces; and ex-situ and in-situ methods to determine the band alignment of the active material with the charge transport layers.

9:30 AM BREAK

9:45 AM *
Interface Design and Characterization using Photoelectron Spectroscopy Sebastian Siol; Swiss Federal Institute of Materials Science and Technology, Switzerland

The instructor will cover characterization of semiconductor interfaces using photoelectron spectroscopy; high-throughput experiments and band alignment engineering; and advanced chemical state analysis and characterization of buried interfaces using Hard X-ray Photoelectron Spectroscopy.

11:15 AM BREAK

11:30 AM *
Optoelectronic Device Physics—Quantifying Electrical and Optical Losses in Solar Cells and LEDs Thomas Kirchartz; Forschungszentrum Jülich GmbH, IEK-5 Photovoltaics, Germany

The instructor will cover fundamental efficiency limits of photovoltaic devices (Shockley-Queisser model) and deviations from the Shockley-Queisser model that lead to efficiency losses; characterizing losses due to interfaces and contact layers and methods of characterizing these losses in different material systems; terminology used to quantify the ability of contacts and interfaces that lead to lossless photovoltaic or optoelectronic operation (selectivity, passivity and resistivity of contacts and how these parameters are eventually related to performance).

Improved Infrared Light Management with Amorphous Silicon in High Efficiency Silicon Heterojunction Solar Cells Weiyuan Duan, Karsten Bittkau, Andreas Lambertz, Paul Steuter, zhirong yao, Kaifu Qiu and Kaining Ding; IEK5-Photovoltaik, Forschungszentrum Jülich GmbH, Germany

Silicon heterojunction (SHJ) solar cells coupled with hydrogenated intrinsic amorphous silicon (a-Si:H) layers enable high open-circuit voltages (V_{oc}) of up to 750 mV, but suffer from short-circuit current density (J_{sc}) losses due to parasitic absorption in a-Si:H, transparent conductive oxide (TCO) layers and shadowing of the metal fingers. Significant improvement in V_{oc} is expected only for thinner wafer. Increasing J_{sc} is a more promising route to further improve cell efficiency. Besides the use of high bandgap materials such as nanocrystalline silicon oxide or low carrier density TCO layers to reduce parasitic absorption, an improved light trapping that enables more light to be absorbed within the silicon wafer represents another important opportunity for J_{sc} improvement, which becomes even more significant when thinner wafers are used. In this work, a thin intrinsic a-Si:H layer was introduced after metallization of SHJ solar cell, formed a TCO/a-Si:H back reflector. Unlike sophisticated structures such as diffraction gratings, black silicon or other kind of nanophotonics, TCO/a-Si:H back reflector is much easier to be fabricated. Compared with the very often used silver back reflector, a-Si:H is less expensive and can still keep some of the bifaciality of the cells.

The intrinsic a-Si:H layer was deposited by plasma enhanced chemical vapor deposition (PECVD). It has a refractive index of around 4 at infrared (IR) wavelengths extracted from ellipsometry measurement. Sentaurus TCAD simulation was used for the rear optics in terms of optimizing the thickness of TCO/a-Si:H stack. We systematically investigated how the TCO/a-Si:H back reflector increases rear internal reflectance by measuring reflectance and external quantum efficiency before and after deposition of the a-Si:H layer. As predicted from simulation, due to increased IR reflection, J_{sc} was 0.4 mA/cm^2 higher with TCO/a-Si:H back reflector when applied on SHJ solar cells using 110 mm thickness wafer, while fill factor (*FF*) and V_{oc} remained constant. Combined with an optimized front MgF_2 double antireflection coating, we could demonstrate a 0.9 mA/cm^2 improvement in J_{sc}, which boosts the cell efficiency by 0.5%. Ultimately, a M2 size total area cell efficiency of 23.7% has been achieved with V_{oc} of 745 mV, J_{sc} of 39.4 mA/cm^2 and *FF* of 80.8% on 110 um thin wafer. It's worth noting that the cell still kept a bifaciality of more than 50%. The reflector concept introduced here has a possibility to be used in advanced double-glass module encapsulation.

11:50 AM *F.EN03.04.06
Efficient Hole-Selective Passivating Contacts for Si Photovoltaics Takuya Matsui and Hitoshi Sai; AIST, Japan

Hydrogenated amorphous silicon (a-Si:H) is a key material in realizing efficient passivating contacts for Si solar cells known

as the silicon heterojunction (SHJ) technology. However, one drawback of the SHJ solar cells is that the a-Si:H, particularly when doped with boron, gives rise to a parasitic optical absorption loss due to its high absorption coefficients in the visible wavelengths. This adverse effect is pronounced in bifacial solar cells, as this type of device allows illumination from both the front and the rear surfaces. Here we pursued alternative materials focusing on hole-selective passivating contacts: one is the hydrogenated nanocrystalline Si (nc-Si:H) and the other is the novel metal-oxide material. For the nc-Si:H material, it is demonstrated that the replacement of (*p*)a-Si:H by (*p*)nc-Si:H provides not only an increase of J_{sc}, but also improvements in V_{oc} and FF. This results in an efficiency increase by 0.6% absolute compared to our reference cell with (*p*)a-Si:H, and a best cell efficiency of 23.5%. The factors that alter the optimum hole contact layer thickness depending on the material and deposition condition will be discussed. For the metal-oxide material, we have developed an atomic-layer-deposited TiO_x nanolayer that functions as an efficient and transparent hole-selective passivating contact, leading to proof-of-concept solar cells with efficiencies above 20%. This new function of TiO_x is opposite from the previous understanding that it acts solely as electron contact.

12:10 PM *F.EL06.06.05
Organic-Silicon Heterojunction for Solar Cell and Integrated Flexible Energy Devices Baoquan Sun; Soochow University, China

Numerous alternative materials and solar cell device structures have been widely explored in order to reduce the cost of photovoltaic (PV) manufacture. Organic-inorganic component solar cells based on nanostructured semiconductor have built up in past two decades, which may promise the potentially low cost and high performance. However, the device performances are generally lower than its pristine all-inorganic PV devices, resulting from the numerous surface defect and improper organic-inorganic phase segregation. Here, we demonstrate that hybrid PVs based on organic conjugated molecular and nanostructured silicon can achieve a high power conversion efficiency by controlling the interface contact as well as surface passiviation.
An advantage of this type heterojunction devices presents the excellent light harvest capability of nanostructured as well as benefiting likely simple fabrication process. Especially, the composite of conjugated organic materials and nanostructured inorganic materials are potential candidates for cost-effective and efficient solar-energy-harvesting devices[1]. This device can be operated by a light-modulated field effect solar cell, which can improve the device performance under accumulation of light illumination[2]. In addition, this type device can be easily integrated with other type energy device, for example, an energy harvesting structure that integrates an organic-silicon heterojunction solar cell and a triboelectric nanogenerator (TENG) device is built to realize power generation from both sunlight and raindrop[3]. In addition, a self-charging power unit based on an organic-Si heterojunction solar cell and an organic supercapacitor, which simultaneously achieved both photoelectric conversion and energy storage[4]. Finally, we will demonstrate that low temperature processed conductive silver-based ink has wide application usage for low temperature processed solar cell and related plastic electronics.

12:50 PM PLACEHOLDER FOR 2 EN02 SPEAKERS

SESSION F.EL06.10/F.EL08: Live Keynote Joint Session II: Contacts and Interfaces in Halide Perovskite Devices
Session Chairs: Philip Schulz and Yuanyuan Zhou
Wednesday Afternoon, December 2, 2020
F.EL06

5:15 PM *F.EL06.04/F.EL08.11.03
Vacuum Deposited Perovskite Solar Cells with Multilayer Charge Selective Contacts Michele Sessolo, Sang-Hyun Chin, Chris Dreessen, Lidón Gil-Escrig, Ana M. Igual-Muñoz, Beom-Soo Kim, Daniel Perez-del-Rey, Isidora Susic, Kassio P. Zanoni and Henk Bolink; Universitat de València, Spain

In solar cells, perovskite films are typically sandwiched in between charge selective layers, either organic or inorganic semiconductors, as well as their combinations. Electron/hole selectivity results from appropriate alignment of the electronic transport levels of these layers with the electronic bands of the perovskite. While transport layers should efficiently extract the photogenerated charge carriers, they should also not quench the perovskite luminescence to avoid a reduction of the quasi-Fermi level splitting and hence the maximum attainable photovoltage. Finally, ohmic charge injection/extraction and a high built-in potential are desirable to maximize fill factor both in single junction and tandem perovskite solar cells. We will review these design rules using fully vacuum deposited solar cells as a platform, as every layer can be fine-tuned or exchanged without substantially alter the device fabrication. The focus will be on wide bandgap, mixed halide perovskite solar cells, which suffer from a higher voltage deficit as compared to narrow bandgap analogous. We will highlight the importance of using non-quenching, energetically-matched hole and electron transport layers in order to reduce non-radiative charge recombination losses. Novel strategies and multilayers structures (including inorganic, organic and ionic compounds) to improve the device functioning will be presented. The implication for the perovskite compositional stability as well as for the device lifetime will also be discussed.

5:35 PM *F.EL06.04/F.EL08.11.02
Implications of Defects in Defect Tolerant Materials—Understanding Surfaces in Metal Halide Perovskite Solar Materials, Device and Related Systems Joseph J. Berry[1,2]; [1]National Renewable Energy Laboratory, United States; [2]University of Colorado Boulder, United States

Photovoltaic (PV) devices based on metal halide perovskite (MHP) absorbers have reached outstanding performance over the past few years, surpassing power conversion efficiency of over 25% for lab cells and with large area devices in excess of 16%. For the solar application stability, the most demanding requirement to assess for PV, remains the outstanding issue. The problem of stability motivates basic science driven work on MHP based PV at NREL. Material and device insight can enable MHP PV stability along with the associated opportunities to further improve efficiency, scalability and realize unique device architectures. This talk will highlight work at NREL to develop understanding of defects and interfaces in MHPs and what these experiments indicate regarding the requirements to enhance stability of HPSCs. Discussion will focus on efforts to more carefully understand the implications of processing on a range of defects and interfaces to provide a foundation for enabling the technological requirements for PV and other devices. Ongoing efforts make, measure and ultimately control defects via material formation and processing in the context of high-volume manufacturing will also be touched upon. Hypothesized links between device architecture choices, questions regarding materials integration and coupling of formation along with resulting defects to stability will be discussed. More importantly approaches to move from hypothesis to insight using different experimental approaches will be presented. Work at NREL along these lines to provide critical insight regarding interface formation and passivation that appears to have direct implications for performance and its evolution over time in the resulting devices will be presented. New approaches to understanding the critical physical, chemical and electronic properties to provide predictive insight will also be discussed.

5:55 PM *F.EL06.04/F.EL08.11.04
Approaches to Defect Mitigation in Halide Perovskites Nakita K. Noel; Princeton University, United States

Within a decade, there has been a surge of interest into halide perovskite semiconductors. With tuneable bandgaps, versatile and facile deposition processes and excellent optoelectronic properties, these materials have found applications in photovoltaics (PV), broad-spectrum photodetectors, light-emitting diodes and lasers. While research into using these materials for emission and X-ray detection applications is now beginning to surge; currently, halide perovskites are most well known for their remarkable PV performance, with perovskite solar cells achieving certified power conversion efficiencies exceeding 25% in a remarkably short developmental timescale. Despite the truly impressive device performance, these materials have not yet reached their full potential. The major obstacle to this is an incomplete understanding of crystallisation processes, as well as defects which exist on the surfaces and interfaces of perovskite thin-films. Deficiencies at these interfaces, likely formed during the crystallisation process, are responsible for the major losses in perovskite-based optoelectronic devices; limiting charge extraction, increasing non-radiative recombination, contributing to hysteresis and increasing the voltage-loss of perovskite photovoltaics. Herein, I will present various effective strategies to reduce the defect densities of perovskite films and thus improve the performance of perovskite optoelectronic devices. First, I will discuss how manipulating precursor solutions can have significant impact on the quality of the perovskite films, through enabling reduced defect density. Consequently, this is one approach which can be used to boost device performance. Next, I will focus on a strategy in which we extrinsically modify the bottom interface of perovskite solar cells such that the crystallization of the perovskite yields films with fewer defects. Specifically, we show that ionic liquids can have a dramatic effect on the interfacial trap density in a perovskite solar cell. And finally, I will illustrate an approach in which we manipulate the charge-

carrier density in the perovskite thin-film after its fully crystallized. We utilise molecular dopants to significantly alter the interfacial energetics in order to suppress non-radiative recombination losses. As a result, we observe a boost in both performance and stability. Importantly, these interface modification strategies can be used in tandem, resulting in further improvements in device efficiency. The utility of these defect mitigation strategies can readily be applied beyond perovskite PV and is likely to also improve the performance of a range of other perovskite-based optoelectronic devices.

6:15 PM *F.EL06.04/F.EL08.11.01
Passivated Interfaces and Surface Recombination Velocities in Mixed Cation Mixed Halide Perovskites David S. Ginger; University of Washington, United States

Surfaces and charge-extracting contacts remain major sources of non-radiative recombination loss; limiting the performance of perovskite PV compared to theoretical limits. We investigate mixed-cation mixed-halide perovskites and demonstrate that, with chemical surface passivation, they can achieve >4 μs minority carrier lifetimes, and >20% external PL quantum yields (PLQY), and nearly single-exponential decay kinetics. This high PLQY observed corresponds to ~97% of the Shockley-Queisser theoretical quasi-fermi level splitting, a first for MA-free mixed-cation mixed-halide compositions. The high PLQY and long PL lifetimes allow us to measure average surface recombination velocities (SRV) <10cm/s, with a champion low of ~1cm/s (a conservative estimate). We show how such improvements in SRV should lead to an absolute improvement in PCE of >4% even with the best of contact alignments. We investigate different MA-free high bandgap compositions, including bandgaps relevant for tandem applications (1.7-1.8eV), and demonstrate performance improvements across all these compositions with our surface passivation strategy. Lastly, using a combination of surface characterization techniques, we show Lewis base interactions of the passivating agent with the perovskite surfaces.

6:35 PM *F.EL08.01.06
Processing Dependent Signature of Electronic States in the Gap of Metal Halide Perovskites Antoine Kahn; Princeton University, United States

An important area of research on metal halide perovskites (MHP) concerns the presence and role of surface and interface electronic gap states introduced by defects inherent to film processing, degradation under stress (T, irradiation, environment) or chemical reaction with neighboring layers, and the restrictions that these states impose on device performance, i.e., limit in Fermi level split, or aid carrier recombination, leading to reduction of solar cell open circuit voltage. This talk reports results on the determination of the presence and density of electronic states tailing above the valence band maximum of several MHPs, e.g., MAPbI3, CsPbI3, and FA0.85MA0.15Pb(I0.85Br0.15)3. Detailed measurements of the top of the valence band of these materials are performed using high-sensitivity UPS achieved in logarithmic detection. We focus specifically on MAPbI3 films processed with different additives mixed in the precursor-DMF solution: (i) no additives; (ii) DMSO; (iii) NH4++DMA+; and (iv) N-methyl-2-pyrrolidone thione (NMPT). The latter, an S-donor solvent, was investigated for its stronger coordination to Pb2+ as compared to the O-donor solvent DMSO, the additive widely used for improving film morphology. Significant differences are revealed between films processed with DMSO and NMPT. Once carefully treated via (experimental) background and parasitic satellite line contribution subtraction, the DMSO processed film exhibits a clear density of gap states extending from the valence band maximum to the Fermi level, whereas the NMPT processed film does not. The study was then complemented by Kelvin probe-based contact potential difference measurements to address the issue of surface photovoltage (SPV) during UPS. KP-based SPV measurements on these films show a significantly larger SPV (150 mV) and EF-VBM on the DMSO-treated films than on the NMPT-treated ones (SPV= 40 mV), confirming both the presence of the gap states and their impact on the electronic structure of the MHP films. The origin and nature of these gap states are still under investigation.

Multifunctionality of Interfacial Agents in Organic and Inorganic Electronics Norbert Koch[1,2]; [1]Humboldt-Universität

zu Berlin, Germany; [2]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

The electronic properties of interfaces in (opto-) electronic devices play a key role to reach the desired functionality and high efficiency. A wide range of organic and inorganic materials to tune interfacial properties is available today, and a comprehensive understanding of how they interact at interfaces is a prerequisite for realizing their full potential, particularly motivating their use in novel settings. This is exemplified here for the widely used interface modification agent polyethylenimine (PEI), which helps reducing electron injection barriers between electrodes and organic semiconductors. It is shown that PEI mixed with a polymer semiconductor in solution in fact serves two beneficial purposes simultaneously. PEI phase-separates from the semiconductor upon spin-coating and forms low work function bottom and top layers, which enhance electron injection. At the same time, minute amounts of PEI slightly n-dope poly{[N,N'-bis(2-octyldodecyl)naphthalene-1,4,5,8-bis(dicarboximide)-2,6-diyl]-alt-5,5'-(2,2'-bithiophene)} [P(NDI2OD-T2)] in the bulk film, thereby also increasing the electron mobility and boosting the conductivity overall by four orders of magnitude. The full capability of PEI interlayers for optimized electron injection at contacts, however, can only be reached by carefully excluding water during processing and applying mild annealing for improved surface coverage. With this, PEI interlayers reduce the work function of ZnO and graphite electrodes to a record low value of 2.3 eV.
Also the combination of organic conductive polymers and inorganic semiconductors provides a rich playground for interface manipulation. It has been demonstrated before that n-type Si coated with a layer of poly(3,4-ethylenedioxythiophene): poly(styrenesulfonate) (PEDOT:PSS) actually returns fully functional solar cells, despite the absence of a pn-junction in Si. We could now provide direct evidence that PEDOT:PSS induces indeed a large upward band bending in n-Si, even reaching inversion conditions. From a variation of processing conditions, suggestions on further improvements for this attractive approach to surface-dope inorganic semiconductors to the extreme can be derived.
It will further be noted how molecular photochromic switches, in the form of a monolayer at the interface between electrodes and an organic semiconductor, can be employed to facilitate multifunctionality of a device. As an example, an organic light emitting diode (OLED) will be discussed, whose brightness can be controlled reversibly during operation by both applied bias and external short-time light irradiation.

Schottky Barriers and Selective Contacts Using Atomic Layer Deposited Interface Layers Nick C. Strandwitz; Lehigh University, United States

Electrical contacts are critical to nearly all semiconductor devices, and the behavior of these contacts can have massive implications to overall device performance. Decades of research into metal-semiconductor contacts continues today because of their complexity and our modern ability to control and probe these interfaces.
Our work, primarily in the context of photovoltaics, examines two classifications of modified metal-semiconductor contacts: Metal-insulator-semiconductor (MIS) Schottky barriers, and selective contacts based on metal oxides. MIS contacts were indeed the foundation of some of the first PV devices, but quickly gave way to p-n junction architectures because of greater stability and power conversion efficiency in the latter architecture. Using device physics simulations, we show that if proper junction properties can be created (Schottky barrier height, interface passivation), MIS-type PV devices can approach efficiencies of p-n homo- and hetero-junction cells. Our work exploring the interface properties of MIS structures for PV makes use of purposeful chemical surface preparation and the deposition of well-controlled oxide insulators using atomic layer deposition (ALD). I will discuss several observations including the role of fixed interface charge and interface layer thickness on Schottky barrier height.
Secondly, so-called "selective contacts" have been examined to boost efficiency of p-n and heterojunction silicon PV, and also to provide PV junctions without the need for traditional p-n junctions, similar to the MIS Schottky barrier case. In both cases, it can be argued that such contacts may reduce processing costs due to the low temperatures for the deposition of these materials. Notable developments include electron and hole-selective thin films that provide selective transport for one carrier while often reducing interfacial recombination rates. Our studies explore the introduction of aluminum oxide tunnel layers sandwiched between crystalline silicon and selective contact materials such as MoO_x. The potential impact of this configuration is to 1) increase in stability of the junction and 2) and increase in performance through minimization of carrier recombination at the contact. We have examined the role of the alumina layer thickness on interface quality and specific contact resistance. We also examined the role of several deposition techniques and explore the different processing conditions that modify the interfacial electronic properties of these passivated contacts.

Machine Learning and Design of Impurity Levels and Band Alignments in Optoelectronic Materials Arun Kumar Mannodi Kanakkithodi and Maria Chan; Argonne National Laboratory, United States

The prediction of electronic levels introduced by impurities and electronic level alignment at interfaces is critical to the design of optoelectronic materials, particularly for photovoltaic applications, for optimal function. Such prediction is possible using first principles density functional theory (DFT) calculations. Due to both a need to reduce computational cost and a desire to extract design principles, machine learning has increasingly been used to extract relationships between these computed quantities and physical or chemical descriptors of the semiconductor system. In this talk, we will discuss our work on machine learning (ML) of impurity levels in optoelectronic materials including classical II-VI [1], III-V, and group IV semiconductors, as well as hybrid perovskite halides. We will discuss the accuracy and uncertainty quantifications of different approaches for ML. We will also discuss the extension of this approach to prediction of electronic band alignments at interfaces.

Optoelectronic Properties of Halide Perovskites from First Principles—Challenges, Results and Surprises Linn Leppert; University of Twente, Netherlands

Halide perovskites are a chemically and electronically diverse class of compounds. They encompass 3D materials like the hybrid organic-inorganic $CH_3NH_3PbI_3$ and the all-inorganic double perovskite $Cs_2BiAgBr_6$, solar absorbers with excellent features for photovoltaic applications and beyond. This diversity of structures and optoelectronic properties is further expanded when reducing the dimensionality of these systems, as exemplified by the Ruddlesden-Popper perovskite $(BA)_4AgBiBr_8$ (BA=butylammonium), which can be thought of as a double perovskite monolayer with alternating $AgBr_6$ and $BiBr_6$ octahedra, separated by an organic spacer layer [1,2].
Accurately predicting the fundamental band gaps and excited state properties of this zoo of materials from *first principles* is challenging because of the intricate coupling of structural and electronic degrees of freedom [3], complex structural dynamics and strong spin-orbit interactions. In this contribution, I will discuss our recent progress in describing the optoelectronic properties of halide perovskites using density functional theory (DFT) and Green's function-based many-body perturbation theory [4]. DFT-based molecular dynamics simulations allow us to consider temperature dynamics of halide perovskites and design structural models for our electronic structure calculations. A particular focus of this talk will be our calculations of the electronic structure and optical excitations of the double perovskite series Cs_2AgBX_6 (B=Bi, Sb; X=Br, Cl) and their 2D derivatives – a set of materials with unusual and highly tunable optoelectronic properties.

Searching for Materials with Exceptional Opto-Electronic Properties Using *Ab Initio* High-Throughput Computing Geoffroy Hautier; Université Catholique de Louvain, Belgium

New opto-electronic devices from solar cells to transparent transistors require high performance materials. Ab initio high-throughput computations offer an accelerated path towards the discovery of these exceptional materials. We can now screen thousands of materials by their computed properties even before the experiments. This computational paradigm allows experimentalists to focus on the most promising candidates, and enable researchers to efficiently and rapidly explores new chemical spaces.
In this talk, I will present the challenges and opportunities in materials discovery offered by high-throughput ab initio computing in searching for materials with exceptional opto-electronic properties. Recent examples from our work in the fields of transparent conducting materials and solar absorbers will be used to illustrate the approach. I will discuss the materials highlighted by these computational searches but also show how trends and design rules can be extracted from high-throughput data sets. Finally, I will report on our efforts in scaling up to high-throughput new properties from point defects to carrier mobilities.

4:40 PM *F.EL06.02.01
Interfacing Scandium Nitride with GaN and AlN for Enhanced Performance Chris G. Van de Walle; University of California, Santa Barbara, United States

Scandium nitride (ScN) is a semiconducting nitride that has the rocksalt crystal structure, but with a lattice parameter that provides a close match to GaN; the lattice mismatch is less than 1%. One reason ScN has attracted recent interest is because adding ScN to AlN enhances the piezoelectric properties, and may even lead to ferroelectricity. Here I will focus on interfaces between ScN and GaN. ScN can be highly *n*-type doped and can thus serve as an almost metallic contact or current spreading layer to GaN. If rocksalt ScN is grown along the [111] direction on top of c-axis-oriented wurtzite GaN, interesting phenomena related to spontaneous polarization occur. GaN is polar with a large spontaneous polarization, while ScN is centrosymmetric. This suggests the possibility of a very large spontaneous polarization difference at the interface. We have examined the properties of such interfaces using first-principles calculations based on density functional theory [1]. We first apply the modern theory of polarization to obtain the bulk properties of the individual materials. The resulting difference in polarization constants yields a polarization discontinuity at the ScN/GaN interface of -1.358 C/m^2. As a result, we expect a high-density electron gas on the N-polar GaN/ScN interface, and a high-density hole gas on the Ga-polar GaN/ScN interface, with carrier concentrations up to 8.5E14/cm^2. This value is over an order of magnitude larger than what can be achieved at GaN/AlGaN interfaces. We have confirmed the presence of strong electric fields and bound interface charges in explicit interface calculations. The large polarization difference and small strain makes ScN a promising material for applications in polarization-enhanced *p*-GaN/ScN/*n*-GaN tunnel junctions. Current tunnel junctions make use of InGaN interlayers to reduce the effective barrier and increase the polarization field across the *p*-*n* junction to reduce the junction width. ScN is a promising alternative, with a higher polarization field, smaller bandgap, and much smaller strain.

Work performed in collaboration with N. L. Adamski and C. E. Dreyer, and supported by AFOSR.

Interfacial Doping in Organic Semiconductors with Self Assembled Monolayers at Electodes Kalyani Patrikar[1], Valipe Ramgopal Rao[1,2] and Dinesh Kabra[1]; [1]IIT Bombay, India; [2]IIT Delhi, India

Organic semiconductors (OSC) have a low intrinsic carrier density. Devices based on OSC thinfilms require carriers to be doped by chemical, optical, or electrical means. Many types of devices such as light emitting diodes or transistors consist of metal electrodes which inject the carriers that are conducted across the thinfilm. For hole transporting OSC devices, electrodes of metals with high work function are needed for efficient injection. However, at any metal-OSC interface, mismatch in energy levels creates an energy barrier to hole injection. Energy barrier at interface introduces an additional resistance at interface, hampering device performance. Self Assembled Monolayers (SAM) of polar molecules are used as interlayers at metal-OSC interface to reduce the energy barrier.[1] We show that SAM can act as an agent for interfacial doping along with for work function tuning, thus having dual mechanism for reducing device resistance.

We show this with the case of bottom contact field effect transistor (FET) of the OSC pentacene. Copper electrodes are used for source-drain, and are coated with SAM of different fluorine containing molecules perfluorobenzenethiol (PFBT) or perfluorodecanethiol (PFDT). We find that work function of copper increases from ~4.82 eV to ~5.2 eV for PFBT/Cu and ~-5.4 eV for PFDT/Cu. Drain current was found to be higher with SAM/Cu electrodes as compared with unmodified Cu electrodes, however the trends were in contradictory to those of work function. We show that the drain current increase can be explained on the basis of interfacial carrier doping of pentacene by SAM/Cu. During interface formation, holes are transported from high work function electrode to OSC, accompanied by bending of energy levels, which increases its the equilibrium hole density. We obtain doping profiles by applying a solution to Poisson's equation, and find that the excess hole concentration decreases exponentially away from interface. PFBT/Cu leads to larger average hole concentration (10^{16} cm^{-3}) as compared to PFDT/Cu (10^{14} cm^{-3}) which is in accordance with trends of drain current.

We thus show, by experimental device characteristics and applying analytical models, that interfacial SAM at electrodes can influence characteristics of OSC based devices by a two-fold mechanism of doping along with electrode work function tuning. Depending on the molecules SAM comprise of, doping amount and profile can be controlled. SAM thus has the twin advantage of enabling us to enhance device characteristics due to doping, as well as control device behaviour by doping amount.

Interface Engineering Materials and Methods for Efficient and Stable Perovskite Solar Cells Nam-Gyu Park; Sungkyunkwan University, Korea (the Republic of)

Since the seminal report on the 9.7% efficient and 500 h-stable solid-state perovskite solar cell (PSC) in 2012, following two seed reports on perovskite-sensitized liquid junction solar cells in 2009 and 2011, perovskite photovoltaics has been surged swiftly due to high power conversion efficiency (PCE) obtainable via facile fabrication procedure. As a result, a PCE of 25.2% was recorded in 2019. According to Web of Science, number of publications on PSCs increases exponentially since 2012, leading to the accumulated publications of more than 16,500, which indicates that PSC, needless to say, is promising next-generation photovoltaics. High photovoltaic performance was realized by compositional engineering, device architecture and fabrication methodologies for the past 10 years. Toward theoretical efficiency over 30% and commercialization of PSC, further studies on removal of recombination and scalable technologies are required for next 10 years. In this talk, importance of interface engineering is emphasized to reach the theoretical efficiency with voltage over 1.3 V and fill factor over 0.9. Material selection rule and interface engineering methodologies will be introduced. For commercialization, materials may be issued because the current precursor mixture is problematic due to the underlying aging effect. We developed cost-effective materials based on delta $FAPbI_3$ powder for reproducibly high efficiency PSC. Large-area uniform perovskite coating is also important in upscaling PSC. Acetonitrile-based and 2 methoxy ethanol-based coating solutions were developed for large-area perovskite films. In addition, additive engineering and bifacial stamping technique were found to be effective ways for the upscaling PSC. A paradoxical approach is discussed for improving stability of PSCs. PCEs over 23% could be achieved by the interface engineering, the additive engineering and the topographical approach.

5:40 AM *F.EL06.01.04

Perovskite Solar Cells—Lessons from a Device Model Lambert Jan Anton Koster; University of Groningen, Netherlands

To improve the performance of existing perovskite solar cells (PSCs), a detailed understanding of the underlying device physics during their operation is essential. We have developed and validated a numerical device model that describes the operation of PSCs and quantitatively explains the role of contacts and of (doped) transport layers (TLs), ionic movement, carrier generation, drift and diffusion of carriers and recombination. We fit the simulation to experimental data of various perovskite solar cells to identify the main losses and routes to optimization.

The performance of PSCs can be limited by losses due to the poor transport properties of the commonly used TLs. State-of-the-art TLs suffer from rather low mobilities when compared to the mobilities of perovskites. We introduce a conductivity criterion to guarantee the design of a good TL through a combination of experimental and modelling data.

We use large-scale drift-diffusion simulations to get a better understanding of the light intensity dependence of the open-circuit voltage and how it correlates to the dominant recombination process. We introduce an automated identification tool using machine learning methods to pinpoint the dominant loss using the light intensity-dependent performances as an input. The machine learning was trained using over 150,000 simulations and gives an accuracy of the prediction up to 80%.

Space-charge limited current (SCLC) measurements have been widely used to study the mobility and trap density in semiconductors. While such measurements have proven to be valuable to investigate the properties of organic semiconductors, their applicability to perovskite materials is not straightforward.

We present a description of the pitfalls of SCLC measurements when considering perovskite semiconductors with an emphasis on the effect of mobile ions, inherent properties of these materials, on the measurements. We show using drift-diffusion simulations that the presence of ions strongly affects the measurement and that the usual analysis and interpretation of the values extracted from SCLC needs to be refined. In particular, the trap density and mobility cannot be directly quantified using classical methods. We also discuss the advantages of pulsed SCLC measurements to get reliable data that are less influenced by ionic motion and degradation of the perovskite under voltage stress. Fitting the pulsed SCLC measurement using drift-diffusion modelling appears to be a reliable method to extract simultaneously mobility, trap and ion densities. We were able to obtain a trap density of 10^{13} cm^{-3}, ion density of 10^{13} cm^{-3} and mobility of 13 cm^2/Vs for $MAPbBr_3$ single-crystal.

5:55 AM F.EL06.01.05
Photoelectron Spectroscopy Investigation of the Electronic and Chemical Properties of Perovskite-Based Devices Under Operating Conditions Maryline Ralaiarisoa[1], Johannes Frisch[2,3], Mathieu Frégnaux[4], Armelle Yaiche[5], Jean Rousset[5], Muriel Bouttemy[4], Arnaud Etcheberry[4], Regan Wilks[2,3], Marcus Bär[2,3,6] and Philip Schulz[1]; [1]Helmholtz-Zentrum für Materialien und Energie GmbH, Germany; [2]Helmholtz-Zentrum Berlin für Materialien und Energie GmbH (HZB), Germany; [3]Helmholtz-Zentrum Berlin, Germany; [4]Université de Versailles Saint-Quentin en Yvelines, Université Paris-Saclay CNRS, France; [5]EDF R&D, France; [6]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany

The long-term viability of perovskite-based solar cells is contingent on the evolution of their performance and the improvement of their stability, which primarily require a deep understanding of their property-function relationships. A comprehensive description of the electronic and chemical properties of the device layers and interfaces is particularly relevant, since these properties ultimately dictate the charge transport across the interfaces and throughout the device. Still, an accurate understanding of the mechanisms governing device operation requires a controlled *operando* monitoring of the respective layers' electronic properties, i.e. when indispensable biases such as light and electrical bias are applied.
In our study, in order to establish an X-ray photoelectron spectroscopy (XPS) *operando* procedure, we primarily designed and investigated perovskite half-devices consisting of a multi-cation mixed halide perovskite layer between a FTO/TiO_2 substrate and a partial Au top electrode. We consistently monitor the electronic and chemical properties across the surface of the device sample, which reveals a change of the iodine and lead species from the Au to perovskite side, consistent with a previously observed underpotential deposition process[1]. Then, we use synchrotron-based photoelectron spectroscopy (PES) that allows investigation under operating conditions. The X-ray beam provided by the synchrotron light source also provides the spatial resolution required to use the designed sample configuration and to monitor the changes of the electronic and chemical properties as a function of applied electrical bias and illumination.. A positive electrical bias applied to the Au anode produces a shift in binding energy of the core levels of the perovskite layer, as expected, although it is consistently smaller than the bias. This effect could be attributed to inhomogeneous electric potential across the surface, as it is notably observable close to the Au/perovskite boundary, highlighting the importance of sample design for *operando* studies. We further discuss the possible implications of transient and dynamic processes in these changes. Moreover, by varying

measurement parameters and monitoring the effects on chemical reactions - that may be at the core of degradation processes in perovskite solar cells -, we attempt to disentangle these effects from those induced by the external biases. Importantly, our results indicate a gradual shift of the core level binding energy towards lower values over the early course of the measurements on the perovskite side, potentially indicating an X-ray-induced photovoltage effect. The results provide first insight into perovskite device electronic properties under operating conditions and guidelines for XPS *operando* studies.

6:05 AM F.EL06.01.06
Late News: Tuning the Work Function of Electrodes through Elucidation of Coordination Reaction at Organic/Inorganic Interfaces Tsubasa Sasaki[1], Kazuma Suzuki[2], Hirokazu Ito[2], Kaito Inagaki[2], Taku Oono[1], Munehiro Hasegawa[3], Katsuyuki Morii[3,4], Takahisa Shimizu[1] and Hirohiko Fukagawa[1]; [1]NHK Science & Technology Research Laboratories, Japan; [2]Tokyo University of Science, Japan; [3]Nippon Shokubai Co., Ltd., Japan; [4]Nippon Shokubai Research Alliance Laboratories, Osaka University, Japan

Understanding the carrier injection/extraction mechanism at organic/inorganic interfaces is of pivotal importance for the future progress of organic optoelectronic devices such as organic light-emitting diodes (OLEDs), organic thin-film transistors (OTFTs), organic solar cells (OSCs), perovskite solar cells (PSCs), and organic semiconductor laser diodes (OSLDs). Since barrier-free contacts for holes and electrons are essential for efficient organic optoelectronic devices, the method of tuning the work function (WF) of electrodes and related phenomena has been intensively studied. A higher WF is ideal for efficient hole injection/extraction, and the surface WF of anodes has been tuned to above 5 eV by using metal oxides such as p-type dopants and molybdenum trioxide, both of which have relatively high electron affinity. On the other hand, a cathode surface WF has been mainly tuned using reactive materials such as alkali elements with low WFs of less than 3 eV. Because such alkali elements are highly chemically reactive and easily oxidize in the presence of ambient oxygen and moisture, there is a strong desire to eliminate reactive materials from devices, especially flexible optoelectronic devices.
As a promising electron injection/extraction technique, the utilization of a coordination reaction between phenanthroline derivatives and metals has been studied. Yoshida [1] reported that the high electron injection and current collection efficiency at the Ag electrode/batocuproin (BCP) interface is due to the formation of Ag–BCP complexes. Very recently, Bin et al. [2] have reported that the electron injection efficiency of Ag-doped 4,7-dimethoxy-1,10-phenanthroline (p-MeO-Phen) films is higher than that of not only Ag-doped BPhen films, but also Cs-doped p-MeO-Phen films. It was also reported that the introduction of an electron-donating dimethoxy substituent in Phen results in greater electron exchange between p-MeO-Phen and Ag than between BCP and Ag, therefore improving the electron injection efficiency. However, the coordination reaction around the cathode is not yet systematically understood, and a feasible alternative material to reactive metals has not yet been found.
Here, we have found a novel phenanthroline derivative that can be a feasible alternative to reactive metals in electron injection through an in-depth elucidation of the coordination reaction [3]. The surface WF of the ITO/ZnO electrode with 4.10 eV can be tuned in the range of 3.29–2.43 eV by forming thin films of the Phen derivative on ITO/ZnO. From density functional theory (DFT) calculations, the change in WF (ΔWF) was found to be strongly correlated with the amount of electron transfer associated with the coordination reaction compared with the other physical properties that likely affect WF, such as the molecular dipole moment of Phen derivatives. The electrode modified with 4,7-bis(1-pyrrolidinyl)-1,10-phenanthroline (p-Pyrrd-Phen) shows a lower WF than the electrode modified with p-MeO-Phen and a higher electron injection efficiency than LiF. Furthermore, the air stability of the p-Pyrrd-Phen-modified electrode is about 10 times higher than that of LiF, and the operational stability of the OLED using the p-Pyrrd-Phen-modified electrode is comparable to that of the OLED using LiF. Since both the air stability and operational stability of this phenanthroline-modified cathode was demonstrated to be high, our findings open the way to the fabrication of electronic systems that do not require air-sensitive materials.

6:15 AM F.EL06.01.07
Late News: Surface Ligand Penetration into Methylammonium Lead Iodide Perovskites and the Impact on Interfacial Energetics and Photovoltaic Performance So Min Park, Ashkan Abtahi, Alex Boehm and Kenneth R. Graham; University of Kentucky, United States

Surface ligand treatment of organic metal halide perovskites is a promising route to passivate surface defect states, improve

material and device stability, alter interfacial energetics, and ultimately increase the perovskite solar cell (PSC) performance. In this work surface ligands with different binding groups are investigated to determine their extent of surface coverage, whether they form a surface monolayer or penetrate into $MAPbI_3$, how they influence $MAPbI_3$ surface energetics and photoluminescence, and how this combination of factors affects PSC performance. Using angle-dependent X-ray photoelectron spectroscopy (XPS) we show that surface ligands with ammonium and phosphonic acid binding groups often penetrate into $MAPbI_3$, which can significantly impact surface energetics, as determined through ultraviolet and inverse photoelectron spectroscopy measurements. These changes in surface energetics significantly impact the PSC performance, with solar cell performance decreasing for ligands that create less favorable energy landscapes for electron transfer from $MAPbI_3$ to the electron transport layer, C_{60}. Through investigating a series of ammonium containing surface ligands, we propose guidelines to select ligands that will either penetrate into $MAPbI_3$ or remain only on the $MAPbI_3$ surface.

Interfacing Scandium Nitride with GaN and AlN for Enhanced Performance Chris G. Van de Walle; University of California, Santa Barbara, United States

Scandium nitride (ScN) is a semiconducting nitride that has the rocksalt crystal structure, but with a lattice parameter that provides a close match to GaN; the lattice mismatch is less than 1%. One reason ScN has attracted recent interest is because adding ScN to AlN enhances the piezoelectric properties, and may even lead to ferroelectricity. Here I will focus on interfaces between ScN and GaN. ScN can be highly *n*-type doped and can thus serve as an almost metallic contact or current spreading layer to GaN. If rocksalt ScN is grown along the [111] direction on top of c-axis-oriented wurtzite GaN, interesting phenomena related to spontaneous polarization occur. GaN is polar with a large spontaneous polarization, while ScN is centrosymmetric. This suggests the possibility of a very large spontaneous polarization difference at the interface. We have examined the properties of such interfaces using first-principles calculations based on density functional theory [1]. We first apply the modern theory of polarization to obtain the bulk properties of the individual materials. The resulting difference in polarization constants yields a polarization discontinuity at the ScN/GaN interface of -1.358 C/m^2. As a result, we expect a high-density electron gas on the N-polar GaN/ScN interface, and a high-density hole gas on the Ga-polar GaN/ScN interface, with carrier concentrations up to 8.5E14/cm^2. This value is over an order of magnitude larger than what can be achieved at GaN/AlGaN interfaces. We have confirmed the presence of strong electric fields and bound interface charges in explicit interface calculations. The large polarization difference and small strain makes ScN a promising material for applications in polarization-enhanced *p*-GaN/ScN/*n*-GaN tunnel junctions. Current tunnel junctions make use of InGaN interlayers to reduce the effective barrier and increase the polarization field across the *p*-*n* junction to reduce the junction width. ScN is a promising alternative, with a higher polarization field, smaller bandgap, and much smaller strain.

Work performed in collaboration with N. L. Adamski and C. E. Dreyer, and supported by AFOSR.

Solution-Processed Ceria Quantum Dots as Interface Layer for Enhancing Performance of Avalanche Amorphous-Selenium Photodetectors Haripriya Kannan[1], Jann Stavro[2], Atreyo Mukherjee[2], Sebastien Leveille[3], Kim Kisslinger[4], Lizhu Guan[5,1], Wei Zhao[6], Ayaskanta Sahu[1] and Amir H. Goldan[6]; [1]New York University, Tandon School of Engineering, United States; [2]Stony Brook University, College of Engineering and Applied Sciences, United States; [3]Analogic Canada, Canada; [4]Brookhaven National Laboratory, United States; [5]Harbin University of Science and Technology, China; [6]Stony Brook University, School of Medicine, United States

Photo-sensing devices using amorphous-selenium (a-Se) have gained significant attention in medical imaging due to their avalanche phenomena. a-Se photodetectors are wide bandgap (E_g) semiconductor with high fill-factor, offers a high-gain ($\sim 10^2 - 10^3$) with negligible low excess noise, and has ~90% quantum efficiency to blue wavelength facilitating a scintillator-based conversion detector for gamma rays and X-rays. At electric fields above 70 V/μm, holes in a-Se undergo impact ionization which increases the effective sensitivity of the photodetector. However, at these high electric fields required for

avalanche gain, dark current due to charge injection from the metallic electrode can become a significant source of noise, limiting the dynamic range of the photodetector. Hole-blocking layer (HBL)/ electron transport layer (ETL) is an n-type semiconductor typically incorporated at the interface between positive electrode and a-Se to minimize the dark current from charge injection while conducting only electrons. However, the avalanche gain of the a-Se sensor has been limited so far by the use of inefficient hole-blocking layers. Two factors are necessary to achieve efficient a-Se devices with HBL. One is, the device should be fabricated with HBL on top of a-Se (*p-i-n* fabrication sequence where '*p*' denotes *p*-type electron-blocking layer, '*i*' is for intrinsic a-Se and '*n*' for *n*-type HBL) to develop a scalable imager that is compatible with pixelated read-outs. Second, a-Se crystallizes at ~50°C which emphasizes a room-temperature deposition technique of HBL on a-Se. Among previously reported HBLs/ETLs, vacuum-deposited bulk cerium dioxide (CeO_2) has been successfully utilized in avalanche a-Se sensors. Bulk CeO_2 cannot be directly deposited on a-Se, as the high-temperature required for the vacuum deposition crystallizes a-Se and is fabricated in the *n-i-p* sequence, with a-Se deposited on top of CeO_2. a-Se with bulk CeO_2 suffers from the high dark current due to a lower effective hole barrier of CeO_2 (2.8 eV). In our work, we successfully synthesized colloidal CeO_2 quantum dots (QDs) with a large bandgap (E_g = 3.77 eV), which are electronically passivated by surfactants/ligands and spin-coated directly on a-Se at room temperature without inducing any crystallization. As a large bandgap semiconductor, CeO_2 is extremely transparent at the 450 nm wavelength during photo-response measurement of a-Se. Our best performing device with 40 nm thick CeO_2 HBL achieved an avalanche gain of 42. Also, our prototype device of 150 nm thick CeO_2 achieved an ultra-low dark current of 30 pA/cm^2 at 70 V/μm which is three orders of magnitude lower than any avalanche a-Se device previously reported and might be the lowest dark current ever recorded for an avalanche device operated at room temperature.

Generic Electroluminescent Device for Emission from Long-Wave Infrared to Ultraviolet Wavelength Yingbo zhao[1,2], Der-Hsien Lien[1,2], Vivian Wang[1,2] and Ali Javey[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

The scope of luminescent materials that can be used for electroluminescent devices has been limited due to material processability and band alignment considerations. These limitations impede the development of electroluminescent devices at extreme wavelengths and hinder the use of electroluminescence (EL) spectroscopy as an analytical technique. Herein we report a device that can excite EL from various materials independent of their physical form and chemical composition. The device produces EL from the long-wave infrared (0.13 eV) to ultraviolet (3.3 eV) range depending on the emitting layer drop casted on top, with onset voltages closely approaching the optical energy gap of the emitting materials. The two-terminal device employs a carbon nanotube network as the source contact and utilizes an AC gate voltage to achieve charge injection through transient band bending. The concept of EL spectroscopy is demonstrated by probing a chemical reaction in a liquid droplet and an EL sensor is developed for detecting organic vapors.

Pushing Correlated Metals Towards UV Transparency Joseph Roth[1], Arpita Paul[2], Turan Birol[2] and Roman Engel-Herbert[1]; [1]The Pennsylvania State University, United States; [2]University of Minnesota, United States

The development of ultraviolet (UV) LEDs has long been a focus due to the wide application space including germicidal disinfection of water, medical sterilization of surfaces, UV polymer curing, DNA sensing, and solar blind detectors. The COVID-19 pandemic has further fueled the need for a time effective and economic solution to disinfect public areas from the coronavirus. Current UV-light disinfection devices use mercury-based gas discharge lamps because high-performance UV LEDs require an electrically conducting electrode material that is highly transparent in the UV range.[1]
In this talk we will demonstrate that the correlated metal $SrNbO_3$ is an ideal transparent electrode for UV applications due to its high optical transmission coupled with a metallic like electrical conductivity superior to indium tin oxide. We will present electrical and optical properties of $SrNbO_3$ films grown by pulsed laser deposition[2] and by magnetron sputtering.[3] The optical transmission was found to be in excess of 80% throughout the visible range and near ultraviolet down to 270 nm for films with thicknesses smaller than 12 nm while maintaining an electrical resistivity lower than 2×10^{-5} Ωcm, giving rise to a sheet resistance of about 68Ω/sq due to its metal-like carrier concentration of ~1×10^{22} cm^{-3}, comparing favorably to conventional UV transparent conductor materials such as doped Ga_2O_3 or $ZnGa_2O_4$. In addition, we will share insights obtained by density functional theory and experiments how sizeable Sr vacancy concentrations affect electrical and optical properties of $SrNbO_3$ films.

Comparison of the Performance and Stability of Top-Emitting and Bottom-Emitting Polymer Light Emitting Devices Sumant R. Wasule and Deirdre O'Carroll; Rutgers University, United States

Organic light emitting devices (OLEDs) are one of the fascinating topics in both academic and industrial fields. Certain properties of OLEDs make them exciting prospects for next generation lighting and display applications, such as the large-area emission characteristics not found in other light sources. OLEDs are fabricated in either a conventional configuration or an inverted configuration. In the conventional configuration, the anode is the transparent electrode and the cathode is the metal electrode. For the inverted configuration the cathode and anode materials are reversed (metal as anode, transparent electrode as cathode). OLEDs are also divided based on the direction of light emitted from the device - bottom-emitting (BE) or top-emitting (TE). Most BE OLEDs are fabricated on indium-tin-oxide (ITO) coated glass substrates; however, this device type has some disadvantages. For example, the emitted light has to pass through a high refractive index ITO layer and a thick glass substrate to exit the device, which traps light in these layers. Additionally, ITO is brittle so this limits its application in flexible OLEDs. TE OLEDs are more compatible with n-type active matrix display-driven OLED technologies. In these devices, the top transparent electrode can be very thin (<100 nm) and the bottom metal layer is thicker so that it acts a reflecting surface. Therefore, TE OLEDs have reduced light trapping, and, therefore, increased light-extraction efficiency compared to BE OLEDs.

In this work, the main objective is to compare the performance and stability of both inverted BE and TE OLEDs fabricated using organic light-emitting polymer semiconductor active layers. The inverted BE OLED has the following layers in order from bottom to top: glass, ITO, zinc oxide (ZnO), cesium carbonate (Cs_2CO_3), poly(9, 9-dioctylfluorene-alt-BT) (F8BT), molybdenum trioxide (MoO_3), aluminium (Al). ITO and Al are the cathode and anode respectively; ZnO and Cs_2CO_3 are the electron injection layers; F8BT is the light-emitting polymer where electron and holes combine to emit light; and MoO_3 is the hole injection layer. Cs_2CO_3 is deposited on ZnO because it lowers the barrier for electron injection into thick polymer films [1]. The inverted TE OLED has the following layers in order from bottom to top: glass, silver (Ag), titanium dioxide (TiO_2), F8BT, MoO_3, silver (Ag) [2]. The performance and stability of both devices is compared by studying current-voltage, current-light flux and voltage-light flux variations. In addition, optoelectronic simulations are employed to aid in optimization of the thickness of the device layers and to validate the experimental results.

Elucidating the PEDOT:PSS/Perovskite Interface for Perovskite Light-Emitting Diodes Simon Sandrez[1,2], Lionel Hirsch[1], Tony Maindron[2] and Guillaume Wantz[1]; [1]Université de Bordeaux, France; [2]CEA-LETI, France

Lead halide perovskites have witnessed in the last few years a major progress as active materials for light-emitting applications. In only four years, efficiencies of perovskite light-emitting diodes (PeLEDs) soared up from less than 1% in 2014[1] to more than 20%[2–4] in 2018. These high efficiencies, together with remarkable properties such as cheap solution processes at low temperatures, efficient charge injection/transport, high color purity and easy wavelength tuning, make perovskite materials a very promising route for future display application. Especially, the use of quasi-2D perovskites forming multi-quantum well structures has enabled to improve radiative recombination probability by increasing the exciton binding energy and by inducing energy transfer within the perovskite material[5]. However, the efficiency and stability of PeLEDs are still lagging behind those of more established technologies like OLEDs. One of the main hurdles for the fabrication of efficient and stable PeLEDs is related to interfacial layer properties, adjacent to the perovskite material. Although the Poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS) is famous as an easy-to-use excellent hole injection and transport layer, it is also known that luminescence quenching in perovskite emitter layers can appear when

deposited onto PEDOT:PSS films, which affect performances of the PeLED[6]. Up to now though, exact interactions occurring at the PEDOT:PSS/perovskite interface are not fully understood.

In this contribution, we use a $PEA_2(FAPbBr_3)_{n-1}PbBr_4$ quasi-2D perovskite and discover a very significant conductivity doping phenomenon located at this PEDOT:PSS/perovskite interface. It translates into unwanted light emission outside of the delimited active area of the PeLED, which may lead to calculation error of device efficiencies. It is demonstrated that this doping is specific to the association of perovskite and PEDOT:PSS materials through a singular behavior. In addition, a study of different interlayers is proposed in order to eliminate the interactions at the PEDOT:PSS/perovskite interface, with emphasis on deposition issues we encountered such as wettability of the perovskite material on those interlayers, which can drastically affect PeLED performances and the manufacture reproducibility from one batch to another.

Transparent Oxide Semiconductors for Contact in OLEDs and Halide Perovskite LEDs Hideo Hosono[1,2]; [1]Tokyo Institute of Technology, Japan; [2]National Institute for Materials Science, Japan

Contact materials for electron injection is critical for OLEDs and halide perovskite LEDs. This type of materials requires several properties; low work function, chemically stable, optically transparent and ohmic contact formation with cathode. In this talk, Iwould like to show 3 new transparent amorphous semiconductors which were developed for OLEDs/QLEDs along with materials design concepts. First is amorphous electride C12A7:e with very small work function and chemical stability [1]. Second is X-ray amorphous ZnO-SiO_2 thin films with small work function and easy Ohmic contact formation with various metals and semiconductors [2,3]. Such a feature makes it possible to fabricate tandem-type OLED devices without significant voltage drop [4]. The last is amorphous transparent p-type semiconductor, Cu-Sn-I with large mobility (~10cm2/Vs) which can be fabricated by spin-coating at low temperature [4]. Applying a-ZSO as the electron injection layer [5].led very high green and red light emission from perovskite LEDs, revealing the critical role of exciton confinement and carrier injection.

6:20 AM F.EL06.02.08
Micro LED Defect Analysis via Photoluminescent and Cathodoluminescent Imaging Keith Behrman[1], Julie Fouilloux[2], Terry Ireland[2], George R. Fern[2], Jack Silver[2] and Ioannis Kymissis[1]; [1]Columbia University, United States; [2]Brunel University London, United Kingdom

Micro light-emitting diodes (micro LEDs) are a promising technology for next-generation displays given their high brightness and efficiency, color gamut coverage and self-emissive design. Most applications require red, green and blue (RGB) pixel integration, which is currently not possible from a single epitaxially grown LED wafer in a fully self-emissive design [1]. To overcome this limitation, several transfer methods have been proposed to allow integration of singulated micro LEDs from red, green, and blue LED wafers [2]. These transfer methods result in lesser fabrication yields and a higher percentage of displays with inactive pixels requiring the display to either be discarded or repaired

[3]. Device short-circuits can be caused by chlorine-based dry etching-related damage or redeposited GaN/GaAs during mesa formation [4]. Defects in the wiring or interconnects can also cause inactive pixels. A non-destructive method to examine for pixel damage would significantly improve yield and fabrication quality. Here we investigate the viability of photoluminescence (PL) and cathodoluminescence (CL) imaging as two non-destructive test methods for defects in micro LED displays.

Blue LEDs (448 nm) of epitaxially grown GaN and InGaN on sapphire were formed into 800 square pixels of side lengths varying from 5 to 500 um by dry etching in a chlorine plasma. CL images were taken using a Zeiss Supra 35VP field-emission scanning electron microscope [5]. PL images were recorded using a LEICA SP8 stimulated emission depletion microscope. After both non-destructive images were collected, we continued device fabrication to electrically connect individual pixels to wire bond pads for attachment to a driving PCB. We recorded electroluminescence (EL) images to compare to PL and CL as defect predictors.

All 800 pixels showed luminescent activity centered at 448 nm under PL imaging. While 582 pixels showed bright luminescence from CL imaging, the remainder showed dim or faded luminescence. An LED with little or no luminescence is indicative of a defect causing an electrical short between the anode and cathode. This provides a shunt resistance current return path around the emissive InGaN multiple quantum wells (MQWs). We explored this phenomenon further by examining the edges from a subset of the inactive pixels under SEM with a SE detector and found dry-etching related damage to the pixel sidewalls.

When comparing these results to the EL images, CL is a strong predictor of inactive pixels in EL. Additional pixels beyond those predicted from CL were inactive so we reexamined a subset of the devices with CL imaging with the die attached to the PCB creating a new measurement paradigm with multiple current return paths for incident electrons. The second set of CL images showed a variety of brightness levels from the individual LED pixels. The average brightness value of each LED was measured using a script in MATLAB and was found to correlate to the inactive pixels from EL imaging and could also predict the nature of the defect as a short or open circuit.

We found that PL imaging did not provide any information on predicting defects in micro LEDs. However, by comparing CL imaging results after mesa etching and after wire and bump fabrication, we show for the first time that it is possible to identify micro LED defects as either shorts from dry etching related damage, shorts from wiring defects, or open circuits from wiring defects. CL imaging is a promising solution for robust and non-destructive analysis for micro LED fabrication.

Laser-Induced Graphene Electrodes for Biosensor Application Elvira Fortunato; Universidade NOVA de Lisboa, Portugal

Graphene has emerged as a novel material with enhanced electrical and structural properties that can be used for a multitude of applications from super-capacitors to biosensors. In this context, an ultra-sensitive biosensor was developed using a low-cost, simple and mask-free method based on laser-induced graphene technique for electrodes patterning. The graphene was produced on a polyimide substrate, showing a porous multi-layer structure with a resistivity of 102.4 ± 7.3 Ω/square. The biosensor was designed as a 3-electrode system. Auxiliary and working electrodes were made of graphene by laser patterning and the reference electrode was handmade by casting a silver ink. A molecularly-imprinted polymer (MIP) was produced at the working electrode by direct electropolymerization of eriochrome black T (EBT). As proof-of-concept, the MIP film was tailored for chloramphenicol (CAP), a common contaminant in aquaculture.

6:40 AM F.EL06.02.10
Industrial Waste Residue Converted into Value-Added ZnO for Optoelectronic Applications Elvira Fortunato; Universidade NOVA de Lisboa, Portugal

The present study shows a simple, fast and cost-effective way of converting industrial waste into a lightweight optoelectronic

device to detect UV radiation. An innovative recycling process of ZnO-rich (> 95% ZnO) residues from the brass industry has been investigated through the preparation of ceramic targets to be used in the deposition of ZnO thin films. A comparison between optical, structural and morphological properties of ZnO thin films deposited by sputtering technique on glass and polyimide substrates was carried out. The ZnO thin films deposited on polyimide substrates were used as seed layers for an ultrafast growth of ZnO nanorods arrays by hydrothermal method assisted by microwave radiation. Laser-induced graphene electrodes were fabricated on the polyimide substrates prior to the ZnO thin film deposition for UV sensor characterization. The produced UV sensor exhibits a responsivity around 12 μA/W for an UV light of 365 nm under 10 V bias. The photoresponse measurements showed a stable UV sensor without significant variations in the sensor's responsivity when tested for long periods of time.

Searching for Materials with Exceptional Opto-Electronic Properties Using *Ab Initio* High-Throughput Computing Geoffroy Hautier; Université Catholique de Louvain, Belgium

New opto-electronic devices from solar cells to transparent transistors require high performance materials. Ab initio high-throughput computations offer an accelerated path towards the discovery of these exceptional materials. We can now screen thousands of materials by their computed properties even before the experiments. This computational paradigm allows experimentalists to focus on the most promising candidates, and enable researchers to efficiently and rapidly explores new chemical spaces.
In this talk, I will present the challenges and opportunities in materials discovery offered by high-throughput ab initio computing in searching for materials with exceptional opto-electronic properties. Recent examples from our work in the fields of transparent conducting materials and solar absorbers will be used to illustrate the approach. I will discuss the materials highlighted by these computational searches but also show how trends and design rules can be extracted from high-throughput data sets. Finally, I will report on our efforts in scaling up to high-throughput new properties from point defects to carrier mobilities.

5:15 AM F.EL06.03.03
Enabling and Boosting Size Convergence for Surface Calculations of Materials Exhibiting Spontaneous Polarization Su-Hyun Yoo[1], Mira Todorova[1], Chris Van de Walle[2] and Jorg Neugebauer[1]; [1]Max-Planck-Insitut für Eisenforschung GmbH, Germany; [2]University of California, Santa Barbara, United States

The most common approach to describe surfaces in density-functional theory is the repeated slab geometry based on periodic boundary conditions. A common strategy to avoid artificial charge transfer from one side of the slab to the other when modelling semiconductor surfaces is to passivate partially filled surface dangling bonds at the backside of the slab. Using the example of wurtzite (0001) surfaces we demonstrate that conventionally used passivation schemes (e.g. pseudo H or surface reconstructions) break down for materials exhibiting spontaneous polarization. We have therefore developed a generalized passivation method that accounts for the effect of spontaneous polarization and correctly describes the asymptotic bulk limit for pyroelectric materials. It is robust and ensures quick convergence of total energies and electronic structure with respect to system size. The performance of our approach will be demonstrated using the example of wurtzite ZnO polar surfaces.

5:25 AM F.EL06.03.04
Graphene Oxide Encapsulated Silver Nanowire Transparent Electrodes—Stability and Device Applications Woo Hyun Chae, Thomas Sannicolo and Jeffrey C. Grossman; Massachusetts Institute of Technology, United States

Among many candidate materials that can overcome the high cost and brittleness of indium tin oxide (ITO), silver nanowire (AgNW) networks appear as a promising substitute. The percolating networks of AgNWs exhibit high flexibility and excellent optoelectronic properties, with sheet resistance of a few Ω/sq and total transmittance of 90% at 550 nm, fulfilling the requirements for many applications such as solar cells or transparent heaters.[1,2] In addition, the fabrication of these electrodes can be achieved by scalable solution-based methods. However, AgNW's susceptibility to corrosion and thermal instability remain limiting factors to its widespread market adoption. Depending on the application target, bare AgNW networks usually require stabilization by encapsulation layers to increase resilience to chemical or electrical stress.

In this study, we present a scalable and economically viable process involving electrophoretic deposition (EPD) to fabricate a highly stable hybrid transparent electrode with a sandwich-like structure where the AgNW network is covered by GO on both sides.[3] The newly developed process allows the conductive transparent film to be transferred to an arbitrary surface after deposition and demonstrates excellent sheet resistance (15 Ω/sq) and transmittance (87% at 550 nm) on glass substrates. Unlike the uncoated AgNW network, the hybrid electrode was found to retain its original conductivity under long-term storage at 80°C. This chemical resilience was explained by the absence of major silver corrosion products for the AgNW encapsulated by GO as indicated by X-ray photoelectron spectroscopy (XPS).

In situ electrical ramping and resistance measurement up to 20V combined with Infrared Thermography were also conducted in order to assess the electrical stability of our electrodes. The electrical behavior of bare AgNW networks typically undergoes distinct phases comprising "optimization" (Joule-effect-induced sintering of the junctions) at first,[4] then "degradation" (Joule-effect-induced morphological instabilities of some AgNWs), and finally "breakdown". It was demonstrated experimentally that the latter breakdown stage involves the formation and propagation of a crack parallel to the contact electrodes.[5] On the other hand when encapsulating in GO, the results indicate a novel stabilization mechanism enabled by the presence of GO that prevents abrupt divergence of the resistance to the MΩ range.

Finally, we will explain the benefits of using these transferrable GO-stabilized AgNW networks in devices by giving some examples of successful integration into organic solar cells (OSC). Importantly, our film can be used as a transparent top electrode for OSC, paving the way for transparent photovoltaics with longer lifetimes. Our unique double-sided EPD-GO/AgNW/GO design where GO is already integrated with the AgNW network serves a dual purpose of encapsulating the entire device as well as enhancing the contact between AgNW and underlying device stack. This results in an enhanced device performance along with increased lifetime by a factor of 5 compared to an unencapsulated device with sprayed AgNWs as top contact.

$BaBi_2O_6$—A Novel Sustainable, Solution-Processable Electron Transport Layer Alex M. Ganose, Kieran B. Spooner, Winnie Leung, John Buckeridge, Benjamin A. Williamson, Robert Palgrave and David O. Scanlon; University College London, United Kingdom

A vast array of modern electronic devices require electron transport layers (ETLs), including photovoltaic cells and batteries. In order to be efficient, various constraints need to be fulfilled with respect to material it is contacting, including structural compatibility and band alignment, so a wide range of different possible electron transport layers is needed for current and future technologies. It is also vital that these materials are produced sustainably, to minimise resource depletion and global heating.
Here, $BaBi_2O_6$ has been synthesised by a solution-based method at ambient temperatures from relatively non-toxic elements. $BaBi_2O_6$ was shown to crystallise in the layered $PbSb_2O_6$ structure, which is shared by a number of other materials,[1] some of which have magnetic and catalytic capabilities; and is stable up to around 600ºC.
Hybrid density functional theory (DFT) calculations were then used to analyse its potential as an ETL. The electronic transport properties were calculated from two codes, BoltzTraP,[2] which solves the Boltzmann transport equations using the relaxation time approximation (RTA); and AMSET, a new code which does not use this approximation. Using AMSET, the

rates of polar optical phonon, acoustic deformation potential and ionised impurity scattering were each calculated, leading to a much more accurate approximation of the electrical conductivity compared to BoltzTraP. Via AMSET it is estimated that $BaBi_2O_6$ possesses an electrical conductivity of around 6,800 S m^{-1} with 10^{-19} electrons cm^{-3} at 300 K in the in-plane direction, or a mobility of approximately 42 cm^2 V^{-1} s^{-1}. By calculating the full set of intrinsic defects using hybrid DFT, it was then shown that $BaBi_2O_6$ is intrinsically n-type, and by also calculating extrinsic La and F defects, it was shown La in particular is an effective donor dopant.
Overall, we show to a high level of theory that $BaBi_2O_6$ is a sustainable material which possesses the high electron mobility and dopability required to be a promising ETL.

Growth of Transparent Conductor $SrMoO_3$ via Molecular Beam Epitaxy Tatiana Kuznetsova, Joseph Roth and Roman Engel-Herbert; The Pennsylvania State University, United States

The search for a cheaper and more efficient alternative to transparent conductor tin-doped indium oxide (ITO) in light-emitting devices, displays, and solar cells is still going. Strontium molybdate ($SrMoO_3$) is known to be a transparent conductor with the lowest electrical resistivity among all known perovskite oxides and might be a better substitute for ITO. Optical transparency and electrical conductivity greatly depend on the concentration of defects; therefore, materials of exceptional quality are desirable. Currently used techniques for the growth of $SrMoO_3$, such as pulsed laser deposition and electron beam evaporation, are based on the use of high energy species, and it may lead to the unintentional formation of defects and degraded quality of the material. Molecular beam epitaxy enables the growth of single-crystalline thin films of exceptional quality, provides unparalleled control over film stoichiometry and only utilizes low-energy particles; therefore, it is a suitable technique for the growth of $SrMoO_3$.
However, it is challenging to grow high quality $SrMoO_3$ thin films via MBE because molybdenum has very low vapor pressure, making it difficult to supply Mo atoms through a conventional effusion cell. One solution might be to use MoO_3 as a source of molybdenum atoms instead of a pure metal. In this talk, I will provide the results of the growth of transparent conductor $SrMoO_3$ thin films via molecular beam epitaxy (MBE) using MoO_3 pellets as a source of molybdenum atoms. Thermodynamic calculations of vapor pressure and stability of MoO_3 will be presented. I will show the images of custom-built effusion cell we used to prevent the reduction of volatile MoO_3 to non-volatile MoO_2 in vacuum. Additionally, I will present reflection high energy electron diffraction, x-ray diffraction, and atomic force microscopy data, as well as the results of optical and electrical measurements to prove that high-quality transparent conducting $SrMoO_3$ thin films can be grown via MBE in a self-regulated manner.

Optoelectronic Properties of Halide Perovskites from First Principles—Challenges, Results and Surprises Linn Leppert; University of Twente, Netherlands

Halide perovskites are a chemically and electronically diverse class of compounds. They encompass 3D materials like the hybrid organic-inorganic $CH_3NH_3PbI_3$ and the all-inorganic double perovskite $Cs_2BiAgBr_6$, solar absorbers with excellent features for photovoltaic applications and beyond. This diversity of structures and optoelectronic properties is further expanded when reducing the dimensionality of these systems, as exemplified by the Ruddlesden-Popper perovskite $(BA)_4AgBiBr_8$ (BA=butylammonium), which can be thought of as a double perovskite monolayer with alternating $AgBr_6$ and $BiBr_6$ octahedra, separated by an organic spacer layer [1,2].
Accurately predicting the fundamental band gaps and excited state properties of this zoo of materials from *first principles* is challenging because of the intricate coupling of structural and electronic degrees of freedom [3], complex structural dynamics and strong spin-orbit interactions. In this contribution, I will discuss our recent progress in describing the optoelectronic properties of halide perovskites using density functional theory (DFT) and Green's function-based many-body perturbation theory [4]. DFT-based molecular dynamics simulations allow us to consider temperature dynamics of halide perovskites and design structural models for our electronic structure calculations. A particular focus of this talk will be our calculations of the electronic structure and optical excitations of the double perovskite series Cs_2AgBX_6 (B=Bi, Sb; X=Br, Cl) and their 2D derivatives – a set of materials with unusual and highly tunable optoelectronic properties.

Bottom-up Filling of Nanosized Trenches with Silver to Fabricate Transparent Conducting Electrodes Yorick Bleiji, Andrea Cordaro, Stefan W. Tabernig, Albert Polman and Esther Alarcon-Llado; AMOLF, Netherlands

Transparent conducting electrodes (TCEs) are essential in many optoelectronic devices including solar cells, LEDs, sensors and displays. The most common approach for TCEs is the use of transparent metal oxide layers, in particular Indium tin oxide (ITO). However, ITO comes with numerous drawbacks such as the relatively high cost, fragility, rarity of Indium, strong UV absorption and relatively high sheet resistance. An exciting TCE alternative is the use of interconnected metallic nanowires, where their sub-wavelength cross-sections makes them transparent to visible light [1,2,3].

In this work, we show a promising cost-effective method to fabricate metal nanowire structures using selective-area electrochemical deposition (SAEC). SAEC is based on electrochemical deposition through an insulating template onto a conductive substrate. Next to the low fabrication cost, electrochemical depositions is a bottom-up method with numerous advantages such as scalability, ambient operation conditions, control over nucleation and high purity. While submicron sized features have been already demonstrated by SAEC [4,5], obtaining homogeneous void free filling of features below 100 nm using direct plating is a major challenge because of the terminal effect and the poor control of nucleation of the seed layer.

Here, we have explored the SAEC fabrication of silver nanowire grids over a large area by using soft-conformal imprint lithography as means to fabricate the template on ITO or Si substrates. Numerical simulations of the full electrochemical 3D system have been performed to highlight the influence of ion diffusion, concentration, kinetic parameters and trench aspect ratio on the homogeneous bottom-up filling of the trenches in the template. Finally, we compare the optical and electrical properties of the SAEC-fabricated metal grids with those fabricated using conventional thermal or e-beam evaporation followed by lift-off. This work represents a low-cost and scalable strategy to fabricate sub 100 nm predefined metal structures, enabling the commercial viable fabrication of nanowire based transparent conductive electrodes for optoelectronic devices.

6:20 AM *F.EL06.03.09
Computationally Driven Design of Improved Transparent Conducting Oxides David O. Scanlon; University College London, United Kingdom

The combination of electrical conductivity and optical transparency in a single material gives transparent conducting oxides (TCOs) an important role in modern optoelectronic applications such as in solar cells, flat panel displays, and smart coatings. The most commercially successful TCO so far is tin doped indium oxide (Indium Tin Oxide – ITO), which has become the industrial standard TCO for many optoelectronics applications; the ITO market share was 93% in 2013. Its widespread use stems from the fact that lower resistivities have been achieved in ITO than in any other TCO; resistivities in ITO have reached as low as $7.2 \times 10^{-5}\Omega$ cm, while retaining >90% visible transparency. In recent years, the demand for ITO has increased considerably, however, indium is quite a rare metal, having an abundance in the Earth's crust of only 160 ppb by weight, compared with abundances for Zn and Sn of 79000 ppb and 2200 ppb respectively, and is often found in unstable geopolitical areas. The overwhelming demand for ITO has led to large fluctuations in the cost of indium over the past decade. There has thus been a drive in recent years to develop reduced-indium and indium-free materials which can replace ITO as the dominant industrial TCO.[1,2] In this talk I will outline the strategies that we use in the Materials Theory Group to look beyond the current TCO materials, highlighting the interplay of theory and experiment.[3,4]

Combinatorial Development of P-Type Transparent Conductive Phosphides Andrea Crovetto[1,2], Thomas Unold[1] and Andriy Zakutayev[2]; [1]Helmholtz-Zentrum Berlin, Germany; [2]National Renewable Energy Laboratory, United States

Despite long-standing research efforts to develop p-type transparent conductive materials (TCMs), the current generation of optoelectronic devices still relies exclusively on n-type TCM contacts due to their much better trade-off between conductivity and transparency. An important issue in oxide-based p-type TCMs is the deep energy and localized nature of the 2p oxygen states in the valence band, which has negative consequences on both hole dopability and hole mobility in most oxides.

Recent computational work [1,2] has identified several phosphides (particularly BP and CaCuP) that could potentially outperform the existing p-type TCMs. These phosphides have shallow, disperse valence bands that are ideal for high hole dopability and mobility. Although their indirect band gaps are rather low (around 2 eV), their direct band gaps are much wider and could ensure transparency in thin film samples. However, thin films of CaCuP have not been made yet, and previously reported BP thin films have not been thoroughly evaluated as transparent contacts [3].

Using a unique combinatorial sputter chamber with reactive PH_3 gas, we have mapped the compositional and thermal phase space in BP and CaCuP. To evaluate their potential as p-type TCMs, we have characterized their application-relevant properties (optical transmission, carrier concentration, and mobility) with high-throughput methods.

In this contribution, we will discuss the pros and cons of sputter-deposited BP and CaCuP as prospective p-type TCMs. We will also contextualize their performance metrics by considering their thermal budget, air stability, and compatible substrates. Based on our experience, we will propose potential search strategies for new p-type transparent phosphides.

Optically Transparent Electrodes Based on Electrically Conductive Boron-Doped Diamond Films for Photoelectrochemical and Optoelectronic Applications Petr Ashcheulov[1], Andrew Taylor[1], Vincent Mortet[1,2], Ondrej Hak[1], Marina Davydova[1], Pavel Hubik[1] and Zdenek Remes[1]; [1]FZU - Institute of Physics of the Czech Academy of Sciences, Czechia; [2]Czech Technical University, Czechia

Transparent conductive electrodes based on metal oxide layers (such as indium tin oxide - ITO and fluorine-doped tin oxide - FTO) are commonly used materials in a variety of optoelectronic devices as they offer adjustable electrical and optical characteristics. However, these conventional transparent conductive oxide (TCO) electrodes possess several drawbacks, such as chemical and/or thermal instability. Such obstacles limit application of TCO's in advanced device structures, which require suitable optoelectronic characteristics following high temperature or chemical treatment [1].
A broad range of carbon-based materials is currently under development as a promising alternative to conventional TCO electrodes. Particularly, synthetic diamond in the form of thin polycrystalline films doped with boron can be optimized for suitable optical transparency and electrical conductivity, such that it enables favorable chemical and thermal characteristics over conventional TCO electrodes [1,2]. Tunable electrical, optical and chemical properties of boron-doped diamond (BDD) predestine the potential for BDD based electrodes for implementation in optoelectronic and energy conversion devices [2,3]. In this work, we report on the development of optically transparent BDD electrodes synthesized using microwave plasma enhanced chemical vapor deposition. The BDD layers with a nanocrystalline form (thickness below 500 nm) were grown on transparent glass substrates and optimized for high optical transmission and low electrical resistivity. To expand potential applicability of fabricated electrodes in various temperature-sensitive structures, synthesis temperature was varied between 250 and 750 °C. The effect of the BDD synthesis temperature on the structural, morphological and optoelectronic properties of fabricated BDD electrodes is discussed. The BDD electrodes were examined by scanning electron microscopy, Raman spectroscopy, optical transmission measurements, Hall effect measurements and secondary ion mass spectroscopy. Additionally, electrochemical characteristics of synthesized BDD electrodes is presented, to highlight applicability of such electrodes in integrated photoelectrochemical systems as a multi-functional coating [2].

Machine Learning and Design of Impurity Levels and Band Alignments in Optoelectronic Materials Arun Kumar Mannodi Kanakkithodi and Maria Chan; Argonne National Laboratory, United States

The prediction of electronic levels introduced by impurities and electronic level alignment at interfaces is critical to the design of optoelectronic materials, particularly for photovoltaic applications, for optimal function. Such prediction is possible using first principles density functional theory (DFT) calculations. Due to both a need to reduce computational cost and a desire to extract design principles, machine learning has increasingly been used to extract relationships between these computed quantities and physical or chemical descriptors of the semiconductor system. In this talk, we will discuss our work on machine learning (ML) of impurity levels in optoelectronic materials including classical II-VI [1], III-V, and group IV semiconductors, as well as hybrid perovskite halides. We will discuss the accuracy and uncertainty quantifications of different approaches for ML. We will also discuss the extension of this approach to prediction of electronic band alignments at interfaces.

Late News: Modifying the Surface of NiO for Perovskite Solar Cells Sofia Apergi[1], Geert Brocks[2,1] and Shuxia Tao[1]; [1]Eindhoven University of Technology, Netherlands; [2]University of Twente, Netherlands

During the last decade, metal halide perovskites have revolutionized the area of renewable energy research. However, the performance of a perovskite solar cell (PSC) depends, not only on the perovskite, but also on the combination and alignment of all its comprising layers, such as electrodes and charge transport layers. NiO is a very promising hole transport layer and its electronic levels need to be optimally aligned with a given perovskite for maximum PSC efficiency. Applying surface modifiers is one of the most widespread strategies to tune its energy levels. Here, we investigate the effect of single layer adsorption of twenty different alkali halides on the electronic levels of NiO, using Density Functional Theory (DFT). Our results show that alkali halides can shift the position of the valence band maximum (VBM) of NiO to a surprisingly large extend in both directions, from -3.10 eV to +1.59 eV. Our results indicate that with alkali halide surface modifiers, the electronic levels of NiO can be tuned robustly and potentially match those of many perovskite compositions in perovskite solar cells.

Passivated Interfaces and Surface Recombination Velocities in Mixed Cation Mixed Halide Perovskites David S. Ginger; University of Washington, United States

Surfaces and charge-extracting contacts remain major sources of non-radiative recombination loss; limiting the performance of perovskite PV compared to theoretical limits. We investigate mixed-cation mixed-halide perovskites and demonstrate that, with chemical surface passivation, they can achieve >4 μs minority carrier lifetimes, and >20% external PL quantum yields (PLQY), and nearly single-exponential decay kinetics. This high PLQY observed corresponds to ~97% of the Shockley-Queisser theoretical quasi-fermi level splitting, a first for MA-free mixed-cation mixed-halide compositions. The high PLQY and long PL lifetimes allow us to measure average surface recombination velocities (SRV) <10cm/s, with a champion low of ~1cm/s (a conservative estimate). We show how such improvements in SRV should lead to an absolute improvement in PCE of >4% even with the best of contact alignments. We investigate different MA-free high bandgap compositions, including bandgaps relevant for tandem applications (1.7-1.8eV), and demonstrate performance improvements across all these compositions with our surface passivation strategy. Lastly, using a combination of surface characterization techniques, we show Lewis base interactions of the passivating agent with the perovskite surfaces.

Implications of Defects in Defect Tolerant Materials—Understanding Surfaces in Metal Halide Perovskite Solar Materials, Device and Related Systems Joseph J. Berry[1,2]; [1]National Renewable Energy Laboratory, United States; [2]University of Colorado Boulder, United States

Photovoltaic (PV) devices based on metal halide perovskite (MHP) absorbers have reached outstanding performance over the past few years, surpassing power conversion efficiency of over 25% for lab cells and with large area devices in excess of 16%. For the solar application stability, the most demanding requirement to assess for PV, remains the outstanding issue. The problem of stability motivates basic science driven work on MHP based PV at NREL. Material and device insight can enable MHP PV stability along with the associated opportunities to further improve efficiency, scalability and realize unique device architectures. This talk will highlight work at NREL to develop understanding of defects and interfaces in MHPs and what these experiments indicate regarding the requirements to enhance stability of HPSCs. Discussion will focus on efforts to more carefully understand the implications of processing on a range of defects and interfaces to provide a foundation for enabling the technological requirements for PV and other devices. Ongoing efforts make, measure and ultimately control defects via material formation and processing in the context of high-volume manufacturing will also be touched upon. Hypothesized links between device architecture choices, questions regarding materials integration and coupling of formation along with resulting defects to stability will be discussed. More importantly approaches to move from hypothesis to insight using different experimental approaches will be presented. Work at NREL along these lines to provide critical insight regarding interface formation and passivation that appears to have direct implications for performance and its evolution over time in the resulting devices will be presented. New approaches to understanding the critical physical, chemical and electronic properties to provide predictive insight will also be discussed.

5:30 AM *F.EL06.04/F.EL08.11.03
Vacuum Deposited Perovskite Solar Cells with Multilayer Charge Selective Contacts Michele Sessolo, Sang-Hyun Chin, Chris Dreessen, Lidón Gil-Escrig, Ana M. Igual-Muñoz, Beom-Soo Kim, Daniel Perez-del-Rey, Isidora Susic, Kassio P. Zanoni and Henk Bolink; Universitat de València, Spain

In solar cells, perovskite films are typically sandwiched in between charge selective layers, either organic or inorganic semiconductors, as well as their combinations. Electron/hole selectivity results from appropriate alignment of the electronic transport levels of these layers with the electronic bands of the perovskite. While transport layers should efficiently extract the photogenerated charge carriers, they should also not quench the perovskite luminescence to avoid a reduction of the quasi-Fermi level splitting and hence the maximum attainable photovoltage. Finally, ohmic charge injection/extraction and a high built-in potential are desirable to maximize fill factor both in single junction and tandem perovskite solar cells. We will review these design rules using fully vacuum deposited solar cells as a platform, as every layer can be fine-tuned or exchanged without substantially alter the device fabrication. The focus will be on wide bandgap, mixed halide perovskite solar cells, which suffer from a higher voltage deficit as compared to narrow bandgap analogous. We will highlight the importance of using non-quenching, energetically-matched hole and electron transport layers in order to reduce non-radiative charge recombination losses. Novel strategies and multilayers structures (including inorganic, organic and ionic compounds) to improve the device functioning will be presented. The implication for the perovskite compositional stability as well as for the device lifetime will also be discussed.

5:45 AM *F.EL06.04/F.EL08.11.04
Approaches to Defect Mitigation in Halide Perovskites Nakita K. Noel; Princeton University, United States

Within a decade, there has been a surge of interest into halide perovskite semiconductors. With tuneable bandgaps, versatile and facile deposition processes and excellent optoelectronic properties, these materials have found applications in photovoltaics (PV), broad-spectrum photodetectors, light-emitting diodes and lasers. While research into using these materials for emission and X-ray detection applications is now beginning to surge; currently, halide perovskites are most well known for their remarkable PV performance, with perovskite solar cells achieving certified power conversion efficiencies exceeding 25% in a remarkably short developmental timescale. Despite the truly impressive device performance, these materials have not yet reached their full potential. The major obstacle to this is an incomplete understanding of crystallisation processes, as well as defects which exist on the surfaces and interfaces of perovskite thin-films. Deficiencies at these interfaces, likely formed during the crystallisation process, are responsible for the major losses in perovskite-based optoelectronic devices; limiting charge extraction, increasing non-radiative recombination, contributing to hysteresis and increasing the voltage-loss of perovskite photovoltaics. Herein, I will present various effective strategies to reduce the defect densities of perovskite films and thus improve the performance of perovskite optoelectronic devices. First, I will discuss how

manipulating precursor solutions can have significant impact on the quality of the perovskite films, through enabling reduced defect density. Consequently, this is one approach which can be used to boost device performance. Next, I will focus on a strategy in which we extrinsically modify the bottom interface of perovskite solar cells such that the crystallization of the perovskite yields films with fewer defects. Specifically, we show that ionic liquids can have a dramatic effect on the interfacial trap density in a perovskite solar cell. And finally, I will illustrate an approach in which we manipulate the charge-carrier density in the perovskite thin-film after its fully crystallized. We utilise molecular dopants to significantly alter the interfacial energetics in order to suppress non-radiative recombination losses. As a result, we observe a boost in both performance and stability. Importantly, these interface modification strategies can be used in tandem, resulting in further improvements in device efficiency. The utility of these defect mitigation strategies can readily be applied beyond perovskite PV and is likely to also improve the performance of a range of other perovskite-based optoelectronic devices.

6:00 AM F.EL06.04/F.EL08.11.05

Transparent Conducting Oxides for Upscalable Solar Cells—Assessing Deposition Methods Yury Smirnov[1], Laura Schmengler[1], Riemer Kuik[1], Pierre-Alexis Repecaud[1], Mehrdad Najafi[2], Sjoerd Veenstra[2], Erkan Aydin[3], Stefaan De Wolf[3] and Monica Morales-Masis[1]; [1]University of Twente, Netherlands; [2]TNO-Solliance, Netherlands; [3]King Abdullah University of Science and Technology (KAUST), Saudi Arabia

Transparent electrodes are essential components of several kinds of high-efficiency solar cells. The photovoltaic devices working in the broadband spectra, from the ultraviolet (UV) to the near-infrared (NIR), require minimized parasitic absorption and high conductivity for these electrodes. Transparent conductive oxide (TCO) thin films are widely accepted choices for such applications. Among various successful TCOs, recently, Zr-doped indium oxide (IZrO) has been demonstrated as a broadband transparent and conductive material suitable for silicon heterojunction (SHJ) and silicon/perovskite tandem solar cells.[1,2] The main advantage of IZrO is combining specifications of wide bandgap, high carrier density, and high electron mobility in the same material.

Magnetron sputtering is by far the most established technique to fabricate TCO layers. During sputtering target material is removed in a ballistic process that sensitively depends on many interconnected processing parameters. This makes a stoichiometric transfer of target material challenging, while high kinetic energies of the arriving species may damage sensitive functional layers beneath. Conversely, in Pulsed Laser Deposition (PLD), the energy source for material ablation is physically decoupled from the vacuum equipment. This favors the stoichiometric transfer of the target material as well as provides a larger choice for deposition pressures and thermalizing the arriving species.

Despite these advantages, PLD is still considered an exotic fabrication method within the photovoltaic community due to the common concerns about the scalability of the technique reasoned by the small sample size for uniform coating and low deposition rates. In fact, significant progress in the upscaling of PLD[3] has already allowed fabrication of high-quality films by on 200 mm circular wafers and fabrication of superconducting tape with deposition rates > 750 nm/min[4], which is considerably high deposition rate.

In our work, we introduce wafer-scale (4”) room-temperature fabrication of high-mobility IZrO by PLD with deposition rates on par (>3 nm/min) with lab-scale RF sputtering equipment. We studied the optoelectronic properties and microstructure of the films and made a comparison with IZrO films grown by RF sputtering, both fabricated from an IZrO solid target with the same composition.

X-ray diffraction (XRD) reveals that as-deposited IZrO films are amorphous with small embedded nanocrystals. Their orientation is preserved as the preferred one after solid-phase crystallization at 200 °C. IZrO films exhibit excellent optoelectrical properties combining low absorptance (<10%) in the measured range (300-1500 nm) with high mobility (>60 cm^2/Vs) leading to impressive sheet resistivity (R_{sh}) of <20 Ohm/sq for a 100-nm PLD grown film.

When applied as a front electrode in solar cells, IZrO enables high short circuit currents and the possibility to reduce the amount of indium by reducing the thickness of the films compared to standard ITO, which is critical considering the large scale utilization of such materials. On the other hand, higher deposition pressures during PLD fabrication offer a promising way to mitigate the sputter-induced damage for the deposition of rear transparent electrodes on top of sensitive functional layers as in the perovskite solar cells, which opens new opportunities for the development of high-efficiency tandem solar cells.

6:10 AM F.EL06.04/F.EL08.11.06

Overcoming Redox Reactions at Perovskite/Nickel Oxide Interfaces to Boost Voltages in Perovskite Solar Cells Caleb C. Boyd[1], R. C. Shallcross[2], Neal R. Armstrong[2] and Michael McGehee[3]; [1]Stanford University, United States; [2]The University of Arizona, United States; [3]University of Colorado Boulder, United States

Metal halide perovskite solar cells have largely fulfilled their potential of combining III-V-like optoelectronic properties with low-cost, solution-processing deposition techniques, achieving single-junction power conversion efficiencies (PCEs) >25%. A semiconducting nickel oxide (NiO_x) thin film is a highly desirable wide bandgap hole harvesting contact for perovskite solar cells and organic solar cells because it is low-cost, stable, and readily scalable.(*1*)Perovskite solar cells with NiO_x HTLs have delivered some of the best reported stability results under a variety of stressors, including the 85°C/85% relative humidity damp heat test, temperature cycling from -40°C to 85°C, and extended operational stability at elevated illumination and temperature.(*2*, *3*) However, perovskite solar cells made with NiO_x HTLs typically result in lower open-circuit voltages (V_{OC}) compared to ultra-thin, undoped organic hole transport layers, which are more expensive and present problems for both scalability and stability. Enhancing the V_{OC} and increasing efficiency of NiO_x-based devices will directly result in a decreased photovoltaic module cost ($/W).
Here, we identify a surface-assisted electron transfer-proton transfer (ET-PT) mechanism at the NiO_x/perovskite interface leading to barriers for hole harvesting and device V_{OC} loss. Specifically, under-coordinated metal cation sites ($Ni^{\geq 3+}$) act both as a Lewis acid/oxidant towards dissociated lead halide precursors (i.e. I^-) and as a Brønsted base (proton-acceptor) with protonated amine precursors, forming A-site deficient – and therefore $PbI_{2-x}Br_x$-rich – perovskite at the perovskite/NiO_x interface. This defective perovskite region both increases recombination at the interface and acts as a hole extraction barrier, resulting in device V_{OC} loss.
We demonstrate the elimination of the extraction barrier via a simple, easily scaled approach: titration of surface oxide proton-acceptor sites by incorporating 1-5 mol% excess A-site cation to the perovskite precursor solution. This amount is sufficient to counteract the loss of organic cation, preventing formation of a $PbI_{2-x}Br_x$ layer at the interface, ultimately leading to a V_{OC} increase >200 mV. We demonstrate that this mechanism applies to all forms of NiO_x, including thin films created from sol-gel precursors, nanoparticles, atomic layer deposition (ALD), and radio frequency (RF) sputtering, and is generalizable across multiple perovskite active layers, including state-of-the-art single junction and tandem relevant compositions. A p-i-n perovskite solar cell with 19.7% PCE at maximum power point (MPP) and V_{OC} up to 1.15 V is achieved. Devices maintain >90% of their initial performance after 2000 hours of thermal stability testing at 85 °C or >80% of their initial performance after 400 hours of accelerated operational stability testing under illumination and 55 °C in nitrogen. Our results extend the generality of acid/base-coupled oxidation-reduction reactions as the driving force for interface equilibration at metal oxide/perovskite interfaces, suggesting that metal halide perovskites have similar reactions with many types of metal oxide layers.

Balancing the Electronic Structure of Flexography-Printed NiO for Rapid Scaling of Perovskite Solar Cells Julia Huddy, Andrew B. Hamlin, Francesco Guarnieri and William J. Scheideler; Dartmouth College, United States

Perovskite solar cells (PSCs) have potential to deliver TW-scale energy via low-cost manufacturing. However, scaling is limited by slow, high temperature annealing of the inorganic transport layers and insufficient understanding of how scalable processing impacts interfacial device physics. This study addresses the NiO, a leading hole transport layer (HTL) for both high-stability single junction architectures and tandem cells. We present a method for scaling ultrathin NiO HTLs by pairing high-speed (60 m/min) flexographic printing with a rapid annealing Cu:NiO sol-gel ink. By engineering precursor rheology for rapid film-leveling, large area (> 50 cm^2) NiO HTLs were flexographically printed with high uniformity and photovoltaic performance matching that of spin coated films. Doping and the combustion precursor design enables 30X faster annealing while reducing intrinsic variability of work function and conductivity originating from NiOH surface species.

Integrating these printed transport layers in planar inverted PSCs allows rapid fabrication of high-efficiency (PCE > 16 %) $Cs_xFA_{1-x}PbI_{1-y}Br_y$ solar cells with low hysteresis and open circuit voltages (V_{OC}) of 1.11 V. XPS studies of the transition from

Ni-OH to Ni-O bonding for low-temperature annealed NiO clarify the balance required for both effective carrier collection and high photostability. Paired with variable illumination intensity measurements and detailed transient photovoltage characterization, these measurements provide an improved understanding of the intrinsic defects present at the NiO-perovskite interface and the impact of scalable synthesis of interfacial charge transport layers.

Late News: Interfacial Engineering in High Efficiency Vacuum Deposited Perovskite Solar Cells—From Metal Oxide Extraction Layers to Large Area Devices Daniel Perez-del-Rey[1], Henk Bolink[1] and Pablo P. Boix[2]; [1]University of Valencia, Spain; [2]Institut de ciència del materials, Spain

Vacuum deposition is a key technique in the field of perovskite photovoltaics due to the advantages it presents with respect to the classical deposition methods such as solution processed perovskites. The lack of solvents and the need of annealing makes it a good candidate for industrialization and upscaling as it has already been demonstrated in the OLED field. Despite its advantages, tuning the interfaces is essential to reach the high power conversion efficiencies found in solution processed perovskite solar cells. Metal oxides are an interesting choice for extraction layers due to their improved stability and reduced parasitic absorption. In this work we present our recent advances in using metal oxides as extraction layers optimising the interfaces in order to reach record open circuit voltages in CH3NH3PbI3 perovskite and using MoO3 as extraction layer by molecular passivation in both PiN and NiP structure improving the stability and opening new possibilities for tandem applications. We also show how we implemented this stable pinhole-free bottom layers in large area devices and mini modules, which is very promising for future industrial purposes.

Atomic Layer Deposition of Electron and Hole Transport Layers for Perovskite Solar Cells Stacey F. Bent; Stanford University, United States

The power conversion efficiency (PCE) of metal halide perovskite solar cells has shown rapid improvement since their inception over a decade ago, recently surpassing 25%. Stabilizing these devices for long-term operation is needed for their future commercial success. In addition to good external encapsulation, engineering electron and hole contact layers and their interfaces with the perovskite absorber are a means to achieving this goal. Atomic layer deposition (ALD) has emerged as a powerful tool for the growth of these contact layers due to the nanoscale control it affords over film thickness and composition. In this work, we will describe the significant impact that ALD metal oxide contacts can have on improving the long-term operational stability of perovskite solar cells. We show that unencapsulated, single-junction p-i-n perovskite devices with metal electrodes that incorporate ALD SnO_2 electron contacts exhibit high initial PCEs (up to 18.5%), and maintain on average 82% of their initial PCE following 250 hours of continuous, illuminated operation at maximum power in air at 60 °C. This result is a marked improvement over devices with only organic contacts, which lose all PCE after only 20 hours in the same harsh testing conditions. We also describe the development of ALD VO_x hole contact layers for n-i-p perovskite solar cells. We demonstrate that unencapsulated devices with ALD VO_x, a more stable alternative to the commonly used material of evaporated MoO_x, retain on average 71% of their initial PCE when aged for 1100 hours in ambient atmosphere with constant illumination and bias at 70 °C. The vapor deposition strategies described in this work can be applied to various perovskite solar cell designs, including tandem or non-planar devices, and provide a framework for improving the quality of barrier/encapsulation layers in other optoelectronic technologies.

5:15 AM F.EL06.05.02
Scalable Open-Air Deposition of Compact ETL TiO_x on Perovskite for Fullerene-Free Solar Cells Justin P. Chen[1], Florian Hilt[2], Nicholas Rolston[1] and Reinhold H. Dauskardt[1]; [1]Stanford University, United States; [2]Institut Photovoltaïque d'Île-de-France, France

Inorganic charge transport layers have not been readily adopted as the sole charge transport layer on top of perovskite in inverted P-I-N architectures because processing methods that involve high temperature annealing, particle bombardment, or

sol-gels damage the perovskite layer. We report on a scalable, low-temperature TiO_x electron transport layer (ETL) produced directly on top of perovskite in an inverted architecture device by an open-air chemical vapor deposition (OA-CVD) process. It is an attractive low-energy and low-temperature alternative involving simple equipment that can be adopted for roll-to-roll and sheet-to-sheet processing, compatible with industrial manufacturing.
The OA-CVD pyrolysis of a titanium ethoxide precursor forms a fully inorganic, conformal, and compact TiO_x film while preserving the underlying perovskite structure. The resultant film is mechanically robust and exhibits a fracture toughness 30-fold higher than commonly used fullerene-based ETL films. The TiO_x is an effective barrier layer against environmental degradation—unencapsulated devices with the TiO_x ETL retain 60% of their initial efficiency after 1000 hours in ambient aging conditions—compared to devices with a fullerene ETL which were inoperable after 144 hours. TiO_x ETL films on top perovskite demonstrate comparable photoluminescence responses with a commonly used organic C_{60} ETL counterpart. Inverted architecture devices with an optimized TiO_x ETL thickness of 70nm exhibited high open-circuit voltages of 1.08V. We comment on the photocatalytic properties of $TiO_x$and the influence of an amorphous film on maximum power point stability.

5:25 AM F.EL06.05.03
Rapid Vapor-Phase Deposition of High-Mobility *p*-type Buffer Layers on Perovskite Photovoltaics for Efficient Semi-Transparent Devices Rob Jagt[1], Tahmida Huq[1], Sam A. Hill[1], Maung Thway[2], Tianyuan Liu[2], Mari Napari[1], Bart Roose[1], Krzysztof Galkowski[1], Weiwei Li[1], Serena Fen Lin[2], Samuel D. Stranks[1], Judith MacManus-Driscoll[1] and Robert Hoye[3]; [1]University of Cambridge, United Kingdom; [2]Solar Energy Research Institute of Singapore, Singapore; [3]Imperial College London, United Kingdom

Perovskite solar cells (PSCs) with transparent electrodes can be integrated with existing solar panels in tandem configurations to increase the power conversion efficiency. A critical layer in semi-transparent PSCs is the inorganic buffer layer, which protects the PSC against damage when the transparent electrode is sputtered on top. The development of *n-i-p* structured semi-transparent PSCs has been hampered by the lack of suitable *p*-type buffer layers. In this presentation we develop a *p*-type CuO_x buffer layer, which can be grown uniformly over the perovskite device without damaging the perovskite or organic charge transport layers, can be grown using industrial scalable techniques and has high hole mobility (4.3 ± 2 cm^2 V^{-1} s^{-1}), high transmittance (>95%), and a suitable valance band maximum for hole extraction (5.3 ± 0.2 eV). Semi-transparent PSCs with efficiencies up to 16.7% are achieved using the CuO_x buffer layer. Using these as top-cells, we demonstrate four-terminal tandems with two types of silicon bottom cells made using industrially-relevant methods, achieving efficiencies reaching 24.4%. Our work provides a new approach to integrate the most efficient architecture for PSCs in tandems, as well as other applications requiring semi-transparent devices, such as photoanodes for bias-free solar fuel production, transistors with transparent electrodes, or for spectroscopy on devices under operation.

5:35 AM F.EL06.05.06
Uniform Deposition of 1D and 2D Materials Driven by Superhydrophilicity for Transparent Conductive Interfaces David W. Fox, Anthony Schropp, Trisha Joseph, Nilab Azim, Yuen Yee Li Sip and Lei Zhai; University of Central Florida, United States

Transparent conductive film (TCF) materials have become a critical area of research in the field of optoelectronics. Although indium tin oxide (ITO) has traditionally excelled as such a material, device specifications have moved towards flexible designs with milder treatments, and with indium a scarce resource, other materials have begun to replace ITO. Electrodes composed of 1D and 2D materials have matched the high performance of ITO, with very mild deposition processes. We utilized a superhydrophilic antireflective surface to investigate the impact of nanocapillary forces on the deposition of 1D and 2D materials using silver nanowires (AgNWs) and graphene oxide (GO), as model 1D and 2D materials, respectively. A layer-by-layer deposition of silica nanoparticles (SiNPs) and poly(allylamine hydrochloride) (PAH) was used to produce the superhydrophilic antireflective surfaces. The influence of the nanocapillary forces on the deposition of AgNWs and GO from their suspensions solution processed films was investigated. It was discovered that the coffee-ring effect during deposition was suppressed by the nanocapillary forces. The performance of our TCFs prepared with AgNWs on the superhydrophilic antireflective coatings was evaluated. A TCF of 25.0 Ω sq^{-1} with a transparency of 92.1 % transmittance was obtained without removing the substrate background. This TCF reached a figure of merit of 1.76×10^{-2} and retained the wetting properties of the nanoporous coating. The superhydrophilic antireflective surfaces with AgNWs showed an areal root mean square roughness (S_q) 28.41 nm, and the roughness was brought down to 15.67 nm with gradual coating of GO.

5:45 AM *F.EL06.05.07
Schottky Barriers and Selective Contacts Using Atomic Layer Deposited Interface Layers Nick C. Strandwitz; Lehigh

University, United States

Electrical contacts are critical to nearly all semiconductor devices, and the behavior of these contacts can have massive implications to overall device performance. Decades of research into metal-semiconductor contacts continues today because of their complexity and our modern ability to control and probe these interfaces.
Our work, primarily in the context of photovoltaics, examines two classifications of modified metal-semiconductor contacts: Metal-insulator-semiconductor (MIS) Schottky barriers, and selective contacts based on metal oxides. MIS contacts were indeed the foundation of some of the first PV devices, but quickly gave way to p-n junction architectures because of greater stability and power conversion efficiency in the latter architecture. Using device physics simulations, we show that if proper junction properties can be created (Schottky barrier height, interface passivation), MIS-type PV devices can approach efficiencies of p-n homo- and hetero-junction cells. Our work exploring the interface properties of MIS structures for PV makes use of purposeful chemical surface preparation and the deposition of well-controlled oxide insulators using atomic layer deposition (ALD). I will discuss several observations including the role of fixed interface charge and interface layer thickness on Schottky barrier height.
Secondly, so-called "selective contacts" have been examined to boost efficiency of p-n and heterojunction silicon PV, and also to provide PV junctions without the need for traditional p-n junctions, similar to the MIS Schottky barrier case. In both cases, it can be argued that such contacts may reduce processing costs due to the low temperatures for the deposition of these materials. Notable developments include electron and hole-selective thin films that provide selective transport for one carrier while often reducing interfacial recombination rates. Our studies explore the introduction of aluminum oxide tunnel layers sandwiched between crystalline silicon and selective contact materials such as MoO_x. The potential impact of this configuration is to 1) increase in stability of the junction and 2) and increase in performance through minimization of carrier recombination at the contact. We have examined the role of the alumina layer thickness on interface quality and specific contact resistance. We also examined the role of several deposition techniques and explore the different processing conditions that modify the interfacial electronic properties of these passivated contacts.

6:00 AM F.EL06.05.09
High-Performance Perovskite Optoelectronic Devices with Inorganic Nanopillar Arrays Functioning as Charge Transport Layers Zhifeng Huang; Hong Kong Baptist University, Hong Kong

One-dimensional (1D) nano-arrays can reduce light reflection loss, suppress recombination dynamics, guide charge carrier transport, and relax stress and strain in flexible optoelectronic devices, and thus result in improving optoelectronic function and stability under mechanical bending. However, *in-situ* fabrication of 1D nano-arrays, especially on polymer-based flexible electrodes, is very challenging, mainly due to degradation of the flexible electrodes at high temperature of the *in-situ* growth. In this talk, I will present that nanopillar arrays (NaPAs), made of NiO_x (function as hole transport layers)[1] and TiO_2, SnO_2 and metal Ti (serving as electron transport layers), are *in-situ* deposited onto a rigid/flexible electrode by glancing angle deposition (GLAD), and then are hybridized with perovskite to generate solar cells and photodetectors. The as-grown NaPAs enhance light transmittance, facilitate light harvesting in perovskite, facilitate the formation of large perovskite grains, prohibit exciton recombination dynamics, promote charge carrier transport and collection, and prevent the perovskite decomposition. All these advanced features lead to excellent performance of the hybrid perovskite-based optoelectronic devices with good anti-aging and mechanic stability. We devise an advanced technique of low-substrate-temperature GLAD generally adapted to *in-situ* deposit charge carrier transport layers made of inorganic NaPAs on flexible electrodes, to significantly enhance optoelectronic performance of flexible devices.

Improved Infrared Light Management with Amorphous Silicon in High Efficiency Silicon Heterojunction Solar Cells Weiyuan Duan, Karsten Bittkau, Andreas Lambertz, Paul Steuter, zhirong yao, Kaifu Qiu and Kaining Ding; IEK5-Photovoltaik, Forschungszentrum Jülich GmbH, Germany

Silicon heterojunction (SHJ) solar cells coupled with hydrogenated intrinsic amorphous silicon (a-Si:H) layers enable high open-circuit voltages (V_{oc}) of up to 750 mV, but suffer from short-circuit current density (J_{sc}) losses due to parasitic absorption in a-Si:H, transparent conductive oxide (TCO) layers and shadowing of the metal fingers. Significant improvement in V_{oc} is expected only for thinner wafer. Increasing J_{sc} is a more promising route to further improve cell efficiency. Besides the use of high bandgap materials such as nanocrystalline silicon oxide or low carrier density TCO layers to reduce parasitic absorption, an improved light trapping that enables more light to be absorbed within the silicon wafer represents another important opportunity for J_{sc} improvement, which becomes even more significant when thinner wafers are used. In this work, a thin intrinsic a-Si:H layer was introduced after metallization of SHJ solar cell, formed a TCO/a-Si:H back reflector. Unlike sophisticated structures such as diffraction gratings, black silicon or other kind of nanophotonics, TCO/a-Si:H back reflector is much easier to be fabricated. Compared with the very often used silver back reflector, a-Si:H is less expensive and can still keep some of the bifaciality of the cells.

The intrinsic a-Si:H layer was deposited by plasma enhanced chemical vapor deposition (PECVD). It has a refractive index of around 4 at infrared (IR) wavelengths extracted from ellipsometry measurement. Sentaurus TCAD simulation was used for the rear optics in terms of optimizing the thickness of TCO/a-Si:H stack. We systematically investigated how the TCO/a-Si:H back reflector increases rear internal reflectance by measuring reflectance and external quantum efficiency before and after deposition of the a-Si:H layer. As predicted from simulation, due to increased IR reflection, J_{sc} was 0.4 mA/cm^2 higher with TCO/a-Si:H back reflector when applied on SHJ solar cells using 110 mm thickness wafer, while fill factor (*FF*) and V_{oc} remained constant. Combined with an optimized front MgF_2 double antireflection coating, we could demonstrate a 0.9 mA/cm^2 improvement in J_{sc}, which boosts the cell efficiency by 0.5%. Ultimately, a M2 size total area cell efficiency of 23.7% has been achieved with V_{oc} of 745 mV, J_{sc} of 39.4 mA/cm^2 and *FF* of 80.8% on 110 um thin wafer. It's worth noting that the cell still kept a bifaciality of more than 50%. The reflector concept introduced here has a possibility to be used in advanced double-glass module encapsulation.

5:15 AM *F.EL06.06.02
Efficient Hole-Selective Passivating Contacts for Si Photovoltaics Takuya Matsui and Hitoshi Sai; AIST, Japan

Hydrogenated amorphous silicon (a-Si:H) is a key material in realizing efficient passivating contacts for Si solar cells known as the silicon heterojunction (SHJ) technology. However, one drawback of the SHJ solar cells is that the a-Si:H, particularly when doped with boron, gives rise to a parasitic optical absorption loss due to its high absorption coefficients in the visible wavelengths. This adverse effect is pronounced in bifacial solar cells, as this type of device allows illumination from both the front and the rear surfaces. Here we pursued alternative materials focusing on hole-selective passivating contacts: one is the hydrogenated nanocrystalline Si (nc-Si:H) and the other is the novel metal-oxide material. For the nc-Si:H material, it is demonstrated that the replacement of (*p*)a-Si:H by (*p*)nc-Si:H provides not only an increase of J_{sc}, but also improvements in V_{oc} and FF. This results in an efficiency increase by 0.6% absolute compared to our reference cell with (*p*)a-Si:H, and a best cell efficiency of 23.5%. The factors that alter the optimum hole contact layer thickness depending on the material and deposition condition will be discussed. For the metal-oxide material, we have developed an atomic-layer-deposited TiO_x nanolayer that functions as an efficient and transparent hole-selective passivating contact, leading to proof-of-concept solar cells with efficiencies above 20%. This new function of TiO_x is opposite from the previous understanding that it acts solely as electron contact.

5:30 AM F.EL06.06.03
Atomic Layer Deposited Metal Oxide Bilayers for Metal-Insulator-Semiconductor Photovoltaics Benjamin Davis and Nick C. Strandwitz; Lehigh University, United States

The use of metal-insulator-semiconductor (MIS) tunnel diodes as photovoltaics (PVs) relies on the Schottky barrier between the metal and semiconductor, which induces band bending in the semiconductor absorber allowing for efficient separation of

electrons and holes. In the years following early MIS PV research in the 1970s and 1980s, the advent of atomic layer deposition (ALD) has provided a tool for enhanced control of ultrathin film deposition. One method to potentially improve MIS PV performance is the use of ALD oxide bilayers as tunnel insulators. Oxides with different oxygen areal densities have been demonstrated to form interfacial dipoles, manipulating the Schottky barrier. Previous studies have only explored the impact of dipoles between a single ALD oxide and interfacial SiO_x. The present work combines two ALD oxides, one (AlO_x) with oxygen areal density higher than that of SiO_x and another (LaO_x) with oxygen areal density lower than that of SiO_x according to literature. It has been hypothesized that the greater oxygen areal density difference would result in a greater impact on the Schottky barrier. It is demonstrated that, compared to AlO_x alone, an ALD LaO_x/AlO_x stack increases the average n-Si/Ni Schottky barrier height from 0.63 to 0.70 eV, and the average p-Si/Al barrier height from 0.81 to 0.90 eV. LaO_x was the oxide in direct contact with the Si substrate. The observation that the barrier height increases for both substrate types suggests that the effect is due to the ability of LaO_x to depin the Fermi level rather than an interfacial dipole.

5:40 AM F.EL06.06.04
Exploiting Fixed Charge to Control Schottky Barrier Height in Si|Al_2O_3|MoO_x—Based Tunnel Diodes Ben Garland, Benjamin Davis and Nick C. Strandwitz; Lehigh University, United States

Carrier selective contacts have become one of the leading advancements in photovoltaics with the most efficient structures exceeding 26% conversion efficiency. Selective carrier conduction implies that one type of charge carrier is preferentially collected at an electrical contact. Carrier selectivity increases the efficiency of solar cells by reducing recombination at metal contacts and avoiding highly doped emitter layers. Popular selective contact materials are often transition metal oxides (TMOs) due to high optical transparencies and large work functions that are useful for hole selective contacts to silicon. In contrast to previous articles, recent studies have indicated that the interface of p-type silicon and the molybdenum oxide (MoO_x) exhibits a significant Schottky barrier that decreases the efficiency of hole-selective contacts by impeding majority carrier hole collection. To alleviate this issue, atomic layer deposited (ALD) alumina (Al_2O_3) might be added between Si wafer and MoO_x with the expectation to generate a negative interface fixed charge (N_f) after annealing, decreasing band bending. ALD Al_2O_3 also has the ability to passivate interface traps with diffusion of precursor hydrogen during annealing. In this work, we hypothesize that insertion of a tunneling ALD Al_2O_3 layer between MoO_x and p-type Si will enable Schottky barrier height (Φ_{bh}) minimization that is tunable with N_f, enabling a high efficiency hole-selective contact.
Since there should not be quantifiable N_f in tunneling Al_2O_3 using capacitance-voltage (C-V) analysis, non-tunneling n-Si|Al_2O_3|Al MOSCAP structures were used to determine ideal processing for maximum negative N_f. The ALD growth of Al_2O_3 utilized trimethylaluminum and H_2O at 4 deposition temperatures. Half of the samples were annealed at 425°C in a nitrogen atmosphere prior to the application of Al contacts. After N_f quantification, p-Si|Al_2O_3|MoO_x|Al tunnel diodes with thin (~1 nm) as-deposited and annealed Al_2O_3 layers were fabricated to determine Φ_{bh}. Current density-voltage-temperature (J-V-T) and Mott-Schottky $1/C^2$-V measurements were used to establish a range for Φ_{bh}. Both methods showed that the as-deposited tunneling Al_2O_3 diodes had a higher Φ_{bh} compared to the diodes with annealed tunneling Al_2O_3, and therefore also supported the existence of a Φ_{bh} at the Si|MoO_x interface. Future work will involve using larger barrier height diodes using n-Si to more accurately calculate Φ_{bh} and confirm or reject the phenomenon observed.

5:50 AM *F.EL06.06.05
Organic-Silicon Heterojunction for Solar Cell and Integrated Flexible Energy Devices Baoquan Sun; Soochow University, China

Numerous alternative materials and solar cell device structures have been widely explored in order to reduce the cost of photovoltaic (PV) manufacture. Organic-inorganic component solar cells based on nanostructured semiconductor have built up in past two decades, which may promise the potentially low cost and high performance. However, the device performances are generally lower than its pristine all-inorganic PV devices, resulting from the numerous surface defect and improper organic-inorganic phase segregation. Here, we demonstrate that hybrid PVs based on organic conjugated molecular and nanostructured silicon can achieve a high power conversion efficiency by controlling the interface contact as well as surface passiviation.
An advantage of this type heterojunction devices presents the excellent light harvest capability of nanostructured as well as benefiting likely simple fabrication process. Especially, the composite of conjugated organic materials and nanostructured inorganic materials are potential candidates for cost-effective and efficient solar-energy-harvesting devices[1]. This device can be operated by a light-modulated field effect solar cell, which can improve the device performance under accumulation of light illumination[2]. In addition, this type device can be easily integrated with other type energy device, for example, an energy harvesting structure that integrates an organic-silicon heterojunction solar cell and a triboelectric nanogenerator (TENG) device is built to realize power generation from both sunlight and raindrop[3]. In addition, a self-charging power unit based on an organic-Si heterojunction solar cell and an organic supercapacitor, which simultaneously achieved both

photoelectric conversion and energy storage[4]. Finally, we will demonstrate that low temperature processed conductive silver-based ink has wide application usage for low temperature processed solar cell and related plastic electronics.

6:05 AM F.EL06.06.06
Evaluation of Carrier Transport Mechanism by Systematic Defect Level Modulation in TiOx Protective Layers of n-Si/TiOx/Ni Photoanodes for Water Splitting Songwoung Hong[1,2], Woo Lee[1,2], Seungwoo Song[1] and Ansoon Kim[1,2]; [1]Korea Research Institute of Standards & Science, Korea (the Republic of); [2]University of Science and Technology, Korea (the Republic of)

Photo-corrosion of anode participating the oxygen evolution reaction (OER) in photoelectrochemical cell (PEC) for water splitting is one of the obstacles for the long term stability and efficient solar to hydrogen conversion. In order to prevent the phot-corrosion, “electrically leaky” thick TiO_2 film was deposited onto a n-Si photoanode surface. However, the carrier transport mechanism through the thick dielectric layer and the influence of oxygen vacancy-related midgap states on the mechanism are still unclear. In order to verify the carrier transport through the midgap states of thick TiO_2 film, we only modulated the defect density of the protective TiO_2 film with no significant change of optical, physical, and chemical properties. It has been demonstrated that the defect density of the TiO_2 film is proportional to water-splitting activity. This result enables to explain the hole transport mechanism of the previously reported electrically leaky TiO_2 protection layer in n-Si photoanode. For the defect-level optimization, titanium sub-oxide (*sub*-TiO_x) protection layer with higher defect density compared to the TiO_2 layer was also investigated. The controlled incorporation of defects into TiO_x dramatically enhances the hole transport from the photoanode surface to electrolyte solution. The relationship between band structure and PEC activity of the photoanode system was explored depending on the defect density of the protection layer. Mott-Schottky analysis of this system suggests that the defect level of TiO_x films influences the band bending of n-Si, which governs the accessible density of defect states and the carrier recombination.

Improvement in the Passivation Quality of Titanium Oxide Electron-Selective Contacts by Tantalum Doping Seira Yamaguchi[1], Hyunju Lee[1,2] and Yoshio Ohshita[1]; [1]Toyota Technological Institute, Japan; [2]Meiji University, Japan

We report on improvement in the passivation quality of titanium oxide (TiO_x) by doping with tantalum (Ta). TiO_x has been considered one of the most promising materials for electron-selective contacts (ESCs) for crystalline silicon (c-Si) solar cells. There has been a high efficiency of 23.1% successfully achieved for a c-Si solar cell with a TiO_x rear-side ESC [1]. To realize higher efficiencies, it is necessary to further improve the passivation quality. One possible candidate for realizing such improvements is Ta doping. Ta doping reportedly causes a negative shift of the flat band voltage of TiO_x films [2], and the passivation quality of TiO_2 ESCs can therefore be improved by Ta doping. In addition, tantalum oxide (TaO_x) has long-term stability against UV light irradiation [3,4], and it is possible that Ta doping may also improve the long-term stability. In this work, we focus on an improvement in the passivation quality of TiO_x ESCs by doping with Ta.

We deposited TiO_x:Ta films by atomic-layer deposition on the both-sides of n-type c-Si substrates which were in advance oxidized in 30% hydrogen peroxide solution at 80 °C. Ta doping was realized by inserting a unitcycle of TaO_x monolayer into unitcycles of TiO_x. In this study, Ta doping concentration is characterized by a ratio of the number of TaO_x unitcycles to that of TiO_x unitcycles. The thickness of TiO_x:Ta passivation films was basically set to 3.5 nm. After the deposition, the TiO_x:Ta-passivated c-Si substrates were annealed at 130 °C in air. The effective minority-carrier lifetimes (τ_{eff}s) were acquired from quasi steady-state photoconductance measurements, which were used as an indicator for the passivation qualities of the TiO_x:Ta ESCs.

The All the samples passivated with undoped TiO_x films and with TiO_x:Ta films with unitcycle ratios of 0.05, 0.09, 0.17, and 0.50 showed improvements in the τ_{eff} by annealing at 130 °C. However, the τ_{eff} of samples with TiO_x:Ta after annealing was, in most cases, higher than that of samples with undoped TiO_x. This indicates that doping with Ta improves the passivation quality of TiO_x ECSs. In addition, TiO_x:Ta with a relatively low amount of Ta doping tended to have high passivation

qualities. The TiO_x:Ta with a unitcycle ratio of 0.05 showed the highest τ_{eff} of 784 μs in this study, which corresponded to an effective surface recombination quality of 24.9 cm/s. The TiO_x:Ta with a unitcycle ratio of 0.50 exhibited a rather lower passivation quality than that of the undoped TiO_x, which indicates excess Ta doping rather degrades the passivation quality.

The above results imply that TiO_x:Ta is one of the promising materials for ESCs. The results of experiments to elucidate the mechanism of the improvements in the passivation quality will be presented.

Advances in Material Properties for Perovskite-Perovskite Tandems Giles Eperon[1,2]; [1]Swift Solar, United States; [2]National Renewable Energy Laboratorty, United States

Multijunction all-perovskite solar cells offer a route towards efficiencies of III-V materials at low cost by combining the advantages of low thermalization loss in multijunction architectures with the beneficial properties of perovskites - namely low processing cost, high throughput fabrication, and compatibility with flexible substrates. Here, I will discuss why flexible all-perovskite tandems are a very attractive iteration of the perovskite technology. I will focus on what is needed to make a good perovskite-perovskite tandem on a flexible substrate, and the advances that we have made towards this goal.
I will cover advances including a) the development and understanding of wide bandgap materials that leverage a novel bandgap-tuning strategy (without increasing bromine, hence avoiding significant phase segregation) to reach the ideal bandgaps for all-perovskite tandems, resulting in efficient devices that are stable to the combined stresses of heat and light; b) advances that we have made in interlayer design, working towards more ideal material properties for reducing shunt resistance; and c) the integration of these approaches to develop >23% efficient monolithic all-perovskite tandems on rigid substrates and 21% efficient devices on flexible plastic substrates.

The Many Faces of Characterization in Developing a Commercial Perovskite on Silicon Tandem Solar Cell Laura Miranda; Oxford PV, United Kingdom

Perovskite solar absorbers have the potential to disrupt the photovoltaic industry predominantly with their simultaneous promise of high efficiency and low cost. Whilst these two properties ensure a steady stream of research and development opportunities, commercial scaling requires assuring that the devices are sufficiently characterized to be confident of their long-term performance. Oxford PV has been addressing the challenges associated with commercially scaling its perovskite on silicon tandem solar cell design. Key practices that have been adopted during the development of highly efficient, reliable, and cost-competitive solar cells are the use of rigorous characterization tools and techniques, and the development of necessary models. This talk will highlight some of the challenges and considerations associated with bringing perovskite on silicon tandem solar cells from a laboratory prototype to a commercial product ready for manufacturing and how characterization has shaped and continues to inform that process.

5:30 AM *F.EL06.07/F.EL08.10/F.EN02.08.03
Passivation Strategies and Interlayers for Perovskite-Based Tandem Photovoltaics Ulrich W. Paetzold, Saba Gharibzadeh, Tobias Abzieher, Ihteaz M. Hossain, Hang Hu, Thomas Feeney, Somayeh Moghadamzadeh, Mahdi Malekshahi Byranvand,, Bahram Abdollahi Nejand, Paul Fassl and Bryce Sydney Richards; Karlsruhe Institute of Technology, Germany

Single-junction crystalline silicon solar cells dominate the photovoltaics market today, but their power conversion efficiencies (PCEs) are approaching the practical limit for this technology. The emergence of hybrid organic-inorganic metal

halide perovskite semiconductors over the past decade has opened a window of opportunity to advance the performance of the market-dominating photovoltaic technologies through the development of tandem solar cells. These tandem solar cells promise high PCEs (>33%). To reach this landmark, a number of scientific and technological challenges related to high-efficiency perovskite-based tandem solar cell architectures, stable and high-quality perovskite semiconductor materials, and light management concepts need to be addressed. In this presentation, our progress on passivation strategies and novel interlayers to reduce the voltage losses in wide-bandgap and low-bandgap perovskite solar cells (PSCs), and in turn to increase the PCE of perovskite-based tandem photovoltaics, will be presented.
The search for efficient passivation interlayers for wide-bandgap perovskite top solar cells in *n-i-p* architecture directed our research in the past towards solution-processed 2D/3D perovskite heterostructures. Making use of these heterostructures for interface passivation, wide-bandgap PSCs (E_g ~1.72 eV) with record open-circuit voltage for this bandgap and very high PCEs of up to 19.4% were demonstrated [1]. The reduced voltage deficit is a result of the decreased non-radiative recombination losses at the perovskite/hole-transport layer (HTL) interface. The solution-processed 2D/3D perovskite heterostructure is compatible with 3D perovskite absorber layers of a wide range of bandgaps (1.65 eV ≤ E_g ≤ 1.85 eV) [2]. Using this strategy in 4-terminal perovskite/silicon and perovskite/CIGS tandem solar cells, high PCEs > 27% [3], and > 25% [2] were demonstrated, respectively, thereby significantly exceeding the record PCESs reported for the respective single-junction solar cell technologies.
Beyond these past results, at the MRS fall meeting we will further present our latest work on novel interlayers and passivation strategies to minimize the voltage loss in wide-bandgap (1.65 eV ≤ E_g ≤ 1.75 eV) as well as low-bandgap (E_g ~ 1.26 eV) perovskite solar cells in *p-i-n* architecture. The *p-i-n* architecture is a key to realize high-performance 2-terminal perovskite/silicon as well as perovskite/perovskite tandem solar cells. Moreover, we will present a novel route to deposit uniform ultra-thin polymer passivation layers onto perovskite thin films by chemical vapor deposition (CVD) [4]. The CVD polymerization promises reliable, scalable, and homogeneous deposition for future large-area processing of perovskite-based tandem solar cells.

5:45 AM *F.EL06.07/F.EL08.10/F.EN02.08.05
Towards Highly Efficient Monolithic 2- and 3-Terminal Perovskite Silicon Tandem Solar Cells Lars Korte, Eike Koehnen, Philipp Wagner, Philipp Tockhorn, Marko Jost, Amran Al-Ashouri, Lukas Kegelmann, Marcel Roß, Bernd Stannowski and Steve Albrecht; Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

Integrating metal halide perovskite top cells with crystalline silicon (c Si) bottom cells into monolithic tandem devices has recently attracted increased attention due to the high efficiency potential of these cell architectures. To further increase the tandem device performance to a level well above the best single junctions, optical and electrical optimizations as well as a detailed device understanding for such architectures need to be developed [1]. Here we present our recent results on such monolithic tandem cells in the common 2-terminal (2T) as well as in a novel 3-terminal (3T) contacting scheme.
In the 2T design, we recently demonstrated a certified power conversion efficiency (PCE) of 29.15% [2,3]. I will discuss some key elements to this result: using a silicon heterojunction cell electron contact on the rear side, enabling the integration of a perovskite top cell in the p-i-n configuration; employing self-assembled monolayers (SAMs) as hole selective contacts for further reduction of non-radiative recombination losses, etc. With the latter, efficiencies of up to ~ 21 % were demonstrated for p-i-n perovskite single junctions [3].
In 3T tandems, one of the three contacts is shared by both subcells, allowing for the individual operation of both subcells in a monolithic device with a single substrate, thus combining the characteristic advantages of 2T and 4-terminal (4T) devices: high combined photogeneration currents as in state-of-the-art 2T tandems, and ideally independent electrical operation similar to 4T tandems, making the cell more robust against varying spectra. I will discuss our recent proof-of-concept study [4], demonstrating a 3T perovskite/silicon tandem cell by manufacturing an n-i-p perovskite top cell on an interdigitated back contact (IBC) silicon heterojunction solar cell. In our proof-of-concept device, the combined PCE of ~ 17% is still limited both optically and electrically, and it will be discussed how optimizations of the cell stack can bring this architecture to a

PCE level comparable to 2T tandems. Furthermore, I will demonstrate that the subcells can indeed be operated largely independently at their individual maximum power points, allowing to extract the maximum power output for varying spectral conditions similar to 4T cells. A minimized series resistance at the shared electron contact on the cell's rear side is identified as the crucial parameter for independent operation of the subcells, and I will discuss pathways to approach the simulated efficiency potential by an optimized device design.

Solution Processed Perovskite Subcell in Monolithic Perovskite/Si Tandem Solar Cells and Their Cost and Stability Concerns Qi Chen[1] and Huanping Zhou[2]; [1]Beijing institute of Technology, China; [2]Peking University, China

Among all commercialization routes for perovskite photovoltaics (PV), the perovskite/Si tandem is of particular interest as it capitalizes the mature silicon industry with decades of experience. Here we report low-temperature solution process for efficient two-terminal perovskite/Si tandem solar cells, wherein electrical and optical properties of the tunneling junction are carefully modulated. Moreover, we improve materials stability by introducing Eu^{2+}/Eu^{3+} "redox shuttle" to suppress the Pb^0/I^0 impurities which inevitably occurred during device operation. In addition, we carefully analyze the cost of tandem devices in terms of levelized cost of energy (LCOE) by adopting the "bottom-up cost model". It reveals perovskite PV exhibit low materials cost, which reduces the LCOE substantially in tandem devices. We conclude that further efforts are required to simultaneously improve the efficiency and lifetime of perovskite modules, which ultimately endows the competitiveness of perovskite tandem solar cells.

SESSION F.EL06.08: Poster Session: Contacting Materials and Interfaces for Optoelectronic Devices

Vacancy Defects Induced Changes in the Electronic and Optical Properties of NiO Studied by Spectroscopic Ellipsometry and First-Principles Calculations Kingsley O. Egbo[1], Chao Ping Liu[2], Chinedu E. Ekuma[3] and Kin Man Yu[1]; [1]City University of Hong Kong, Hong Kong; [2]Shantou University, China; [3]Lehigh University, United States

Native defects in semiconductors are known to play an important role in determining their optoelectronic properties. Nickel oxide (NiO) is one of the few wide gap oxide semiconductors broadly applied as the hole transport layer in many optoelectronic devices. NiO exhibits *p*-type conductivity and its conductivity is believed to be controlled by Ni vacancy acceptors. Herein, we present a systematic study comparing the optical and electronic properties of *p*-type oxygen-rich NiO with Ni vacancies (NiO:V_{Ni}) and insulating Ni-rich NiO with O vacancies (NiO:V_O) and stoichiometric NiO. The optical properties were obtained by spectroscopic ellipsometry while valence band spectra were probed by high-resolution X-ray photoelectron spectroscopy. The experimental results are directly compared to first-principles DFT + *U* calculations. The absorption spectra for the NiO:V_{Ni} sample show significant defect-induced features below 3.0 eV compared to NiO, and NiO:V_O samples. The increase in sub-gap absorptions in the NiO:V_{Ni} can be attributed to gap states observed in the electronic density of states. Computational results confirm that gap states in NiO:*V*o are predominantly Ni 3*d* states while those of NiO:V_{Ni} is composed of both the Ni 3*d* and O 2*p* states. This work reveals the relations between native vacancy defects and optical properties of NiO and provides insights that would aid in designing optoelectronic devices utilizing NiO with native defects.

Solvent Toolkit for Electrochemical Characterization of Hybrid Perovskite Films Jason D. Slinker[1], Alexander Zakhidov[2] and Sauraj Jha[1]; [1]The University of Texas at Dallas, United States; [2]Texas State University San Marcos, United

States

Organohalide lead (hybrid) perovskites have emerged as competitive semiconducting materials for photovoltaic devices due to their high performance and low cost. To further the understanding and optimization of these materials, solution-based methods for interrogating and modifying perovskite thin films are needed. In this work, we report a hydrofluoroether (HFE) solvent-based electrolyte for electrochemical processing and characterization of organic–inorganic trihalide lead perovskite thin films. Organic perovskite films are soluble in most of the polar organic solvents, and thus until now, they were not considered suitable for electrochemical processing. We have enabled electrochemical characterization and demonstrated a processing toolset for these materials utilizing highly fluorinated electrolytes based on a HFE solvent. Our results show that chemically orthogonal electrolytes based on HFE solvents do not dissolve organic perovskite films and thus allow electrochemical characterization of the electronic structure, investigation of charge transport properties, and potential electrochemical doping of the films with in situ diagnostic capabilities

F.EL06.08.04

Structural, Optical and Electrical Properties of NiO_x Thin Films Obtained by Various Techniques Jhonathan R. Castillo[1,2], Nicola R. Nedev[1], Benjamín Valdez[1] and Maria Bernechea[2,3,4]; [1]Institute of Engineering, Autonomous University of Baja California, Blvd. Benito Juárez s/n, Mexico; [2]Institute of Nanoscience of Aragon (INA), University of Zaragoza, Spain; [3]Instituto de Ciencia de Materiales de Aragón (ICMA-CISC), Spain; [4]ARAID, Spain

NiO_x is a transparent conductive oxide (TCO) that has attracted a lot of attention because of its electrical and optical properties. Most of the available TCOs are n-type semiconductors, while the development of efficient p-type TCOs remains a challenge. NiO_x is one of the promising p-type candidates, because of its superior chemical stability and optical transparency. Some potential optoelectronic applications of NiO_x are as a p-type channel in transparent thin film transistors (TFTs) and as a hole transport layer in perovskite solar cells. In this work thin NiO_x films were obtained by Pulsed Laser Deposition (PLD), d.c. sputtering, e-beam evaporation and sol-gel techniques.
All films were deposited on glass substrates with a size of 2×2 cm. The PLD films were deposited from a NiO target at room temperature. D.C sputtering and e-beam evaporation were used to deposit pure Ni films, which were then oxidized in air at various temperatures. The sol-gel NiO_x was obtained by depositing chemical precursors and subsequent thermal treatment. Various parameters were varied in the experiments and it was found that the structural, optical and electrical properties of the PLD films depend strongly on the oxygen pressure. The most important parameter for the other three types of oxides was the annealing temperature.
All samples were characterized by UV-Vis spectroscopy, X-ray diffraction, X-ray photoelectron spectroscopy, scanning electron microscopy and atomic force microscopy. Results for the properties of NiO_x films deposited by the above techniques will be presented and a discussion for their possible application in TFTs and solar cells will be given.

F.EL06.08.05

The Role of Post Synthetic Treatment and Ligand Population on Optoelectronic Properties of PbS Quantum Dot Films and Devices Fiaz Ahmed, Adam Roberge and Andrew B. Greytak; University of South Carolina, United States

Colloidal quantum dots (CQDs) are promising semiconducting materials to engineer photovoltaic and optoelectronic devices due to tunable size-dependent absorption and emission properties. Great efforts have been made to find suitable surface ligand to reduce spacing between the adjacent quantum dots to ease charge transport but there has been negligible attention given to purification strategies and systematic efforts to find the ideal ligand populations to optimize device performance. Charge transport could be hindered in the presence of excess free ligands forming interparticle barriers; on the contrary, an under-passivated QD can have high density of trap states and could also undermine the nanocrystal's stability toward coalescence. Precipitation and redissolution (PR) methods are widely used purification techniques that must typically be repeated to get clean CQDs with appropriate populations of surface-bound molecules (ligands). PR often results in loss of native ligands bound to the surface which induces more surface traps and/or compromise the chemical stability of these nanocrystals.
Gel permeation chromatography (GPC) has been proven to be an effective technique to remove the byproducts and impurities from CQDs without damaging the QDs surface. In this study, we demonstrate the effectiveness of GPC in removing byproducts and unbound ligands from pre and post ligand exchanged PbS CQDs.
NMR and UV-Vis-NIR spectroscopy of oleate-capped PbS quantum dots shows that despite removal of unbound surfactants, PbS QDs remain stable in solution following GPC. These purified nanocrystals were used to made CQDs photodetectors and photovoltaic devices.
We show that films fabricated using GPC purified PbS QD solutions exhibit higher charge transport, and low contact resistance, as investigated through in-plane conductivity and photoresponse. The charge carrier mobility was extracted from

the mobility lifetime product and recombination lifetime determined by the spatial profiles of the photocurrent obtained through scanning photocurrent microscopy (SPCM), and transient photocurrent measurements, respectively. Furthermore, our findings show that post synthetic purification and optimum ligand population can significantly improve physical characteristics including reduced surface roughness, suggesting that impurities and optimum ligand coverage play an important role in film morphology and device performance.

F.EL06.08.07

Revisiting *c*-type Screw Dislocations in GaN by First Principles—Implications on Nanopipes Formation Liverios Lymperakis, Su-Hyun Yoo and Jorg Neugebauer; Max-Planck-Institut für Eisenforschung GmbH, Germany

Dislocations in III-Nitrides constitute a long standing controversial topic. The lattice and thermal mismatch associated with the heteroepitaxy of GaN results in high dislocation densities in the order of 10^8 to 10^{10} cm^{-2}. Although III-Nitride optoelectronic devices can operate even at these high dislocation densities, recent investigations indicate that *c*-type screw dislocations may have a detrimental effect on the properties and reliability of high-power electronic as well as of optoelectronic devices: For example, the observed high reverse (forward) leakage current in electronic (optolectronic) devices is attributed to screw type dislocations [1]. Recently, it has been proposed that these defects are associated with open core structures, thus forming nanopipes with diameters of a few nms [2]. However, imaging screw dislocations at atomic resolution by electron microscopy to validate this model is not trivial. Moreover, first principles calculations that can accurately describe the energetics and atomic and electronic structure of these defects, have been restricted to MBE growth and/or did not explicitly consider the highly strained core region of these defects [3].

In the present study we combine density functional theory (DFT) with large scale empirical potential calculations within an Implicit Boundaries Mutliscale Scheme calculations [4] to investigate the energetics, atomic structure and electronic properties of *c*-type screw dislocations in GaN. We explicitly consider both closed and open core screw dislocations as well as more than 100 different core reconstructions. Based on these calculations we construct a *c*-type screw dislocation phase diagram which describes the energetically most favorable core structures as function of the Ga, N and H chemical potentials. Our calculations indicate, in agreement with previous DFT studies, that growth under typical MBE growth conditions, i.e. metal rich growth, that these defects stabilize a Ga filled core. Moreover, under N rich conditions the core is stoichiometric, though a column of Ga-N dimers is removed form the core. However, the energy of the free *m*-plane surfaces under MBE conditions cannot be compensated by the core and strain energy and hence nanopipe formation is highly unfavorable. In contrast, under typical MOCVD or MOVPE growth conditions the Ga and N dangling bonds at the open core inner surfaces are passivated by NH_x molecules and H atoms, respectively. This reduces considerably the surface energy under these conditions enabling the formation of nanopipes with hexagonal cross section and diameters ranging for ≈1 to ≈2 nm. Our calculations show that these nanopipes obey electron counting rule and hence are semiconducting. Nevertheless, they have important implications on the efficient diffusion and/or incorporation of impurities and/or dopants at the side facets and at the neighborhood of the open core, which will be discussed in detail. We will also discuss in detail the energetics and structure of superscrew dislocations and their implications on the diameter of the nanopipes as well as the potential implications of the nanopipes on the properties and the efficiency of the electronic devices.

F.EL06.08.08

The Role of Third Cation Doping on Phase Stability, Carrier Transport and Carrier Suppression in Amorphous Oxide Semiconductors Xingyu Wang[1], Austin Reed[2], Han Wook Song[3] and Sunghwan Lee[1]; [1]Purdue University, United States; [2]Baylor University, United States; [3]KRISS, Korea (the Republic of)

Transparent electronics and optoelectronics have been garnering increasing attention for use in high performance devices such as next generation displays, photovoltaics, electrochromic devices and sensors. Metal oxides are considered to be necessary components in these applications due to their excellent optical transparency ranging from visible to near infrared regime as well as pseudo-metallic electrical conductivity[1, 2]. These metal oxides have been implemented in devices,

depending on their electrical conductivity, as transparent electrodes by degenerately-doped oxides such as InSnO and doped ZnO; semiconducting active layers based on indium oxides, ZnO or SnO_2; and insulators (e.g., SiO_2, Al_2O_3, HfO_2) for dielectrics or encapsulations.

Thin film transistors (TFTs) are one of the key elements in displays as a pixel driving switch of which the required properties include high carrier mobility, low thermal budget processing, structural phase stability and reliable device performance in the presence of thermal and bias stress conditions. In recent years, amorphous oxide semiconductors based on indium oxides have been considerably investigated due to their promising carrier mobility, >5-25 cm^2/Vs, compared to conventional amorphous Si (<1 cm^2/Vs); low temperature processing; mechanical flexibility compared to the crystalline counterparts; and large area process-ability. Indium oxide-based binary and ternary cation material systems have shown tremendous promises for next generation displays since these materials meet the property and process needs that are described above. A binary cation material of indium zinc oxides (IZO) has been considered since the addition of Zn into In_2O_3 stabilizes the amorphous phase of In_2O_3 while the amorphous phase of undoped In_2O_3 is rapidly crystallized at very low homologous temperatures (T/T_m<0.19) at 150 °C [3, 4]. The reported carrier mobility of IZO is as high as 20-50 cm^2/Vs for both Hall and TFT field effect mobilities. A ternary cation system of InGaZnO (IGZO) [5, 6] has been more popular than binary systems since the addition of Ga in IGZO suppresses the channel carrier density in TFT application, which is preferred for TFT devices to obtain low device off-state current. Other third cation species such as Hf, Si and Zr were implemented. However, the carrier mobility of those ternary cation systems is significantly lower, 3-10 cm^2/Vs, which is 3-10 fold lower than that of In_2O_3 or IZO.

Therefore, securing strategies to develop a material system that maintains high carrier mobility (>20 cm^2/Vs) and suppresses carrier generation for TFT channel application is of significant importance, which is expected to expedite the realization of next-generation transparent displays exhibiting reliable performance, fast switching speed and, consequently ultra high definition resolution.

Here, we report on a ternary cation material system of InAlZnO (IAZO) where the optimized carrier mobility is as high as 25-45 cm^2/Vs. Further, the IAZO demonstrates an enhanced capability of stabilizing the amorphous phase during thermal stresses compared to InZnO. The effect of Al incorporation on the structural, electrical, optoelectronic and chemical properties of IAZO is systemically investigated and compared to those of IZO. The carrier transport behaviors (ionized impurity scattering; neutral scattering; charge screening) as well as the dominant mechanisms for carrier density and resistivity are discussed. The high mobility and greater phase stability may lead to high performance and sustainable device applications in next generation electronic and optoelectronic devices such as transparent displays.

Investigation of Optical Bleaching Effect in InN-Based Films Junjun Jia[1], Takashi Yagi[2], Taiki Ito[1] and Toshiki Makimoto[1]; [1]Waseda University, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan

Indium nitride (InN) was reported to have a large optical bleaching effect [1], which provides potential application as high-speed and high-frequency optical switches in the optical communications. Due to its narrow direct bandgap (~0.7 eV), the bandgap engineering with GaN allows the ternary InGaN system to cover a range of bandgap energies from the infrared of InN to the ultraviolent of GaN. Such wide bandgap tuning provides spectral flexibility for InGaN as optical switches. In order to materialize the potential of InGaN for optical device applications, we investigated the optical bleaching behavior and ultrafast carrier dynamics in epitaxial InN and InGaN films, and proposed a phenomenological model to explain the carrier relaxation behavior.

InN and InGaN films with the thickness of 300 nm were deposited on *c*-sapphire substrates by molecular beam epitaxy. The optical bleaching effect and ultrafast carrier dynamics in InN-based epitaxial films was investigated by using femtosecond time-resolved pump-probe transmittance/reflectance measurements with a photon energy of 1.50 eV, which is based on open-aperture Z-scan technique.

Both epitaxial InN and InGaN films show large optical bleaching effect from Z-scan measurements, where a nearly 3 times increase in transmittance was observed at 800 nm without the dependence of the film composition. The time-resolved pump-probe transmittance results indicate that hot carriers are relaxed within a time scale of subpicosecond. The carrier lifetime was found to be independent of the film composition and the fabrication condition. The maximum value in the transient transmittance shows a nonlinear increase with increasing the pump-beam power, which may be associated to a change in the nonlinear refractive index. The detailed mechanism on the carrier relaxation behavior will be given in the conference.

This work was supported by JSPS KAKENHI Grant-in-Aid for Scientific Research (C) (Grant No. 20K05368).

Atomistic Insight in The Band Tailing of Kesterite Solar Absorbers Wei Chen, Gian-Marco Rignanese and Geoffroy Hautier; Université catholique de Louvain, Belgium

The low open-circuit voltage V_{OC} of the earth-abundant kesterite $Cu_2ZnSnS(Se)_4$ (CZTSSe) solar absorbers is often associated with the large band tails, the origin of which has been tentatively assigned to the Cu-Zn disorder. Such an assignment has recently been questioned by some experiments. Here, by using the cluster expansion method and first-principles calculations, we investigate the role of cation disorder in the band tailing of CZTS. Our results show that the formation of local Cu-Cu-Cu-Sn tetrahedral motif as a result of the disorder is responsible for the band-gap narrowing, leading to a redshift of optical absorption onset by up to 0.2 eV. The Urbach energy, however, is hardly modified by the cation disorder, thereby excluding Cu-Zn disorder as a main source of the large band tails observed in stoichiometric CZTS. On the other hand, we find that extensive Cu-Zn disorder could stabilize the formation of point defects to a large extent. In particular, the defect concentration of Sn_{Cu} can be as high as 10^{12} cm^{-3} under typical Cu-poor growth conditions. The defect level is found at 0.2 eV above the VBM, suggesting that Sn_{Cu} could be a hole trap. Sn_{Zn} remains the predominant deep donor with defect levels near the midgap and hence is responsible for nonradiative recombination. We show that Sn antisites could be the main culprit of the low V_{OC} and the persistence of the two donors in the presence of cation disorder presents a major challenge towards a high-efficiency CZTS absorber.

Interface Engineering for Perovskite Solar Cells Based on Tin (IV) Oxide Nanostructures Zhuldyz Yelzhanova[1], Zhiwei Ren[1], Damir Aidarkhanov[1], Gaukhar Nigmetova[1], Bakhytzhan Baptayev[1], Mannix Balanay[1], Patrick W. K. Fong[2], Aleksandra Djurisic[3] and Annie Ng[1]; [1]Nazarbayev University, Kazakhstan; [2]Hong Kong Polytechnic University, Kazakhstan; [3]The University of Hong Kong, China

Tin(IV) oxide (SnO_2) is an n-type wide bandgap semiconductor, which is widely used as an electron transport layer (ETL) in organometal perovskite solar cells (PSCs) due to its promising properties such as high transmittance, high electron mobility, good photostability, good energy alignment and easy processing. In this work, SnO_2 nanostructures were synthesized by a solvothermal technique. The impacts of each growth parameter for the SnO_2 nanostructures were demonstrated. By investigating the relations among different growth conditions, optimized recipes were developed for SnO_2 nanostructured ETLs employing in PSCs. Furthermore, the interfaces between the FTO/ETL and ETL/perovskite are optimized in order to enhance the charge extraction efficiency of the devices. Detailed characterizations such as scanning electron microscopy, electrochemical impedance spectroscopy, atomic force microscopy spectroscopy, X-ray diffraction, *I-V* characteristics etc. have been performed on the SnO_2 ETL alone, material interfaces and the SnO_2 nanostructures-based PSCs. The obtained results provide a valuable insight into the community for preparing desired PSCs with nanostructured ETL.

Dual-Period Guided-Mode Resonance Filters for SWIR Multi-Spectral Image Sensors Md Ataul Mamun, Rezwan Mohammad Sayeed, Ümit Özgür and Vitaliy Avrutin; Virginia Commonwealth University, United States

Since their introduction in the early 1990s, subwavelength grating guided-mode resonance (GMR) filters have attracted considerable attention due to their simple and compact structures and versatile spectral characteristics. These outstanding features allow miniaturization of filters to pixel scale and high-density of integration for visible and short-wave infrared (SWIR) image sensors where a mosaic of transmission filters of different resonances can produce selective spectral signals to individual pixels of focal plane arrays. However, the conventional GMR-based transmission filter design, essentially unchanged for more than two decades, remains as a limiting factor for practical implementation of such an array of filters on

the same substrate. The conventional design based on a single-period grating necessarily involves a homogeneous layer (of subwavelength thickness) underneath a subwavelength grating of a dielectric material to achieve a narrow transmission peak and a wide stop-band. Maintaining the other spectral characteristics, the transmission peak can then be tuned to the desired wavelength by scaling all the dimensions including the grating and homogeneous layer heights. However, to integrate different filters into a compact mosaic, this conventional design requires either different substrates of corresponding thicknesses or a very complicated non-planar fabrication process to use a single wafer leading to low throughput. In this work, we demonstrate a dual-period design to eliminate this issue by fetching additional design flexibilities. First, the dual-period filters possess two fill-fractions and thus unlike their single-period counterparts allow more degrees of freedom to vary the lateral profile parameters (e.g., fill-fractions and periods) for producing desired resonances at different wavelengths as well as to tune a resonance while keeping the grating height constant. Second, to produce a narrow passband with a wide stopband, these filters, unlike the single-period counterparts, do not require a homogeneous layer, allowing a planar fabrication process for integration of different filters on the same substrate. Moreover, dual-period filters show less sensitivity to the fabrication deviations such as sidewall roughness and to those related to grating and/or homogeneous layer heights where the latter, especially, remains as another limiting problem for the conventional narrow passband single-period based filters. For example, a small variation in grating and/or homogeneous layer thickness (while other parameters remain constant) causes the resonance peaks to disappear or be suppressed significantly and thus the fabrication requires very high precision. In this work, we report dual-period GMR filters of dimensions smaller than on silicon-on-quartz (SOQ) wafers using conventional electron beam lithography (EBL) and reactive ion etching (RIE). The filters demonstrate efficiencies as high as 80% at the peak transmission wavelength, e.g. 1550 nm. The passbands are as small as 15 nm with over 350-nm-wide stopband. The spectra of the fabricated filters are in a good agreement with the results of simulations using the finite element method (FEM) in COMSOL Multiphysics® software. Tunability of narrow passband resonances has also been achieved by only varying the fill-factors and/or period while keeping the substrate thickness constant. An array of four filters (all based on dual-period) have been demonstrated on same substrate to generate well-separated passbands in the SWIR region (1.2-1.6 μm) to work as a pixel. While smaller filter size would allow integration into compact chips, filters should be sufficiently spaced to eliminate the potential cross-talk. In order to produce an optimum pixel size to work in the concerned SWIR region, any potential cross-talk along with filter size effects are also analyzed theoretically and experimentally.

High Power Generation of Double-Junction III-V Solar Cells by Strategically Designed Luminescent Waveguides Shin Hyung Lee, Mun-Jong Kim and Sung-Min Lee; Kookmin University, Korea (the Republic of)

III-V compound solar cells have been considered as the leading photovoltaic devices due to their superior properties including the high carrier mobility, direct bandgap, and controllable bandgap against the solar spectrum. The extremely high solar-to-electric power conversion efficiency can be achieved with III-V solar cells by forming monolithic multi-junction structures through series processes of the epitaxial growth. Nevertheless, their prohibitively high materials and process (i.e. epitaxial growth) cost has limited the application to terrestrial photovoltaic systems. To reduce the cost per watts of III-V solar cells, several approaches have been suggested, such as transfer-printing-assisted assembly for re-using the expensive III-V substrate and solar light concentrator for boosting the power generation in a given cell area. A format of III-V solar cell arrays transfer-printed within the luminescent solar concentrator (LSC) has been particularly of interest due to the potential to mitigate the materials cost and simultaneously to augment the power generation. In spite of the successful demonstration with single-junction (e.g. GaAs) solar cells, the effect of power generation improvement by the LSC system cannot be simply achieved with multi-junction solar cells, because the balanced enhancement of photon absorption at each subcell is required for increasing overall photocurrent of series-connected multi-junction cells. In this regard, here we present a facile route to integrate the transfer-printed multi-junction III-V solar cells with the LSC medium for significantly raising their power generation. Monolithically grown indium gallium phosphide (InGaP)/gallium arsenide (GaAs) double-junction solar cells are completed implanted into a LSC printing medium by the transfer-printing-based fabrication assembly, where luminescent quantum dots (QDs) with the 610 nm emission wavelength are non-uniformly distributed in the LSC. Since the short-circuit current of InGaP/GaAs double-junction cells is limited by a level of photocurrent produced at the InGaP subcell, the LSC is designed for the emitted 610 nm photons of QDs to be preferentially guided into the InGaP subcell. At the optimal LSC configuration, the power generation of 26%-efficient InGaP/GaAs solar cells can be considerably improved by ~50% compared to the identical cells but without add of the LSC.

F.EL06.08.14
Selective Contacts Using Dipole Amino Acid Layers Eloi Ros Costals, Gerard Masmitjà, Estefania Almache, Benjamin Pusay, Gema Lopez, Kunai Tiwari, Edgardo Saucedo, Pablo Ortega, Isidro Martin, Cristobal Voz and Joaquim Puigdollers; Universitat Politècnica de Catalunya, Spain

There has been a recent trend to use molecular dipole layers as a part of a novel strategy to fabricate selective contacts. Conceptually, a thin film of oriented molecular dipoles mimics a 2D capacitor, and the build-in voltage within the layer affects the final contact equilibrium state. When the dipoles are oriented in a certain direction one achieves larger accumulation of either holes or electrons by modifying the workfunction of the metal. Amongst many of the dipols used amino acids have particularly interesiting properties, for instance easy deposition by PVD methods such as spincoating and thermal evaporation and strong molecular dipole moment due to the presence within the molecule of a negatively charged carboxylic group and a positively charged amino group.
We tested the effect on the contact resistance of a Silicon/dipole/Aluminium stack using Transfer Length Method and testing different amino acids as the dipole layers (e.g. Cysteine, Glycine, Histidine...).
Preliminary results show an enhanced contact resistivity of orders of magnitude when dipoles are used on both p and n type silicon wafers, circumventing the problematic Fermi level pinning in Silicon aluminium as deposited contacts.
Finally, experiments on Histidine using different passivating layers show a clear difference in contact resistance with the change of the substrate dopant. Probably indicating that macroscopic orientation of the dipole layer can be promoted when using proper seed layers.

Nucleation Site Tailoring at the 2D/3D Interface Using He-Ion Beam Patterning Vera A. Zarubin, Kate Reidy, Joachim D. Thomsen, Julian Klein and Frances M. Ross; Massachusetts Institute of Technology, United States

For many of their applications, 2D materials must be connected to the macroscale world, implying interfaces between the 2D atomic layer and a 3D bulk material. The structure and defects at the interface between a 2D material and a 3D thin film influence (opto-)electronic properties of nanoscale devices such as contact resistance, photo-response and high frequency performance [1]. If the interface is between a 2D material and a 3D nanostructure, the ability to control the nanostructure geometry and lateral positioning is important in enabling nano-optoelectronic applications such as plasmonic arrays or arrays of wires or lines in individual circuits interfaced with 2D materials. When 3D nanoislands are grown on conventional, bulk substrates, “directed self-assembly” is a useful approach where growth takes place spontaneously but is favored at particular nucleation sites. The control of nucleation sites involves control of surface topography, geometry and local interactions [2]. Here we focus on extending this approach to the case of 3D nanoislands on 2D surfaces. We create specific defect locations on 2D materials (graphene, MoS2, WSe2) that act as heterogeneous nucleation sites for 3D metals (Au, Ti), and we tune the 3D metal deposition conditions to produce specific island shapes by self-assembly.

Since directed self-assembly requires avoidance of extraneous nucleation, as well as reliable nucleation at the patterned sites, we first discuss the control of metal island nucleation on unpatterned 2D materials. In particular, the nucleation density is expected to depend on the adatom diffusion distance on the 2D material surface. On 2D materials in the form of suspended layers, we use post-growth imaging by transmission electron microscopy (TEM) to measure the shape and distance between metal islands deposited in an ultra-high vacuum (UHV) evaporation system. We find that nucleation density and island shape depend on factors such as the substrate temperature, topography, background pressure, time, and partial pressure of the deposited material. We achieve the largest island diffusion distance (>2 μm) by removing polymeric residues in the 2D material transfer process, suspending the 2D material samples on TEM grids, using medium (100-200 ºC) temperature deposition, and minimising defect sites such as wrinkles. We next induce locally reduced adatom diffusion distances using He-Ion beam patterning to create periodic defects in the 2D material. The He-Ion dose rates are calibrated and resulting defects characterised using high resolution scanning transmission electron microscopy. We show that these defects act as heterogeneous sites and we discuss the extent to which they can be exploited to produce patterned, periodic Au nanoisland arrays. We develop automated image analysis techniques and perform statistical analysis of the nucleation site density and location. We believe that this templating and nucleation control opens routes towards self-assembled and tailored interface design. In particular, we discuss the possibilities of interface structures built from self-assembled 3D nanostructures for development of plasmonic nanoarrays with tunable and well-defined resonance frequencies.

Late News: Correlation of Nano-Morphology with Structural and Spectroscopic Studies in Organic Solar Cells Urvashi Bothra[1,2], Chris McNeill[2] and Dinesh Kabra[1]; [1]IIT Bombay, India; [2]Monash University, Australia

The nano-morphology of bulk heterojunction (BHJ) blends based on poly[[4,8-bis[(2-ethylhexyl)oxy]benzo[1,2-b:4,5-b']dithiophene-2,6-diyl][3-fluoro-2-[(2-ethylhexyl)carbonyl]thieno[3,4-b]thiophenediyl]] (PTB7) blended with [6,6]-phenyl-C_{71}-butyric acid methyl ester ($PC_{71}BM$) is systematically varied by changing the volume fraction of the solvent additive 1,8-diiodooctane (DIO) from 0 vol% to 20 vol% in the casting solution to prepare organic solar cells (OSCs). With increasing addition of DIO, the photoluminescence (PL) from the blend is reduced; however, a relative increase in PL from 750 nm onwards is observed for blends with 20 vol% DIO. As quenching of the blend PL is related to the donor/acceptor (D/A) interface, structural characterizations in real-space (microscopy) and *k*-space (scattering) are performed to unravel the morphology of blend systems to correlate nano-morphology with photophysical and charge transport processes. Blends prepared with 0 vol% DIO form large phase separated domains of $PC_{71}BM$, hundreds of nanometer in diameter. With the addition of 3 vol% DIO the size of $PC_{71}BM$ domains is supressed resulting in a more mixed morphology due to the selective dissolution of DIO in $PC_{71}BM$. On the addition of up to 20 vol% of DIO, the film becomes rougher with a finer interconnected morphology due to polymer aggregation, which contrasts with previous reports. Electron-transport length scales measured by scanning photocurrent microscopy (SPM) are found to increase with the addition of up to 3 vol% DIO associated with the break-up of the large $PC_{71}BM$ aggregates, while the hole-transport length is found to increase on adding DIO up to 20 vol% due to aggregation of polymer chains. Finite-difference time-domain (FDTD) simulations are performed to take into account for optical beam spread due to associated roughness of BHJ blend films which further strengthen the experimental findings to take into account for waveguiding/scattering components of excitation beam.The structural results are found to be in good agreement with the PL quenching and the effective transport lengths. Hence, this work represents a complete set of results systematically examining the effect of nanomorphology on structural and opto-electronic properties of BHJ blends, which can have a direct implication on better understanding of the emerging high efficiency OSC blend systems.

Late News: Low Interfacial Thermal Resistance for BeO-on-Diamond Kiumars Aryana[1], Yoonseo Jang[2], David Olson[1], John Gaskins[1], Dohwan Jung[2], Jung H. Yum[3], Eric S. Larsen[4], Christopher W. Bielawski[3,4,5], Sean King[6], Jungwoo Oh[2] and Patrick Hopkins[1,1,1]; [1]University of Virginia, United States; [2]Yonsei University, Korea (the Republic of); [3]Institute for Basic Science (IBS), Korea (the Republic of); [4]Ulsan National Institute of Science and Technology, Korea (the Republic of); [5]Ulsan National Institute of Science and Technology (UNIST), Korea (the Republic of); [6]Intel Corporation, United States

Diamond, by far, is the most thermally conductive material at room temperature and a great candidate for thermal management applications in microelectronic devices. Yet, its application has been discouragingly hindered due to its large thermal barrier at the interface when paired with other CMOS materials. Beryllium oxide (BeO) is a potential material candidate to bridge this thermal barrier between diamond and other wide bandgap semiconductors such as gallium nitride (GaN) and Silicon carbide (SiC) owing to its large bandgap, high thermal conductivity, and large spectral phonon overlap with diamond. In this study, using time-domain thermoreflectance we report the thermal conductivity and interfacial thermal resistance at BeO/diamond and Beo/Si interface across various temperatures. We measure the thermal conductivity of amorphous BeO for thicknesses below 30 nm to be ~10 +- 0.7 W/mK, which is significantly lower than its bulk crystalline value. Our results suggest that the interfacial thermal resistance at BeO/diamond interface is significantly lower than that of GaN/diamond and BeO/Si. This observation paves the way towards more thermally efficient integrated circuits.

Late News: The High Near-Infrared Transparency of Silver Nanowire Transparent Electrodes Jon Atkinson and Irene Goldthorpe; University of Waterloo, Canada

Transparent electrodes are a necessary component of many optoelectronic devices. Networks of silver nanowires have emerged as a promising alternative to commonly-used metal oxides such as indium tin oxide (ITO). Their transparency and conductivity values are as high as ITO, while being mechanically flexible, less expensive and can be fabricated using high-throughput roll-to-roll methods. In this talk I will outline an additional advantage that has thus far received less attention: the high transparency of silver nanowire networks in the near-infrared region (NIR). This property is highly desirable for some applications such as window coatings and solar cells. I will show that for electrodes that are 96% transparent in the visible, ones made from ITO are only 35% transparent at a wavelength of 2500 nm, whereas those made from silver nanowires maintain a transparency as a high as 94%. I will present results that show that the nanowires in the network should be sparse

and larger in diameter to maximize NIR transparency. Modelling of the nanowire networks will also be shown and help demonstrate the physical reasons this is the case.
At the end of my talk I will present my results on passivating silver nanowire electrodes for capacitive-type devices such as smart windows and displays. To fully realize the advantages of silver nanowire electrodes, candidate passivation materials must be optically transparent (including in the NIR range), inexpensive, mechanically flexible and simple to deposit using high-throughput methods. I will present our findings of the passivation effectiveness of polyurethane, PMMA, a commercial optical adhesive and cyclotene passivation layers on silver nanowire networks.

F.EL06.08.19
Late News: Reduced Non-Radiative Losses via Charge Selectivity Enhancement by Using a Fullerenic Anodic Interlayer in Organic Photovoltaics Donato Spoltore[1], Manasi Pranav Ram[1], Johannes Benduhn[1], Mathias Nyman[2], Jonas Kublitski[1] and Karl Leo[1]; [1]TU Dresden, Germany; [2]Abo Akademi, Finland

Charge transport layers play a fundamental role for efficient charge carrier injection and extraction in opto-electronic devices. Using interfacial layers, the open circuit voltage (V_{OC}) and fill factor (FF) of organic solar cells can improve significantly. Here we show experimentally that the extent of contact between a Molybdenum Oxide (MoO_3) hole extraction layer and the donor molecules in the photoactive layer of organic solar cells causes a proportional increase in non-radiative recombination losses. We quantify this effect by using several planar and bulk heterojunction solar cells device architectures, assigning it to surface recombination. We demonstrate that such losses can be suppressed by inserting a thin fullerenic anodic interlayer. This interfacial layer enhances the built-in potential and reduces the presence of minority charge carriers at the electrodes: a new perspective on the principle of selective charge extraction layers. The improvement to device efficiency is limited by a critical interlayer thickness, which depends on the donor material in bilayer devices. These findings are relevant to different branches of organic electronics, given the popularity of MoO_3 as an efficient hole extraction and injection layer, providing insights for future device design.

8:00 AM WELCOME AND INTRODUCTION

8:10 AM *F.EL07.01.07
Doping of Organic and Inorganic Semiconductors—A Novel Dopant and the Impact of the Dielectric Environment Norbert Koch[1,2]; [1]Humboldt-Universität zu Berlin, Germany; [2]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

Controlled doping of semiconductors is crucial for the functionality and efficiency of modern (opto-) electronic devices. For organic semiconductors, the use of strong molecular electron donors and acceptors is meanwhile established as viable approach for doping. However, diffusion and poor thermal stability of most presently used dopants poses a challenge in applications. It turns out that the salt of the mesitylene-borinium cation (Mes_2B^+) and tetrakis(penta-fluorophenyl)borate anion $[B(C_6F_5)_4]^-$ is a superior p-type dopant for polymer semiconductors, and doping occurs *via* a charge-exchange reaction. Remarkably, the $[B(C_6F_5)_4]^-$ anion enables the stabilization of polarons *and* bipolarons in poly(3-hexylthiophene), and the effective electron affinity of $Mes_2B^+[B(C_6F_5)_4]^-$ is estimated to be 5.9 eV. The comparably high molecular weight and bulkiness of $[B(C_6F_5)_4]^-$ is expected to reduce diffusion, and no negative impact on doped polymer conductivity is observed up to 100 °C.
Notably, many of the molecular dopants used for organic semiconductors can also be employed for doping of transition metal dichalcogenides (TMDCs). When thinned to the monolayer, many are direct semiconductors, e.g., MoS_2 and WS_2, with superior optical properties. Due to the pronounced excitonic nature of TMDCs, their exciton energy and band gap depend strongly on the dielectric constant (ε) of the mechanical support used for the monolayer. Moreover, the electrical nature of the substrate plays a critical role for the mechanism by which doping with molecules occurs. Three fundamentally different charge transfer mechanisms between MoS_2 and molecular dopants have been identified and will be discussed.
Finally, the impact of residual water in conductive polymer films on their work function will receive attention. The high ε of water reduces the polymer's work function by screening of local charge transfer induced dipoles, and the work function varies with temperature as does ε of water. This effect should thus be considered when device characterization includes temperature variation.

8:35 AM *F.EL07.01.05
Chemistry of Dimeric and Hydride-Donor n-Dopants for Organic Electronics Stephen Barlow; Georgia Institute of Technology, United States

Molecular n-dopants can play useful roles in controlling conductivity and charge injection/extraction in organic semiconductors, in lowering the work functions (WFs) of electrode materials, and in controlling the properties of low-dimensional materials such as graphene. However, even molecules that can n-dope C_{60}, which has a fairly high electron affinity of ca. 4.0 eV, through simple one-electron transfer are inevitably sensitive to air and water, while stronger one-electron reductants are even more sensitive. Coupling bond breaking and/or formation to electron transfer provides a way of circumventing this issue. One such approach is based on the dimers, D_2, formed by certain odd-electron species, D, formed on alkali-metal reduction of the corresponding cations, D^+. Another class of relatively stable n-dopant molecules, DH, can be formally regarded as hydride-reduced derivatives of D^+ cations. We have synthesized a range of both organic and organometallic D_2 and DH derivatives, in particular, derivatives of 2-substituted-1,3-dimethylbenzimidazolium cations (Y-$DMBI^+$) , and of 18-electron cationic sandwich compounds such as 1,2,3,4,5-pentamethylrhodocenium and ruthenium pentamethylcyclopentadienyl mesitylene cations. This talk will describe the diversity of structures and reactivity that we have obtained, and will compare the advantages and disadvantages of the organic and organometallic dopants, and of the D_2 and DH approaches, from the point of view of synthesis, stability, dopant strength, kinetics, dopant ion size and shape, and the extent to which these properties can be tuned.

9:00 AM *F.EL07.02.12
Coulomb Interaction in Organic Semiconductor Blends Karl Leo; TU Dresden, Germany

Organic semiconductors systems offer many new exciting device applications with attractive features such as flexibility, low cost, low-temperature processing etc. One key difference to inorganic semiconductors is the usually quite small dielectric constant of organics, leading to much stronger Coulomb interactions. For instance, the exciton binding energy in organic semiconductors is significantly greater than the room temperature thermal energy, thus having profound influence on the optical properties. In this talk, I will discuss the influence of these strong Coulomb interactions on two phenomena, both related to blends of organic materials: First, I will discuss controlled electrical doping where the strong Coulomb interaction might be a curse and should, at least in simple hydrogen-like model, make efficient doping unlikely. I will discuss recent results which clarify that doping is indeed efficient, mainly because of disorder effects. Second, I will discuss how the Coulomb interaction can be a blessing by using it for “band structure engineering” of organic semiconductors: Long range Coulomb interactions allow to continuously tune the energy levels, allowing finely adjustable energy levels without synthesis of new molecules. The electrostatic nature of these phenomena is directly proven by experiments which show the strong influence of these quadrupole effects at interfaces. Finally, I will discuss recent results which show that the energy gap of organic semiconductors can be tuned in a similar way.

9:25 AM *F.EL07.02.07
Enlightening Polymer Electronic Devices Paolo Samori; University of Strasbourg, France

The development of multifunctional devices capable to respond to multiple and independent stimuli is one among the grand challenges in organic electronics. The combination of multiple components, with each one conferring a specific function to the ensemble, is a facile strategy to impart a multifunctional nature to electronic devices. The controlled combination of such components and their integration in real devices can be achieved by mastering the supramolecular approach.
In my lecture I will review our recent works on the combination of carbon-based nanomaterials, in particular comprising organic semiconductors, with photochromic molecules (diarylethenes or azobenzenes) in order to fabricate smart, high-performing and light-sensitive (opto)electronic devices such as field-effect transistors and light-emitting transistors and as well as flexible non-volatile optical memory thin-film transistor device with over 256 distinct levels.

Coherent Photoexcited Dynamics and Intermolecular Conical Intersections Sergei Tretiak; Los Alamos National Laboratory, United States

In this talk, I will overview some applications of Non-adiabatic EXcited-state Molecular Dynamics (NEXMD) framework recently developed at LANL. The NEXMD code is able to simulate tens of picoseconds photoinduced dynamics in large molecular systems with hundreds of atoms in size and dense manifold of interacting and crossing excited states. In particular, I will exemplify ultrafast excitonic dynamics guided by intermolecular conical intersections (CoIns). Both simulations and time-resolved two-dimensional electronic spectroscopy track the coherent motion of a vibronic wave packet passing through CoIns within 40 fs, a process that governs the ultrafast energy transfer dynamics in molecular aggregates. Our results suggest that intermolecular CoIns may effectively steer energy pathways in functional nanostructures. Observed relationships between spatial extent/properties of electronic wavefunctions and resulting electronic functionalities allow us to understand and potentially manipulate excited state dynamics and energy transfer pathways toward optoelectronic applications.

Emissive and Charge-Generating Donor–Acceptor Interfaces for Organic Optoelectronics with Low Voltage Losses Koen Vandewal; Hasselt University, Belgium

Charge transfer (CT) states at the interface between electron-donating (D) and electron-accepting (A) materials in organic thin films are characterized by absorption and emission bands within the optical gap of the interfacing materials. Depending on the used donor and acceptor materials, CT states can be very emissive, or generate free carriers at high yield. The former can result in rather efficient organic light emitting diodes, via thermally activated delayed fluorescence, while the latter property is exploited in organic photovoltaic (OPV) devices. In this talk, I will show that proper control of CT state properties allows simultaneous occurrence of a high photovoltaic and emission quantum yield within a single, visible-light-emitting D–A system. This leads to ultralow-emission turn-on voltages as well as significantly reduced voltage losses upon solar illumination.

12:25 PM *F.EL07.04.10
Understanding and Minimizing Voltage Losses in High-Efficiency Organic Solar Cells Feng Gao; Linkoping University, Sweden

Compared with inorganic or perovskite photovoltaics, the key limiting factor for organic solar cells (OSCs) is large voltage loss, which is usually over 0.7 V. A significant contribution of the large voltage loss in OSCs is due to strong non-radiative recombination, the origin of which has been puzzling the community for a long time, limiting rational design of materials to overcome this critical issue. We systematically investigate a range of low voltage loss systems, where the voltage loss is around or below 0.6 V. We find that the quantum efficiency of electroluminescence in these systems have been significantly increased, leading to decreased non-radiative voltage losses below 0.20 V. Combining spectroscopic and quantum chemistry approaches, we formulate the key rules for minimizing voltage losses: (i) low energy offset between donor and acceptor molecular states, and (ii) high photoluminescence yield of the low-gap material in the blend. We further demonstrate that there is no intrinsic limit for efficient charge separation in OSCs with small voltage losses.

Doping of Organic Systems Explored with the Embedded Many-Body GW and Bethe-Salpeter Formalisms Xavier Blase[1], Ivan Duchemin[2], Jing Li[1,3], David Beljonne[4] and Gabriele D'Avino[1]; [1]Institut Néel, CNRS, Grenoble, France; [2]CEA-IRIG-L_SIM, France; [3]CEA-LETI, France; [4]Laboratory for Chemistry of Novel Materials, Belgium

We study the electronic properties of dopants in organic systems on the basis of state-of-the-art many-body GW and Bethe-Salpeter formalisms accounting for proper electrostatic and dielectric environments. [1,2] We show in particular that the absolute energy position of doping levels and band edges of organic semiconductors can be obtained with accuracy both in the bulk and at the surface. Our calculations reveal in particular that the energy levels of a molecular impurity strongly depend on the host environment as a result not only of the proper environment dielectric properties, but crucially as well on electrostatic intermolecular interactions. [3] Concerning doping mechanisms, we demonstrate that ionisation of the dopants can occur even in situations of very deep acceptor (donor) levels thanks to strong electron-hole Coulomb interactions stabilizing charge-transfer states. [4] The increase of conductivity requires from then on to understand the charge separation of these bound electron-hole pairs in order to generate free carriers. An initial blessing, Coulomb interactions turn into a curse that needs to be overcome.

5:15 AM F.EL07.01.02

An Organic Borate Salt with Superior *p*-Doping Capability for Polymer Semiconductors Berthold Wegner[1,2], Dominique Lungwitz[1], Ahmed E. Mansour[1,2], Claudia Tait[3], Naoki Tanaka[4], Tianshu Zhai[5], Steffen Duhm[5], Michael Forster[6], Jan Behrends[3], Yoshiaki Shoji[4], Andreas Opitz[1], Ullrich Scherf[6], Emil List-Kratochvil[1], Takanori Fukushima[4] and Norbert Koch[1,2,5]; [1]Humboldt-Universität zu Berlin, Germany; [2]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [3]Freie Universität Berlin, Germany; [4]Tokyo Institute of Technology, Japan; [5]Soochow University, China; [6]Bergische Universität Wuppertal, Germany

Molecular doping is of central technological relevance for organic (opto-) electronics since it allows enhancement and precise control of electrical properties of organic semiconductors. Nevertheless, it is currently challenging to efficiently p-dope host materials with ionization energies (IEs) higher than 5.5 eV.

Here, we demonstrate the unique potential of an organic salt consisting of a borinium cation (Mes_2B^+; Mes - mesitylene) and the tetrakis(penta-fluorophenyl)borate anion $[B(C_6F_5)_4]^-$ as p-type dopant for high ionization energy polymer semiconductors, i.e., methylated poly(para-phenylene) (MeLPPP, IE≈5.4 eV) and the donor-acceptor polymer poly(9,9-dioctylfluorene-alt-benzothiadiazole) (F8BT, IE≈5.9 eV). Optical absorption spectroscopy, ultraviolet photoelectron spectroscopy (UPS), X-ray photoelectron spectroscopy (XPS), and conductivity measurements were performed in order to verify successful p-type doping. This range of experimental methods allows to identify the doping mechanism, namely electron transfer from the polymer to Mes_2B^+ combined with stabilization of the positive charge on the polymer chain by $[B(C_6F_5)_4]^-$. From doping studies with further polymer semiconductors, we estimate the EA of $Mes_2B^+[B(C_6F_5)_4]^-$ to amount to an impressive 5.9 eV. Especially, our studies on $Mes_2B^+[B(C_6F_5)_4]^-$-doped poly(3-hexylthiophene) (P3HT) demonstrate the capability of the organic salt to form bipolarons with a high proportion beyond ca. 10% dopant concentration [1]. Thus, the parameter space for doping of polymer semiconductors is significantly extended.

5:25 AM F.EL07.01.03
Electrical Conductivity of Doped Organic Semiconductors Limited by Coulomb Carrier-Carrier Interactions Marten Koopmans[1], Miina A. Leiviskä[1], Jian Liu[1], Jingjin Dong[1], Sylvia Rousseva[1,1], Jan C. Hummelen[1,1], Giuseppe Portale[1], Michael C. Heiber[2] and Lambert Jan Anton Koster[1]; [1]University of Groningen, Netherlands; [2]Northwestern University, United States

High electrical conductivity is a prerequisite for advancing the performance of organic semiconductors for various applications and can be achieved through molecular doping. However, it is often observed that the conductivity is enhanced only up to a certain optimum doping concentration, beyond which it decreases significantly. This is typically attributed to morphological changes upon increasing dopant loading.

Here we address and elucidate the effect of morphology, dopant-carrier interactions, and carrier-carrier interactions on the conductivity of doped organic semiconductors. We first show that the conductivity increases, maximizes and then decreases with increasing doping density for a molecularly doped fullerene derivative. We use grazing-incidence wide-angle X-ray scattering (GIWAXS) measurements to investigate the microstructural changes upon doping and find that even though the conductivity decreases at high doping density, the microstructure does not deteriorate. In other words, the loss of electrical conductivity in this system cannot be explained by changes to the microstructure.
We combine analytical work and Monte-Carlo simulations to demonstrate that repulsive Coulomb interactions between charge carriers can cause this decrease in conductivity. We use Efros-Shklovskii theory on carrier-carrier interactions to predict the carrier density at which the maximum of conductivity occurs.[1] Next, we show kinetic Monte-Carlo simulations exhibiting a maximum in conductivity at a charge carrier density that corresponds to that observed experimentally. The maximum is observed both in the presence and absence of dopants. Overall, we show that carrier-carrier interactions lower the conductivity by orders of magnitude at high doping densities and therefore propose the suppression of carrier-carrier interactions as a key strategy in order to create higher conductivity organic semiconductors.

5:35 AM *F.EL07.01.04
Charge Transport Through Redox and Magnetically Active Molecules Jaume Veciana; ICMAB (CSIC)/CIBER-BBN, Spain

Open-shell organic molecules, like free radicals and radical-cations, exhibit magnetic and optical properties due to the presence of an unpaired electron in a Single Occupied Molecular Orbital (SOMO) with an accessible Single Unoccupied Molecular Orbital (SUMO). This characteristics together with their low spin-orbit couplings and weak hyperfine interactions make them good candidates for molecular spintronics insofar the radical character is preserved in solid state and the molecules are properly arranged on a solid state device. To achieve these properties we used functionalized substituted polychlorinated triphenylmethyl (PTM) radicals attached, as self-assembled monolayers (SAMs), on metallic surfaces, like Au, Ag, Cu, or graphene, exploring the transport properties through such spin-containing organic hybrid systems. [1] In all studied metal-organic systems the conductance through the radical molecules is enhanced two orders of magnitude with respect the corresponding non-radical ones, a result that can be explained by a mediated electron transport through the SUMO orbitals in the open-shell systems. [2-3] These results paves the way towards the use of all-organic neutral radical molecules in spintronics.
In this contribution the use of such radical molecules to attain metallic surfaces with rectifying properties [4,5] as well as to manipulate the electronic properties of metallic surfaces, like the work function, will be presented. Remarkable is the possibility to switch reversibly the work function of the metallic surfaces using an external input like NIR light. [6]
Also molecular junctions based on self-assembled monolayers with a strong donor molecule, like benzotetrathiafulvalene (BTTF), linked to Au, Ag, and Pt surfaces have been prepared and fully characterized exhibiting rectifying properties. Interestingly these solid-state molecular tunnel junctions show a switching of the direction of rectification by controlling the direction of charge transfer between the BTTF redox unit and the bottom-electrode that depend on the nature of the metallic surfaces. [7]

Chemistry of Dimeric and Hydride-Donor n-Dopants for Organic Electronics Stephen Barlow; Georgia Institute of Technology, United States

Molecular n-dopants can play useful roles in controlling conductivity and charge injection/extraction in organic semiconductors, in lowering the work functions (WFs) of electrode materials, and in controlling the properties of low-dimensional materials such as graphene. However, even molecules that can n-dope C_{60}, which has a fairly high electron affinity of ca. 4.0 eV, through simple one-electron transfer are inevitably sensitive to air and water, while stronger one-electron reductants are even more sensitive. Coupling bond breaking and/or formation to electron transfer provides a way of circumventing this issue. One such approach is based on the dimers, D_2, formed by certain odd-electron species, D, formed on alkali-metal reduction of the corresponding cations, D^+. Another class of relatively stable n-dopant molecules, DH, can be formally regarded as hydride-reduced derivatives of D^+ cations. We have synthesized a range of both organic and organometallic D_2 and DH derivatives, in particular, derivatives of 2-substituted-1,3-dimethylbenzimidazolium cations (Y-DMBI$^+$) , and of 18-electron cationic sandwich compounds such as 1,2,3,4,5-pentamethylrhodocenium and ruthenium pentamethylcyclopentadienyl mesitylene cations. This talk will describe the diversity of structures and reactivity that we have obtained, and will compare the advantages and disadvantages of the organic and organometallic dopants, and of the D_2 and DH approaches, from the point of view of synthesis, stability, dopant strength, kinetics, dopant ion size and shape, and the extent to which these properties can be tuned.

6:05 AM F.EL07.01.06
Fingerprints of Strong Coulomb Interactions and Disorder in Doped Organic Semiconductors Artem Fediai[1], Jonas Armleder[1], Franz Symalla[2], Anne Emering[1], Timo Strunk[2], Tobias Neumann[2] and Wolfgang Wenzel[1]; [1]Karlsruhe Institute of Technology, Germany; [2]Nanomatch GmbH, Germany

Doping is a key technology in both organic and inorganic electronics, allowing to control the type and the magnitude of the conductivity over many orders of magnitude. In organic electronics, it is primarily used to reduce injection barriers and voltage drop on the electron/hole transporting layers of organic light-emitting diodes (OLEDs). Doped organic semiconductors, comprising a lot of charged molecules, represent an ideal laboratory for both theoretical and experimental studies on strong Coulomb interactions.
In this talk, I will present several effects, which appear in the doped organic semiconductors due to the cooperative effect of strong Coulomb interactions and energetic disorder: appearance of doping-induced gap states, disorder-driven doping activation [Fediai et al, PCCP, 22, 10256-10264 (2020)] and the superlinear increase of electric conductivity due to the disorder-compensation effect [Fediai et al. Nature Comm. 10, 4547 (2019)]. We predict and consistently explain these experimentally observed features using a kinetic Monte Carlo (kMC) method. In this method, electrons and their interactions are treated individually, so that dynamic Coulomb correlations are taken into account. Moreover, the movement of charge carriers is simulated in the characteristic disordered energy landscape, allowing to study cooperative effects, such as the correlation of the doping-induced and intrinsic material disorder. Remarkably, taking into account only a model morphology and empirical hopping rates, this method qualitatively predicts the vast majority of the experimentally observed doping effects, including the temperature and doping rate dependence of the Fermi level shift, conductivity and ionized dopant rates. It also predicts passivation of the trap states in the ultralow doping regime and other previously reported experimental findings.
Second, I will present a multiscale method that allows to establish a direct link between the type of dopant and host molecules and the properties of the constituent doped material. In this method, the kMC method acts as the last component of the multi-scale approach, in which the morphology of doped materials is generated using the Deposit method (Monte-Carlo protocol that mimics the vacuum deposition [J. Comput. Chem. 2013, 34, 2716-2725]) and the Coulomb interaction in host-dopant charge-transfer complexes are computed using ab-initio methods, based on the previously reported Quantum Patch method [J. Chem. Theory Comput. 2014, 10, 9, 3720-3725]. The latter has been extended here to also treat charge-transfer complexes embedded into morphology. As a use case, we have computed the density of states and the ionized dopant fraction of the prototypical amorphous doped organic material α-NPD:F_4TCNQ. Due to well-balanced approximations, our multiscale approach allows to calculate the Coulomb interaction energies of several tens of host-dopant pairs and obtain the distribution of the charge-transfer states energies, which is of great practical importance for amorphous organic semiconductors, with every host and dopant molecule having a unique conformation and electrostatic environment. In the future these methods offer the opportunities to design materials and devices for optimal performance.

6:15 AM *F.EL07.01.07
Doping of Organic and Inorganic Semiconductors—A Novel Dopant and the Impact of the Dielectric Environment Norbert Koch[1,2]; [1]Humboldt-Universität zu Berlin, Germany; [2]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

Controlled doping of semiconductors is crucial for the functionality and efficiency of modern (opto-) electronic devices. For organic semiconductors, the use of strong molecular electron donors and acceptors is meanwhile established as viable approach for doping. However, diffusion and poor thermal stability of most presently used dopants poses a challenge in applications. It turns out that the salt of the mesitylene-borinium cation (Mes_2B^+) and tetrakis(penta-fluorophenyl)borate anion $[B(C_6F_5)_4]^-$ is a superior p-type dopant for polymer semiconductors, and doping occurs *via* a charge-exchange reaction. Remarkably, the $[B(C_6F_5)_4]^-$ anion enables the stabilization of polarons *and* bipolarons in poly(3-hexylthiophene), and the effective electron affinity of $Mes_2B^+[B(C_6F_5)_4]^-$ is estimated to be 5.9 eV. The comparably high molecular weight and bulkiness of $[B(C_6F_5)_4]^-$ is expected to reduce diffusion, and no negative impact on doped polymer conductivity is observed up to 100 °C.
Notably, many of the molecular dopants used for organic semiconductors can also be employed for doping of transition metal dichalcogenides (TMDCs). When thinned to the monolayer, many are direct semiconductors, e.g., MoS_2 and WS_2, with superior optical properties. Due to the pronounced excitonic nature of TMDCs, their exciton energy and band gap depend strongly on the dielectric constant (ε) of the mechanical support used for the monolayer. Moreover, the electrical nature of the substrate plays a critical role for the mechanism by which doping with molecules occurs. Three fundamentally different charge transfer mechanisms between MoS_2 and molecular dopants have been identified and will be discussed.
Finally, the impact of residual water in conductive polymer films on their work function will receive attention. The high ε of water reduces the polymer's work function by screening of local charge transfer induced dipoles, and the work function varies

with temperature as does ε of water. This effect should thus be considered when device characterization includes temperature variation.

6:30 AM *F.EL07.01.08
Interplay of Polaron Density and Conductivity of Strongly Doped Conjugated Polymers Christian Muller; Chalmers University of Technology, Sweden

Molecular doping of conjugated polymers generates polarons and counterions that can act as charge carriers and Coulomb scattering sites. Knowledge about the charge-carrier density is needed to rationalize the electrical properties that are observed for different degrees of doping. This talk with explore how the charge-carrier density can be estimated through a comparison of the UV-vis-IR absorbance spectra of molecularly doped polymers and electrochemically oxidized material, using a combination of spectroelectrochemistry and chronoamperometry. The interplay of charge-carrier density and electrical conductivity will be discussed for a range of doped polymers. P-doping of polymers with ionization energies ranging from about 4.5 eV to 5.5 eV will be evaluated, using a series of dopants with electron affinities up to 5.8 eV in case of the strong oxidant Magic Blue.

6:45 AM F.EL07.01.09
Towards Molecular Implantation Doping for Enhancing Charge Injection Properties in Organic Field-Effect Transistors Keehoon Kang[1], Youngrok Kim[1], Katharina Broch[2], Woocheol Lee[1], Heebeom Ahn[1], Jonghoon Lee[1], Daekyoung Yoo[1], Junwoo Kim[1], Seungjun Chung[3], Henning Sirringhaus[4] and Takhee Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]University of Tuebingen, Germany; [3]Korea Institute of Science and Technology, Korea (the Republic of); [4]University of Cambridge, United Kingdom

In organic device applications, contact doping has been commonly used method for circumventing a high contact resistance between metal electrodes and organic semiconductors prevents an efficient charge injection and extraction, which fundamentally limits the device performance. We have recently employed an efficient doping method based on solid-state diffusion of 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F_4-TCNQ) in poly(2,5-bis(3-hexadecylthiophen-2-yl)thieno[3,2-b]thiophene) (PBTTT) [1] to selectively bulk-dope contact regions of PBTTT organic field effect transistors (OFETs), which significantly enhanced the charge injection properties [2]. However, adopting such extensive contact doping method compromises the device stability of OFETs due to dopant diffusion problem, which significantly degrades the device stability by damaging the ON/OFF switching performance despite a . In this presentation, we show a significantly improved stability of the contact doping method by incorporating “dopant-blockade molecules” in PBTTT film in order to suppress the diffusion of the dopant molecules. By carefully selecting the dopant-blockade molecules for effectively blocking the dopant diffusion paths, the ON/OFF ratio of PBTTT OFETs can be maintained over 2 months. This result will maximize the potential of contact doping in OFETs by providing a promising route toward achieving stable and low-contact-resistance OFETs.

Coulombic Interactions and Charge Transport Dynamics in Organic Thermoelectrics Meenakshi Upadhyaya, Michael Lu-Díaz, Dhandapani Venkataraman and Zlatan Aksamija; University of Massachusetts Amherst, United States

Organic semiconductors (OSC) hold tremendous potential to address the demand for cheap and sustainable thermoelectric (TE) materials. They are cost-efficient, environmentally friendly, and have a low lattice thermal conductivity well below their inorganic counterparts. Their lightweight and flexibility also make them a promising choice for self-powered wearable medical monitors and sensing electronics.
Polymers are intrinsically insulators and need to be electrochemically doped to induce high levels of carrier density to improve their electrical conductivity. This simple process, however, introduces complexities in the electronic structure because of the charge-charge Coulombic interactions between the dopant and the polymer. Poor screening of the dopant-

polymer interactions increases the energetic disorder, alters the width and the shape of the density of states (DOS) [1-2], and suppresses the density of free charge carriers. In this work, we investigate the effect of the dopant-polymer Coulombic interactions on the DOS and subsequently on the charge transport dynamics and the trend of the Seebeck vs. conductivity trade-off curve. Our charge transport model is based on electron hopping between localized sites with a modified Gaussian disorder model to account for the impact of dopant size and density, and the clustering of dopants on the energies. We iteratively solve the non-linear Pauli's master equation to compute the time-averaged occupational probabilities of the sites from which relevant transport quantities are calculated [3-4].
We find that the energetic disorder caused by doping which results in an increase in the width of the DOS distribution closely follows the Coulomb interaction energy with the nearest dopant. Also, the deep columbic traps cause an additional tail in the otherwise Gaussian DOS which is further enhanced with dopant clustering [1]. The spread in site energies due to a broadened DOS causes a larger difference in energies between neighboring localized sites which reduces the carrier hopping rate and thus the electron mobility [2]. We find that at low doping the carrier mobility first decreases with doping, due to the trap states in the tail of the DOS being filled first, followed by rapidly increasing at high doping levels. Furthermore, our results show that the effect of dopant-polymer Coulombic interactions on the width and tail of the DOS dictate the slope of the Seebeck vs. conductivity plots. We conclude that reducing the dopant-carrier Coulomb interactions and minimizing dopant clustering can have a beneficial impact on the conductivity and the thermoelectric power factor of OSCs.

Late News: Quantum Sensing of Current Flow Perpendicular to DNA Helix Hashem Mohammad and M. P. Anantram; University of Washington, United States

Sensing of quantum mechanical current in DNA is important to the fields of molecular devices, disease detection and next generation of sequencing techniques. Molecular recognition and self-assembly properties exhibited by DNA offer a bottom-up fabrication process as opposed to silicon-based electronics which requires a top-down approach. These properties along with the possibility for long-range charge transport makes DNA an attractive material for nanoelectronics. Further, the self-assembly property is exploited to form complex 3D structures known as DNA Origami. This enables us to potentially create a new class of molecular electronic devices that occupy cross-wired 3D configurations. In addition, the ability to sense changes in current due to modifications in the quantum mechanical interaction between bases as a function of sequence raises the possibility for its use in next generation sequencing techniques.

Quantum tunnel current which flows both along and perpendicular to the helical axis are essential to describing DNA-based materials. For molecular electronics applications involving double strand DNA (ds-DNA), current flow along the helical axis is important. However, for sequencing applications and origami based nanostructures, tunneling both along and perpendicular to the helical axis are crucial.

The fundamental questions in this field relate to the sensitivity of the quantum tunneling rate through a base to (1) changing a single neighboring base as a function of distance and (2) the DNA-substrate or DNA-contact interface. DNA maintains its structure at room temperature in a solvent, so to begin answering these questions it is essential to understand the role of decoherence in altering the coherent quantum tunneling process at room temperature.

We model the effect of decoherence in studying the effect of contact-location and interstrand coupling in a system consisting of a ds-DNA lying on a substrate. Our model allows us to modulate the strength of DNA-substrate binding to simulate DNA lying on a gold surface, which also forms the first electrical contact. The second electrical contact is a gold tip that is perpendicular to the substrate. An example of a simulated sequence is a 15 base pair long, 3'-GGGAAAAAAAAAGGGG-5' double strand. This sequence allows us to probe the effect of the tunnelling current when the tip makes contact to a single single base while its nearest neighbors gradually change. For example, we calculate the tunnelling current through a tip making contact to an adenine either at distant or close proximity to a guanine.

Our results show that the effect of the contact location on charge transport is dependent on the energy and spatial distribution of the HOMO band between two contacts via multiple trajectories through the DNA. Resonant tunneling peaks when a contact is made to an adenine can increase by ten times depending on the nearest neighbor bases. Moreover, a sufficient coupling between adenine and the neighboring guanine is required to maintain the large resonant tunneling peak. Therefore,

by moving the tip to an adenine that is only weakly coupled to a guanine, the resonant tunneling peak almost disappears. We also find that the tunneling current decays more significantly as a function of the neighboring bases in the coherent regime. Our results clearly establish the sensitive nature of tunnelling current to the nearest neighbor bases even in a direction perpendicular to the helical axis. We find that the delocalization of the frontier molecular orbitals responsible for charge transport are significantly affected by the nearest neighbors. To summarize, our results demonstrate the dependence of tunneling current on the local environment which is of relevance to DNA sequencing. We also expect these results to help design DNA nanowires with tolerance to the location of the cross-linking between multiple structures while maintaining the desired conductance value.

Late News: High Performing N-Type Polymer Thermoelectrics Realized Though Heavy P-Doping Zhiming Liang[1], Hyun Ho Choi[2], Xuyi Luo[3], Tuo Liu[1], Ashkan Abtahi[1], Uma Shantini[1], J. Andrew Hitron[1], Kyle Baustert[1], Jacob Hempel[1], Alex Boehm[1], Armin Ansary[1], Doug Strachan[1], Jianguo Mei[3], Chad Risko[1], Vitaly Podzorov[2] and Kenneth R. Graham[1]; [1]University of Kentucky, United States; [2]Rutgers, The State University of New Jersey, United States; [3]Purdue University, United States

Designing doped π-conjugated polymers (CPs) for organic thermoelectric remains a challenging pursuit, in part because of the difficulty in understanding the complete details of charge transport. For example, it is typically assumed that charge-carrier transport in CPs is dominated by one type of charge carrier, either holes or electrons, as determined by whether the dopant reduces or oxidizes the polymer. However, we find that this is not always a correct assumption, as several polymers that are heavily doped with dopants that oxidize the polymer (i.e., *p*-type dopants) show *n*-type charge transport, which is supported by negative Seebeck coefficients and negative (*n*-type) Hall voltages. Here, we show that moderate *p*-doping of a DPP-containing polymer with $FeCl_3$ leads to a *p*-type power factor of 24.5 $\mu W\ m^{-1}\ K^{-2}$, while further increases in doping concentration lead to an *n*-type power factor of 9.2 $\mu W\ m^{-1}\ K^{-2}$, where 9.2 $\mu W\ m^{-1}\ K^{-2}$ is a record power factor for an *n*-type donor-acceptor (D-A) conjugated polymer. Notably, *n*-type behavior upon heavy doping with oxidizing dopants can be realized with multiple dopants ($FeCl_3$ and $NOBF_4$) and with all five of the D-A polymers examined. A mechanistic explanation for the origin of *n*-type charge-carrier transport is presented based on the Seebeck coefficient measurements, Hall effect measurements, density functional theory calculations, ultraviolet and inverse photoelectron spectroscopy (UPS and IPES, respectively), UV-Vis-NIR absorbance, and electron paramagnetic resonance (EPR) spectra. Ultimately, the combination of data points to the presence of hopping-type holes in the amorphous regions and delocalized electrons in the crystalline regions. With two carrier types present the Seebeck coefficient is determined by the energy-weighted contributions of each carrier type to the total electrical conductivity. This work provides fundamental insight to charge-carrier transport in highly doped polymers while presenting a new approach to developing high-performance *n*-type organic thermoelectrics.

Conductive Polymer Work Function Changes Due to Residual Water—Impact of Water's Temperature Dependent Dielectric Constant Ahmed E. Mansour[1,2], Hongwon Kim[3], Soohyung Park[1,2,4], Thorsten Schultz[1,2], David X. Cao[5], Thuc-Quyen Nguyen[5], Wolfgang Brütting[3], Andreas Opitz[2] and Norbert Koch[1,2]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Humboldt-Universität zu Berlin, Germany; [3]Universität Augsburg, Germany; [4]Korea Institute of Science and Technology, Korea (the Republic of); [5]University of California, United States

The development of low-cost and flexible organic electronic and optoelectronic devices is enabled by solution-processed conducting polymer thin films. Residual water present in organic devices and their surrounding environment influences the properties of their polymer thin film components, which accelerates devices degradation and limits their lifetime and reproducibility. For example, poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS) is a high work function conducting polymer, commonly used to achieve Ohmic contacts for holes with many semiconductors. However, it has been shown that residual water in PEDOT:PSS films lowers their work function [1, 2] and is detrimental for device lifetime.[3]
Here, we investigate the fundamental role of residual water in changing the work function of conducting polymers and

confirm an earlier proposed model,[1] which involves the dielectric screening of PEDOT:PSS surface dipoles due to the high dielectric constant (ε) of water.
Photoemission spectroscopy and electrical conductivity measurements in the temperature range from -100 °C to 100 °C were conducted on thin films of different formulations of PEDOT, as well as, molecularly doped polymers. Our results reveal that the work function of PEDOT:PSS films containing residual water follows the same trend as a function of temperature as does ε of water, in the range between 25 °C and -100 °C. For instance, the work function at -100 °C decreases by ca. 270 meV from its value at room temperature and recovers its initial value once the thin film is warmed up to room temperature. After removal of residual water from PEDOT:PSS films by annealing in ultrahigh vacuum, the work function of thin films is much higher as before (reaching 6.1 eV) and, notably, independent of temperature. These findings are further supported by investigating a water-free variant of PEDOT, which shows no temperature dependence of the work function even without annealing. In contrast, we find no indication that the presence of residual water has any impact on the electrical conductivity. From a device perspective, the hole injection barrier at the interface with PEDOT:PSS can be lowered by increasing its work function once residual water is removed. However, from studies of PEDOT:PSS interfaces with the molecular semiconductor 2,2',7,7'-tetrakis(carbazol-9-yl)-9,9-spirobifluorene (s-CBP) we find that the water-removing annealing step should be done prior to molecular deposition, since water desorption is significantly reduced in the presence of s-CBP layer as thin as 5 nm. Furthermore, we find a similar correlation between thin film work function and temperature for the molecularly doped conjugated polymer poly[2,6-(4,4-bis-(2-ethylhexyl)-4H-cyclopenta[2,1-b;3,4-b′]dithiophene)-alt-4,7(2,1,3-benzothiadiazole)] (PCPDTBT) films to that seen for PEDOT:PSS, which might thus be caused by a similar dielectric screening mechanism involving unanticipated residual water.

By mixing two molecular materials in thin films the electrical and optoelectronic properties of organic semiconductors can be tailored. Resulting morphologies include phase separation or mixed crystals, which can form either solid solutions or ordered complexes. At the moment it is difficult to predict *a priori* the resulting morphology for a selected material combination. Here, we study electron transfer between planar, rod-like electron donor molecules and a non-planar electron acceptor molecule in co-evaporated films by analyzing morphological, vibrational and optical properties. [1] For the donor under study here without ground-state electron transfer to the acceptor we find phase separation in the mixed film. If ground-state electron transfer is observed, the relation of the crystal binding energy of the single component materials and the Coulomb attraction between ions formed in the co-deposited film drives these films either into phase separation or mixed crystal formation. The resulting morphology of the co-deposited films can be rationalized within the laws of thermodynamics. Therefore, it is necessary to consider structural incompatibility of the molecules in terms of interaction energies between the molecules as well as the Coulomb attraction between molecular ions after the formation via ground-state electron transfer.

Real-Time Monitoring of Charge Carrier Traps Leads to High-Performance, Stable Organic Field-Effect Transistors Hamna Haneef[1], Qianxiang Ai[2], Karl Thorley[2], Chad Risko[2], John Anthony[2] and Oana D. Jurchescu[1]; [1]Wake Forest University, United States; [2]University of Kentucky, United States

Organic semiconductors (OSCs) are gradually integrated into our lives as parts of various optoelectronic devices given their low-cost processing, light weight, and the opportunities that they offer for the versatile design of new materials with “on-demand” properties. These systems undergo considerable electronic and structural transformations during device fabrication and operation which can profoundly impact their performance and stability. Characterization techniques that can elucidate the mechanisms of the time-dependent transformations occurring in these materials and devices could guide the processing and

design to yield high performance and stable organic devices. Here we introduce a highly efficient methodology to elucidate the microscopic processes occurring within the OSC when deliberately exposed to different external stimuli by accessing in real-time the trap density of states spectrum of the OSC using organic field-effect transistor (OFET) measurements. In the first example, we monitored the generation/annihilation of charge carrier traps in a high-mobility small molecule OSC, 2,8-difluoro-5,11-bis (triethylsilylethynyl) anthradithiophene (diF TES ADT), as a result of microstructural changes occurring in the film during exposure to solvent vapors. The time-dependent changes in charge carrier mobility are correlated with the density and energetic distribution of the electronic states in the bandgap of the OSC providing unprecedented access to processes taking place in all intermediate states during the microstructural transformations. Given the strong dependence of the electrical properties on the film microstructure, such information is instrumental in identifying performance-limiting processes in devices and subsequently guiding material processing to achieve intrinsic limits. The discovery of defect-tolerant intermediate crystalline motifs can provide pathways for fabricating stable, high-performance devices for the next generation of low-cost electronics. We further employed this methodology to investigate the underlying physical process impacting the operational stability of OFETs based on a small molecule trimer, tri(*n*-hexyl) silylethynyl benzodithiophene (TnHS BDT) trimer. A large shift in threshold voltage and a drastic decrease in mobility observed during prolonged transistor operation in ambient air coincided remarkably with the establishment of a peak in the DOS spectrum at ca. 0.3 eV from the valence band edge after 20 min of repetitive transistor measurements. The peak is indicative of charge carrier trapping in discrete electronic states generated in the bandgap of the OSC during operation, which in turn is responsible for the device degradation. This information provided us with unparalleled insights into the microscopic mechanisms leading to device degradation which allowed us to devise a strategy that completely suppressed the formation of the discrete peak in the DOS spectrum, subsequently yielding highly stable OFETs with constant mobilities and threshold voltage shifts below 1 V during 500 min of continuous transistor operation in ambient air.

5:30 AM *F.EL07.02.05
Accessing the Dynamics of the Energetic Disorder in Organic Semiconductors—Implications to Radiation Detection for Medical Applications Oana D. Jurchescu; Wake Forest University, United States

Organic semiconductors bring key advantages to integration into next generation flexible and bendable optoelectronics due to ease of processing and compatibility with arbitrary substrates. These properties are a direct consequence of their van der Waals intermolecular interactions, yet these interactions are also the main cause of the formation of localized electronic states in the band gap, which are responsible for the modest performance and reduced stability of organic semiconductor devices. In this talk, I will discuss the dynamics of trap formation and healing under several different pre, post deposition or in operando stimuli and relate it to the performance and long-term stability of the organic field-effect transistor devices. Charge carrier trapping can also provide a platform for developing sensors and radiation detectors by recording the changes in the trap DOS spectra upon interaction with external factors like impurities (chemical and biological), temperature, light, or radiation. In the second part of my talk, I will introduce radiation dosimeters for medical applications which exploit trap generation/annihilation in organic transistors. These X-ray medical imaging systems are robust and highly sensitive for doses relevant to a variety of medical investigations, including cancer diagnosis and therapy. Placement of the sensor directly onto the human body, coupled with the similarity in the atomic number Z between the electronically active layer and the human tissue, greatly enhances the precision and reduces the complexity of the medical equipment. These findings uncover new opportunities for organic circuits that will not only improve the quality of healthcare, but can have other applications, including wearable personal dosimeters.

5:45 AM *F.EL07.02.06
Exploring Structural Transitions During Ion-Injection into Conjugated Polymers Christine Luscombe; University of Washington, United States

Mixed organic ionic and electronic conductors are being explored for a wide range of applications, from bioelectronics to neuromorphic computing, artificial muscles and energy storage applications. These materials exploit the simultaneous transport properties of ionic and electronic carriers to enable novel device functions. Recently, polymer semiconductors have received significant amounts of attention because of their flexibility, biological compatibility and ease of fabrication. These materials, particularly thiophene-based polymers such as poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate)(PEDOT:PSS) and related derivatives, have demonstrated significant enhancements in performance in a relatively short amount of time, with transconductance values of PEDOT:PSS transistors surpassing those achieved even with graphene.

We explore how small changes in ethylene-glycol functionalized polythiophenes alter ion injection. Specifically, their thin film morphology, and their ionic and electronic conductivities, and comparisons against theoretical predictions will be

discussed. In this talk, the effect on the density of the ethylene-glycol side chains and their pattern of placement on ionic conductivity will be discussed.

6:00 AM *F.EL07.02.07
Enlightening Polymer Electronic Devices Paolo Samori; University of Strasbourg, France

The development of multifunctional devices capable to respond to multiple and independent stimuli is one among the grand challenges in organic electronics. The combination of multiple components, with each one conferring a specific function to the ensemble, is a facile strategy to impart a multifunctional nature to electronic devices. The controlled combination of such components and their integration in real devices can be achieved by mastering the supramolecular approach.
In my lecture I will review our recent works on the combination of carbon-based nanomaterials, in particular comprising organic semiconductors, with photochromic molecules (diarylethenes or azobenzenes) in order to fabricate smart, high-performing and light-sensitive (opto)electronic devices such as field-effect transistors and light-emitting transistors and as well as flexible non-volatile optical memory thin-film transistor device with over 256 distinct levels.

6:15 AM F.EL07.02.08
One-Dimensional Nanowires of Non-Centrosymmetric Molecular Semiconductors Grown by Physical Vapor Deposition Kwang-Won Park, David Bilger and Trisha L. Andrew; University of Massachusetts Amherst, United States

Understanding how dipolar, non-centrosymmetric organic semiconductors self-assemble, nucleate, and crystallize is indispensable for designing new molecular solids with unique physical properties and light-matter interactions. However, some intermolecular interactions, such as dipole-dipole and van der Waals interactions compete to direct the assembly of these compounds, making them difficult to predict how solids are formed from individual molecules. Here, we investigate four small molecules (**TpCPD**, **TpDCF**, **AcCPD**, and **AcDCF**) featuring anisotropic with large dipole moments, and establish robust algorithms to control their molecular self-assembly via simple physical vapor deposition technique. Each molecule contains a central polar moiety, consisting of either a cyclopentadienone (CPD, ca. 3.5 D dipole moment) or dicyanofulvene (DCF, ca. 7.0 D dipole moment) core, that is surrounded by either four twisted phenyl (tetraphenyl, Tp) groups or a fused aromatic (acenaphthene, Ac) ring system. We find that only molecules possessing extended π system form one-dimensional (1D) nanowires due to the stronger van der Waals associations, originating from the planar acenaphthene moieties. We examine the kinetics of self-assembly for **AcDCF** and create diverse 1D morphologies, including both curved and linear nanostructures. Finally, conductive AFM (c-AFM) measurements show that 1D AcDCF wires support their higher current densities relative to randomly-oriented clusters lacking long-range order.

6:25 AM F.EL07.02.09
Zooming in on the Microstructure of Glycolated Polythiophenes with Molecular Dynamics Simulations Micaela Matta[1,2], Bryan D. Paulsen[2], Jonathan Rivnay[2], George C. Schatz[2] and Alessandro Troisi[1]; [1]University of Liverpool, United

Kingdom; [2]Northwestern University, United States

Organic electrochemical transistors (OECTs) are ionic-to-electronic transducers that rely on the ability of the organic active layer to transport both ions and electrons. These devices consist of an aqueous electrolyte in direct contact with a π-conjugated polymer channel. In order to maximize both electronic and ionic transport, a balance between ordered π-stacking and the swelling promoted by the glycolated side chain must be achieved.[1]
Molecular dynamics (MD) simulations offer a unique perspective into the microstructure of conjugated polymers. In this work, we provide an atomistic picture of the polymer-electrolyte interface in the 'off' state of an OECT. Using a combination of MD simulations and X-ray fluorescence, we show how different anions effectively tune the coordination and chelation of cations by the glycolated polymer p(g2T-TT). At the same time, softer and hydrophobic anions such as TFSI and ClO_4 are found to preferentially interact with the p(g2T-TT) phase, further enhancing polymer-cation coordination. These trends are confirmed by X-ray Fluorescence experiments on p(g2T-TT) thin films undergoing passive swelling.[2]
We then use MD to simulate the swelling of another glycolated polymer, p(g3T2-T), mapping the phase diagram of a water-glycolated polymer mix as a function of the water content. This allows us to predict the microstructure changes associated to passive swelling and how different electrolytes penetrate the polymer morphology.
Finally, we discuss the challenges associated to the modelling of ionic doping of glycolated polymers, and analyse the interactions between polymer-electrolyte using a combination of electronic structure and classical simulations.

6:35 AM F.EL07.02.11
Role of Pendant Group in Organic Semiconductor Charge Transport Rate and Energetics Kalyani Patrikar[1], Nakul Jain[1], Dwaipayan Chakraborty[2], Priya Johari[2], Valipe Ramgopal Rao[1,3] and Dinesh Kabra[1]; [1]IIT Bombay, India; [2]Shiv Nadar University, India; [3]IIT Delhi, India

Increasing the charge carrier mobility of organic semiconductors has been a dominating challenge in the field for over a decade, as typical values of mobility of organic materials are orders of magnitude lower than their inorganic counterparts. Various advances in molecular design as well as device fabrication have enabled mobility of organic materials to reach 10 $cm^2V^{-1}s^{-1}$ in recent times. However, the innovations in molecular design have focused on modifying main chain properties. Side chain groups have been considered to play a role in solubility and thin film morphology rather than charge transport energetics. Charge transport in organic semiconductor thinfilms occurs by thermally assisted hopping mechanism, wherein charge carriers are temporally localized on sites, such as a repeat unit of polymer chain, and subsequently hop to energetically favorable neighboring sites. A high mobility represents a higher speed of hopping as applied electric field is increased. Hopping rate is enhanced when orbital overlap between neighboring sites is high, which is achieved by repeat units of high area of conjugation, and when activation energy of hopping is low. Accommodating an incoming hopping charge carrier causes stretching and rotation of the chemical bonds in the newly charged polymer repeat unit. Energy consumed for this physical rearrangement, known as the reorganization energy, acts as an activation barrier to charge hopping process. We present the first report of how changing pendant group connecting the side chain to backbone chain may drastically change the field-effect-mobility of a polymer via reduction of its reorganization energy.[1]

We demonstrate this with the case of two structurally similar polymers with only pendant group different. Polymers PTB7 and PTB7-Th are common solar cell donor polymers.[2] Structure of both polymers are identical, except the pendant group is an oxygen atom in PTB7 while it is a thiophene unit in PTB7-Th.[3] In spite of only a minor difference in the polymer structure, we found charge carrier mobility of PTB7-Th (0.11 $cm^2V^{-1}s^{-1}$) to be a magnitude higher than PTB7 (0.01 $cm^2V^{-1}s^{-1}$) in respective thin film transistors. We show this to be due to the lower reorganization energy of PTB7-Th (0.157 eV) as compared to PTB7 (0.346 eV) as found by calculating from first principles. The values of reorganization energy predict the ratio of rate of charge carrier hopping between the two polymers to be ~10, consistent with our observation of experimental field effect mobility. We find this to be related to rigidity of the thiophene unit of PTB7-Th. During cation formation of polymer segment, side chains in PTB7-Th rotate less (~9°) as compared to PTB7(~19°), thus requiring less energy to attain charged state molecular configuration. This lowers the activation barrier, and hence increases rate of hopping, and consequently the mobility.

We assert the role of reorganization energy as a dominant parameter controlling mobility of conjugated polymer semiconductors, and provide a key to tuning it via molecular design: an efficient pendant group.

Coulomb Interaction in Organic Semiconductor Blends Karl Leo; TU Dresden, Germany

Organic semiconductors systems offer many new exciting device applications with attractive features such as flexibility, low cost, low-temperature processing etc. One key difference to inorganic semiconductors is the usually quite small dielectric constant of organics, leading to much stronger Coulomb interactions. For instance, the exciton binding energy in organic semiconductors is significantly greater than the room temperature thermal energy, thus having profound influence on the optical properties. In this talk, I will discuss the influence of these strong Coulomb interactions on two phenomena, both related to blends of organic materials: First, I will discuss controlled electrical doping where the strong Coulomb interaction might be a curse and should, at least in simple hydrogen-like model, make efficient doping unlikely. I will discuss recent results which clarify that doping is indeed efficient, mainly because of disorder effects. Second, I will discuss how the Coulomb interaction can be a blessing by using it for "band structure engineering" of organic semiconductors: Long range Coulomb interactions allow to continuously tune the energy levels, allowing finely adjustable energy levels without synthesis of new molecules. The electrostatic nature of these phenomena is directly proven by experiments which show the strong influence of these quadrupole effects at interfaces. Finally, I will discuss recent results which show that the energy gap of organic semiconductors can be tuned in a similar way.

Late News: Reaching Double-Digit Dielectric Constants for Molecular Semiconductors Sylvia Rousseva, Felien S. van Kooij, Hugo den Besten, Ryan C. Chiechi and Jan C. Hummelen; University of Groningen, Netherlands

In most presently known organic semiconductors (OSCs), the relative dielectric constant (ε_r) is low ($\varepsilon_r \approx$ 3-4) compared to crystalline inorganic semiconductors such as silicon ($\varepsilon_r \approx 11$). As a result, charges in the material experience strong Coulombic forces which can have a profound effect on the performance of OSC based devices. For instance, at high carrier densities such as found in organic field effect transistors (OFETs), simulations suggest that Coulomb interactions between charge carriers significantly reduce their mobility. Meanwhile, in doped organic semiconductors, the low ε_r can lead to the formation of Coulomb traps and to lower doping efficiencies due to the formation of stable host-dopant charge-transfer complexes. For organic photovoltaics (OPVs), the low ε_r has a significant effect on the exciton binding energy, which represents a crucial barrier to charge separation and extraction. Despite the relevance for many OSC based devices, the effect of ε_r on the electronic and optoelectronic properties of organic materials is largely unexplored due to the scarcity of known organic semiconductors with ε_r higher than 6. Furthermore, ε_r is a frequency dependent property, and it remains unclear which frequency regime (timescale) is most relevant for the different device applications.
In this presentation, a homologous series of fullerene derivatives with varying length and geometrical arrangement of polar ethylene glycol (EG) side chains is investigated and the low-frequency ε_r is measured using impedance spectroscopy. The low frequency ε_r is found to correlate with length for the symmetrical adducts whereas for the unsymmetrical branched adducts, there is no significant difference. For BTrEG-2, the ε_r reaches 10, which is unprecedented in an intrinsic molecular organic semiconductor film. The temperature dependence of the low frequency dielectric response and the optical constants (high frequency ε_r) are also investigated.

7:10 AM F.EL07.02.14
Late News: Superelastic Organic Semiconductors—The Molecular Mechanisms Hong Sun; Purdue University, United States

Organic semiconductors are emerging in printable and flexible electronics. Nevertheless, the charge transport in crystal organic semiconductors is attained at the cost of the deformability. Superelastic organic semiconductors (SOSs) is a recently discovered phenomenon that provides a possibility to achieve the high mechanical deformability yet retaining the molecular

ordering. Compared to the well-studied martensitic phase transition in metallic alloys, superelasticity and ferroelasticity in solid-state organic molecules through polymorphic changes are much less understood. Here we leverage the phase transformation theory, genetic algorithm refined molecular modeling, and experimental validation to study the versatile cooperative transitions in bis(triisopropylsilylethynyl)-pentacene semiconductor crystal. The molecular rotation governed thermoelasticity, interconvertible super- and ferroelastic transitions, and molecular twinning are systematically studied by integrating both the lattice crystallography and molecular motions. The fundamental understanding promotes polymorphism to modulate the optoelectronic properties of organic semiconductors and can breed a new avenue of environmentally responsive organic devices.

Late News: LO-TO Splitting, Coulomb Interactions and Ferroelectricity in Organic Ferroelectrics Sanghamitra Mukhopadhyay[1,2]; [1]ISIS Neutron and Muon Facility, United Kingdom; [2]Rutherford Appleton Laboratory, United Kingdom

Organic ferroelectrics are in the focus of current research for their potential technological applications as materials to address global challenges. These lightweight, flexible and nontoxic ferroelectrics have potential applications as ferroelectric random access memories in computers, super capacitors for energy storage, transducers for medical ultrasound imaging and functional materials in flexible electronics [1-4]. As a result of their excellent dielectric, pyro- and piezo-electric properties comparable to traditional inorganic ferroelectrics, and with unique coexistence of flexibility and ferroelectricity, organic ferroelectrics are candidates of intense research promising of designing new bespoke functional materials. These materials are often hydrogen or halogen bonded molecular crystals [5,6] and dynamics or movements of protons from the centro symmetric to non-centrosymmetric positions are considered as the key mechanisms of their functionality. In case of inorganic ferroelectrics, large LO-TO splitting of normal modes helps to identify modes responsible for the ferroelectric functionality. A large LO-TO splitting is a manifestation of strong coupling with the electric field and contributes more to the dynamical effective charge. The effect of electric field on long range Coulomb interaction can also be identified by inspecting the splitting of LO-TO vibrational modes. Thus to understand the microscopic origin of ferroelectricity the knowledge of these normal modes are crucial.

We have done inelastic neutron scattering (INS) spectroscopy experiments on a number of hydrogen and halogen bonded ferroelectric materials, such as croconic acid ($C_5O_5H_2$), 1-cyclobutene-1,2-dicarboxylic acid (CBDC, $C_6H_8O_4$) and 2-phenylmalondialdehyde (PhMDA, $C_9H_8O_2$) and dichloromethylimidazole ($C_4H_4Cl_2N_2$). Calculations are done using plane wave pseudo potential density functional theory (DFT) using CASTEP code. Temperature dependent INS spectra are interpreted using first principles lattice dynamics within quasi harmonic approximations. Structures and dynamics of these functional materials are correlated to understand the role of hydrogen bonds for ferroelectric polarisation at room temperatures. A large LO-TO splitting of the O-H stretching mode around 2500 cm^{-1} is identified as the mode that has significant contribution to the ferroelectric polarisation. Although this long range Coulomb interaction can be considered as blessings for ferroelctricity in this class of materials, any defect or grain boundary affecting this interacction can kill the ferroelectricity.

In this talk I will present structure and dynamics of few organic ferroelectrics using vibrational neutron spectroscopy and first principles DFT based simulations to find out the finger print of ferroelectricity in this class of materials [7-10]. From INS experiments and DFT simulations, modes sensitive to long range Coulomb interactions and responsible for ferroelectric properties of the material are identified. I would propose vibrational spectroscopy combined with DFT calculations as a characterisation tool to investigate ferroelectric properties in the these molecular crystals.

Late News: Optical Distance Measurement by Exploiting Irradiance-Dependent Photoresponse of Organic Near Infrared Photodetectors Yazhong Wang, Johannes Benduhn, Karl Leo and Donato Spoltore; Dresden Integrated Center of Applied Physics and Photonic Materials (IAPP), Technische Universität Dresden, Germany, Germany

In organic semiconductor devices, extraction barriers are usually undesired since they lead to a reduced device performance. In this work, by intentionally introducing an extraction barrier for holes, near infrared (NIR) organic photodetectors (OPDs) dedicated for distance measurement are realized. The extraction barrier is introduced by replacing the hole transporting layer (HTL) material with a deeper highest occupied molecular orbital (HOMO) HTL material within a well-performing organic solar cell device. Holes pile up at the extraction barrier introducing additional charge recombination. With increasing irradiance, achieved by decreasing the illumination spot area on the OPD, the probability of charge recombination is rising. This allows to determine the distance between the OPD and light source from the irradiance-dependent, non-linear response of the OPD. We extend here this principle to the NIR: We demonstrate fully vacuum-deposited organic NIR optical distance photodetectors with a detection area up to 2.56 cm^2 and detection wavelengths at 850 nm and 1060 nm. Such NIR OPDs have high potential to be utilized as robust, low-cost and simple optical distance measurement setup.

SESSION F.EL07.03: Excitons and TADF

Hyperfine versus Spin-Vibronic Coupling—Or Do Both Drive TADF? Bluebell H. Drummond[1,2], William K. Myers[2], Naoya Aizawa[3], Leah R. Weiss[4], Seth R. Marder[5], Richard Friend[1] and Emrys W. Evans[1]; [1]University of Cambridge, United Kingdom; [2]University of Oxford, United Kingdom; [3]RIKEN, Japan; [4]The University of Chicago, United States; [5]Georgia Institute of Technology, United States

Thermally-activated delayed fluorescence (TADF) organic molecules undergo more efficient light emission than traditional organic fluorescent emitters, making them attractive materials for OLEDs. In TADF devices, indirect emission from dark triplet states via bright singlet excitons is activated and leads to boosted electroluminescence efficiencies.[1] There is general agreement that TADF emitters should be designed to have small singlet-triplet exchange energies that promote forward and reverse intersystem crossing (ISC) between singlet and triplet excited states. However, there is not agreement on the spin interactions and spin-flip mechanisms responsible for singlet-triplet interconversion, with suggestions of hyperfine- and spin-vibronic-based design rules.[2,3] Most studies of TADF use optical spectroscopies which can examine the photophysics and interconversion rates but do not shed light on the critical spin physics.[4] Here we use transient electron spin resonance spectroscopy to study TADF triplets and the role of hyperfine and spin-vibronic couplings on the critical ISC for efficient TADF.

We designed a series of TADF emitters with molecular modifications that led to systematic changes of TADF efficiencies. Solution-based studies of this series revealed the importance of low-lying triplet states and the spin-vibronic mechanism was dominant for ISC. However, in device-relevant thin-films, we find additional signatures of hyperfine coupling mediated triplet formation, proposed to arise from solid-state intermolecular interactions. Our work shows that the singlet-triplet-ground state picture for TADF should be expanded to understand the overall luminescent efficiencies of these materials. Understanding the interplay between molecular design and spin interactions for efficient spin interconversion is integral in establishing the structure-function relationships for the rational design of new TADF emitters.

Emissive and Charge-Generating Donor–Acceptor Interfaces for Organic Optoelectronics with Low Voltage Losses Koen Vandewal; Hasselt University, Belgium

Charge transfer (CT) states at the interface between electron-donating (D) and electron-accepting (A) materials in organic thin films are characterized by absorption and emission bands within the optical gap of the interfacing materials. Depending on the used donor and acceptor materials, CT states can be very emissive, or generate free carriers at high yield. The former can result in rather efficient organic light emitting diodes, via thermally activated delayed fluorescence, while the latter property is exploited in organic photovoltaic (OPV) devices. In this talk, I will show that proper control of CT state properties allows simultaneous occurrence of a high photovoltaic and emission quantum yield within a single, visible-light-emitting D–A system. This leads to ultralow-emission turn-on voltages as well as significantly reduced voltage losses upon solar illumination.

5:25 AM F.EL07.03.03
Radical Design for Efficient Light-Emitting Diodes with Doublet Emission Alim Abdurahman[1], T. J. Cambridge[2], Q. Gu[2], Jiangbin Zhang[2], Qiming Peng[1,3], Ming Zhang[1], Richard Friend[2], Feng Li[1] and Emrys W. Evans[2,4]; [1]Jilin University, China; [2]University of Cambridge, United Kingdom; [3]Nanjing Tech University, China; [4]Swansea University, United Kingdom

Radical materials have unpaired electrons, leading to unusual physics that could be exploited in next-generation organic electronics. We have previously shown that luminescent radicals can be used for overcoming the spin statistical efficiency limit for electroluminescence (EL) in organic light-emitting diodes (OLEDs) due to their quantum-mechanical doublet-spin character[1,2]. However, suitable radical emitters for OLEDs are generally limited in terms of chemistry and color to tris[2,4,5-trichlorophenyl]methyl derivatives and the near-infrared (> 700 nm). Additionally, the presence of the singly-occupied molecular orbital (SOMO) leads to potential efficiency losses in charge trapping mechanisms for EL. Here we present general design rules to increase the absorption and luminescence yields of organic radicals[3]. These insights were used to design a series of radical molecules with pure-red emission, up to 90% photoluminescence quantum yields and over 12% external quantum efficiency in OLEDs. Doublet exciton quenching processes were probed for radical OLEDs in operation by optical spectroscopy. This work may be beneficial for the rational design and discovery of highly luminescent radical materials with new colors and motifs, as well as informing new device strategies for more efficient radical optoelectronics.

5:35 AM F.EL07.03.04
Controlling the Self-Assembly of Cyanine Dyes into Two-Dimensional Excitonic Molecular Aggregates Across Visible and Shortwave Infrared Wavelengths Arundhati P. Deshmukh[1], Austin D. Bailey[1], Niklas Geue[1], Leandra Forte[1], Xingyu Shen[1,2], Ellen M. Sletten[1] and Justin R. Caram[1]; [1]University of California, Los Angeles, United States; [2]Peking University, China

Molecular aggregates are non-covalent self-assemblies of chromophores where long range coulomb coupling of transition dipole moments leads to delocalized excitons with extreme blue or red shifts, called as H- or J-aggregates respectively. Cyanine dye aggregates have garnered tremendous interest due to their robust excitons, chemical tunability and biocompatibility (*1*). As a result, these materials have exciting applications in shortwave infrared (SWIR) imaging, plexitonics and excitation energy transfer (*2–4*). Our research aims to chemically control the excitons in cyanine dye aggregates by leveraging the long range coulomb coupling, which in turn, can be controlled via aggregate morphology as well as energetic disorder. In our previous work, we uncovered design principles for tuning the photophysics of 2-dimensional (2D) aggregates by chemically controlling the position of bright state within the excitonic band (*5*). However, control over the supramolecular self-assembly of cyanine dyes to push the aggregates to a desired H- or J-aggregated structure is still a challenge. Here, we give general principles to tune the self-assembly of cyanine dyes across a vast range of conditions enabling new experimental tools such as diffusion ordered spectroscopy. We predictably stabilize H- or J-aggregate state by independent control of solvent to non-solvent ratio, dye concentration and ionic strength. We observe universal trends in aggregation that can be understood using a simple three component equilibrium model where the

monomers go via an H-aggregated dimer state to form extended 2D J-aggregates. Comparing the model with our vast experimental aggregation space, we provide thermodynamic insights into the underlying principles that govern the self-assembly. We further show the universal applicability of these principles across the broad set of cyanine dyes, including benzothiazole (THIATS) and benzimidazole cyanines (TDBC), and stabilize H-aggregated dimers or extended J-aggregated sheets with absorptions across the visible and SWIR. Additionally, we perform temperature dependent absorption of sugar matrix stabilized 2D aggregates across this library and shed light on the effect of static and dynamic disorder in 2D aggregates. Overall, we will provide structure-property relationships that employ the ubiquitous coulomb coupling to chemically control the excitons in molecular aggregates.

Emissive Isostructural Crystals of Organic Charge-Transfer Complex—Fine-Tuning of Isometric Donor-Acceptor Pairs Soo Young Park[1], Sangyoon Oh[1], Johannes Gierschner[2] and Roland Resel[3]; [1]Seoul National University, Korea (the Republic of); [2]IMDEA nanoscience, Spain; [3]TU Graz, Austria

In this work, we report isostructural systems of mixed-stack CT complexes focusing on the D-A structure-property correlation under identical morphology condition with an aim to unveil the pure electronic mechanism of CT emission. For this, isometric motifs of two donors (D) and two acceptors (A) were rationally designed, of which cocrystals form bright luminescent D:A CT complexes with record high PL quantum yields of 83 %. Notably, four different CT pairs made of isometric D and A molecules all showed the quasi-isostructural intra-stack crystal structure, which allowed us to correlate the electronic CT interaction and their photophysical properties aside from the complicated morphological effect. Our isostructural concept of CT crystals is thus shown to be a crucial strategy for the targeted design of highly emissive CT cocrystals.

6:00 AM F.EL07.03.06
Photon Recycling in Organic Semiconductor Thin Films Zhongkai Cheng, Nasir Javed and Deirdre O'Carroll; Rutgers, The State University of New Jersey, United States

Photon recycling (PR), whereby photons generated by radiative recombination in semiconductors result in the regeneration of electron-hole pairs, plays an important role in the study of optoelectronic semiconductor materials and significantly affects the properties of their applications. Excitons are expected to play important roles in PR because they promote high luminescence quantum yields, which are necessary for the observation of PR. However, PR in low-dielectric-constant exitonic materials, such as organic semiconductors, has not been studied to date. In this work, we investigate the mechanisms of PR in organic semiconductor thin films. We study PR in three different organic semiconducting polymer media (regiorandom poly(3-hexylthiophene-2,5-diyl) (RRa-P3HT), regioregular poly(3-hexylthiophene-2,5-diyl) (RR-P3HT), and poly(9,9-dioctylfluorene-alt-benzothiadiazole) (F8BT)) because of their different quantum efficiencies, morphologies and broadband absorptions. In order to study PR, we fabricate different nanostructured surfaces including silver nanoparticle (AgNP) metasurfaces and silver nanograting (AgNG) metasurfaces. In addition, we also use glass, planar Ag and PMMA/Ag surfaces as control groups to analyze the results of PR in the organic thin films compared to the results from nanostructured plasmonic metasurfaces. Surface photoluminescence (PL) emission spectra and edge PL emission spectra are employed to characterize PR because they show strongly red-shifted peaks from surface emission to edge emission when PR is strong. Surface and edge PL emission spectra also play important roles in calculating photon recycling efficiencies and in evaluating reabsorption coefficients. Finally, PL lifetime and PL quantum yield results are used to further explain the PR effect in the different organic semiconductor media. This work is expected to lead to greater understanding of the role of PR in affecting the performance of organic optoelectronic devices.

Quantum Dynamics of Exciton and Charge Migration in Functional Organic Materials—From Coherent to Diffusive Regimes Irene Burghardt; Goethe University Frankfurt, Germany

We report on quantum dynamical studies of ultrafast photo-induced energy and charge transfer in functional organic materials, complementing time-resolved spectroscopic observations that underscore the coherent nature of the ultrafast

elementary transfer events in these molecular aggregate systems. Our approach combines first-principles parametrized Hamiltonians [1], with accurate quantum dynamics simulations using the Multi-Layer Multi-Configuration Time-Dependent Hartree (MCTDH) method [2], along with semiclassical approaches [3]. The talk will focus on (i) exciton dissociation and free carrier generation in regioregular donor-acceptor assemblies [1,4], and (ii) the elementary mechanism of exciton migration [3,5-7] and creation of charge-transfer excitons [8] in polythiophene and poly(para-phenylene vinylene) type materials. Special emphasis is placed on the interplay of trapping due to high-frequency phonon modes, and thermal activation due to low-frequency "soft" modes which drive a diffusive dynamics [6].

6:25 AM F.EL07.03.08
Modification of Photoinduced Electron Transfer in the Strong Light-Matter Coupling Regime Nina Krainova and Noel C. Giebink; Pennsylvania State University, United States

The notion that optical environment can change the nature of a chemical reaction emerges in the strong coupling regime when molecular electronic (or vibrational) transitions hybridize with light to form polariton states that have different energies, coherence, and dynamical characteristics than the bare (uncoupled) molecules themselves. Photoinduced charge transfer is arguably one of the most important areas to explore such modification since it underlies processes ranging from photolithography to photosynthesis. Here, we explore this possibility by measuring the photoconductivity of a p-doped organic semiconductor in which charged, rather than neutral molecules (i.e. polaronic rather than excitonic states) are strongly coupled to a Fabry-Perot microcavity.
We confirm the existence of polaron polariton modes in the photoconductivity action spectrum and find that their magnitude evolves differently with applied bias than photocurrent that originates from exciting uncoupled polarons in the same cavity. Importantly, the difference in functional dependence changes systematically with the polariton detuning. We explain these observations on the basis of Onsager theory, where strong coupling effectively changes the thermalization length of photoexcited holes that must escape their dopant counter-ions to contribute to the photoconductivity. We propose that this increase originates from an acceleration of the initial electron transfer event associated with the delocalized nature of the polaritonic excitation, which can effectively sample many more intermolecular electronic couplings in the disordered thin film than a localized excitation can. Access to a wider range of intermolecular electronic couplings in the film allows the polariton to benefit from the largest, thereby speeding up the overall rate of charge transfer.[1]

6:35 AM *F.EL07.03.09
Coherent Photoexcited Dynamics and Intermolecular Conical Intersections Sergei Tretiak; Los Alamos National Laboratory, United States

In this talk, I will overview some applications of Non-adiabatic EXcited-state Molecular Dynamics (NEXMD) framework recently developed at LANL. The NEXMD code is able to simulate tens of picoseconds photoinduced dynamics in large molecular systems with hundreds of atoms in size and dense manifold of interacting and crossing excited states. In particular, I will exemplify ultrafast excitonic dynamics guided by intermolecular conical intersections (CoIns). Both simulations and time-resolved two-dimensional electronic spectroscopy track the coherent motion of a vibronic wave packet passing through CoIns within 40 fs, a process that governs the ultrafast energy transfer dynamics in molecular aggregates. Our results suggest that intermolecular CoIns may effectively steer energy pathways in functional nanostructures. Observed relationships between spatial extent/properties of electronic wavefunctions and resulting electronic functionalities allow us to understand and potentially manipulate excited state dynamics and energy transfer pathways toward optoelectronic applications.

6:50 AM F.EL07.03.11
Sharp Thermally Activated Delayed Fluorescence Emission Despite a Rather Large Singlet-Triplet Energy

Gap Ramin Ansari, Jinsang Kim and John Kieffer; University of Michigan, United States

Despite the ability of TADF materials to fully utilize triplet excitons, their inherent limitation is the broad emission spectrum. The torsional mobility about the twist angle between donor and acceptor is considered the principal cause of color impurity, since conventional TADF molecules involve large dihedral angles to facilitate intramolecular charge transfer. However, according to the Franck-Condon principle, electronic transitions are instantaneous compared to nuclear motions, and the emission characteristics should not be subject to molecular rotation. Conversely, there is ample experimental evidence that emission from charge transfer states is broad and diffuse. We submit that the dramatic change of electron configuration between ground and charge-transfer excited states causes the broad emission, as confirmed by our computational and experimental findings. Accordingly, to constrict emission broadening it is preferable to control the charge-transfer character by introducing chromophores with localized emission (LE) character, exhibiting minimal change in electron configuration upon emission. However, molecules with LE emitter states tend to have large singlet-triplet energy gaps (ΔE_{ST}), making TADF pathway inefficient. We have shown that ISC can be further enhanced with a process called "heavy atom oriented El-Sayed rule", which allows us to design TADF emitters with rather large ΔE_{ST} and still result in sharp emission. In this design approach, we incorporate a n-π^* triplet state below the emissive singlet state to boost the reverse ISC, and compensate for the larger ΔE_{ST} of the LE emitter state. Our results can be used to design molecular organic alternatives with sharp emissions for LED applications.

7:00 AM F.EL07.03.13
Late News: Modelling of Ultra-Fast Processes in Organic Semiconductors Using Tensor Network Methods Antonios Alvertis[1], Christoph Schnedermann[1], Andrew J. Musser[2], Akshay Rao[1] and Alex W. Chin[3]; [1]University of Cambridge, United Kingdom; [2]Cornell University, United States; [3]Sorbonne Université, France

Ultrafast photo-induced processes in organic materials are crucial to several applications, including organic solar cells and LEDs. Such processes include exciton transport and singlet fission. Understanding the microscopic mechanism of these processes from a theoretical perspective is crucial in order to formulate molecular design rules and efficiently guide the experimental search for those structures that optimise them. However, the simulation of the real-time dynamics of ultrafast processes poses a significant challenge, due to the hundreds of molecular vibrations that interact very strongly with the excited charge carriers, often constituting traditional perturbative methods insufficient, and causing commonly employed approximations such as the Markov and Born-Oppenheimer approximations to break down.

In this talk, I will present a novel theoretical framework based on tensor network methods, for the simulation of the full quantum mechanical non-perturbative dynamics of ultrafast processes, which does not rely on any of the aforementioned approximations. This methodology is applied to very large molecules with up to 108 atoms. The large size of the studied molecules has allowed us to study them experimentally, subjecting our theoretical approach to a rigorous comparison with experimental results, and revealing its accuracy. We uncover the full microscopic mechanism of singlet fission in a covalent pentacene dimer and find that two different groups of vibrational modes coordinate in a precise manner in order to enable efficient fission through an avoided crossing [1].

For a dimer of tetracene, we reveal the impact of the specific pathway of vibrational relaxation on charge transfer, and show that selective excitation of vibrations can increase its efficiency by up to 26% [2].

Finally, we combine the insights from the above studies to build a simple model for singlet fission, which combines the effects of excess energy photoexcitation, molecular vibrations and the polarity of the molecular environment. We show that utilising the subtle interplay between these factors allows for switching into the coherent regime of singlet fission in a controlled manner, accelerating the process by an order of magnitude, as also confirmed experimentally [3].

7:10 AM F.EL07.03.14
Late News: Influence of Energy Gap Between Charge-Transfer and Locally Excited States on Organic Long Persistence Luminescence Zesen Lin[1], Ryota Kabe[1] and Chihaya Adachi[2,2]; [1]Okinawa Institute of Science and Technology

Graduate University, Japan; [2]Kyushu University, Japan

Long-persistent luminescence (LPL), also known as the glow-in-the-dark effect, noctilucent or long afterglow, is a self-sustained light emission phenomenon by which a material emits light for a very long time (longer than several minutes) after removal the excitation sources which are typically visible light, ultraviolet (UV) light, electron beams or high energy radiation such as X-, α-, β- or γ-rays. Although the LPL phenomenon is often confused with phosphorescence owing to the confusing terminology in history, the LPL is different with phosphorescence reflected in two apparent features: (i) the almost identical spectra between photoluminescence and LPL; (ii) their decay follows the different law: the LPL (refer in particular to the isothermal luminescence) obeys a power law ($I(t) \sim t^{-m}$, with m = 0.5∼2, mostly 1, hyperbola) in the long time scale, while the phosphorescence follows an exponential law. Therefore, LPL materials can realize long emission duration from minutes to even days after cutoff excitation sources, which is quite longer than phosphorescence. Organic LPL (OLPL) materials have significant superiority over inorganic LPL materials in terms of functionality, flexibility, transparency, and solution-processability. OLPL excited by UV-visible light can be regarded as a recombination luminescence in a special organic solar cell. However, the material design strategies for the OLPL is still not clear. Here, we systematically investigate changes in the LPL duration and spectra for three donor materials having similar molecular structures but different energy levels and find that the LPL performance is significantly influenced by the energy gap between the lowest localized triplet excited-state and the lowest singlet charge-transfer excited-state in the exciplex system. When the energy level of the lowest localized triplet excited-state is much lower than that of the charge-transfer excited state, the system exhibits a short LPL duration under the same excitation condition and clear two distinct emission features originating from exciplex fluorescence and donor phosphorescence.

SESSION F.EL07.04: Solar Cells
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020

5:00 AM F.EL07.04.01
Tailoring Energy Levels of Thienothiophene Molecules to Study Photocurrent Generation Mechanism in Fullerene-Based Organic Solar Cells Lakshmi Narayanan Mosur Saravana Murthy[1], Aaron Kramer[1], Jing-Mei Su[2], Yi-Sheng Chen[2], Boya Zhang[1], Ken-Tsung Wong[2,3], William Vandenberghe[1] and Julia W. Hsu[1]; [1]The University of Texas at Dallas, United States; [2]National Taiwan University, Taiwan; [3]Institute of Atomic and Molecular Science, Academia Sinica, Taiwan

Fullerene-based organic solar cells (OSCs), which consist of a dilute amount of donor molecules (< 5 wt.%) in a fullerene matrix, exhibit high open-circuit voltage (V_{oc}) and short circuit current density (J_{sc}) simultaneously, thus overcoming the intrinsic J_{sc}-V_{oc} trade-off observed in traditional bulk heterojunction OSCs. The high V_{oc} in fullerene-based OSCs has been attributed to reduced bimolecular recombination or the Schottky barrier height between fullerene matrix and the anode. However, the origin of the high J_{sc} in these OSCs with a donor concentration much lower than the percolation threshold is still unclear. To investigate the photocurrent generation mechanism, we design and synthesize four variations of thienothiophene (TT) molecules with different center and end groups, tuning their HOMO levels from -6.1 to -5.2 eV. We perform experimental studies and density functional theory (DFT) calculations to understand TT:$PC_{71}BM$ devices with donor concentration varying from 0 to 10 wt.%. We show that photocurrent generation depends strongly on the center groups, which are either cyano (CN) or hexyloxy (OHex). With 1 wt.% donor, TTOHex:$PC_{71}BM$ devices show ten times higher photocurrent than neat $PC_{71}BM$ devices. In contrast, TTCN:$PC_{71}BM$ devices do not generate additional photocurrent even with 10 wt.% donor. The results are the same for both end group, dicyanovinylene (DC) or rhodamine (RH). DFT results also show TTOHex-$PC_{71}BM$ dimers have a shallower HOMO energy than $PC_{71}BM$ monomers, while TTCN-$PC_{71}BM$ dimers have a deeper HOMO energy than $PC_{71}BM$ monomers. Using photoelectron spectroscopy in air (PESA) to measure HOMO levels, we find that the difference between photocurrent in TTOHex:$PC_{71}BM$ and TTCN:$PC_{71}BM$ devices are strongly correlated with the HOMO offset between donor and acceptor. Since HOMO offset is required to dissociate excitons at the donor-acceptor interface, these results indicate that the first requirement of photocurrent generation is efficient exciton dissociation. We then analyze the possibility of three possible hole transport mechanisms—tunneling, percolation pathways, and hole back transfer—for the TT:$PC_{71}BM$ systems. Following exciton dissociation, we find that hole back transfer from donor molecules to $PC_{71}BM$ is primarily responsible for photocurrent generation for the TT:$PC_{71}BM$ devices.

Effects of Acceptor Unit Side Chain Bulk on Electronic Processes and Device Performance of Donor Polymers for Organic Solar Cells Abigail A. Advincula, Ian Pelse and John Reynolds; Georgia Institute of Technology, United States

Semiconducting polymers are considered highly promising for next generation large area organic solar cell (OSC) devices because of their potential for solution processing and film forming ability. This work explores the effect of increasing side chain steric bulk (methyl, isopropyl, isobutyl, and cyclohexylmethyl) on the acceptor unit of a family of donor-acceptor polymers based on thienopyrroledione (TPD) and investigates the steric effects on electronic properties and device performance. Steric effects on solution-state aggregation properties, solid-state microstructures, optical properties, and thermal properties are also explored. Electronic properties (i.e. hole mobilities, ionization potentials, and electron affinities) were found to be relatively invariant, an effect due to the distance of the side chains from the main backbones of the polymers. When tested in photovoltaic devices with $PC_{71}BM$, the devices fabricated from the polymers demonstrated subtle changes in short-circuit current, fill factor, and OSC device efficiency. In contrast to the electronic properties and photovoltaic statistics, the aggregation, thermal, and morphological properties demonstrated pronounced differences. By UV-vis absorption spectroscopy, we found that changes in steric bulk caused substantial differences in solution-state aggregation, with the bulkier side chain TPD polymers aggregating to a lesser extent. The thermal and morphological properties of neat thin films and blend thin films with $PC_{71}BM$ were investigated. By differential scanning calorimetry (DSC), melting/crystallization point depression could be observed with increasing acceptor unit side chain steric bulk, while the heats of fusion/crystallization remained the same. By grazing incidence wide angle x-ray scattering (GIWAXS), out-of-plane lamellar spacing distances (d) correlated directly with acceptor-unit side chain bulk – TPD-methyl (d = 24.4 Å) and TPD-cyclohexylmethyl (d = 26.6 Å). In this work, we demonstrate a unique example of side chain engineering that alters a polymer's solution and solid-state properties but ultimately has little effect on device performance.

Precise Measurements of Hole-Electron Coulomb Binding Energy in Functional Organic Materials Yoshida Hiroyuki; Chiba University, Japan

Owing to the low dielectric constants, the hole and electron pairs in functional organic materials are strongly bound by the Coulomb interaction. It is therefore crucial to measure precisely the Coulomb bounding energies. This energy is the difference between the bound state and the free hole/electron state. While the bound state energy can often be measured by optical spectroscopies, the energy of the free charge state was difficult to determine in organic materials. The free hole and electron energies correspond to the ionization energy and electron affinity, respectively. Thus, the energy of the free hole-electron pair without mutual interaction can be determined as the difference of the ionization energy and electron affinity measured separately. The ionization energies of organic solid materials are routinely examined by ultraviolet photoelectron spectroscopy (UPS). Therefore, the precise value of the electron affinity was the missing piece for the hole-electron interaction energy.

In 2012, we developed low-energy inverse photoelectron spectroscopy (LEIPS) which enable to determine the electron affinity of organic material as precise as the ionization energy determined by UPS. Using the combination of UPS/LEIPS for the free hole-electron energy together with the existing methods for the bound state energy, we are able to measure the hole-electron interaction energy with the uncertainty of 0.1 eV. We have applied this procedure to examine the Coulomb interaction energy of various functional organic materials. In this presentation, I focus on the following two topics:

1. Exciton binding energy
When the hole-electron pair stays in the same material, the interaction energy is the exciton binding energy. We have determined the exciton binding energies of organic materials used for organic light emitting diode (OLED) and organic solar cell (OSC) as well as prototypical organic semiconductors. The exciton binding energies of OLED materials exceeds 1 eV while those of the OSC materials are less than 0.5 eV. The large exciton binding energy may facilitate binding of the free holes and electrons to generate photons in OLED. In contrast, the small exciton binding energy is preferential to the free carrier generation in OSC. Interestingly, we found no distinct differences in the exciton binding energies among the state-of-the-art non-fullerene acceptors, conventional fullerene acceptors and low-bandgap polymers.

2. Charge dissociation energy in organic solar cell (OSC)
If the hole and electron stay in the donor and acceptor, respectively, at the donor/acceptor interface, the Coulomb interaction energy corresponds to the charge dissociation energy in OSC. A simple consideration based on the Coulomb interaction in continuum dielectric media gives a charge dissociation energy of around 0.5 eV. As this estimated value is much larger than

the thermal energy, there has been a long-standing debate how the strongly bound hole-electron pair at the donor/acceptor interface spontaneously dissociate into the free carriers. However, the reliable dissociation energy has never been determined experimentally. We applied the above-mentioned method to the bulk-heterojunction of the low-bandgap polymer/fullerene acceptor and low-bandgap polymer/non-fullerene acceptor. The determined charge dissociation energies (enthalpy difference) are always less than 0.3 eV which is small enough to dissociate the hole/electron pair by the thermal energy with the assistance of the entropy.

The Importance of Terahertz Short-Range Mobility for Free Charge Generation in NFA-Based Organic Solar Cells Natalie Banerji; University of Bern, Switzerland

In the field of organic photovoltaics, efficiencies beyond 17% have recently been achieved by combining low bandgap conjugated polymers with small-molecule non-fullerene acceptors (NFAs). To understand what differentiates non-fullerenes from conventional fullerenes in terms of the charge separation and transport processes, we have used ultrafast transient absorption spectroscopy (TAS), electro-modulated differential absorption spectroscopy (EDA) and terahertz measurements (THz). We have thus investigated how the charge generation and separation processes depend on parameters such as the charge-transfer and recombination energetics, the short-range charge mobility and the morphology. Moreover, to simplify the complexity of the process caused by the phase morphology of bulk heterojunction blends, we have worked with bilayers of the donor polymer with the NFA, and with blends containing dilute concentrations of the acceptor. Our results are combined into a kinetic model that explains the efficiency of free charge generation in various polymer:NFA blends.

5:50 AM F.EL07.04.06
Influence Molecular Orientation on Charge Separation at Organic Donor/Acceptor Interface Jeong Won Kim[1], Heeseon Lim[1], Sena Yang[1], Sang-Hoon Lee[2], Jung-Yong Lee[2], Yeonhee Lee[2] and Yong-Hyun Kim[2]; [1]KRISS, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

For highly efficient organic photovoltaics (OPVs), control of molecular orientation is of prime importance. While molecular orientation within a film influences charge conduction, relative configuration at donor/accepter interface determines energy level alignment as well as electron-hole separation. Here, we report the change in molecular orientation of planar-shape donor molecules, metal phthalocyanine (CuPc or ZnPc) on ITO by adding CuI templating layer. Near edge X-ray absorption fine structure measurement can estimate average tilt angle of the planar molecules with and without CuI underlayer. CuPc reveals a noticeable change from standing-up to lying-down orientation by CuI, but ZnPc keeps standing-up geometry. Ionization potential for both molecular films measured by ultraviolet photoelectron spectroscopy shows consistent results as well. To explain the different templating effect of CuI, we compare chemical interaction between CuI and the two different metal phthalocyanine molecules by DFT calculation. The stronger interaction between Cu-Cu atoms in CuPc and CuI, respectively, might be reason for the distinct influence on the molecular orientation change of CuPc film. Furthermore, the exciton dynamics at MPc/C_{60} (donor/accepter) interface is studied by time-resolved two-photon photoemission spectroscopy. On CuI layer, the lying-down CuPc molecules show a clear charge transfer (CT) exciton characteristics at the CuPc/C_{60} interface, while ZnPc molecules only show long-lived singlet peak even at the ZnPc/C60 interface. Thus, face-on interface of CuPc/C_{60} induces CT exciton by strong π-π overlap between donor and acceptor. Finally, we discuss the influence of molecular orientation on the enhanced carrier transport and overall OPV cell efficiency by measuring device performance.

6:00 AM F.EL07.04.08
Molecular Absorption and Exciton Hybridization Improve the Maximum Achievable Photovoltage in Organic Solar Cells Michel Panhans[1] and Frank Ortmann[1,2]; [1]Technische Universität Dresden, Germany; [2]Technische Universität München, Germany

Understanding optical absorption and excitonic properties is crucial for organic solar cells (OSCs). We study the microscopic origin of exciton bands in molecular blends and investigate their role in OSCs [1]. We simulate low-energy absorption features including molecular excitons, CT-excitons and hybrids including multi-exciton hybridization as well as low-frequency molecular vibrations. For model donor-acceptor blends featuring charge-transfer excitons, our numerical calculations agree very well with temperature-dependent experimental absorption spectra. We are able to predict the low-energy spectral lineshape, which we connect to radiative voltage losses that limit the solar cell's performance.
In addition, we unveil that the quantum effect of zero-point vibrations, mediated by electron-phonon interaction plays a significant role. It causes a substantial exciton bandwidth and reduces the open-circuit voltage, which is predicted from

electronic and vibronic molecular parameters. This effect is surprisingly strong at room temperature and can substantially reduce the OSC's efficiency.
To circumvent such radiative voltage losses, we elaborate on a better understanding of their connection to OSC parameters such as the electronic coupling or the driving force for CT exciton formation. Radiative open circuit voltages are affected by exciton hybridization and delocalization on the order 100 mV or more, depending on the system.
We finally extend our theoretical predictions for a set of different donor-acceptor systems including non-fullerene donor-acceptor blends and different heterojunction and interface geometries. Our proposed strategies to reduce the radiative voltage losses are supported by excellent agreement of the present simulation approach to existing experimental data for the low-energy absorption.

6:10 AM *F.EL07.04.10
Understanding and Minimizing Voltage Losses in High-Efficiency Organic Solar Cells Feng Gao; Linkoping University, Sweden

Compared with inorganic or perovskite photovoltaics, the key limiting factor for organic solar cells (OSCs) is large voltage loss, which is usually over 0.7 V. A significant contribution of the large voltage loss in OSCs is due to strong non-radiative recombination, the origin of which has been puzzling the community for a long time, limiting rational design of materials to overcome this critical issue. We systematically investigate a range of low voltage loss systems, where the voltage loss is around or below 0.6 V. We find that the quantum efficiency of electroluminescence in these systems have been significantly increased, leading to decreased non-radiative voltage losses below 0.20 V. Combining spectroscopic and quantum chemistry approaches, we formulate the key rules for minimizing voltage losses: (i) low energy offset between donor and acceptor molecular states, and (ii) high photoluminescence yield of the low-gap material in the blend. We further demonstrate that there is no intrinsic limit for efficient charge separation in OSCs with small voltage losses.

6:25 AM *F.EL07.04.11
Self Organization in Vacuum Deposited Oligomer-Fullerene Blends for Efficient Organic Photovoltaics Martin P. Pfeiffer; Heliatek GmbH, Germany

Organic solar cells offer the unique opportunity to prepare flexible photovoltaic films based exclusively on abundantly available raw materials in an energy-efficient low-temperature process compatible with low-cost PET as a substrate foil. Due to their light weight and their attractive appearance, the films are especially suitable for building integration in facades and roofs of buildings that cannot bear the weight of traditional solar cells.
Heliatek has chosen the approach to prepare organic solar cells by a clean and solvent-free vacuum based on oligomer absorbers. It enables to manufacture p-i-n-type tandem or triple junction architectures in a fully integrated additive roll-to-roll process including laser-structuring and encapsulation. After the ramp of a 30cm wide pilot line using tailored organic conjugated oligomer absorbers developed within Heliatek, a production line for 120cm wide PET web is currently set up and starts to become productive within 2020.
To get optimum efficiency, we need strong absorption with steep absorption edges, efficient charge separation and good charge transport perpendicular to the substrate. This requires a nanocrystalline morphology with suitable preferential orientation, a close p-stacking mode within the donor domains and a phase separation on the order of at least 10-20nm between donor and acceptor domains. Moreover, the degree of slipping in x and y direction within pairs of p -stacked molecules plays a critical role both for the steepness of the absorption spectra and for the distribution of subgap states (Urbach tail) which strongly influences the achievable open circuit voltage. We will discuss the influence of non-classical hydrogene bridges and specific interactions such as sulfur-nitrogene attractions on self-organization processes. It turns out that these partly Coulombic interactions are essential for the desired growth mode.
We will summarize the state of the art of organic vacuum deposited photovoltaics reaching currently up to 13.2% efficiency and discuss the potential for further breakthroughs. Finally we report on a new small molecule absorber that combines fill factors above 70%, a very steep absorption edge, a low Urbach energy (22meV) and optimum energetic alignment to fullerene C_{60} with excellent processability at high deposition rates.

6:40 AM F.EL07.04.12
Late News: Lateral Alternating Multilayerd Junction for Organic Solar Cells Masahiro Hiramoto; Institute for Molecular Science, Japan

Blended junctions are indispensable for organic solar cells. However, the fabrication of electron and hole transport routes in blended junction remains quite challenging. In this work, we proposed a novel concept of the junction structure of organic solar cell, namely, a lateral alternating multilayered junction [1]. An essential point is that the photogenerated holes and electrons are laterally transported and extracted to the respective electrodes.
Minimum units of proposed junction are hole highway and electron highway. At first, the lateral extraction of photogenerated holes and electrons of the order of 1 mm in the hole and electron highways using ultra-high mobility organic films was demonstrated. Observed macroscopic value of milli-meter order is surprising long compared to the conventional value below 1 mm. Next, the successful operation of organic solar cell having a lateral alternating multilayered junction by combining the hole highway and electron highway was demonstrated. A total of 93% of the photogenerated electrons and holes are laterally collected over a surprising long distance (0.14 mm). The exciton-collection efficiency reaches 75% in a lateral alternating multilayered junction with a layer thickness of 10 nm. Therefore, the lateral junction is proved to have an ability to collect both excitons and carriers almost completely.
A lateral alternating multilayered junction can be regarded to be an alternative blended junction for organic solar cells. Advantage of a lateral cell is its unlimited thickness in the vertical direction. Therefore, tandem solar cells that can utilize the full solar spectrum can be freely designed.

Late News: Nonradiative Voltage Losses in Fullerene-Free, Vacuum Deposited Organic Solar Cells Lukasz K. Baisinger, Donato Spoltore and Karl Leo; Dresden Integrated Center for Applied Physics and Photonic Materials (IAPP), Germany

Organic Solar Cells (OSCs) have been gaining more and more momentum, starting to exhibit efficiencies close to the ones of their inorganic and perovskite counterparts, with recent achievements of certified Power Conversion Efficiency (PCE) above 17% for single-junction devices. The great flexibility in tailoring organic molecules, allowed to design systems that achieve strong absorption with External Quantum Efficiency (EQE) of 80% over whole visible spectrum, while still maintaining efficient charge generation with Fill Factor (FF) above 75%. On the other hand, the open-circuit voltage is still much lower as compared to the most efficient technologies, mainly due to large nonradiative losses, which were identified as intrinsic to devices based on organic molecules. The origin of those losses was proposed to be mainly due to electronic and molecular parameters of the donor and the acceptor molecules.
To study the effect of molecular parameters on nonradiative losses, we built Planar-Heterojunction (PHJ) devices carefully choosing material systems with identical Charge Transfer (CT) state energies while providing different Open-Circuit Voltages (V_{oc}). Moreover, by keeping the optical gap constant thanks to red-absorbing SubNc donor, driving force for all material systems is kept the same. This allows to exclude several mechanisms influencing the overall nonradiative losses and focus only on molecular parameters such as reorganization energies and static dipole moment.
Calculated nonradiative voltage losses are indeed larger for the material systems with smaller V_{oc}, varying by about 100 mV. Subsequent Transient Photovoltage (TPV) measurement further confirm those results, indicating faster decay of free charges in systems with larger voltage losses. To make sure that the TPV is probing bulk recombination kinetics we make use of the novel Transient Photocharge (TPQ) technique, which allows to reliably measure the recombination lifetime of the charge carriers in the bulk.

Nanoscale Effects in Perovskite Solar Cells Observed by Scanning Force Microscopy Stefan Weber; Max Planck

Institute for Polymer Research, Germany

Perovskite solar cells have electrified the solar cell research community with astonishing performance and surprising material properties. However, the widespread commercialization of perovskites in solar cells and other optoelectronic applications still requires a more detailed knowledge about fundamental material properties. My group is specialized in the investigation of these properties on nanometer length scales using scanning force microscopy. We recently discovered a distinct nanoscale stripe domain structure in the piezoresponse on perovskite crystals [1]. The pattern is characteristic for ferro-elastic twin domains. We are currently investigating the influence of the domain walls on the charge carrier dynamics. Next to fundamental physical properties of photovoltaic perovskites, we investigate complete solar cell devices under operation conditions. To map and follow the vertical charge distribution across the functional layers of an operating device, we developed a method to prepare smooth cuts across the device [2]. We subsequently map the potential distribution across the device using a time-resolved Kelvin probe force microscopy (tr-KPFM) [2,3]. We can simulate open- or short circuit conditions, apply an external voltage or illuminate the device. In particular, we found that thin layers of localized charge formed and stabilized at the electrode interfaces when we changed the external voltage or illuminated the device. We could show that ion migration itself is too fast to influence device hysteresis. Instead, the formation and release of ionic interface charges determine the time scales for current-voltage hysteresis in perovskite solar cells. Our results demonstrate that a precise control over the interfaces in perovskite solar cells is the key, not only for controlling and suppressing hysteresis but also for their long-term stability in perovskite solar cells. Beyond Dilute Imperfections—Extended Defects in Halide Perovskites Aron Walsh[1,2]; [1]Imperial College London, United Kingdom; [2]Yonsei University, Korea (the Republic of)

Defects come in a several flavours: conductivity-promoting defects create free carriers that enable electronics; killer defects (deep, charged centres) trigger recombination; and charge scattering defects reduce mobility [1]. Our understanding of the defect processes in halide perovskites is gradually improving through a combination of high-resolution measurements and materials modelling [2]. However, evidence is building for the importance of point defect aggregates and structural defects in higher dimensions. I will discuss recent progress, from theory and experiment, to identify, characterise and control extended defects in metal halide perovskites. In particular, I will cover the role of grain boundaries [3] stacking faults [4]. The use of defect tolerance as a metric to develop and screen post-perovskite materials will be critically addressed. This research is part of a collaboration with the group of Sam Stranks (Cambridge), and used the UK National Supercomputer ARCHER.

Unraveling the Dynamic Behavior of Halide Perovskites from the Macro- to the Nanoscale Marina S. Leite; University of California, Davis, United States

The dynamic optical and electrical responses of halide perovskites are currently not fully understood, and are closely related to the irreversible changes frequently observed in devices. We determine the individual and combined effects of extrinsic (humidity and oxygen) and intrinsic (light, bias, and temperature) stressors in the physical behavior of the archetypal $MAPbBr_3$ and $MAPbI_3$, and Cs-mixed perovskites. First, a detailed comparison between $MAPbBr_3$ and $MAPbI_3$ through time-dependent voltage measurements reveals that, upon illumination, high-energy photons leads to a > 10x slower voltage decline toward equilibrium than low-energy photons in $MAPbBr_3$. Yet, $MAPbI_3$ shows wavelength-independent decay rate, resulting from ion migration. Second, through in situ photoluminescence (PL) under environmentally controlled conditions, we resolve a humidity-induced PL hysteresis. Further, we apply a machine learning algorithm to predict the luminescence response for > 12 hs. Concerning the unique behavior of multi-cation perovskites, a correlative microscopy approach is

realized, combined with environmental-controlled PL measurements.

6:15 PM *F.EL08.01.10
3D Nanoscale Photoconduction in Hybrid Perovskite Thin-Film Grains and Grain Boundaries as Revealed by Tomographic Atomic Force Microscopy Jingfeng Song[1], Yuanyuan Zhou[2], Nitin Padture[2] and Bryan D. Huey[1]; [1]University of Connecticut, United States; [2]Brown University, United States

Although grain boundaries and other interfaces in photovoltaics are generally detrimental for photogenerated carrier transport, their role remains contentious in hybrid perovskite semiconductors. The uncertainty is partially due to the practical challenge that most experimental approaches are performed at the top surface, which is not only insensitive to depth-dependent inhomogeneities but also may be influenced by topographic artifacts. Accordingly, we have developed tomographic atomic force microscopy (T-AFM) for fully 3-Dimensional mapping of photogenerated carrier transport in hybrid perovskite thin films. Via progressive nanoscale planarization and photoconduction mapping during *in-situ* illumination in an AFM, this unambiguously reveals grain boundaries serving as highly interconnected conducting channels for carrier transport in $MAPbI_3$. Voltage dependent measurements reveal enhanced carrier mobilities at most grain boundaries, although careful analysis also reveals the coexistence of 5-10% insipid interfaces. Depth dependencies in photocurrent through the grains, and the grain boundaries, are also assessed. Such insights are critical for engineering hybrid perovskites to be optimized for future solar cells, photodetectors, and light sources.

6:35 PM *F.EL08.01.03
A Bird's Eye View of Composition-Performance Relationships in Halide Perovskites via Correlative Microscopy David P. Fenning and Yanqi Luo; University of California, San Diego, United States

Halide perovskite thin films and devices exhibit a remarkable degree of heterogeneity in structure and composition at the nanoscale, varying frequently from nominal synthesis targets in ways that can be difficult to detect using ubiquitous laboratory analysis. Leveraging synchrotron-based in situ X-ray microscopies to sample composition, structure, and optoelectronic quality at the nanoscale, we reveal the dependence of nanoscale phase separation and variations in charge collection on the local chemistry of A-site perovskite alloys. At times, these stoichiometric variations arise in the as-fabricated film, revealing important chemical dependencies. However, we also find significant evolution in the microstructure of high-performance perovskites during operation and under environmental stress, leading to insights into mechanistic pathways of degradation and new avenues for stabilization in high-performance alloyed perovskites.

6:55 PM *F.EL08.01.02
Nanoscale Heterostructures of Halide Perovskites and the Study of Charge Transfer Mechanisms Song Jin, Dongxu Pan and Matthew P. Hautzinger; University of Wisconsin-Madison, United States

The remarkable solar performance of lead halide perovskites can be attributed to their excellent physical properties that present many mysteries, challenges, as well as opportunities. Better control over the crystal growth of these fascinating materials and fabrication of heterostructures using various halide perovskites with different bandgaps would open up opportunities for exploring new properties and device applications. After a brief summary on the nanowires and nanoplates of various metal halide perovskites we have developed and their lasing properties, I will focus my discussion on the growth of heterostructures of 2D Ruddlesden-Popper (RP) layered lead iodide perovskites with defined n phases and atomically sharp interfaces both in 2D/3D perovskite heterostructures and also as multi-layered multi-colored vertical heterostructures, in which the long chain ammonium ligands serve as the barriers to prevent ion migration across the junctions. We have used these well-defined heterostuctures to study the carrier transfer mechanisms between 2D and 3D perovskites and between different RP phases. The excellent properties of these single-crystal perovskite nanostructures of diverse families of perovskite materials with different cations, anions, and dimensionality make them ideal for fundamental physical studies of carrier transport and decay mechanisms, and for enabling high performance lasers, LEDs, and other optoelectronic applications.

Many-Body Elastic Scattering of Excitonsin Two-Dimensional Hybrid Metal-Halide Perovskites Carlos Silva; Georgia Institute of Technology, United States

We quantify the role of many-body elastic scattering effects on exciton dephasing rates in two-dimensional hybrid metal-halide perovskites by means of nonlinear coherent excitation spectroscopy at a temperature of 5 K. We find that the exciton-density dependence of excitation-induced dephasing (EID) is two to three orders of magnitude lower than in other atomic monolayer semiconductors such as transition metal dichalchogenides. We find that, EID is different for the multiple excitons evident in the excitation line shape, as is their phonon-mediated temperature dependence. We ascribe these observations to screening effects due to polaronic dressingby the lattice. We further examine the evolution of the two-dimensional coherent exciton lineshape at 5 K with population waiting time. We find that the 2D coherent lineshape evolves with over time windows in which the population itself is static, in a manner that indicates time-dependent EID. Specifically, we find that the dephasing slows down with population waiting time. This spectral evolution invokes time-varying inter-exciton coherences, and we discuss the possible role of dark exciton states in these quantum dynamics.

8:20 AM *F.EL08.02.24
Carrier and Spin Dynamics in Perovskite 2D Layered and Nanocrystal Systems Matthew Beard; National Renewable Energy Laboratory, United States

Lead-iodide based perovskite semiconductors are emerging as promising light absorbers for solution-processed thin-film photovoltaic applications. In addition, these materials are also intensively studied for light-emitting diodes, photodetectors, and lasers. Recently, hybrid organic-inorganic perovskite (HOIP) semiconductors are being considered as candidates for spintronic applications due to a large spin-orbit coupling (SOC) and controllable Rashba-splitting. Here we discuss the spin-coherence lifetimes in single crystals of 2D Ruddlesden-Popper perovskites PEA2PbI4(MAPbI3)n?1(PEA, phenethylammonium; MA, methylammonium; n = 1, 2, 3, 4). Room temperature spin-coherence times show a nonmonotonic layer thickness dependence with an increasing spin-coherence lifetime with increasing layer thickness from n = 1 to 4, followed by a decrease in lifetime from n = 4 to ?.Our results are consistent with two contributions; Rashba-splitting increases the spin-coherence lifetime going from the n = ? to the layered systems, whilephonon-scattering which increases for smaller layers decreases the spin-coherence lifetime.The unique tunability of HOIPs offers an unprecedented opportunity to directly incorporate chiral organic molecules in the production of a 2D-layered hybrid perovskite thin film and/or crystal that induces chirality into the inorganic sub-lattice bandedge states. Thus, there is an interesting opportunity to explore how chiral molecules embedded into the multilayers provide spin-control within these hybrid semiconductors. Here, we focus on controlling spin-transport within 2D-layerd chiral Pb-I perovskite systems. We demonstrate spin-polarization of charge-transport through the chiral perovskites by showing that the injected current is preferential to one of the spin-states and depends upon the handedness of the incorporated chiral organic molecules; thus, the hybrid chiral system acts as a spin-filter.

8:40 AM *F.EL08.02.26
Harnessing Free Carriers for Photon Upconversion—Using Lead Halide Perovskites for Triplet Sensitization Lea Nienhaus and Sarah Wieghold; Florida State University, United States

Solid-state nanocrystal-based upconversion (UC) systems have disadvantages with respect to poor exciton diffusion lengths, strong singlet reabsorption and the low resulting achievable UC efficiencies. To circumvent these issues, we employ bulk lead halide perovskite (LHPs) thin films as triplet sensitizers for near-infrared-to-visible UC. The sensitized UC process is based on triplet-triplet annihilation (TTA) in the organic semiconductor rubrene. Conservative estimates result in reported UC efficiencies upwards of 3%.1However, to further boost the UC efficiency, it is required to understand and mitigate the effects of shallow trap states in the LHP sensitizer. Here, we investigate the underlying mechanism of energy transfer at the LHP/rubrene interface, and the effect of the LHP perovskite film thickness on the UC dynamics and efficiency threshold. In the LHP/rubrene bilayer device, we observe two opposing effects caused by interactions between the LHP and rubrene: i) passivation of surface defects by rubrene, which results in a longer native photoluminescence (PL) lifetime, and ii) quenching of the PL lifetime due to energy transfer to the triplet state of rubrene. Our observations indicate that non-radiative trap filling in the LHP film and charge transfer to rubrene are likely competitive quenching pathways. As a result, the threshold Ithat which the UC process becomes efficient, observed as a slope change in the power-dependent upconverted PL, shifts to lower values with increasing film thickness. In contrast to previous reported systems, the slope change is directly dependent on the underlying LHP dynamics:i) below Ith, we find a slope twice the value of the LHP PL, and ii) above Ith, the upconverted PL follows the same power-law as the underlying recombination of electrons and holes in the LHP thin films.2,3However, two

unusual effects are also observed in the system: i) two distinct rise times in the upconverted emission, indicating two distinct triplet sensitization rates. ii) A reversible photobleach of the upconverted emission, which cannot be correlated to a physical degradation of the system. By manipulating the triplet population, we are able to show that a higher triplet population does not necessarily result in a higher UC yield for the LHP/rubrene system demonstrated here, rather can be detrimental to the efficiency due to strong singlet reabsorption.3 (1) Nienhaus, L.; Correa-Baena, J.-P.; Wieghold, S.; Einzinger, M.; Lin, T.-A.; Shulenberger, K. Photophysics of Methylammonium Lead Bromide Perovskite Natalie Banerji, Nikolaos Droseros and Dimitra Tsokkou; University of Bern, Switzerland

Methylammonium Lead Bromide (MAPbBr3) is the most investigated 3D Perovskite for visible LED applications. It is characterized by a much higher exciton binding energy compared to its Iodide equivalent (MAPbI3). This leads to complex excited-state phenomena, with free-carriers, excitons and defect states contributing to the photoluminescence (PL) properties. We have used a variety of spectroscopic techniques to study photoexcited MAPbBr3 films, including time-resolve PL measurements, femtosecond transient absorption (TA) spectroscopy and optical-probe-terahertz-pump (THz) experiments. The co-existence of free carriers and excitons is demonstrated at low excitation densities in as-cast polycrystalline MAPbBr3 (crystal size of the order of few ?m). The excitation wavelength and density are then varied in order to access different free-carrier to exciton ratios in order to evaluate their recombination dynamics and THz conductivities. Finally, we show how reducing the grain size of the Perovskite to the micro- and nanoscale (by using different additives during solution-processing) increases the PL quantum yield, which we explain by the presence of a bright exclusively exitonic population even at low excitation densities, together with reduced surface trapping thanks to passivation by the additives.

Novel Hybrid Perovskites for Spin Control and Magneto-Optics Felix Deschler; Technische Universität München, Germany

Functional materials combining the optoelectronic functionalities of semiconductors with control of the spin degree of freedom are highly sought after for the advancement of quantum technology devices and provide exciting avenues for polarized light-emission. Previous work towards this goal introduced small amounts of magnetic elements into crystalline semiconductor, e.g. through vacuum-based deposition, to obtain dilute magnetic semiconductors (DMS).

In my talk, I will present our efforts on gaining control over spin dynamics and spin interactions through compositional and structural tuning in solution-processable hybrid perovskite semiconductors. We aim to exploit the exceptional optoelectronic properties of these hybrid perovskites, together with their tolerance in the electronic states to dopants and defects, to make advances towards high-performance DMS. I will further discuss how we employ ultrafast optical spectroscopy to gain insights into fundamental excitation and spin dynamics in our novel materials, highlighting the potential of magneto-optic control.

I will present first results on chemical doping of layered Ruddlesden-Popper hybrid perovskites with transition metals. I will report how optical excitations interact with elemental spins in these materials, also on ultrafast timescales, to achieve control over exciton emission through magnetic proximity effects. Harnessing spin-orbit coupling effects, we achieved circular polarization up to 15% in the excitonic photoluminescence at low temperatures and high fields, which keeps a strong magnetic field dependence below 1 Tesla. Our finding constitutes the first example of optical polarization control in magnetically-doped hybrid perovskites and will stimulate research on this highly-tuneable material platform that promises tailored interactions between magnetic moments and electronic states.

9:40 AM *F.EL08.02.02
Ultrafast Studies of Two-Dimensional Hybrid Metal Halide Perovskites Rebecca L. Milot; University of Warwick, United Kingdom

Two-dimensional Ruddlesden-Popper phase hybrid metal halide perovskites have been investigated for use in a range of optoelectronic devices including photovoltaic cells. Their main appeal for photovoltaics is improved aqueous stability, which is enabled by their incorporation of organic cations which are more hydrophobic than those usually used in 3D perovskites. However, quantum and dielectric confinement effects increase the exciton binding energies in these materials to as much as 100s of meV. These increased binding energies correspond to an increase in exciton population at ambient temperatures which can greatly alter the optoelectronic properties. Optical Pump/THz-probe (OPTP) spectroscopy measurements have revealed decreased effective charge-carrier mobilities and significantly shortened charge-carrier lifetimes for 2D perovskites (1). In hybrid 2D-3D materials, incorporating small amounts of the 2D material can improve optoelectronic properties (2), suggesting a balance between excitons and free charges is achievable by tuning the composition. OPTP and other ultrafast spectroscopic techniques are further used to elucidate the interplay between free charges and excitons in these materials and comment on the limits these properties impose on charge transport in devices.

Insight into Layered and Deficient Metal Halide Perovskites from First Principles and Symmetry Claudio Quarti[1], Mikaël Kepenekian[1], Pedesseau Laurent[2], Boubacar Traore[2], Nicolas Mercier[3], Mercouri G. Kanatzidis[4], Constantinos Stoumpos[5], Jacky Even[2] and Claudine Katan[1]; [1]Univ Rennes, ENSCR, INSA, CNRS, ISCR, France; [2]Univ Rennes, INSA Rennes, CNRS, Insttut Foton, France; [3]Université d'Angers, France; [4]Northwestern University, United States; [5]University of Crete, Greece

Currently, many different perovskite -with corner-sharing octahedra- as well as non-perovskite metal-halide solids are synthetized worldwide entailing the need for in-depth understanding of their structure/property relationships. In this regard, combining the huge accumulated knowledge over the last decades, on halide but also oxide perovskites, with modern atomic scale modeling as well as symmetry analysis has proved useful. Among others, new compositions such as $A'_2A_{n-1}M_nX_{3n+1}$ (where A and A' are cations, X is halide and M is metal) afford layered structures with a controlled number (n, currently ≤ 7) of octahedra in the perovskite layer. Those correspond to innate heterostructures that offer an ideal platform for fundamental understanding such as effect of quantum or dielectric confinement.[1]

Efforts have also been successful in building new perovskite structures with cations surpassing the Goldschmidt tolerance factor. For instance, this has been recently demonstrated for layered perovskites with the use of ethylammonium, isopropylammonium or dimethylammonium as perovskitizer, having a perovskite sheet retaining its continuous corner-sharing connectivity.[2] On another note, new three dimensional networks have been achieved by mixing larger cations (e.g., hydroxyethylammonium) with the standard ones (e.g. methylammonium, formamidinium) leading to the formation of voids in the perovskite lattice, either disordered (Hollow perovskites) or with structural signature of a periodic pattern (Deficient perovskites).[3]

In this talk, I will discuss some of our recent theoretical results paying attention on newly discovered halide perovskite phases and opportunities to further engineer their properties in connection with their use in devices.

Polyelemental, Multicomponent Perovskite Semiconductor Libraries Through Combinatorial Screening Michael Saliba; Technical University of Darmstadt, Germany

Perovskites have emerged as low-cost, high efficiency photovoltaics with certified efficiencies of 25.2% approaching already established technologies. The perovskites used for solar cells have an ABX3 structure where the cation A is methylammonium (MA), formamidinium (FA), or cesium (Cs); the metal B is Pb or Sn; and the halide X is Cl, Br or I. Unfortunately, single-cation perovskites often suffer from phase, temperature or humidity instabilities. This is particularly noteworthy for CsPbX3 and FAPbX3 which are stable at room temperature as a photoinactive “yellow phase”instead of the more desired photoactive “black phase”that is only stable at higher temperatures. Moreover, apart from phase stability, operating perovskite solar cells (PSCs) at elevated temperatures (of 85 °C) is required for passing industrial norms. Recently, double-cation perovskites (using MA, FA or Cs, FA) were shown to have a stable “black phase”at room temperature.(1,2) These perovskites also exhibit unexpected, novel properties. For example, Cs/FA mixtures supress halide segregation enabling band gaps for perovskite/silicon or perovskite/perovskite tandems.(3) In general, adding more components increases entropy that can stabilize unstable materials (such as the “yellow phase”of FAPbI3 that can be avoided using the also unstable CsPbI3). Here, we take the mixing approach further to investigate triple cation (with Cs, MA, FA) perovskites resulting in significantly improved reproducibility and stability.(4) We then use multiple cation engineering as a strategy to integrate the seemingly too small rubidium (Rb) (that never shows a black phase as a single-cation perovskite) to study novel multication perovskites.(5) One composition containing Rb, Cs, MA and FA resulted in a stabilized efficiency of 21.6% and an electroluminescence of 3.8%. The Voc of 1.24 V at a band gap of 1.63 eV leads to a very small loss-in-potential of 0.39 V, one of the lowest measured on any PV material indicating the almost recombination-free nature of the novel compound. Polymer-coated cells maintained 95% of their initial performance at 85°C for 500 hours under full illumination and maximum power point tracking. This is a crucial step towards industrialisation of perovskite solar cells. Lastly, to explore the theme of multicomponent perovskites further, molecular cations were revaluated using a globularity factor. With this, we calculated that ethylammonium (EA) has been misclassified as too large. Using the multication strategy, we studied an EA-containing compound that yielded an open-circuit voltage of 1.59 V, one of the highest to date. Moreover, using EA, we demonstrate a continuous fine-tuning for perovskites in the "green gap" which is highly relevant for lasers and display technology. The last part elaborates on a roadmap on how to extend the multication to multicomponent engineering providing a series of new compounds that are highly relevant candidates for the coming years.(6) (1) Jeon et al. Real-Time Investigation of Crystallization Pathways of Organo-Metal-Halide Perovskites Solar Michael F. Toney; University of Colorado Boulder, United States

Organic-inorganic hybrid perovskite solar cells (PSCs) have gained tremendous attention as materials for photovoltaics due to their high efficiencies and their compatibility with low-cost low-temperature fabrication methods (such as solution processing). Perovskite film formation is complex, involving the formation of intermediates and/or metastable phases that strongly affect the final perovskite film microstructure. Therefore, understanding the mechanism of perovskite formation and the crystallization pathways is key for facile control of perovskite formation. We are using time-resolved x-ray scattering to investigate the perovskite formation of $MAPbI_3$-based perovskites and mixed cation (Cs, FA)PbI_3 perovskites *in-situ* during spin coating and the subsequent post-deposition treatments, where FA is formamidinium and MA is methylammonium. For Cs0.15FA0.85PbI3 we study: i) the crystallization pathways during spin coating; ii) the subsequent post-deposition thermal annealing, and iii) crystallization during blade-coating. Our findings reveal that the formation of a non-perovskite FAPbI3 phase during spin coating is initially dominant regardless of the processing and that the processing treatments has a significant impact on the as-cast film structure and affects the phase evolution during subsequent thermal treatment. We show

that blade-coating can be used to overcome the non-perovskite phase formation via solvothermal direct crystallization of perovskite phase. This work show how real-time investigation of perovskite formation can help to establish processing-microstructure-functionality relationships. Our work highlights the importance of real-time investigation of perovskite film formation which can aid in establishing processing-microstructure-functionality relationships and help to provide a fundamental understanding of the mechanisms of perovskite formation.

7:30 PM *F.EL08.03.01
Progress in Homologous 2D Halide Perovskites and Their Impact in Photovoltaics Mercouri G. Kanatzidis; Northwestern University, United States

2D perovskites is a fascinating class of compounds where the 3D perovskite lattice is cut and spatially confined in two dimensions and an "inert" layer of intercalated organic ions is inserted between the layers. The 2D perovskites layers can be formed by the introduction of bulky organic cations that tend to interdigitate between the perovskite sheets. They exhibit a large compositional and structural phase space, which has led to novel and exciting physical properties. The variable thickness of the inorganic slabs presents natural quantum wells (QW) type structures with increased Coulombic shielding, lowering the exciton binding energy and increasing the effective charge carrier mobility. Because these materials have had a strong impact in how record breaking and stable solar cells are constructed, it is critical to understand the thermodynamic and chemical limitations of the maximum thickness that can be sandwiched between the organic bilayers while retaining the structural integrity of the 2D perovskite. What are the limits within which the 2D architecture that define the thickness of the inorganic slabs before the system diverts into the familiar 3D structure? To answer this fundamental question, we employed a combination of synthetic chemistry, calorimetry and crystallography to obtain and identify the thickest known 2D halide perovskite compound characterized to date and we use thermodynamics analysis to assess the enthalpy of formation for these compounds. The application of these low dimensional semiconductors in stable photovoltaics will be discussed.

7:50 PM *F.EL08.03.03
Is the Unit Cell of Solids, Including Halide Perovskites, as Small as the XRD Literature Says? Consequences of the Polymorphous Network Alex Zunger[1], Xingang Zhao[1], Zhi Wang[1] and Gustavo M. Dalpian[2]; [1]University of Colorado Boulder, United States; [2]Universidade Federal do ABC, Brazil

Many common crystal structures can be described by a single (or very few) repeated structural motifs ("monomorphous structures") such as octahedron in cubic halide perovskites. Interestingly, recent accumulated evidence suggests that electronic structure calculations based on such macroscopically averaged monomorphous cubic (Pm-3m) halide perovskites obtained from x-ray diffraction, show intriguing deviations from experiment. These include systematically too small band gaps, dielectric constants dominated by the electronic, negative mixing enthalpy of alloys, and significant deviations from the measured pair distribution function. We show here that a minimization of the systems T = 0 internal energy via density functional theory reveals a distribution of different low-symmetry local motifs, including tilting, rotations, and B-atom displacements ("polymorphous networks"). This is found only if one allows for larger-than-minimal cell size that does not geometrically exclude low symmetry motifs. As the (super) cell size increases, the energy is lowered relative to the monomorphous cell, and stabilizes after ~32 formula units (160 atoms) are included. Being a result of nonthermal energy minimization in the internal energy without entropy, this correlated set of displacements must represent the intrinsic geometry preferred by the underlying chemical bonding (lone pair bonding), and as such has a different origin than the normal, dynamic thermal disorder modeled by molecular dynamics. Indeed, the polymorphous network, not the monomorphous ansatz, is the kernel structure from which high temperature thermal agitation develops. The emerging physical picture is that the polymorphous network has an average structure with high symmetry, yet the local structural motifs have low symmetries. We find that, compared with monomorphous counterparts, the polymorphous networks have significantly lower predicted total energies, larger band gaps, and ionic dominated dielectric constants, and agree much more closely with the observed pair distribution functions. An analogous polymorphous situation is found in the paraelectric phase of a few cubic oxide perovskites where local polarization takes the role of local displacements in halide perovskites, and in the paramagnetic phases of a few 3d oxides where the local spin configuration takes that role. See PHYSICAL REVIEW B 101, 155137 (2020).

8:10 PM *F.EL08.03.14
Facets of Multicomponent Halide Perovskites—How *In Situ* Experiments Can Help us to Understand Formation, Stability and Composition Ana F. Nogueira; University of Campinas, Brazil

Multicomponent perovskite solar cells have reached the recent efficiency breakthrough of 25.2%, higher than silicon polycrystalline photovoltaics. Such fantastic result was only possible due to a precise control and engineering of the

morphology, interfaces and the use of multiple cations in perovskite A-site, as Rb, Cs, MA (methylamonnium) and FA (formamidinium). For tandem perovskite solar cells, a mixture of different anions, as Br and I is also desired to adjust the band gap. Such cocktail of different cations and anions influences the formation of intermediates, new phases, favours halide homogenization, etc; so that at the end, the efficiency of the device is closely related to not only the optical quality of the film (e.g. crystallinity), but morphology and composition.
In this presentation, we will summarize important results using *in situ* experiments to probe perovskite formation (2D and 3D), stability and composition. We employed time-resolved grazing incidence wide angle x-ray scattering (GIWAXS), small angle x-ray scattering (SAXS) and high-resolution XRD taken at the Brazilian Synchrotron National Laboratory and SSRL-Stanford.
In situ GIWAXS experiments allowed us to understand the influence of the relative humidity and time to drop the antisolvent during the preparation of perovskite films and get important information about final composition and morphology [1]. It is well known that a 2D layer on the top of a 3D bulk perovskite improves stability and performance. *In situ* GIWAXS revealed us that during thermal annealing the 2D layer transforms itself into a disorder layer, improving hole transfer and stability [2]. This technique was also employed to identify the first intermediates formed during the degradation of different Cs and Br perovskite compositions under ambient conditions [3].
In situ SAXS is another powerful technique to follow the first stages of the 2D perosvkite's formation. Our results suggest that the formation of the individual slabs in $BA_2[FAPbI_3]PbI_4$ is quite fast (within the first 10 s) and, then, these slabs self-assemble into bulk crystallites during the next 40 minutes [4].
Another topic of interest is the photoinduced phase segregation in FACs-based perovskite films. We investigated this phenomenon by photoluminescence (PL) studies and *in situ* high-resolution XRD (dark and under illumination). We found out that cubic-tetragonal transition is able to stabilize the samples with higher Br and Cs content, however this is not true for the films with 17% Br. Thus, other mechanisms must be operating and ruling phase segregation [5].

Fabrication of Perovskite Solar Cells—Wet Solution Deposition vs Vacuum Evaporation Shengzhong (Frank) Liu[1,2], Jiangshan Feng[1] and Min Huang[3]; [1]Shaanxi Normal University, China; [2]Dalian Institute of Chemical Physics, Chinese Academy of Sciences, China; [3]Academy of Opto-Electronics, Chinese Academy of Sciences, China

With its rapidly increased cell efficiency to as high as over 25% and incredible suitability to process, equipment and operation, the perovskite is truly a rising star for next generation solar cells. In fact, its cell efficiency has surpassed all other thin film solar cells. We have studied a few different deposition technologies, including dry processing such as vacuum-based alternating precursor deposition, partial co-evaporation of inorganic components; dry atmospheric deposition by using direct contact reactive process; and wet solution processing such as small area spin-coating, large-area blade coating and high-throughput slot-die coating. At present, the wet solution deposition processes are well-advanced with significantly higher efficiencies over 23%. In comparison, the vacuum processes are under development with best cell efficiency still lower than 22%. This article is intended to compare and opt for the best one with most promises for future largescale processing by screening these technologies developed in research laboratories. With mature industrial equipment and engineering processes, we improved the vacuum deposited perovskite cell efficiency to 21.32%, highest for this type to our knowledge. In addition, the films produced using dry deposition seem to show better stability against high humidity, temperature and light-soaking.

11:50 AM *F.EL08.07.03
Cationic Management for Efficient and Stable $FAPbI_3$-Based Perovskite Solar Cells Sang Il Seok; Ulsan National Institute of Science and Technology (UNIST), Korea (the Republic of)

Highly efficient perovskite solar cells (PSCs) with power conversion efficiencies (PCEs) > 25% are fabricated with formamidinium (FA)-based lead triiodide ($FAPbI_3$) perovskites. In general, mixed cations and anions containing FA, methylammonium (MA), Cs, I and Br ions are used to stabilize the black α-phase against d-phase of the pristine $FAPbI_3$. Disadvantageously, the additives such as MA, Cs and Br to $FAPbI_3$ widen its bandgap and reduce the thermal stability due to the lower thermal decomposition of MA to FA. Therefore, in order to further increase PCE through the enhanced

photocurrent density due to the increased light harvesting, stabilizing the a-$FAPbI_3$ without blue-shift of the bandgap is needed. In addition, structural dimensions, distortion, and dielectric properties can vary significantly depending on the ionic radius and type of the A-site cation. In this presentation, I would like to introduce the impact of cationic management on the efficiency and long-term stability of perovskite solar cells.

12:10 PM *F.EL08.07.04
Defect Related Charge Traps and Doping in Perovskites, Solar Cells and Tandem Devices Jinsong Huang; University of North Carolina-Chapel Hill, United States

In this talk, I will present our recent progress in understanding the fundamental properties of metal halide perovskites and the related device developments. First, the nature of defects induced charge traps and doping in perovskite materials will be discussed, and their chemical origin will be analyzed. A recent development in characterizing the spatial and energetic distributions of defects will be presented, which revealed the significant difference in trap density between single crystals and polycrystalline films, but similarity in distribution of the traps. Second, the healing of defects and tuning the doping in perovskites by multiple processes will be presented that boost the efficiency and stability of perovskite solar cells and modules. TFinally, a new charge recombination layer for all perovskite tandem solar cells will be presented which not only simply the fabrication process, but also significantly enhance tandem solar cell efficiency and stability.

12:30 PM *F.EL08.07.01
Metal Halide Perovskite Materials Development at Hunt Perovskite Technologies, LLC Michael Irwin; Hunt Perovskite Technologies, LLC, United States

An overview of Hunt Perovskite Technologies, LLC (HPT) metal halide perovskite (MHP) PV research program will be presented. Founded in 2013, HPT has focused their research on stabilizing the MHP material through better chemistry, as highlighted by stabilizing the pure alpha-phase $FAPbI_3$ MHP material in 2015. In this materials study, we have come to appreciate the unique defect structure of the MHP material by way of its ionic composition. Descriptions of MHP macro and molecular defect structure will be discussed, as well as their effect on the material's durability and PV device performance.

12:50 PM *F.EL08.08.01
Halide Perovskites—Unprecedented Opportunities for Semiconductor Design and Processing David Mitzi; Duke University, United States

Although known for many years, organic-inorganic hybrid and related inorganic halide-based perovskites have received extraordinary attention recently, in part due to the unique physical properties and chemical diversity offered by these structures, which make them outstanding candidates for applications in photovoltaic and other semiconductor devices (especially for systems based on Pb, Sn and Ge). Perovskite structures consist of networks of corner-sharing metal halide octahedra that can extend in three or lower dimensions, providing opportunity to probe how dimensionality of the inorganic framework impacts semiconducting character. Further, incorporation of more complex organic cations within lower-dimensional perovskites enables combining outstanding inorganic-derived semiconducting character with organic-derived properties (e.g., luminescence, chirality), a feature extending well-beyond what is attainable with more established inorganic semiconductors (e.g., Si or GaAs) and underlying the creation of multifunctional organic-inorganic compounds and electronics [1]. This talk will emphasize chemical/structural versatility [2] and implications for semiconductor design (both with regards to properties and processing), as well as new characterization approaches for elucidating materials properties. Examples of topics that may be covered include custom-designed organic cations that template or stabilize the formation of difficult-to-realize lead-free perovskite structures [3], merging computational/experimental approaches to predict/verify optoelectronic character and guide design of complex organic-inorganic hybrids [4] and the use of a new carrier-resolved photo-Hall (CRPH) technique [5] to explore the impact of additive engineering on majority/minority carrier properties in perovskite films. Outstanding functionality and versatile processing provide two pillars for future application and study of this exciting and evolving materials family. References: [1] D. B. Mitzi, K. Chondroudis, C. Phase Stable and Less-Defect Perovskite Quantum Dots—Optical Property, Photoexcited Carrier Dynamics and Application to Solar Cells Qing Shen, Feng Liu, Chao Ding and Yaohong Zhang; The University of Electro-Communications, Japan

Perovskite quantum dots (QDs) as a new type of colloidal nanocrystals have gained significant attention for both fundamental research and commercial applications owing to their appealing optoelectronic properties and excellent chemical processability.[1] For their wide range of potential applications, synthesizing colloidal QDs with high crystal quality is of crucial importance. However, like most common QD systems, those reported perovskite QDs still suffer from a certain density of trapping defects, giving rise to detrimental non-radiative recombination centers and thus low photoluminescence quantum yield (PL QY). Halide vacancy in perovskites has been widely accepted to be the main factor preventing near-unity PL QY by creating uncoordinated Pb octahedra and the subsequent localized deep trap states.[2] Very recently, we have succeeded in synthesis of phase-stable and less-defect perovskite QDs, including $FAPbI_3$ QDs, $CsPbI_3$ QDs and Sn-Pb alloyed QDs.[3-6] We have demonstrated that a high room-temperature PL QY of up to 100% can be obtained in $FAPbI_3$ and $CsPbI_3$ perovskite QDs, signifying the achievement of almost complete elimination of the trapping defects. This is realized by the modulation of halide precursor involved in the synthesis, in which trioctylphosphine (TOP) is used to dissolve halide salts. For Sn-Pb alloyed QDs, although the alloyed QDs possess much improved structural stability than that of the pure Pb- and Sn-based one, they still suffer from an extremely low PL QY of ~0.3%, indicative of the severe charge trapping in these Sn-containing perovskites. Such low PL QY is believed to result from the widely known facile oxidation of Sn^{2+} to Sn^{4+}. To address this issue, we have demonstrated very recently that the deep-level trap states in Sn-based perovskites can be well suppressed by Na^+ doping, which gives rise to a dramatically improved PL QY of ~28% without alerting their favorable electronic structure. X-ray photoelectron spectroscopy (XPS) studies suggest the formation of a stronger chemical interaction between I^- and Sn^{2+} ions upon Na doping. On the other hand, though the reported TOP-based route has demonstrated efficacy in producing $CsSn_xPb_{1-x}I_3$ QDs (x = 0~0.6) with superior structural stability, such synthetic protocol can only find success in making these I-related QDs, preparing those pure Cl- and Br-based analogues remains challenging because of the insufficient solubility of $PbBr_2$ and $PbCl_2$ in TOP. Therefore, by taking advantage of the strong coordinating ability of trioctylphosphine oxide (TOPO), we have recently reported the first synthesis of $ASn_xPb_{1-x}X_3$ QDs (A = Cs, FA, MA) with excellent tunability in both Sn/Pb ratio and a full range of halide covering. The ability to generate all possible, unique combinations has offered great material versatility for the perovskite QD family. Further, by employing ultrafast spectroscopic techniques, we have resolved the fundamental photoexcited charge carrier dynamics in these alloyed QDs, which shall pave the way for future study for enhancing their usefulness in optoelectronic applications.[7-9] We expect the successful synthesis of the "ideal" perovskite QDs will exert profound influence on their applications to both QD-based light-harvesting and -emitting devices in the near future.

1:45 PM *F.EL08.09.01
Molecular Engineering of Two-Dimensional Organic-Inorganic Hybrid Perovskites Letian Dou; Purdue University, United States

Two-dimensional halide perovskites are exciting new semiconductors that show great promising in low cost and high-performance optoelectronics devices including solar cells, LEDs, photodetectors, transistors, etc. In the first part of this talk, I

will present a molecular approach to the synthesis of high-quality organic-inorganic hybrid perovskite quantum wells through incorporating widely tunable organic semiconducting building blocks as the surface capping ligands. By introducing sterically tailored groups into the molecular motif, the strong self-aggregation of the conjugated organic molecules can be suppressed, and single crystalline organic-perovskite hybrid quantum wells and superlattices can be easily obtained via one-step solution-processing. Energy transfer and charge transfer between adjacent organic and inorganic layers are extremely fast and efficient, owing to the atomically-flat interface and ultra-small interlayer distance. In the second part, I will present the synthesis and characterization of a stable lead-free Sn (II)-based two-dimensional perovskite featuring a p-conjugated oligothiophene ligand. The conjugated ligands facilitate formation of micrometer-size large grains, improve charge injections, and stabilize the inorganic perovskite layers. Thin film field-effect transistors based on (4Tm)2SnI4 exhibit enhanced hole mobility up to 2.3 cm2V-1s-1, and dramatically improved stability over the previous benchmark material (PEA)2SnI4. Stabilization mechanisms were investigated via single crystal structure analysis as well as density functional theory calculations. It was found that the large conjugated organic layers not only serve as thick and dense barriers for moisture and oxygen, but also increase the crystal formation energy via strong intermolecular interactions.

Bismuth-Based Colloidal Nanocrystals—Lead-Free Materials for Solution-Processed Solar Cells Maria Bernechea; INA - Institute of Nanoscience of Aragon, Spain

In the last years, the field of solution-processed solar cells based on inorganic semiconductors has seen a great progress, showing the highest efficiencies among the emerging photovoltaic technologies. Indeed, of quantum dot solar cells have reached an efficiency over 16%, and solar cells based on perovskites have surpassed 25% efficiency. However, the future development of these cells could be limited due to the presence of highly toxic elements in their composition, more specifically lead (Pb). Efforts are thus required in searching for earth-abundant, and non-toxic materials. Inorganic colloidal nanocrystals (NCs) are attractive materials for their use as active layers in quantum dot solar cells. They are generally composed of earth-abundant elements, and they can be processed from solutions, allowing an easy and cheap fabrication of devices. Moreover, they have additional attractive properties, like high absorption coefficients, tunable bandgaps, and band energy level engineering through ligand exchange. In this context, bismuth-based colloidal NCs, appear as an attractive alternative for environmentally friendly, low cost solar cells. We have developed ways to modify the size and shape of the bismuth-based nanocrystals, and we have observed how this affects their optoelectronic properties. We have studied the modulation of Fermi level and energy bands introducing different ligands on the surface of the NCs. We have employed these NCs to fabricate solution-processed solar cells, focusing on completely non-toxic devices, achieving a certified efficiency of more than 6%, employing very thin layers (~35 nm) of AgBiS2 NCs. A summary of these results will be presented and future directions will be discussed.

2:25 PM *F.EL08.05.01
Is There Any Hope for Efficient Sn-Based Perovskite Solar Cells? Maria Antonietta Loi; University of Groningen, Netherlands

Organic lead halide perovskite based solar cells (HPSCs) have achieved certified power conversion efficiency (PCE) over 25.0%. Despite the high efficiency achieved, there are still many concerns about the large-scale applicability of this solar cells because of the water soluble toxic Pb2+. The simpler approach to address this issue is to find a benign or less toxic metal to replace the lead atom in the perovskite structure, with the resulting perovskite still showing the excellent optical and electrical properties. Theoretically, tin based perovskite holds the promise to produce similar or even higher PCE compared to their Pb counterpart. However, for relatively long time the tin-based HPSCs held a PCE lower than 7% though intensive research efforts were devoted to their investigation. The facile formation of tin vacancies and easy oxidation of Sn2+ have been identified as the main reason determining the low PCE. In my presentation I will report as a small amount of 2D tin perovskite templates the growth of highly crystalline and oriented 3D FASnI3 grains (2D/3D mixtures), suppressing effectively the appearance of tin vacancies and Sn2+ oxidation. As a consequence of the reduced background charge carrier density and trap assisted charge recombination, the device showed a 50% improvement in the PCE (up to 9%) compared to that using pure 3D tin perovskite. We further succeeded reducing the defects in the 2D/3D tin perovskite films by adding ethylammonium iodide (EAI) into the corresponding perovskite precursor solution. These films display larger crystalline grains and a more compact and uniform film morphology when compared to their counterparts without EA cation. These features lead to a much lower trap density, background charge carrier density and charge recombination loss in the corresponding devices. Results, which allow hopping for future highly efficient Sn-based hybrid perovskite solar cells.

Data-Science Methods Enable Perovskite Stability and Performance Improvements Tonio Buonassisi, Shijing Sun, Clio

Batali, Antonio Buscemi, Alex Encinas, Janak Thapa, Noor Titan Putri Hartono, Felipe Oviedo and Armi Tiihonen; Massachusetts Institute of Technology, United States

Data-sceince methods, including advanced statistics and machine learning, can help researchers diagnose, optimize, and design more efficiently. In this talk, I'll summarize the MIT PVLab's recent progress optimizing bare films and record-efficiency perovskite devices with capping layers using data-science methods. These include combining density-functional theory (DFT) and Bayesian inference to accelerate the search for stable compositions, and optimizing capping layers for combined performance and stability. Lastly, I'll highlight our progress searching for lead-free perovskite-inspired, defect-tolerant semiconductors.

3:05 PM *F.EL08.006.05
Unravelling the Impacts of Mobile Ions on Perovskite Solar Cell Performance Rebecca Belisle; Wellesley College, United States

Defect tolerance has emerged as a central theme for the success of halide perovskites as photovoltaics. Some current estimates put the number of mobile ionic defects in common halide perovskites above 1017 cm-3, yet the halide perovskite band structure and resulting shallow nature of the hypothesized dominant defects limits their ability to act as recombination centers in these materials. However, this defect tolerance does not imply that these ionic defects have no impact on device performance. Current-voltage hysteresis, reverse-bias breakdown, photo-brightening, photodegradation, thermal stability, and other behaviors related to perovskite performance have all been attributed to the appreciably ionic transport in perovskites made possible by this large defect population. In this work I will present recent advances in both the development of experimental methods for analyzing the formation and behavior of mobile ions in halide perovskites, and our understanding of the effects of these mobile ions on device performance. I will discuss methods to investigate defect formation and transport, including our results using in situ photoluminescence and X-ray diffraction techniques to track ion movement and correlate that with the optoelectronic properties of methylammonium perovskites. Additionally, I will share our work looking at the impacts of mobile ions on device performance, particularly with regards to limits on the open-circuit voltage of perovskite solar cells. Finally, I will highlight the unique roles that contacts and surfaces can play in optimizing the performance and stability of perovskite solar cells in light of these mobile ionic defects.

3:20 PM F.EL08.05.06
Enhancement of Efficiency for Pb Free Perovskite Solar Cells Consisting of Sn2+ Doped with Ge2+ Shuzi Hayase[1], Kohei Nishimura[1], Muhammad Akmal Kamarudin[1], Daisuke Hirotani[2], Kengo Hamada[2], Qing Shen[1], Satoshi Iikubo[2], Takashi Minemoto[3] and Kenji Yoshino[4]; [1]The University of Elector-Communications, Japan; [2]Kyushu Institute of Technology, Japan; [3]Ritsumeikan University, Japan; [4]Miyazaki University, Japan

The certified efficiency of Pb-perovskite solar cells with more than 1 cm2 area is reported to be 20.9%(1). In the smaller cell, the cell efficiency with 25.2% has been reported, which is close to 22.3 % of multi Si solar cells (2). However, the use of Pb in electronic devices is limited according to the EU RoHS Directive. Thus, it is needed to develop Pb-free perovskite solar cells. Among Pb-free perovskite candidates, Sn perovskite is one of the most promising candidates for the light harvesting layer for the Pb-free perovskite, because they have perovskite structure similar to Pb-perovskite. However, the efficiency iwas not as high as those for Pb-perovslite solar cells. We have already reported that the efficiency was enhanced by Ge2+ doping to the Sn-perovskite layer, because the carrier density in the Sn-perovskite layer was reduced (3,4). Now, we discuss the further enhancement of the Sn-perovskite solar cells from the view point of the lattice strain (disordering) relaxation and the surface passivation on the perovskite slayer to show the direction of the research. We report post-treatment of Sn-perovskite layer with Lewis base (NH2-CH2-CH2-NH2) to suppress the recombination reaction in Sn-perovskite solar cells resulting in efficiencies of 10.2 %. Upon analyzing the X-ray photoelectron spectroscopy and impedance spectroscopy data, we came to the conclusion that the amine-group bonded the under-coordinated tin, passivating the dangling bonds and defects resulting in suppressed charge carrier recombination (5). This also has the effect of prolonged lifetime and higher charge carrier mobility. These findings provide the groundwork for improving the efficiency of Sn-halide PSCs to compete with that of lead-based PSCs by simple post-treatment with organic molecules (6). We and other research groups have reported that the efficiency of Sn-perovskite solar cells increases spontaneously during the storage, which we explained by the perovskite lattice strain (disordering) relaxation. This prompted us to examine the relationship between between relative lattice strain and photovoltaic performances. It is shown that the efficiency of the Sn-perovskite solar cells has good relationship with the lattice strain (disordering). By decreasing the lattice strain (disordering), Ge doped Sn-perovskite solar cells with 11.7% was prepared. The mechanism wil be discussed. 1. SESSION F.EL08.01: Micro- and Nanoscale Characterization of Halide Perovskites
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-EL08

5:00 AM *F.EL08.01.01
Microscopic Insights About Metal Halide Perovskite Surfaces Yabing Qi; Okinawa Institute of Science and Technology, Japan

Metal halide perovskite solar cell research keep progressing on various fronts. My group at OIST uses surface science and advanced characterization to obtain fundamental understanding about perovskite materials and solar cells. Surfaces and interfaces play an important role in dictating performance and stability of perovskite solar cells. In this talk, I focus on surface science understanding and microscopic insights about perovskite surfaces [1-3]. [1] R. Ohmann, Y. Li*, N.-G. Park*, Y. B. Qi* et al., J. Am. Chem. Soc. 137, 16049 (2015); [2] J. Hieulle, X. Wang, Y. Yan*, Y. B. Qi* et al., J. Am. Chem. Soc. 141, 3515 (2019); [3] C. Stecker, K. Liu, G. Wang*, Y. B. 5:15 AM *F.EL08.01.02
Nanoscale Heterostructures of Halide Perovskites and the Study of Charge Transfer Mechanisms Song Jin, Dongxu Pan and Matthew P. Hautzinger; University of Wisconsin-Madison, United States

The remarkable solar performance of lead halide perovskites can be attributed to their excellent physical properties that present many mysteries, challenges, as well as opportunities. Better control over the crystal growth of these fascinating materials and fabrication of heterostructures using various halide perovskites with different bandgaps would open up opportunities for exploring new properties and device applications. After a brief summary on the nanowires and nanoplates of various metal halide perovskites we have developed and their lasing properties, I will focus my discussion on the growth of heterostructures of 2D Ruddlesden-Popper (RP) layered lead iodide perovskites with defined n phases and atomically sharp interfaces both in 2D/3D perovskite heterostructures and also as multi-layered multi-colored vertical heterostructures, in which the long chain ammonium ligands serve as the barriers to prevent ion migration across the junctions. We have used these well-defined heterostuctures to study the carrier transfer mechanisms between 2D and 3D perovskites and between different RP phases. The excellent properties of these single-crystal perovskite nanostructures of diverse families of perovskite materials with different cations, anions, and dimensionality make them ideal for fundamental physical studies of carrier transport and decay mechanisms, and for enabling high performance lasers, LEDs, and other optoelectronic applications.

5:30 AM *F.EL08.01.03
A Bird's Eye View of Composition-Performance Relationships in Halide Perovskites via Correlative Microscopy David P. Fenning and Yanqi Luo; University of California, San Diego, United States

Halide perovskite thin films and devices exhibit a remarkable degree of heterogeneity in structure and composition at the nanoscale, varying frequently from nominal synthesis targets in ways that can be difficult to detect using ubiquitous laboratory analysis. Leveraging synchrotron-based in situ X-ray microscopies to sample composition, structure, and optoelectronic quality at the nanoscale, we reveal the dependence of nanoscale phase separation and variations in charge collection on the local chemistry of A-site perovskite alloys. At times, these stoichiometric variations arise in the as-fabricated film, revealing important chemical dependencies. However, we also find significant evolution in the microstructure of high-performance perovskites during operation and under environmental stress, leading to insights into mechanistic pathways of degradation and new avenues for stabilization in high-performance alloyed perovskites.

5:45 AM *F.EL08.01.04
Nanoscale Spectroscopy of Halide Perovskite Marina S. Leite; University of California, Davis, United States

Halide perovskites for optoelectronics are often composed by micro- and nano-scale inhomogeneous constructs. Therefore, high spatial resolution characterization methods are required for mapping and quantifying their electrical behavior. In this talk I will present our latest developments on atomic force microscopy (AFM) methods to assess the dynamic physical and chemical processes that take once perovskite materials and photovoltaic devices are exposed to light. Briefly, we realize a 4D imaging method that enables mapping open-circuit voltage (Voc) changes with in real-time (16 seconds per scan), and at the nanoscale (< 50 nm in spatial resolution) based on illuminated Kelvin probe force microscopy (KPFM). Using this paradigm, we have demonstrated ion motion within a single nanoscale grain in MAPbI3 solar cells upon 1-sun illumination, which results in a residual Voc that lasts for several minutes even under dark conditions. For multi-cation structures, we found that Cs-based perovskites deliver fully reversible and stable nanoscale voltage response, in excellent agreement with macroscopic measurements. We correlate the Voc nanoscale maps with chemical imaging through nano-IR and discover that the local variations in voltage are related to the power conversion efficiency enhancement in KI-treated perovskite. The heterogeneity revealed in both the local electrical and chemical responses reveals that the KI additive migrates our of the perovskite films, yet surprisingly; does not affect device performance. Our functional imaging platform can be extended to other perovskite materials, including Pb-free options.

6:00 AM *F.EL08.01.05
Multi-Modal Microscopy Approaches to Probe Halide Perovskite Device Operation Samuel D. Stranks; University of Cambridge, United Kingdom

Halide perovskites are generating enormous excitement for their use in high-performance yet inexpensive optoelectronic applications. Nevertheless, a number of fundamental questions about these materials still remain and need to be answered to push devices to their theoretical performance limits. For example, we still know very little about the specific nature of the defects leading to trap states, carrier recombination pathways or anisotropies of carrier diffusion. I will present results on new techniques we are developing to address these open questions in 2D and 3D halide perovskite semiconductors. These techniques focus on understanding charge carrier behavior, including recombination, trapping and diffusion, and how these properties link to chemical and material properties. I will present high-resolution luminescence microscopy techniques employing two-photon excitation to allow us to visualize and time-resolve carrier diffusion in three-dimensions, revealing anisotropic and depth-dependent carrier diffusion properties. Furthermore, we link the local luminescence properties to high-resolution crystallographic and chemical properties using synchrotron nano-probe X-Ray beamlines and low-dose scanning electron diffraction measurements. Through these measurements, we reveal the nature of the defects associated with local non-radiative power losses and heterogeneous diffusion. Furthermore, we provide guidelines about how we can ultimately eliminate these unwanted loss pathways and homogenize carrier diffusion.

6:15 AM *F.EL08.01.06
Processing Dependent Signature of Electronic States in the Gap of Metal Halide Perovskites Antoine Kahn; Princeton University, United States

An important area of research on metal halide perovskites (MHP) concerns the presence and role of surface and interface electronic gap states introduced by defects inherent to film processing, degradation under stress (T, irradiation, environment) or chemical reaction with neighboring layers, and the restrictions that these states impose on device performance, i.e., limit in Fermi level split, or aid carrier recombination, leading to reduction of solar cell open circuit voltage. This talk reports results on the determination of the presence and density of electronic states tailing above the valence band maximum of several MHPs, e.g., MAPbI3, CsPbI3, and FA0.85MA0.15Pb(I0.85Br0.15)3. Detailed measurements of the top of the valence band of these materials are performed using high-sensitivity UPS achieved in logarithmic detection. We focus specifically on MAPbI3 films processed with different additives mixed in the precursor-DMF solution: (i) no additives; (ii) DMSO; (iii) NH4++DMA+; and (iv) N-methyl-2-pyrrolidone thione (NMPT). The latter, an S-donor solvent, was investigated for its stronger coordination to Pb2+ as compared to the O-donor solvent DMSO, the additive widely used for improving film morphology. Significant differences are revealed between films processed with DMSO and NMPT. Once carefully treated via (experimental) background and parasitic satellite line contribution subtraction, the DMSO processed film exhibits a clear density of gap states extending from the valence band maximum to the Fermi level, whereas the NMPT processed film does not. The study was then complemented by Kelvin probe-based contact potential difference measurements to address the issue of surface photovoltage (SPV) during UPS. KP-based SPV measurements on these films show a significantly larger SPV (150 mV) and EF-VBM on the DMSO-treated films than on the NMPT-treated ones (SPV= 40 mV), confirming both the presence of the gap states and their impact on the electronic structure of the MHP films. The origin and nature of these gap states are still under investigation.

6:30 AM *F.EL08.01.07

Nanoscale Effects in Perovskite Solar Cells Observed by Scanning Force Microscopy Stefan Weber; Max Planck Institute for Polymer Research, Germany

Perovskite solar cells have electrified the solar cell research community with astonishing performance and surprising material properties. However, the widespread commercialization of perovskites in solar cells and other optoelectronic applications still requires a more detailed knowledge about fundamental material properties. My group is specialized in the investigation of these properties on nanometer length scales using scanning force microscopy. We recently discovered a distinct nanoscale stripe domain structure in the piezoresponse on perovskite crystals [1]. The pattern is characteristic for ferro-elastic twin domains. We are currently investigating the influence of the domain walls on the charge carrier dynamics. Next to fundamental physical properties of photovoltaic perovskites, we investigate complete solar cell devices under operation conditions. To map and follow the vertical charge distribution across the functional layers of an operating device, we developed a method to prepare smooth cuts across the device [2]. We subsequently map the potential distribution across the device using a time-resolved Kelvin probe force microscopy (tr-KPFM) [2,3]. We can simulate open- or short circuit conditions, apply an external voltage or illuminate the device. In particular, we found that thin layers of localized charge formed and stabilized at the electrode interfaces when we changed the external voltage or illuminated the device. We could show that ion migration itself is too fast to influence device hysteresis. Instead, the formation and release of ionic interface charges determine the time scales for current-voltage hysteresis in perovskite solar cells. Our results demonstrate that a precise control over the interfaces in perovskite solar cells is the key, not only for controlling and suppressing hysteresis but also for their long-term stability in perovskite solar cells. [1] J. Phys. Chem C, 120(10), 5724 (2016). [2] ACS Appl. Mat. Interfaces, 8(30), 19402 (2016). [3] Energy Environmental Science, 11, 2404 (2018).

6:45 AM *F.EL08.01.08
Beyond Dilute Imperfections—Extended Defects in Halide Perovskites Aron Walsh[1,2]; [1]Imperial College London, United Kingdom; [2]Yonsei University, Korea (the Republic of)

Defects come in a several flavours: conductivity-promoting defects create free carriers that enable electronics; killer defects (deep, charged centres) trigger recombination; and charge scattering defects reduce mobility [1]. Our understanding of the defect processes in halide perovskites is gradually improving through a combination of high-resolution measurements and materials modelling [2]. However, evidence is building for the importance of point defect aggregates and structural defects in higher dimensions. I will discuss recent progress, from theory and experiment, to identify, characterise and control extended defects in metal halide perovskites. In particular, I will cover the role of grain boundaries [3] stacking faults [4]. The use of defect tolerance as a metric to develop and screen post-perovskite materials will be critically addressed. This research is part of a collaboration with the group of Sam Stranks (Cambridge), and used the UK National Supercomputer ARCHER.

Unraveling the Dynamic Behavior of Halide Perovskites from the Macro- to the Nanoscale Marina S. Leite; University of California, Davis, United States

The dynamic optical and electrical responses of halide perovskites are currently not fully understood, and are closely related to the irreversible changes frequently observed in devices. We determine the individual and combined effects of extrinsic (humidity and oxygen) and intrinsic (light, bias, and temperature) stressors in the physical behavior of the archetypal $MAPbBr_3$ and $MAPbI_3$, and Cs-mixed perovskites. First, a detailed comparison between $MAPbBr_3$ and $MAPbI_3$ through time-dependent voltage measurements reveals that, upon illumination, high-energy photons leads to a > 10x slower voltage decline toward equilibrium than low-energy photons in $MAPbBr_3$. Yet, $MAPbI_3$ shows wavelength-independent decay rate, resulting from ion migration. Second, through in situ photoluminescence (PL) under environmentally controlled conditions, we resolve a humidity-induced PL hysteresis. Further, we apply a machine learning algorithm to predict the luminescence

response for > 12 hs. Concerning the unique behavior of multi-cation perovskites, a correlative microscopy approach is realized, combined with environmental-controlled PL measurements.

7:15 AM *F.EL08.01.10
3D Nanoscale Photoconduction in Hybrid Perovskite Thin-Film Grains and Grain Boundaries as Revealed by Tomographic Atomic Force Microscopy Jingfeng Song[1], Yuanyuan Zhou[2], Nitin Padture[2] and Bryan D. Huey[1]; [1]University of Connecticut, United States; [2]Brown University, United States

Although grain boundaries and other interfaces in photovoltaics are generally detrimental for photogenerated carrier transport, their role remains contentious in hybrid perovskite semiconductors. The uncertainty is partially due to the practical challenge that most experimental approaches are performed at the top surface, which is not only insensitive to depth-dependent inhomogeneities but also may be influenced by topographic artifacts. Accordingly, we have developed tomographic atomic force microscopy (T-AFM) for fully 3-Dimensional mapping of photogenerated carrier transport in hybrid perovskite thin films. Via progressive nanoscale planarization and photoconduction mapping during *in-situ* illumination in an AFM, this unambiguously reveals grain boundaries serving as highly interconnected conducting channels for carrier transport in $MAPbI_3$. Voltage dependent measurements reveal enhanced carrier mobilities at most grain boundaries, although careful analysis also reveals the coexistence of 5-10% insipid interfaces. Depth dependencies in photocurrent through the grains, and the grain boundaries, are also assessed. Such insights are critical for engineering hybrid perovskites to be optimized for future solar cells, photodetectors, and light sources.

7:30 AM F.EL08.01.11
Size-Dependent Lattice Structure and Confinement Properties in CsPbI3 Perovskite Nanocrystals—Negative Surface Energy for Stabilization Joseph Luther[1], Qian Zhao[1], Laura Schelhas[2], Abhijit Hazarika[1], Michael F. Toney[2] and Peter C. Sercel[3]; [1]National Renewable Energy Laboratory, United States; [2]SLAC National Accelerator Laboratory, United States; [3]California Institute of Technology, United States

CsPbI3 nanocrystals are widely reported to be more stable in the perovskite phase than thin film CsPbI3 which rapidly converts into the non-perovskite orthorhombic phase. In this work, we answer why the phase stability is enhanced at the nanoscale. In addition, contrary to many reports, we confirm that the actual perovskite phase for CsPbI3 NCs is the gamma phase, rather than the alpha cubic phase. In this work, $CsPbI_3$ with narrow size distributions between 5 and 15 nm were prepared to study the size-dependent properties. The size dependent structural lattice constants were characterized and found to systematically vary by 3% across the size range, with unit cell volume increasing linearly with the inverse of size to 2.1% for the smallest size. This size dependent volume change correllates to negative surface energy between -3.0 to -5.1 eV nm^{-2} for ligated $CsPbI_3$ nanocrystals. This negative surface energy leads to strain on the nanocrystals which, when present, causes stability in the perovskite phase, whereas thin film, strain-free $CsPbI_3$ is only metastable in the perovskite phase. Moreover, the size-dependent bandgap is also studied and found to be best described using a nonparabolic intermediate confinement model. Using this new model, we can experimentally determine constants such as the bulk bandgap, effective mass, and exciton binding energy, and conclude that many of these main material constants vary from the bulk α-phase values. This work provides a robust route to understanding γ-phase properties of $CsPbI_3$.

CsPbBr3 Nanocrystal Films—Charge Localization and Deviations from Bulk Properties Silvia G. Motti[1], Franziska Krieg[2], Jay Patel[1], Maksym V. Kovalenko[2], Michael Johnston[1] and Laura Herz[1]; [1]University of Oxford, United Kingdom; [2]ETH Zürich, Switzerland

Metal halide perovskites are highly promising semiconductors for light-emitting and photovoltaic applications. The colloidal synthesis of nanocrystals (NC) is an effective approach for obtaining nearly defect-free semiconducting materials that can be processed into inks for low cost, high performance device fabrication. However, disentangling the effects of surface ligands, morphology and boundaries on charge-carrier transport in thin films fabricated with these high-quality NCs is inherently difficult. To overcome this fundamental challenge, here we employ terahertz (THz) spectroscopy to optically probe the photoconductivity of CsPbBr3 nanocrystal films. We compare the vibrational and optoelectronic properties of the NCs with those of a corresponding bulk polycrystalline perovskite and find significant deviations. We demonstrate a dependence of the charge-carrier mobilities and recombination rates on the nanocrystal size that derives from the localized nature of charge-carriers within nanocrystals, with local mobilities dominating those associated with inter-particle transport. We further show that the colloidally synthesized NCs have distinct vibrational properties with respect to the bulk perovskite, exhibiting blue-shifted optical phonon modes with enhanced THz absorption strength that also manifest as strong modulations in the THz photoconductivity spectra. Such fundamental insights into NC versus bulk properties will guide the optimization of

nanocrystalline perovskite thin films for optoelectronic applications.

7:50 AM F.EL08.01.13
***In Situ* and *Operando* Strain and Defect Characterization Using Coherent X-Ray Diffractive Imaging in Bragg Geometry** Wonsuk Cha; Argonne National Laboratory, United States

Coherent x-ray diffractive imaging in Bragg geometry (BCDI) is a powerful technique to image three-dimensional morphology as well as internal deformation field distribution of nano-scaled materials [1]. Because of unique sensitivity to lattice, BCDI has been employed to map strain and defect distribution inside metal, metal oxide, and minerals with non-destructive measurements. In this talk, I will introduce current state-of-art of BCDI and the 34-ID-C beamline in the Advanced Photon Source where one can perform this experiment. This talk will also cover recent experimental results on in-situ and operando BCDI, e.g. unique lattice distortion in ZSM-5 zeolites [2], annealing effect on gold grains on gold thin films [3], oxidation induced strain and defects in magnetite [4], and defect dynamics on platinum during catalytic reaction [5]. In addition, some estimates of BCDI in the future will be discussed. [1] M. A. Pfeifer, et al., Nature 442, 63 (2006). [2] W. Cha, et al., Nat. Mater. 12, 729 (2013). [3] A. Yau, et al., Science 356, 739 (2017). [4] K. Yuan, et al., Nat. Commun. 10, 703 (2019). [5] D. Kim, et al., Nano Lett. 19, 5044 (2019).

Imaging Light-Induced Phase Separation Dynamics of Inorganic Halide Perovskites Siying Peng, Andrew Meng, Wanliang Tan, Michael Braun, Balreen Saini, Kayla Severson, Ann Marshall and Paul McIntyre; Stanford University, United States

Halide perovskites have emerged as promising materials for optoelectronics with superior photoconversion efficiency and low cost. Moreover, optical properties of halide perovskite with mixed bromide and iodide composition can be substantially tuned via light-induced ion migration. Bromide-rich and iodide-rich domains starts to form during the process, which can be initiated at low intensity of light. Phase separation is subsequently reversible under the dark. Photoluminescence emission energy redshifts as a result of phase separation, while optical constants also change. The tunability of photoluminescence emission and optical constants in a wide spectral range makes halide perovskite alloys a promising, dynamically tunable photonic materials system. Unlike conventional tunable photonic materials such as ITO, TCO, and VO2, which rely on tuning of carrier density or an abrupt structural transformation, the speed and degree of phase separation/optical property evolution of mixed halide perovskite alloys can be tuned monotonically by varying the photon intensity. Inorganic mixed halide perovskites have been widely investigated for high-efficiency solar cells, with a focus on improving stability of their light absorption by reducing ion migration. To integrate halide perovskites for tunable nanophotonics, it is essential to understand light-induced phase separation in halide perovskites such as the spacing of phase separated domains, the influence of perovskite crystallite size and orientation, etc. We have synthesized crystallographically-textured polycrystalline films of the inorganic halide perovskite alloy CsPb(BrxI1-x)3 on SrTiO3 (STO) substrates by chemical vapor transport (CVT) at 620°C (at the precursor position) with N2 as the carrier gas. These perovskite films have large single crystal domains in the [001] orientation on the order of millimeters in lateral size and are stable under ambient laboratory conditions. X-ray diffraction confirms the perovskite phase of the film and the predominantly (001) orientation. EDX mapping shows a homogeneous initial distribution of Br, I as well as Cs and Pb. Photoluminescence characterization reveals initial light emission at 2.15 eV. By shining an HgXe lamp on the film, light emission at 2.0 eV starts to occur and dominate the emission spectrum. Time dependent photoluminescence characterization at 2.0 eV shows that the forward phase separation process has a time constant of 2000s and the reverse phase separation process also has a time constant on the order of 2000s. The film remains stable under many cycles of the forward and reverse phase separation process. In-situ X-ray diffraction confirms that halide perovskite film under phase separation has diffraction shoulders corresponding to iodide-rich and bromide-rich domains, while the initial film and reverse phase separated film show the same diffraction peak. In-situ ellipsometry reveals 0.2 difference in the refractive index before and after phase separation, with 50 nm blue shift of the excitonic features of the optical constants. To understand the length scale of phase separation, we CVT synthesized CsPb(BrxI1-x)3 films with < 200nm thickness on TEM compatible Si3N4 membranes, where the film exhibit similar optical properties to those deposited on STO. We probed the perovskite film before and after light-driven phase separation with the electron beam at cryogenic temperatures. The film showed no degradation while strong cathodoluminescence and STEM EELS signals were collected with nanometer scale spatial resolution. We compare the results with optical confocal microscopy which has subwavelength resolution. Efforts on mapping the phase separation length scale with X-ray diffraction will also be discussed.

8:10 AM F.EL08.01.16
Inhomogeneous Doping of Perovskite Materials by Dopants from Hole-Transport Layer Chuanxiao Xiao; National Renewable Energy Laboratory, United States

Dopants, which are often indispensable in the organic hole-transport layer (HTL) in perovskite solar cells (PSCs), significantly impact the device performance, hysteresis, and stability. The primary roles of the HTL dopants are to enhance HTL conductivity and tune the energy level of HTLs. Here, we show that the lithium dopant from HTLs can significantly dope the perovskite absorber layer through diffusion. Kelvin probe force microscopy mapping shows that lithium diffusion increases the surface potential of the perovskite film. The potential at grain boundaries showed more increase than in grain interiors, indicating inhomogeneous distribution of Li dopant in the perovskite layer. Accumulation of Li at the grain boundaries was further confirmed by lateral elemental mapping using time-of-flight secondary-ion mass spectrometry. For both p-i-n and n-i-p device structures, the diffusion and nonuniform distribution of Li+ ions are shown to influence the carrier-transport properties of perovskites and device characteristics. This work reveals the hidden doping effects of the HTL dopants on perovskite films and their impact on PSC performance. Property changes of the perovskite thin films in actual devices from their pristine states should be considered for future understanding of device physics, characterization studies, and device engineering.

8:20 AM F.EL08.01.17
Development and Application of Novel Multi-Modal *In Situ* Probes to Reveal Precursor Chemistry-Property Dynamics of Halide Perovskites Tze-Bin Song[1], Shambhavi Pratap[2], Nobumichi Tamura[1], Jonathan Slack[1] and Carolin M. Sutter-Fella[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]Technische Universität München, Germany

Progress made to date in terms of higher efficiency and stability in the field of halide perovskites is based on increasing material complexity that is, formation of multicomponent halide perovskites comprising multiple cations and anions. Each precursor component and synthetic variable can influence the reaction pathway during the formation of halide perovskites as well as influence key properties such as morphology and radiative efficiency. Here, we present the development of a multi-modal platform that is attached to a synchrotron end station and capable of in situ monitoring the dynamic transformation processes from the chemical precursor to the final halide perovskite film. By remotely controlling the spin-coating process and precursor heating we are able to characterize perovskite formation already during spin coating and the very early stages of annealing. In two independent studies we investigate the influence of the Pb-salt on CH3NH3PbI3 formation and the Br/(I+Br) concentration on the formation pathway of mixed CH3NH3Pb(I1-xBrx)3 perovskites. We show the correlation between Pb-salt and morphology as well as Br-content and crystallization mechanisms. This multi-modal platform enables efficient screening of complex multicomponent precursors and establishing chemistry-property relationships.

8:30 AM F.EL08.01.18
Photoexcited Carrier Dynamics on the Nanoscale in Perovskite Photovoltaics Samuel Berweger[1], Obadiah Reid[2], Fei Zhang[2], Axel Palmstrom[2], Thomas M. Wallis[1], Andrew Ferguson[2], Kai Zhu[2], Joseph J. Berry[2], Sanjini Nanayakkara[2] and Pavel Kabos[1]; [1]National Institute of Standards and Technology, United States; [2]National Renewable Energy Laboratory, United States

We present time-domain conductivity measurements of optically excited free carriers in perovskite photovoltaics using microwave near-field microscopy. Using a pulsed excitation source that is continuously tunable through the visible spectrum we demonstrate the capability to measure local photoconductivity transients with 10 ns temporal resolution and spatial resolution as high as 50 nm. We study the effect of surface treatment on the local response of [(CsPbI3)0.05(FAPbI3)0.85(MAPbBr3)0.15] perovskite films as well as their deterioration. We find a strong dependence of the free carrier lifetimes on surface treatment, where the presence of an electron transport layer is seen to result in carrier lifetimes of less than 100 ns. Similarly, surface passivation using conformal alumina encapsulation leads to reduced carrier lifetimes compared to untreated films and imparts significant resistance to deterioration. We find that film deterioration leads to strong spatial inhomogeneities in the photoconductive response across films and results in overall longer carrier lifetimes and a redshift in the absorption onset as measured using local action spectra.

8:40 AM F.EL08.01.19
Spatially Resolved Bulk and Interfacial Recombination Dynamics in Perovskite Optoelectronic Devices Haralds Abolins[1], Arjun Ashoka[1], Yu-Hsien Chiang[1], Gregory Tainter[1,1], Bart Roose[1], Hannah Joyce[1], Stephan Hofmann[1], Jack Alexander-Webber[1], Richard Friend[1] and Felix Deschler[2]; [1]University of Cambridge, United Kingdom; [2]Technical University of Munich, Germany

We report the in-situ charge carrier recombination dynamics in perovskite bulk and at interfaces with electrodes by employing a novel photocurrent modulation technique, which enables us to achieve micrometre spatial and sub-microsecond temporal resolution of photocurrent transients. Our capacity to identify and isolate significant loss channels for device

operation, by characterizing the performance of individual electrodes and charge selective layers, has previously only been achieved via indirect techniques. We find a charge trapping length for holes in the perovskite bulk of 21 μm with an associated trapping timescale of 2 μs, demonstrating that bulk trapping is not a major limiting factor for long-distance charge transport in perovskite-based devices. We observe significant photocurrent losses on and near gold electrodes due to the formation of a reduced charge carrier mobility region near the perovskite-gold interface with an associated trapping timescale of 0.7 μs. We further determine the length and timescales of carrier transport via diffusion and photon recycling. Our ability to expand the steady-state operation of the device in space and time allows us to characterise a broad range of processes in-situ with crucial insights into device operation, and paves the way for high throughput optimisation of interfaces for high-efficiency optoelectronics.

8:50 AM F.EL08.01.21
The Nanoscale Structural and Chemical Mass Spectrometry Imaging of Photovoltaic Perovskite Semiconductors
Onovbaramwen J. Usiobo[1], Hiroyuki Kanda[2], Jean-Nicolas Audinot[1], Tom Wirtz[1] and Mohammad Nazeeruddin[2]; [1]Luxembourg Institute of Science and Technology, Luxembourg; [2]École Polytechnique Fédérale de Lausanne, Switzerland

Solar power has a key role in the crucial transition to low carbon energy generation. Perovskite solar cells, in particular, are a great photovoltaic alternative as they exhibit excellent energy harvesting abilities and do not require energy-intensive manufacturing techniques [1]. The photo-conversion efficiency of perovskite photovoltaics rapidly increased like no other contemporary photovoltaic technology and as such, there is an industry-wide gap in the fundamental understanding of the relationship between microstructure and properties [2]. In addition, poor stability against UV light, moisture and elevated temperature during scale-up of perovskite photovoltaics limits and serves as an impediment for their widespread commercial use [3]. Nanoscale structural and chemical characterization is one alternative to better relate microstructural features to their resultant properties and to further fine-tune the perovskite properties beyond the current state of the art. For this to be achieved, a reliable and effective analytical strategy is not only necessary, but also key for resolving the microstructure of perovskite semiconductors at the nanoscale.

We have developed a magnetic sector Secondary Ion Mass Spectrometer (SIMS) and coupled it to a Helium Ion Microscope (HIM) [4]. Owing to this, we combine the best of both worlds; the high lateral resolution in secondary electron (SE) imaging of the HIM (<0.5 nm with He^+) with the high detection limit of the SIMS technique (at least in ppm for a wide variety of elements and clusters). In SIMS mode, we are able to detect elements in the full mass range (from H to U) with a lateral resolution below 20 nm. With correlative microscopy, the chemical SIMS micrographs can be co-registered with sub-nm resolution secondary electron (SE) micrographs [5].

We will show several analytical studies completed with HIM-SIMS, among them, a cross-sectional chemical map of a mixed cation perovskite device where different thin films at the nanoscale can be distinguished morphologically and chemically. HIM-SIMS analysis in positive polarity reveals a heterogeneous distribution of Cs and Pb, where specific grains are depleted of these elements. Surface analysis of a multi-cation and multi-halide perovskite in both negative and positive polarity, show a different heterogeneous elemental distribution. Here, the chemical maps of the ions of Cs, Br, I and an organic cluster display a similar distribution while Pb enrichment occurs at selected grains. HIM-SIMS is a versatile and powerful technique for the improved understanding of the impact of microstructure, such as interfaces, grain boundaries and grains, on the photovoltaic stability and performance.

5:00 AM *F.EL08.02.01
Novel Hybrid Perovskites for Spin Control and Magneto-Optics Felix Deschler; Technische Universität München, Germany

Functional materials combining the optoelectronic functionalities of semiconductors with control of the spin degree of freedom are highly sought after for the advancement of quantum technology devices and provide exciting avenues for polarized light-emission. Previous work towards this goal introduced small amounts of magnetic elements into crystalline semiconductor, e.g. through vacuum-based deposition, to obtain dilute magnetic semiconductors (DMS).

In my talk, I will present our efforts on gaining control over spin dynamics and spin interactions through compositional and structural tuning in solution-processable hybrid perovskite semiconductors. We aim to exploit the exceptional optoelectronic properties of these hybrid perovskites, together with their tolerance in the electronic states to dopants and defects, to make advances towards high-performance DMS. I will further discuss how we employ ultrafast optical spectroscopy to gain insights into fundamental excitation and spin dynamics in our novel materials, highlighting the potential of magneto-optic control.

I will present first results on chemical doping of layered Ruddlesden-Popper hybrid perovskites with transition metals. I will report how optical excitations interact with elemental spins in these materials, also on ultrafast timescales, to achieve control over exciton emission through magnetic proximity effects. Harnessing spin-orbit coupling effects, we achieved circular polarization up to 15% in the excitonic photoluminescence at low temperatures and high fields, which keeps a strong magnetic field dependence below 1 Tesla. Our finding constitutes the first example of optical polarization control in magnetically-doped hybrid perovskites and will stimulate research on this highly-tuneable material platform that promises tailored interactions between magnetic moments and electronic states.

5:15 AM *F.EL08.02.02
Ultrafast Studies of Two-Dimensional Hybrid Metal Halide Perovskites Rebecca L. Milot; University of Warwick, United Kingdom

Two-dimensional Ruddlesden-Popper phase hybrid metal halide perovskites have been investigated for use in a range of optoelectronic devices including photovoltaic cells. Their main appeal for photovoltaics is improved aqueous stability, which is enabled by their incorporation of organic cations which are more hydrophobic than those usually used in 3D perovskites. However, quantum and dielectric confinement effects increase the exciton binding energies in these materials to as much as 100s of meV. These increased binding energies correspond to an increase in exciton population at ambient temperatures which can greatly alter the optoelectronic properties. Optical Pump/THz-probe (OPTP) spectroscopy measurements have revealed decreased effective charge-carrier mobilities and significantly shortened charge-carrier lifetimes for 2D perovskites (1). In hybrid 2D-3D materials, incorporating small amounts of the 2D material can improve optoelectronic properties (2), suggesting a balance between excitons and free charges is achievable by tuning the composition. OPTP and other ultrafast spectroscopic techniques are further used to elucidate the interplay between free charges and excitons in these materials and comment on the limits these properties impose on charge transport in devices.

5:30 AM F.EL08.02.03
Unveiling Hidden Carrier Dynamics in Hybrid-Halide Perovskites Sean A. Bourelle[1], Xie Zhang[2], Sascha Feldmann[1], Angus Mathieson[1], Lissa Eyre[1,3], Chris Van de Walle[2], Felix Deschler[3] and Thomas Winkler[4,1]; [1]University of Cambridge,

United Kingdom; [2]University of California, United States; [3]Technische Universität München, Germany; [4]Aarhus University, Denmark

There remains debate on the nature of electronic states in hybrid metal-halide perovskite thin films, and their impact on charge-carrier dynamics, due to the unique dependence of its band structure on lattice deformations. Here, we present our unique combination of single- and two-photon transient absorption and photoluminescence spectroscopy experiments to map bright and dark transitions in the bulk and at the surface of methylammonium lead bromide thin films. Supported by first-principles calculations, we report a peculiar alignment of energy levels throughout the film, which efficiently funnels carriers away from trap-rich surface states and into the bulk, where an efficient and strong radiative recombination takes place. We show that, for operational carrier densities, these effects lead to high emission rates from heavily occupied bright states within Rashba split bands. Our findings unify the debate on the indirect-direct nature of the hybrid perovskites and have crucial relevance for charge extraction and injection processes at perovskite interfaces, which need to be optimized for maximum device efficiencies.

5:40 AM F.EL08.02.04
Light Induced Passivation in Triple Cation Mixed Halide Perovskites—Interplay Between Transport Properties and Surface Chemistry Stefania Cacovich[1], Davina Messou[2,3], Adrien Bercegol[4], Solène Béchu[3], Armelle Yaiche[4], Jean Rousset[4], Philip Schulz[1], Muriel Bouttemy[3] and Laurent Lombez[1]; [1]CNRS IPVF UMR 9006, France; [2]IPVF, France; [3]ILV, France; [4]EDF, France

Over the last years we have witnessed a tremendous interest into hybrid organic-inorganic perovskite solar cells (PSCs) research. However, the physical and chemical phenomena occurring in different regions in the film (electrode interface, air interface, grain boundaries) and time scales under different stresses (light, oxygen, moisture, temperature, potential) have been identified to limit the attainable device performance. Especially, the chemistry at the interfaces critically affects the fundamental optoelectronic properties of the perovskite-based absorber as well as the working principles of the corresponding solar cells.
Here, we employed advanced and complementary characterisation techniques, namely multidimensional absolute photoluminescence (PL) and X-Ray Photoelectron Spectroscopy (XPS), to correlate optoelectronic and chemical properties. On the one side, through hyperspectral imaging (HI) and time-resolved fluorescence imaging (TR-FLIM) we investigated intrinsic material and carrier transport properties with quantitative indicators such as Quasi Fermi Level Splitting (QFLS), carrier mobility and recombination rates. On the other side, complementary XPS analyses were implemented on the same batch of samples to precisely determine chemical changes to the surface but also in the bulk, as investigated by XPS depth profiling, to correlate the modification of optoelectronic properties with changes in the composition of the perovskite layer. We have investigated the behaviour of a triple cation mixed halide perovskite thin film deposited on a glass/FTO/c-TiO_2/m-TiO_2 stack. A series of mixed halide multi-cations perovskite thin films were light soaked for 10 minutes, 1 hour, 5 hours and 15 hours in air. We found that light exposure for a short time (10 minutes or 1 hour) results in a net enhancement of the optoelectronic properties of the material. Indeed, the QFLS of the perovskite thin films increases from 1.31 to 1.36 eV, remaining the same for longer exposure times. Time-resolved PL measurements confirm that the passivated recombination centers are located at the front interface (perovskite/air). As such, both steady-state and transient measurements evidence a surface passivation effect. For longer light soaking times (5 and 15 hours), persistent changes to the perovskite layer composition are observed. The modifications of the chemical environments suggest the formation of a stable PbO_x passivation layer starting from 5 hours of continuous light soaking in air atmosphere. The formation of this oxidized passivation layer goes along with sample degradation. Starting from 5 hours light soaking a phase segregation appears leading to a degradation of the transport properties of the material. XPS depth profiles indicate that the main responsible of this sample degradation is the oxygen diffusion through the perovskite active layer.

5:50 AM F.EL08.02.05
Dimensional Mixing and Formation Mechanisms of 2D/3D Perovskite Interfaces Andrew H. Proppe, Andrew Johnston, Sam Teale and Edward H. Sargent; University of Toronto, Canada

2D/3D heterojunction perovskite solar cells have demonstrated superior efficiency and stability compared to their fully 3D counterparts. These interfaces are formed by exposing the 3D perovskite surface to ligands that induce the formation of 2D layers, though this transformation is not yet understood. We used *in situ* Grazing-Incidence Wide-Angle X-Ray Scattering (GIWAXS) to identify intermediate states in the transformation from 3D to 2D. For $(MAPbBr_3)_{0.05}(FAPbI_3)_{0.95}$ perovskites treated with a dilute ligand solution, we observe the initial formation of $n = 3$ and $n = 2$ quantum wells before the final formation of $n = 1$ wells, suggesting a gradual reduction in dimensionality rather than immediate conversion to 2D perovskite monolayers. For $MAPbI_3$, we instead observe intermediate PbI_2 sheets that eventually turn into ligated perovskite quantum

wells. A molecular picture of these transformations will help guide the design of superior 2D/3D interfaces for perovskite solar cell devices.

6:00 AM F.EL08.02.06
***In Situ* Ultrafast Carrier Transport Dynamics in Perovskite Nanocrystal Film** Kanishka Kobbekaduwa[1], Exian Liu[1], Zhao Qian[2], Pan Adhikari[1], CHENDI XIE[1], Joseph Luther[3], Matthew Beard[3] and Jianbo Gao[1]; [1]Clemson University, United States; [2]Tianjin University, China; [3]National Renewable Energy Laboratory, United States

CsPbI3 perovskite nanocrystals boost their promising applications in high efficiency solar cells, LEDs, and photodetectors because of low-cost, and solution-processing. However, for these optoelectronic applications, the fundamental question of carrier transport mechanism remain unclear, in particular*, in-situ* devices.
In this report, we use the ultrafast photocurrent spectroscopy with sub-20 ps time resolution to elucidate the nature of carrier transport. In early time before 200 ps, the ultrafast photocurrent dependence with temperature clearly demonstrates a phonon-scattering mechanism, wherein the photocurrent increase with decreasing temperature. This unusual transport mechanism, which is absent in the disordered system of nanocrystal arrays, is consistent with the high carrier mobility ~ 10 cm2/Vs, and long carrier travelling length ~ 100 nm. After 200 ps, the carriers carry out hopping transport mechanism, which is manifested by the defect scattering effect.

6:10 AM F.EL08.02.07
Quantifying Photon Recycling in Halide Perovskite Solar Cells and Light Emitting Diodes Alan Bowman, Miguel Anaya, Neil Greenham and Samuel D. Stranks; University of Cambridge, United Kingdom

The re-absorption of emitted photons within a material, photon recycling, has received increased attention in recent years following its observation in halide perovskite thin films and light-emitting diodes[1,2]. It has been shown to lower the effective bimolecular recombination rate and thus increase excitation densities within a material[3]. However, the relationship of photon recycling to controllable device parameters is poorly understood, as is photon recycling's relative importance in different optoelectronic devices.

Here we present a general framework to quantify photon recycling in any material or device. Using experimental parameters, we apply our model to idealized methylammonium lead iodide ($MAPbI_3$) solar cells and cesium lead iodide ($CsPbI_3$) light-emitting diodes (LEDs) at operating voltages. Specifically, we explore the relationship of photon recycling to controllable parameters: thickness; charge-trapping rate; non-ideal interface transmission; and absorptance. We show that in $MAPbI_3$ solar cells the number of photon recycling events per absorbed photon at maximum power point is 0.4 in the (optimal) case of no charge trapping, due to most charges being extracted to the external circuit before they can radiatively recombine. Conversely, in a $CsPbI_3$ LED there can be up to 8 photon recycling events per injected charge in this optimal case (for emission into a full 2π hemisphere and applied voltage giving emission of ~1000 lm m^{-2}). In both device types we demonstrate that photon recycling and device performance (efficiency or amount of emitted light for solar cells and LEDs respectively) improve with thicker cells, those with less charge-trapping and improved back reflection. However, while device performance improves with better front transmission and light scattering, the degree of photon recycling rapidly reduces. For example, for a solar cell with a high degree of light scattering (to improve absorptance), there is less than 0.1 photon recycling event per initially absorbed photon. Similarly, in LEDs, the number of photon recycling events reduces to less than 1 when the emitter has a rough surface, but there is a significant increase in the quantity of light emitted from the system due to fewer trapped photon modes.

Our experimentally parameterized simulations reveal that photon recycling is significantly more important in LEDs than solar cells at operating voltages. Furthermore, we show that maximizing absorption and emission processes remains paramount for optimizing devices, even if this is at the expense of photon recycling. We therefore demonstrate that photon recycling cannot always be seen as a beneficial process in perovskite solar cells and LEDs.

Nonradiative Energy Transfer in Halide Perovskite Nanocrystal Heterosystems Alexander S. Urban, Andreas Singldinger, Carola Lampe, Moritz Gramlich and Christoph Gruber; LMU Munich, Germany

Halide perovskite nanocrystals (NCs) hold great promise for optoelectronic applications because of their large absorption cross-sections and high photoluminescence quantum yields. Moreover, by varying either their halide composition or their size/dimensionality, the absorption onsets and emission maxima can be tuned throughout the entire visible spectrum. Commercialization is currently impeded however due to several issues. Susceptibility to environmentally-induced degradation necessitates the use of stabilizing and encapsulation, which hinders charge injection and halide ion diffusion impedes the realization of heterostructures.
In this presentation, we look at nonradiative energy transfer (FRET) in mixed halide perovskite nanosystems, for enhancing the stability and integration into optoelectronic devices and novel architectures. Halide perovskite nanoplatelets (NPls) enable a precise tuning of absorption and emission by controlling the number of layers in the NPls. We look at energy transfer between $CsPbBr_3$ NPls of different thicknesses and analyze efficiency and transfer times.[1] Using this, we then look into realizing multi-layer heterojunctions comprising different NC thicknesses for concentrating charge carriers or promoting charge carrier collection. We also show how highly stable polymer micelle-encapsulated NCs can be integrated into light-emitting devices through energy transfer.[2] We specifically investigate how the polymer shell and NC size affect the transfer efficiencies and device performance. These results open up pathways for realizing new device architectures and enhance the stability of the perovskite NCs, both important for pushing perovskite NCs from a mainly scientific state toward commercialization.

Femtosecond Charge Transfer Between the Organic and Inorganic Sub-Lattices in the Halide Perovskite Methylammonium Lead Tri-Iodide Gabriel J. Man[1], Pabitra Nayak[2], Konstantin A. Simonov[1], Sebastian Svanström[1], Anders Sandell[1] and Håkan Rensmo[1]; [1]Uppsala University, Sweden; [2]Tata Institute of Fundamental Research, India

Halide perovskite (HaP) materials have attracted substantial renewed research interest for over a decade, largely due to initially dramatic gains in photovoltaic power conversion efficiencies demonstrated by lead HaP-based solar cells [1]. Efforts to commercialize HaP-based solar cells, light-emitting diodes (LED's) and other opto-electronic devices are currently underway around the globe. The prototypical hybrid organic-inorganic HaP is methylammonium lead tri-iodide ($MAPbI_3$ or MAPI) which features an organic cation (methylammonium or MA) located at the A-site embedded within a lead-iodide (B-X) inorganic sub-lattice. Since the early demonstrations of MAPI solar cells, device applications of HaPs have transitioned towards the use of mixed-cation (with/without MA plus other A-site cations) formulations due to concerns about the thermal and chemical stability of MA in device-relevant, ambient conditions [2]. The role of MA in the HaP matrix was considered by some to be structural only, which indirectly influences the optical and electrical properties of MAPI [3,4]. Density-functional theory (DFT) calculations of the electronic structure supported that view [5,6]. Selective thermal excitation of the MA did not alter the optical properties of MAPI[7]. Mechanical nano-indentation studies of $APbBr_3$ crystals showed that the type of A-site cation, be it organic or inorganic, has little effect on the chemical bonding in HaPs [8].
In spite of the considerable evidence for the passive opto-electronic role and thermal instability of MA, the highest-performing HaP solar cells typically incorporated some fraction of MA in the absorber layer [9]. Hot fluorescence was observed from $APbBr_3$ crystals with an MA or FA, but not cesium, cation [10]. In this work, we demonstrate that MA is an active participant in the nitrogen 1s (N1s) core-excited electronic structure of MAPI. In doing so, we reveal the existence of additional mechanisms: (i) ultrafast <7 fs charge transfer between molecular unoccupied states in the MA and MAPI conduction band states and (ii) MA carrier lifetime > 7 fs. Using Resonant Photoelectron Spectroscopy (RPES), which involves resonantly exciting the nitrogen in MA with soft X-rays and measuring the N1s decay spectra (KVV Auger and autoionization), we convert MA into a core-excited microscopic probe of the electronic coupling to its environment. The N1s decay spectra corresponding to N1s-to-2p* resonant excitations to bound states below the ionization threshold show evidence of spectator and participator autoionization and normal Auger decay. We find MA to be quasi-localized electronically,

meaning its electronic coupling to the Pb-I sub-lattice is intermediate between weak and strong coupling, since a fraction of the resonantly-excited N1s core electrons de-localize into the environment surrounding the MA with a timescale that is comparable to the N1s core hole lifetime (~7 fs). To access the intrinsic materials physics of MAPI, the experiments were performed with in-vacuum cleaved single crystals at a low photon flux synchrotron beamline. Beam-induced sample damage was judiciously checked with XPS and was found to be negligible.
The presence of MA-to-(Pb-I) charge transfer in the N1s core-excited state reveals that the MA cation is not chemically and electronically inert, and suggests that bi-directional MA-(Pb,I) charge transfer may be possible in valence-excited states, which is relevant for the operation of MA-based HaP solar cells, LED's, and other opto-electronic devices.

Deep-Level Transient Spectroscopies for the Detailed Experimental Assessment of Defect Tolerance in Lead-Free Perovskite-Inspired Semiconductors Vincenzo Pecunia[1], Chaewon Kim[1], Jing Zhao[1], Robert Hoye[2], Tahmida Huq[3] and Judith MacManus-Driscoll[3]; [1]Soochow University, China; [2]Imperial College London, United Kingdom; [3]University of Cambridge, United Kingdom

The exploration of lead-free perovskite-inspired semiconductors for optoelectronic applications has captured ever-growing attention, driven by their promise to replicate the success of the lead-based counterparts, but without the toxicity concerns associated with the latter.[1] In the search for lead-free perovskite-inspired semiconductors, emphasis has been placed on the identification of materials with a defect-tolerant character, as this has been associated with a high optoelectronic potential.[2] While computational studies have been of fundamental importance in screening lead-free perovskite-inspired semiconductors for defect tolerance, the detailed experimental assessment of the defect tolerance in such materials is lacking in the field. This has been particularly limiting in regard to the experimental identification of the most promising lead-free perovskite-inspired semiconductors. In fact, at an experimental level, investigators have most often relied on phenomenological findings to probe the defect tolerance of such materials. For instance, device performance boosts achieved through specialized processing strategies have often been linked to defect passivation, while photoluminescence lifetimes have been regarded as the default indicator of defect tolerance.[3,4]

Recognizing that an experimental quantitative assessment of the defect parameters (volumetric densities, characteristic energies, and capture cross sections) is key to developing a detailed understanding of defect tolerance in perovskite-inspired semiconductors, in this study we have explored the applicability of deep-level transient spectroscopy methods to reliably characterize the defect properties of a range of lead-free perovskite-inspired compounds. In particular, we have focused on a number of antimony- and bismuth-based perovskite-inspired materials, as they have been generally associated with a defect-tolerant character.[2] Herein, we firstly examine the applicability of conventional deep-level transient spectroscopy (DLTS) for their experimental defect characterization. We then discuss current-based deep-level spectroscopy variants, of which we show the particular configurations that we have found to be widely applicable to the defect characterization of lead-free perovskite-inspired compounds. Finally, by comparing with the reported approaches for the quantitative defect characterization of lead-halide perovskites, we discuss the defect tolerance of the antimony- and bismuth-based perovskite-inspired materials we have characterized (e.g., $A_3Sb_2I_9$ absorbers with A being a monovalent cation, bismuth oxyiodide,[5] silver iodobismuthates). This study thus contributes to identifying a viable strategy for the experimental screening of defect tolerance in lead-free perovskite-inspired materials, potentially enabling the experimentally-grounded identification of the most promising compositions towards high-performance low-toxicity optoelectronics.

Investigation of Ion Migration in Methylammonium Lead Bromide (MAPbBr3) Perovskite Crystals Using Current Deep Level Transient Spectroscopy (I-DLTS) Mmantsae M. Diale, Nosicelo Mrwetyana and Matshisa Legodi; University of Pretoria, South Africa

Despite the rapid development of halide perovskite with power conversion efficiency over 25% to date, there are many unresolved issues such as the identification and characterization of defects affecting device performance. This dearth of knowledge is inhibiting the commercialization of HAP solar cells. The migration of ionic species in HAPs influences the degradation of perovskite solar cells and their long-term reliability and robustness. In this work, we investigated ion migration in crystalline methylammonium lead bromide C/$MAPbBr_3$/Au solar cells in the dark using the hp DC Voltage source 4140B picoAmmeter in the temperature range 255 K < T < 320 K and various bias pulse sequences. Arrhenius plots constructed from the data were used to determine ion migration activation energies for various ion species. Atypical temperature dependency of the current transients was observed: fast transients at low temperature and slower ones at elevated temperatures. In addition, characteristic features typical of ion migration such as scan rate and bias sensitivity with hysteresis accompanying temperature cycling were also observed. The ion transport mechanisms in the C/$MAPbBr_3$/Au perovskite crystals agree with observations in the $MAPbI_3$ analogue. We conclude that the fast exponential corresponds to the migration of the negatively charged halide species, Br, with activation energy of 0.41 eV; and, the slower exponential is due to the positively charged lead (Pb^{2+}) species with activation energy of 2.82 – 2.87 eV.

PbI_2 Phase Impurities Trap Electrons in Lead Halide Perovskites Young-Kwang Jung[1] and Aron Walsh[1,2]; [1]Yonsei University, Korea (the Republic of); [2]Imperial College London, United Kingdom

The use of excess lead iodide (PbI_2) during the synthesis and processing of lead halide perovskites has been exploited as a way to improve performance of perovskite solar cells [1,2]. On the other hand, it has also been proposed that excess PbI_2 can increase the trap-state density [3] and enhance the thermal decomposition to PbI_2 [4]. Although the presence of PbI_2 in perovskite films plays an important role, the current understanding of how PbI_2 phase impurities form interfaces with halide perovskites and affect their electronic properties is poor. Here, we model $CsPbI_3$-PbI_2 superlattices and identify their interfacial geometry, thermodynamic stability, and electronic structure. Our first-principles density functional theory (DFT) calculations reveal that PbI_2 present in $CsPbI_3$ can induce electron trap state at the interface between these two phases. However, the electron trapping tendency is sensitive to the atomic nature of the phase boundary, which can explain the variation reported in different investigations.

Microscopic Mechanisms of Halide Diffusion in Perovskite Solar Cells Young Won Woo[1], Young-Kwang Jung[1], Sunghyun Kim[2] and Aron Walsh[1,2]; [1]Yonsei University, Korea (the Republic of); [2]Imperial College London, United Kingdom

It is now well established that metal halide perovskites are mixed ionic-electronic conductors. The halide ions are highly mobile at room temperature [1]. Ion migration is speculated to be the origin, or an important contributing factor, for many unusual phenomena in photovoltaic devices, such as current-voltage hysteresis, and photoinduced phase separation and transformations [2,3]. Illumination of a photovoltaic device will result in electical and thermal changes. Absorption of light can access metastable charge states of defects due to the trapping of electrons or holes and result in hot carriers with excess

energy, which cool to the lattice temperature by phonon emission that could enhance the rate of ion migration [4]. Thus, these ionic migration processes must be supressed in such device structures. The rate of halide ion jumps in halide perovskites depends not only on the activation energy but also on the pre-exponential factor of diffusion. Here, we report the microscopic mechanisms for iodine ion diffusion mediated by vacancies from first-principles density functional theory (DFT) calculations. We quantify the potential energy landscsape for chemical transport including the activation energies of ions migration and the migration frequency at the room temperature.

7:20 AM F.EL08.02.14
Using Time-Resolved Photoconductivity Measurements to Reveal the Urbach Tail and Two Photon Absorption in MHPs Valentina Caselli[1], Dengyang Guo[1], Zimu Wei[1], Jos Thieme[1], Claudine Katan[2], Jacky Even[2] and Tom J. Savenije[1]; [1]Delft University of Technology, Netherlands; [2]Université Européenne de Bretagne, INSA, FOTON, France

The unprecedented rise in power conversion efficiency of solar cells based on metal halide perovskites (MHPs) has led to an enormously growing research effort over the last 6 years. In this paper, we report how the electrodeless transient microwave photoconductivity technique (TRMC) can reveal detailed information, regarding the interesting photo-physical properties of MHPs. First, we recorded two photon absorption (2PA) spectra of MHP thin films over a wavelength regime between $0.5E_g$ and E_g, from which the 2PA coefficients have been calculated. A two-step upward trend is observed in the 2PA coefficient spectrum for $CH_3NH_3PbI_3$. Using a parameterized tight binding model, spectra were calculated by integration over all Brillouin zones showing compelling similarity with experimental results. We conclude that the second upward trend in the 2PA spectrum originates from additional optical transitions to the heavy and light electron bands formed by the strong spin-orbit coupling.
Next, we performed TRMC measurements using optical excitation above and below the band-gap on pristine $MAPbI_3$, $MAPbI_3$/C60, and $MAPbI_3$/Spiro-OMeTAD thin films. In pristine $MAPbI_3$ we have observed a band-like charge transport for photon energies down to 1.40eV, from which we calculated an Urbach energy of approximately 16 meV, indicative of a relatively low structural disorder. Our TRMC measurements on the bilayers revealed that electrons in defect states close to the VB can be excited by photons with an energy as low as 1.30 eV. Their excitation leads to free electrons in the CB that undergo charge injection into the C60 yielding long-lived charge separation. In contrast, excitation of $MAPbI_3$/Spiro-OMeTAD at 1.3 eV shows a rapidly decaying signal implying that holes are localized and cannot be transferred over the interface to the Spiro-OMeTAD.

7:30 AM F.EL08.02.15
Below-Bandgap, Low-Frequency Raman Spectroscopy to Probe Lattice Vibrations in $CsPbI_3$ Polymorphs Yi Yang, Jason Robbins, Lotanna Ezeonu, Yichen Ma, Nicholas Sparta, Xiaoqing Kong, Stefan Strauf, Simon G. Podkolzin and Stephanie Lee; Stevens Institute of Technology, United States

The coupling of electrons with lattice vibrations is thought to play a crucial role in determining the efficiency of optoelectronic processes in metal-halide perovskites. Herein, we report the first comparison of the low-frequency Raman (LFR) spectra of thermodynamically-stable, inactive δ-$CsPbI_3$ and metastable, active γ-$CsPbI_3$ in the range of 5 – 150 cm^{-1} [1]. While previous reports have suffered from material degradation during measurements, our successful recording of these spectra was enabled by a combination of nanoconfinement to stabilize the respective $CsPbI_3$ phases against temperature- and humidity-induced polymorph transitions,[2] as well as the use of a below-bandgap 976-nm wavelength laser to avoid laser-induced degradation. Temperature-dependent LFR spectra confirmed that γ-$CsPbI_3$ could be stabilized to temperatures as low as 77 K upon nanoconfinement. The main vibrational modes at these low frequencies were determined via density functional theory calculations to primarily involve bending and stretching of Pb-I bonds. We further explored the compositional dependence of the γ phase phonon modes via systematic substitution of Cs cations with methylammonium cations ($Cs_yMA_{y-1}PbI_3$) or I anions with Br anions ($CsPbI_xBr_{3-x}$). The three main peaks exhibited in γ-$CsPbI_3$ were found to be present in all variations of the composition, with peak locations shifting to lower frequencies with expanding lattice dimensions. These results indicate that the phonon modes in these MHPs depend primarily on the structure of the metal-halide framework, not

the specific nature of the A-site cations and halide anions.

7:40 AM F.EL08.02.16
Late News: Phonon Vibrational Dynamics Reveals Intrinsic Lattice Anharmonicity in Hybrid Perovskite Nanocrystals Tushar Debnath[1], Debalaya Sarker[2], He Huang[1], Zhong-Kang Han[2], Amrita Dey[1], Lakshminarayana Polavarapu[1], Sergey V. Levchenko[2] and Jochen Feldmann[1]; [1]Ludwig-Maximilians-University (LMU), Germany; [2]Skolkovo Institute of Science and Technology, Russian Federation

Organic–inorganic halide perovskite nanocrystals (PNCs) are gaining increasing attention in contemporary research due to their promising optoelectronic performance. Photoexcitation of these PNCs with an ultrashort laser pulse can produce coherent phonons along the lattice displacement coordinate, leading to lattice vibrations. The halide ions of organic-inorganic hybrid perovskites can strongly influence the interaction between the central organic moiety and the inorganic metal halide octahedral units and thus their lattice vibrations. Here, we employ femtosecond pump–probe spectroscopy to initiate the photophysics by the formation of coherent phonons and to observe the subsequent coherent vibrational dynamics of formamidinium lead halide ($FAPbX_3$, X=Br, I) PNCs. We find that the $FAPbX_3$ PNCs generate halide-dependent coherent vibronic wave packets upon non-resonant excitation, and the dominant contributions are attributed to the Pb–X bending and stretching modes of PbX_6^{4-} octahedral units of the lattice. More importantly, for the first time, we observe higher harmonic vibrational modes in $FAPbI_3$ PNCs, which points to a more anharmonic potential energy surface in the case of $FAPbI_3$ as compared to $FAPbBr_3$ PNCs. This is likely due to the weaker interaction between the central FA moiety (which sits in a larger octahedral interstitial site) and the inorganic cage for $FAPbI_3$ PNCs, and thus the PbI_6^{4-} unit can vibrate more freely. This weakening reveals the intrinsic anharmonicity in the Pb-I framework, and thus facilitating the energy transfer into overtone and combination bands. Furthermore, our control experiment with $MAPbBr_3$ reveals the energy transfer between framework phonons due to the intrinsic anharmonicity of the lead-halide framework is indeed influenced by the interaction between the framework and the organic molecules, and not only by the halide nature. The insights interestingly not only unravel the underlying reason for the halide-dependent stability of these materials but also shed light on their charge-carrier mobility and polaronic properties.

7:50 AM *F.EL08.02.17
Photophysics of Methylammonium Lead Bromide Perovskite Natalie Banerji, Nikolaos Droseros and Dimitra Tsokkou; University of Bern, Switzerland

Methylammonium Lead Bromide (MAPbBr3) is the most investigated 3D Perovskite for visible LED applications. It is characterized by a much higher exciton binding energy compared to its Iodide equivalent (MAPbI3). This leads to complex excited-state phenomena, with free-carriers, excitons and defect states contributing to the photoluminescence (PL) properties. We have used a variety of spectroscopic techniques to study photoexcited MAPbBr3 films, including time-resolve PL measurements, femtosecond transient absorption (TA) spectroscopy and optical-probe-terahertz-pump (THz) experiments. The co-existence of free carriers and excitons is demonstrated at low excitation densities in as-cast polycrystalline MAPbBr3 (crystal size of the order of few ?m). The excitation wavelength and density are then varied in order to access different free-carrier to exciton ratios in order to evaluate their recombination dynamics and THz conductivities. Finally, we show how reducing the grain size of the Perovskite to the micro- and nanoscale (by using different additives during solution-processing) increases the PL quantum yield, which we explain by the presence of a bright exclusively exitonic population even at low excitation densities, together with reduced surface trapping thanks to passivation by the additives.

8:05 AM F.EL08.02.19
Novel Absorption and Emission Processes in FAPbI3 Adam D. Wright; University of Oxford, United Kingdom

Due to a larger organic cation, formamidinium lead triiodide (FAPbI3) has a narrower, more optimal band gap than MAPbI3, which extends the photocurrent generation onset into the near-infrared. FAPbI3 is also more resistant to heat stress than MAPbI3 while retaining a comparable charge-carrier mobility[1] long charge-carrier diffusion length[2] and impressive solar cell efficiencies as high as 16%[3]. The current most efficient single-junction perovskite photovoltaics are based on FAPbI3,

albeit with chemical substitution to enhance the stability of the perovskite phase. Improving our understanding of the fundamental optoelectronic properties of FAPbI3 is therefore essential to improving the performance of the semiconductor devices based on it. However, despite its remarkable promise, the photophysics of FAPbI3 remains under-studied compared to MAPbI3 [4]. In this study, I report on novel and intriguing emission and absorption processes in FAPbI3. First, we investigated [5] the influence of sub-bandgap trap states on charge-carrier recombination through an analysis of the low-temperature photoluminescence (PL) of FAPbI3. We observed a power-law time dependence in the emission intensity and an additional low-energy emission peak that exhibits an anomalous relative Stokes shift. Using a rate-equation model and a Monte Carlo simulation, we revealed that both phenomena arise from an exponential trap-density tail with characteristic energy scale of ?3 meV. Since charge-carrier recombination from sites deep within the tail causes emission with energy downshifted by up to several tens of meV, such phenomena may in part be responsible for Voc losses commonly observed in these materials. Secondly, we investigated the temperature-dependent absorption of FAPbI3, supported by first-principles modelling. Altogether, we elucidate how the polar FA cation affects the optoelectronic properties of FAPbI3. [1] W. Rehman, R. L. Milot, G. E. Eperon, C. Wehrenfennig, J. L. Boland, H. J. Snaith, M. B. Charge-Carrier Cooling and Polarization Memory Loss in Formamidinium Tin Triiodide Kimberley J. Savill, Matthew Klug, Rebecca L. Milot, Henry Snaith and Laura Herz; University of Oxford, United Kingdom

Reports of slow charge-carrier cooling in hybrid metal halide perovskites have prompted hopes of achieving higher photovoltaic cell voltages through hot-carrier extraction. However, observations of long-lived hot charge carriers even at low photoexcitation densities and an orders-of-magnitude spread in reported cooling times have been challenging to explain. In this work we present ultrafast time-resolved photoluminescence measurements on formamidinium tin triiodide, showing fast initial cooling over tens of picoseconds and demonstrating that a perceived secondary regime of slower cooling instead derives from electronic relaxation, state-filling, and recombination in the presence of energetic disorder. We identify limitations of some widely used approaches to determine charge-carrier temperature and make use of an improved model which accounts for the full photoluminescence line shape. The adoption of this model offers a path to more accurate determination of charge-carrier temperatures, and ready comparison between perovskite compositions to assess the true potential for hot-carrier solar cells. Further, we do not find any persistent polarization anisotropy in FASnI3 within 270 fs after excitation, indicating that excited carriers rapidly lose both polarization memory and excess energy through interactions with the perovskite lattice. References Kimberley J. Savill, Matthew T. Klug, Rebecca L. Milot, Henry J. Snaith, and Laura M. Herz, Charge-Carrier Cooling and Polarization Memory Loss in Formamidinium Tin Triiodide. J. Phys. Chem. Lett. 2019, 10 (20), 6038-6047

8:25 AM F.EL08.02.21

Excitonic Finestructure and Evidence of Dark States in Two-Dimensional Tin Iodide and Lead Iodide Perovskites Ajay Ram Srimath Kandada[1], Giulia Folpini[2], Daniele Cortecchia[2] and Annamaria Petrozza[2]; [1]Wake Forest University, United States; [2]Istituto Italiano di Tecnologia, Italy

We report on the origin of the multiple excitonic states reported previously by us [1,2] in two-dimensional hybrid perovskites, by systematic analysis of the optical observables with the variation of the metal cation from lead to tin. We particulary discuss the temperature dependence of the exciton recombination dynamics obtained via time-resolved photo-luminescence (PL) and transient absorption spectroscopies. We quantitatively analyze the monotonous increase in the exciton lifetime as well as PL quantum yield with increasing temperature in the range of 5 K — 290 K. We consider such a behaviour as an evidence for the presence of dark excitonic states within the finestructure that are de-populated at higher temperatures with an activation energy of ~8-10 meV. We discuss the role of the phonons in the exciton inter-conversion dynamics through non-adiabatic exciton-phonon couplings [3]. [1] A. R. Srimath Kandada and C. Spectroscopic Investigations of Hybrid 2D-3D and Lead-Free Perovskite Materials for Photovoltaics Leonardo R. Buizza; University of Oxford, United Kingdom

Lead-halide perovskite solar cells have improved dramatically over the past decade, increasing in efficiency and overcoming hurdles of temperature- and humidity-induced instability [1]. Materials that combine the high charge-carrier lifetimes and mobilities, strong absorption and good crystallinity of 3D perovskites with the hydrophobic properties of 2D perovskites have become leading candidates for use in solar cells [2]. In order to fully understand the optoelectronic properties of these 2D-3D hybrid systems, we investigate the hybrid perovskite BAx(FA0.83Cs0.17)1-xPb(I0.6Br0.4)3 across the compositional range 0 - x - 0.8. Small amounts of butylammonium (BA) are found to help improve crystallinity and passivate grain boundaries, reducing trap-mediated recombination and enhancing charge-carrier mobilities. However, over-hybridisation leads to poor crystallinity and inhomogeneous film formation, greatly reducing charge-carrier mobilites. We find long charge-carrier diffusion lengths up to 7.7 -m at low BA content of x = 0.167, paving the way for highly efficient and stable perovskite solar cells based on 2D-3D hybrid materials [3]. Separately, lead-free all-inorganic materials have become of interest in order to address issues surrounding the stability of lead-halide perovskites, and concerns around the toxicity of PbI2 [4]. Here we investigate a novel silver-bismuth material that shows ultrafast charge-carrier dynamics, observed via optical-pump terahertz-probe spectroscopy. A wide-ranging spectroscopic and temperature-based investigation of this material points towards localisation effects and strong charge-lattice interactions, whilst still showing good charge-carrier transport properties, lending promise for potential applications of this material to photovoltaics. Reversible Photochromic and Photoluminescence in Iodide Perovskites Md Wayesh Qarony[1], Mohammad Kamal Hossain[2], Mohammad Hossain[1] and Yuen Hong Tsang[1]; [1]The Hong Kong Polytechnic University, Hong Kong; [2]City University of Hong Kong, Hong Kong

Functional materials with photochromism behaviors are highly attractive for various potential applications, such as sensors, displays or lighting devices, clothing, decoration, memory, and commercial consumer products (e.g. photochromic cars, sunglases, T-shirts, shoes, and umbrella), where a reversible color change occurs with changes in light intensity. Photochromic properties are commonly observed in large molecular organic compounds or polymer materials with several states of different colors. However, most of the materials exhibit photochromic behavior with various states in the solution state of that material, limiting the potential and extensive applications. Light-induced phase segregation with photoluminescence (PL) peak shift in mix-halide perovskites owing to reversible energy bandgap tunability of halide-rich domains under illuminations allows to obtain photochromic behaviors in solid-state materials beyond organic polymers. Inspired by this phenomenon, our color imaging experiment demonstrates a nice photochromic behavior of such mixed-halide perovskites upon dark and light excitation, while the color emitted by the crystals changes from red to yellow and vice versa with the intensity of excitation light source. Interestingly, this photochromic light-emitting characteristic can be well-matched with the laser light-induced reversible PL. Unlike the photochromic property commonly observed in solution-state polymer materials, solid-state perovskite materials with photochromic behavior might open wide applications in consumer products and electronic devices. In the next part, we report on a reversible PL peak in iodide-based organic-inorganic lead halide perovskite materials under a two-photon absorption (TPA) process, while tuning the excitation wavelength. This phenomenon occurs when the incoming femtosecond (fs) laser photon energy is higher than threshold energy. Intriguingly, two shorter wavelength peaks are visible and become prominent when the excitation photon energy is being tuned in the high energy spectrum, while laser power is remained constant. The same phenomenon of reversible PL peak is also observed in various iodine-based organic-inorganic halides as well as all-inorganic perovskite single crystals and polycrystals. We attribute to the reversible PL peak phenomenon to the photoinduced structural deformation and the associated change in the optical bandgap of iodide perovskites under the (fs) laser excitation. Our findings will introduce a new degree of freedom in future research as well as adding new functionalities to optoelectronic applications in these emerging perovskite materials.

Carrier and Spin Dynamics in Perovskite 2D Layered and Nanocrystal Systems Matthew Beard; National Renewable Energy Laboratory, United States

Lead-iodide based perovskite semiconductors are emerging as promising light absorbers for solution-processed thin-film photovoltaic applications. In addition, these materials are also intensively studied for light-emitting diodes, photodetectors, and lasers. Recently, hybrid organic-inorganic perovskite (HOIP) semiconductors are being considered as candidates for spintronic applications due to a large spin-orbit coupling (SOC) and controllable Rashba-splitting. Here we discuss the spin-coherence lifetimes in single crystals of 2D Ruddlesden-Popper perovskites PEA2PbI4(MAPbI3)n?1(PEA, phenethylammonium; MA, methylammonium; n = 1, 2, 3, 4). Room temperature spin-coherence times show a nonmonotonic layer thickness dependence with an increasing spin-coherence lifetime with increasing layer thickness from n = 1 to 4, followed by a decrease in lifetime from n = 4 to ?.Our results are consistent with two contributions; Rashba-splitting increases the spin-coherence lifetime going from the n = ? to the layered systems, whilephonon-scattering which increases for smaller layers decreases the spin-coherence lifetime.The unique tunability of HOIPs offers an unprecedented opportunity to directly incorporate chiral organic molecules in the production of a 2D-layered hybrid perovskite thin film and/or crystal that induces chirality into the inorganic sub-lattice bandedge states. Thus, there is an interesting opportunity to explore how chiral molecules embedded into the multilayers provide spin-control within these hybrid semiconductors. Here, we focus on controlling spin-transport within 2D-layerd chiral Pb-I perovskite systems. We demonstrate spin-polarization of charge-transport through the chiral perovskites by showing that the injected current is preferential to one of the spin-states and depends upon the handedness of the incorporated chiral organic molecules; thus, the hybrid chiral system acts as a spin-filter.

9:10 AM *F.EL08.02.25
Many-Body Elastic Scattering of Excitonsin Two-Dimensional Hybrid Metal-Halide Perovskites Carlos Silva; Georgia Institute of Technology, United States

We quantify the role of many-body elastic scattering effects on exciton dephasing rates in two-dimensional hybrid metal-halide perovskites by means of nonlinear coherent excitation spectroscopy at a temperature of 5 K. We find that the exciton-density dependence of excitation-induced dephasing (EID) is two to three orders of magnitude lower than in other atomic monolayer semiconductors such as transition metal dichalchogenides. We find that, EID is different for the multiple excitons evident in the excitation line shape, as is their phonon-mediated temperature dependence. We ascribe these observations to screening effects due to polaronic dressingby the lattice. We further examine the evolution of the two-dimensional coherent exciton lineshape at 5 K with population waiting time. We find that the 2D coherent lineshape evolves with over time windows in which the population itself is static, in a manner that indicates time-dependent EID. Specifically, we find that the dephasing slows down with population waiting time. This spectral evolution invokes time-varying inter-exciton coherences, and we discuss the possible role of dark exciton states in these quantum dynamics.

Harnessing Free Carriers for Photon Upconversion—Using Lead Halide Perovskites for Triplet Sensitization Lea Nienhaus and Sarah Wieghold; Florida State University, United States

Solid-state nanocrystal-based upconversion (UC) systems have disadvantages with respect to poor exciton diffusion lengths, strong singlet reabsorption and the low resulting achievable UC efficiencies. To circumvent these issues, we employ bulk lead halide perovskite (LHPs) thin films as triplet sensitizers for near-infrared-to-visible UC. The sensitized UC process is based on triplet-triplet annihilation (TTA) in the organic semiconductor rubrene. Conservative estimates result in reported UC efficiencies upwards of 3%.1However, to further boost the UC efficiency, it is required to understand and mitigate the effects of shallow trap states in the LHP sensitizer. Here, we investigate the underlying mechanism of energy transfer at the LHP/rubrene interface, and the effect of the LHP perovskite film thickness on the UC dynamics and efficiency threshold. In the LHP/rubrene bilayer device, we observe two opposing effects caused by interactions between the LHP and rubrene: i) passivation of surface defects by rubrene, which results in a longer native photoluminescence (PL) lifetime, and ii) quenching of the PL lifetime due to energy transfer to the triplet state of rubrene. Our observations indicate that non-radiative trap filling in the LHP film and charge transfer to rubrene are likely competitive quenching pathways. As a result, the threshold Ithat which the UC process becomes efficient, observed as a slope change in the power-dependent upconverted PL, shifts to lower values with increasing film thickness. In contrast to previous reported systems, the slope change is directly dependent on the underlying LHP dynamics:i) below Ith, we find a slope twice the value of the LHP PL, and ii) above Ith, the upconverted PL follows the same power-law as the underlying recombination of electrons and holes in the LHP thin films.2,3However, two unusual effects are also observed in the system: i) two distinct rise times in the upconverted emission, indicating two distinct

triplet sensitization rates. ii) A reversible photobleach of the upconverted emission, which cannot be correlated to a physical degradation of the system. By manipulating the triplet population, we are able to show that a higher triplet population does not necessarily result in a higher UC yield for the LHP/rubrene system demonstrated here, rather can be detrimental to the efficiency due to strong singlet reabsorption.3 (1) Nienhaus, L.; Correa-Baena, J.-P.; Wieghold, S.; Einzinger, M.; Lin, T.-A.; Shulenberger, K. Progress in Homologous 2D Halide Perovskites and Their Impact in Photovoltaics Mercouri G. Kanatzidis;
Northwestern University, United States

2D perovskites is a fascinating class of compounds where the 3D perovskite lattice is cut and spatially confined in two dimensions and an “inert” layer of intercalated organic ions is inserted between the layers. The 2D perovskites layers can be formed by the introduction of bulky organic cations that tend to interdigitate between the perovskite sheets. They exhibit a large compositional and structural phase space, which has led to novel and exciting physical properties. The variable thickness of the inorganic slabs presents natural quantum wells (QW) type structures with increased Coulombic shielding, lowering the exciton binding energy and increasing the effective charge carrier mobility. Because these materials have had a strong impact in how record breaking and stable solar cells are constructed, it is critical to understand the thermodynamic and chemical limitations of the maximum thickness that can be sandwiched between the organic bilayers while retaining the structural integrity of the 2D perovskite. What are the limits within which the 2D architecture that define the thickness of the inorganic slabs before the system diverts into the familiar 3D structure? To answer this fundamental question, we employed a combination of synthetic chemistry, calorimetry and crystallography to obtain and identify the thickest known 2D halide perovskite compound characterized to date and we use thermodynamics analysis to assess the enthalpy of formation for these compounds. The application of these low dimensional semiconductors in stable photovoltaics will be discussed.

Real-Time Investigation of Crystallization Pathways of Organo-Metal-Halide Perovskites Solar Michael F. Toney;
University of Colorado Boulder, United States

Organic-inorganic hybrid perovskite solar cells (PSCs) have gained tremendous attention as materials for photovoltaics due to their high efficiencies and their compatibility with low-cost low-temperature fabrication methods (such as solution processing). Perovskite film formation is complex, involving the formation of intermediates and/or metastable phases that strongly affect the final perovskite film microstructure. Therefore, understanding the mechanism of perovskite formation and the crystallization pathways is key for facile control of perovskite formation. We are using time-resolved x-ray scattering to investigate the perovskite formation of $MAPbI_3$-based perovskites and mixed cation (Cs, FA)PbI_3 perovskites *in-situ* during spin coating and the subsequent post-deposition treatments, where FA is formamidinium and MA is methylammonium. For Cs0.15FA0.85PbI3 we study: i) the crystallization pathways during spin coating; ii) the subsequent post-deposition thermal annealing, and iii) crystallization during blade-coating. Our findings reveal that the formation of a non-perovskite FAPbI3 phase during spin coating is initially dominant regardless of the processing and that the processing treatments has a significant impact on the as-cast film structure and affects the phase evolution during subsequent thermal treatment. We show that blade-coating can be used to overcome the non-perovskite phase formation via solvothermal direct crystallization of perovskite phase. This work show how real-time investigation of perovskite formation can help to establish processing-microstructure-functionality relationships. Our work highlights the importance of real-time investigation of perovskite film formation which can aid in establishing processing-microstructure-functionality relationships and help to provide a fundamental understanding of the mechanisms of perovskite formation.

Is the Unit Cell of Solids, Including Halide Perovskites, as Small as the XRD Literature Says? Consequences of the Polymorphous Network Alex Zunger[1], Xingang Zhao[1], Zhi Wang[1] and Gustavo M. Dalpian[2]; [1]University of Colorado Boulder, United States; [2]Universidade Federal do ABC, Brazil

Many common crystal structures can be described by a single (or very few) repeated structural motifs ("monomorphous structures") such as octahedron in cubic halide perovskites. Interestingly, recent accumulated evidence suggests that electronic structure calculations based on such macroscopically averaged monomorphous cubic (Pm-3m) halide perovskites obtained from x-ray diffraction, show intriguing deviations from experiment. These include systematically too small band gaps, dielectric constants dominated by the electronic, negative mixing enthalpy of alloys, and significant deviations from the measured pair distribution function. We show here that a minimization of the systems T = 0 internal energy via density functional theory reveals a distribution of different low-symmetry local motifs, including tilting, rotations, and B-atom displacements ("polymorphous networks"). This is found only if one allows for larger-than-minimal cell size that does not geometrically exclude low symmetry motifs. As the (super) cell size increases, the energy is lowered relative to the monomorphous cell, and stabilizes after ∼32 formula units (160 atoms) are included. Being a result of nonthermal energy minimization in the internal energy without entropy, this correlated set of displacements must represent the intrinsic geometry preferred by the underlying chemical bonding (lone pair bonding), and as such has a different origin than the normal, dynamic thermal disorder modeled by molecular dynamics. Indeed, the polymorphous network, not the monomorphous ansatz, is the kernel structure from which high temperature thermal agitation develops. The emerging physical picture is that the polymorphous network has an average structure with high symmetry, yet the local structural motifs have low symmetries. We find that, compared with monomorphous counterparts, the polymorphous networks have significantly lower predicted total energies, larger band gaps, and ionic dominated dielectric constants, and agree much more closely with the observed pair distribution functions. An analogous polymorphous situation is found in the paraelectric phase of a few cubic oxide perovskites where local polarization takes the role of local displacements in halide perovskites, and in the paramagnetic phases of a few 3d oxides where the local spin configuration takes that role. See PHYSICAL REVIEW B 101, 155137 (2020).

5:45 AM F.EL08.03.04
TiO_2-Assisted Halide Ion Segregation in Mixed Halide Perovskite Films Jeffrey DuBose[1,2] and Prashant Kamat[1,2]; [1]University of Notre Dame, United States; [2]Radiation Laboratory, University of Notre Dame, United States

In metal halide perovskite solar cells, electron transport layers (ETLs) such as TiO_2 dictate the overall photovoltaic performance. However, the same electron capture property of ETL indirectly impacts halide ion mobility and overall phase stability, as is evident from the TiO_2-assisted halide ion segregation in mixed halide perovskite (MHP) films under pulsed laser excitation (387 nm, 500 Hz). This segregation is only observed when deposited on an ETL such as TiO_2 but not on insulating ZrO_2 substrate. Injection of electrons from excited MHP into the ETL ($k_{et} = 10^{11}$ s^{-1}) followed by scavenging of electrons by O_2 causes hole accumulation in the MHP film. Localization of holes on the iodide site in the MHP induces instability causing iodide from the lattice to move away toward grain boundaries. Suppression of segregation occurs when holes are extracted by a hole transport layer (spiro-OMeTAD) deposited on the MHP, thus avoiding hole build-up. These results provide further insight into the role of holes in the phase segregation of MHPs and hole mobility in perovskite solar cells.

5:55 AM F.EL08.03.05
Enhanced Functionality in 2D Hybrid Halide Perovkites Through Engineering of the Organic Component Ferdinand C. Grozema; Delft University of Technology, Netherlands

Two-dimensional halide perovskites have properties that are markedly different than those of the corresponding 3D perovskites, for instance a considerably larger band gap and much stronger interactions between electrons and hole in the inorganic part of the material, i.e. a much large exciton binding energy. The exciton binding energy and other opto-electronic properties can be tuned by modifications in the composition of the inorganic layer, or by changing the layer thickness, for instance in Ruddlesden-Popper structures, as we hav shown recently.

Until now, most of the large organic cations used in 2D or quasi-2D perovskite materials only act as a spacer, defining the dimensionality of the system. Their HOMO-LUMO gap is generally very large and the electronic properties of the resulting materials are fully determined by the properties of the inorganic layers. Currently, is an increased interest in the introduction of specific functionality in the organic component of the material.

In this work, we aim to introduce such additional functionality in the organic part. An example of such functionality is the introduction of electron donors or acceptors resulting in enhanced charge separation. We have explored the introduction of functional organic chromophores theoretically by density functional theory calculations and show that it is possible to introduce conjugated molecules that have a significant effect on the electronic structure. Strong electron acceptors or donors lead to conduction band or valence band edges that are localized on the organic part of the materials. This could lead to enhanced charge separation.

In a subsequent step, several 2D perovskites with functional organic components have been synthesized. These systems include colloidal perovskite platelets with strongly electron accepting perylenebisimids on the surface, solid 2D materials with electron donating conjugated molecules such as benzothieno[3,2-b][1]benzothiophene (BTBT) and pyrene, and materials that include two-component charge transfer complexes (pyrene:TCNQ) between the inorganic layers. Using a combination of time resolved fluorescence spectroscopy and ultrafast transient absorption we show that introduction of such functional components can directly affect the excited state behavior, in several cases leading to charge separation between the inorganic perovskite layer and the organic layer. In a next step, we show that this can indeed lead to the formation of mobile charges in the perovskite layer with a much higher yield and a much longer lifetime than in the analogous materials without functionality in the organic component. This shows that careful engineering of the organic part in 2D perovskite materials shows a lot of promise for the programmed design of functionality in these materials.

6:05 AM F.EL08.03.06
Dopants, Isotope, Pressure and Lead Sequestrion for Hybride Perovskite Materials Tao Xu; Northern Illinois University, United States

The soaring power conversion efficiency (PCE) of solution process-based organic-inorganic hybrid perovskites solar cells (PSCs) assures their membership in the competitive photovoltaic technologies. However, stability, toxicity and scalability are the three grand challenges that still impedes the market adoption of PSCs. Careful fundamental studies on how their fascinating optoelectronic properties is related to their structures may provide leads to these challenges and also spin off new applications. In this talk, I will present our recent study on the dopants, isotope and pressure effects on hybrid perovskite materials (HPMs). We discovered an interesting bipolar electron injection in LiCl-doped MAPbI3-based UV detectors that respond to the energy of UV photons in distinguished photocurrents polarity. We also investigated how the underline interaction between the mass of the cationic rotors and the inorganic lattice in HPMs by isotope effect. In-situ synchrotron X-ray and time-resolved photoluminescence revealed abnormal optoelectronic properties of HPMs by modulating their bond angles and bond lengths using high pressure techniques. Moreover, I will also discuss our new technology to sequestrate lead leakage on perovskite solar cells that can absorb >96% leaked Pb ions under severe device damge while without sacrificing the PCE under normal operational conditions.

6:15 AM F.EL08.03.07
Direct Backbone Attachment of Polyesters on Grain Boundaries Enhances Chemical Stability and Suppressing Ion Migration in $CH_3NH_3PbI_3$ Hybrid Perovskite Solar Cells Chang-Yong Nam; Brookhaven National Laboratory, United States

Organic-inorganic halide perovskites feature excellent optoelectronic properties but poor chemical stability. While passivating perovskite grain boundary (GB) by polymers shows prospects on long-term performance of perovskite solar cells (PSCs), its detailed impact on the ion migration phenomenon, which largely deteriorates the PSC stability, remains less probed. Here, we introduce a new polar polymer, polycaprolactone (PCL), to passivate GBs of methylammonium lead triiodide ($MAPbI_3$) perovskites with only 1 – 2 polymer monolayers via direct backbone attachment. The PSCs with passivated $MAPbI_3$, using classic but less stable Spiro-OMeTAD (2,2′,7,7′-tetrakis[N,N-di(4-methoxyphenyl)amino]-9,9′-spirobifluorene) hole transport layer (HTL), exhibit improved power conversion efficiencies up to 20.1 %, with 90 % of the initial PCE being preserved after 400-h ambient storage, and 80 % even after 100-h, 85 C aging. The improved PSC stability indicates critical roles of PCL GB passivation in retarding moisture-induced decomposition and suppressing ion migration within the perovskite. Time-of-flight secondary ion mass spectrometry reveals that I^- ions can actively migrate into electrode, HTL, and their interface in non-passivated PSCs, even without externally applied electric field, while such migrations are significantly mitigated in PCL-passivated PSCs. This effective GB passivation by PCL suggests an important potential of polymer additives towards the development of stable high-performance PSCs.

A Matter of Mixing—Chemical Heterogeneity in Mixed Perovskites Laura E. Mundt[1], Junwei Xu[1], Leah L. Kelly[1], Axel Palmstrom[2], Joseph J. Berry[2] and Laura Schelhas[1,2]; [1]SLAC National Accelerator Laboratory, United States; [2]National Renewable Energy Laboratory, United States

One of the key features of halide perovskite photovoltaics (PV) is the absorber's ability to accommodate various ions of different sizes in the crystal lattice. Consequently, halide perovskite solar cells yield the highest efficiency and stability when absorbers comprised of a mixture of ions are utilized. However, some compositions such as $FAPbI_3$ (FA = formamidinium) or the fully inorganic composition $CsPbI_3$ exhibit non-ideal geometric conditions and are prone to form non-perovskite δ-phases that are detrimental for their application in PV. Alloying compositions allows for a fine tuning of the geometric conditions and therefore the inherent structural stability.[1] Nevertheless, any chemical heterogeneity in the film can instigate phase segregation of the material into pure phases which as noted prefer their non-perovskite δ-phases and consequently lead to degradation of the device performance. In this study, we present X-ray scattering-based characterization technique as a novel approach of probing the nanoscale heterogeneity.
Spatially resolved analyses have repeatedly revealed microscopic heterogeneity in halide perovskite thin films, including compositional heterogeneity. Evidence has been found that decomposition upon exposure to the aforementioned stress factors is triggered/facilitated by local compositional variation from the averaged mixed phase.[2] Consequently, a lack of homogeneity even on the nanoscale may eventually lead to decomposition and device degradation. Characterizing the chemical heterogeneity in these delicate materials on small length scales, however, has proven challenging and we herein present a novel approach of probing the nanoscale heterogeneity.
Analyzing the structural change across phase transitions allows us to probe the nanoscale heterogeneity in perovskite thin films. More precisely, we hypothesize that the cubic to tetragonal phase transition width is a measure of the chemical heterogeneity in the mixed perovskite composition. To analyze the perovskite phase transition from the tetragonal to the cubic phase at higher temperatures, temperature-dependent in situ wide angle X-ray scattering is utilized. Whereas the transition is abrupt for pure MAPbI3 (MA = methyl ammonium), the transition is stretched over a temperature range for mixed compositions.[3] We hypothesize that this is due to heterogeneity in the probed area. Local variations in the chemical composition can exhibit slightly varying transition temperatures from the completely mixed phase and thereby lead to the observed "smearing" of the phase transition. To test our hypothesis, we prepare a set of $FA_{0.83}Cs_{0.17}PbI_3$ perovskite thin films, choosing a variation of annealing conditions. The annealing temperature has previously been shown to impact the compositional heterogeneity.
Here, we report a systematic study of the influence of annealing conditions on the phase transition in state-of-the-art perovskites, indicating a correlation between the thermodynamic limit of mixing and the processing conditions. If the slope in the tilt angle over temperature is an indicator for the nanoscale heterogeneity, we can expect this to be related to the device stability and therefore be of high relevance for future processing protocols.

Understanding and Mitigating Damage in Hybrid Organic-Inorganic Perovskites Using Pulsed Electron Beams Elisah VandenBussche, Catherine P. Clark, Russell J. Holmes and David J. Flannigan; University of Minnesota, United States

Transmission electron microscopy (TEM) has significant potential to advance fundamental understanding of hybrid organic-inorganic perovskite (HOIP) behavior via high resolution characterization of structure and morphology, chemical analysis, beam-induced current mapping, or even ultrafast structural dynamics at high spatial resolution. However, the organic components and van der Waals bonding critical to the hybrid nature of the material renders HOIPs susceptible to degradation under various environmental conditions, including electron beam irradiation. One promising technique to mitigate this damage is through temporally modulated electron beams, which deliver electron doses with prescribed regularity in place of a thermionic beam in which electron emission is randomly distributed in time. In the present work, the temporally-modulated electron beam is created by training a femtosecond pulsed laser on the source material in the TEM gun region. Importantly, the range of pulsed-electron beam parameters that can be covered in this way is directly dependent upon the pulsed-laser properties, amounting to fine control over both the specimen relaxation time between packets and the instantaneous dose rate. This enables exploration of a host of factors, from spatially-localized specimen heating to complex cumulative, molecular to nanoscale energy-deposition effects. Here, we use a systematic approach to demonstrate the ways in which pulsed beams consisting of discrete packets of photoelectrons delivered to the specimen at precise times can be used to reduce damage to polycrystalline methyl-ammonium lead iodide ($MAPbI_3$) specimens, demonstrated quantitatively by using Bragg-peak-intensity attenuation to track damage as a function of total dose and dose rate. We also discuss insights garnered from these

experiments into damage mechanisms in HOIPs, and report real-space imaging studies on the material using temporal modulation techniques. Because of the two-fold aspect of this work, in which damage is both mitigated and studied, it is of both fundamental and practical relevance.

Structure-Mechanical-Property Relationship of 2D Hybrid Organic-Inorganic Perovskites Qing Tu[1], Ioannis Spanopoulos[2], Eugenia S. Vasileiadou[2], Xiaotong Li[2], Mercouri G. Kanatzidis[2], Gajendra Shekhawat[2] and Vinayak Dravid[2]; [1]Texas A&M University, United States; [2]Northwestern University, United States

Mechanical stability of hybrid organic-inorganic perovskites (HOIPs) is essential to achieve long-term durable HOIP-based devices. While HOIPs in two-dimensional (2D) form offer numerous options in the structure and composition to tune their mechanical properties, little is known about the structure/mechanical-properties relationship in this family of materials. Here we investigated a series of 2D lead-halide HOIPs by nano-indentation to explore the impact of critical factors controlling the properties of both the organic and inorganic layers on the materials' out-of-plane mechanical performance. We find that the presence of soft organic layer and weak Van der Waals (VdW) interfaces renders 2D Ruddlesden-Popper (RP) HOIPs more compliant than their 3D counterparts. For 2D RP lead iodide HOIP crystals with n-alkylammonium as spacer molecules, shorter alkyl chain and higher n number (*i.e.,* thicker PbI_6^{4-} inorganic slab between organic layers) result in higher Young's Moduli and hardness values, which gradually converge to those of 3D HOIPs. We further discover that the lead-halide bond in the inorganic framework can significantly influence the mechanical properties of 2D RP HOIPs with n = 1. Like 3D HOIPs, stronger lead-halide bond strength leads to higher Young's modulus in these 2D HOIPs, *i.e.* $E_{Cl}>E_{Br}>E_I$, while the hardness of 2D RP HOIPs follows a trend different from that in 3D HOIPs (i.e., $H_{Br}>H_{Cl}>H_I$ for 2D HOIPs), probably due to the combined effects from the Pb-X bond strength and inorganic framework structural change (*e.g.*, symmetry and distortion). Moreover, we uncover that the interface between the organic layers in 2D HOIPs can be an effective route to engineer the materials' mechanical properties. Replacing the weak CH_3-CH_3 VdW forces by covalent bonds or phenyl-phenyl interactions in the interface can lead to a much stiffer and harder 2D HOIPs. Finally, we show that the mechanical performance of 2D HOIPs with linear aliphatic diammonium spacer molecules is affected by the two basic structural parameters, *i.e.*, the thicknesses of the organic and inorganic layers. Thinner organic layer and thicker inorganic layer can result in 2D HOIPs with larger elastic modulus and hardness values, similar to what is found in 2D RP HOIPs. 2D HOIPs exhibit hybrid mechanical features of those from metals, ceramics and polymers, which are tunable over a wide range through the vast compositional choices. Our results offer intriguing insights into the structure-property relationship of 2D HOIPs from a mechanical perspective, providing guidelines and inspirations to achieve materials design with required mechanical properties for applications.

Probing Solution Dynamics in Organic-Inorganic and All-Inorganic Perovskite Solutions by ^{207}Pb NMR Investigations Feray Ünlü, Ufuk Atamtürk, Eunhwan Jung, Khan Lê and Sanjay Mathur; University of Cologne, Germany

Organic-inorganic lead halide perovskites with ABX_3 structure, established as rapidly emergent energy materials for optoelectronic applications, such as photovoltaics (PV) and light emitting devices (LED). The power conversion efficiencies (PCE) of perovskite solar cells (PSC) reached threshold values beyond 25% competing with silicon counterparts. The versatility of compositions and structures lead to various application forms such as thin films for PSCs or nanocrystals for LEDs or quantum dot solar cells. To obtain the perovskite semi-conductor in preferred form, solution-based synthesis is done using a variety of lead precursors, solvents and additives. These perovskite inks dictate the crystallization and grain morphology of thin films or nanocrystals, however, the nucleation dynamics in solution are not well understood yet. For this purpose, perovskite precursor solutions were investigated via solution nuclear magnetic resonance (NMR) spectroscopy. The Pb^{2+} coordination behavior in perovskite solution was tracked very extensively for the first time by ^{207}Pb NMR spectroscopy and chemical shifts in the range of -500 to 2500 ppm were obtained in deuterated DMF and DMSO solutions. Since the signals obtained by NMR spectroscopy are the direct response from the local electronic structure of the ^{207}Pb-nuclei, any changes in the structural environment are reflected as chemical shift δ^{207}Pb. The lead iodide species in solution are part of an equilibrium, which was investigated via detecting the chemical shift δ^{207}Pb upon variation of accessible solution parameters, such as molarity, temperature, iodide amount and coordinating solvent. In DMSO, 2D and 3D structures of connected lead iodide octahedra are dominant, whereas structures of lower dimensionality are mainly found in DMF solutions. Therefore, ^{207}Pb NMR spectroscopy acts as a valuable probe for studies on the solution species and dynamic processes, that are involved in the formation of the perovskite crystals.

Late News: Eppur si muove—Proton Diffusion in Halide Perovskite Single Crystals Davide R. Ceratti[1], Arava Zohar[1],

Roman Kozlov[2], Hao Dong[3], Gennady Uraltsev[4], Olga Girshevitz[5], Iddo Pinkas[1], Liat Avram[1], Gary Hodes[1] and David Cahen[1,5]; [1]Weizmann Institute of Science, Israel; [2]Academician Semenov, Russian Federation; [3]Nanjing University, China; [4]Cornell University, United States; [5]Bar-Ilan University, Israel

Ion diffusion has been demonstrated to seriously affect the optoelectronic properties of Halide Perovskites (HaPs). Till now the fastest diffusion has been attributed to the movement of the halide anions, largely neglecting the contribution of mobile protons, on the basis of computed estimates of their density. In this talk, I will show the proofs of the process of proton diffusion inside HaPs following deuterium-hydrogen exchange and migration in $MAPbI_3$, $MAPbBr_3$ and $FAPbBr_3$ single crystals through D/H NMR quantification, Raman spectroscopy and Elastic Recoil Detection Analysis, challenging the original assumption of halide-dominated diffusion. These results are confirmed by impedance spectroscopy, where $MAPbBr_3$-based solar cells respond at very different voltage frequencies compared to $CsPbBr_3$-based ones. I will show that water plays a key role in allowing the migration of protons as we do not detect deuteration in its absence. The water contribution is modeled to explain and forecast its effect as a function of its concentration in the perovskite structure. These findings are of great importance as they evidence how unexpected, water-dependent proton diffusion can be at the basis of the ~7 orders of magnitude spread of diffusion (attributed to I^- and Br^-) coefficient values, reported in the literature. The reported enhancement of the optoelectronic properties of HaP when exposed to small amounts of water, may be related to our finding.

Late News: The Role of Additives in Efficient and Stable Perovskite Solar Cells—Atomistic Insights from Both Experiments and DFT Simulations Shuxia Tao; TU Eindhoven, Netherlands

Perovskite solar cells have gained prominence for their high efficiency and ease of fabrication, yet are hampered by instability. While ion mixing improves device efficiency and stability in general, recent work is demonstrating that incorporation of ions of particularly small or large size (via applying additives in the fabrication process) enhances both further. However there is a lack of understanding of the mysterious mechanisms through which these ions modify material properties (either in the bulk or grain boundaries) or alter the crystallization pathways. In this talk, I will outline recent advances in material characterization (from both experiments and atomistic simulations using DFT) of the impact of several additives (organic salts (PEAI, BAI, GAI) or inorganic salts (alkali halide)) and investigate how they modify the microstructure of the perovskites. I will also discuss the proposed mechanisms and their prospects in the evolution of efficiency and long term stability perovskite solar cells.

7:25 AM *F.EL08.03.14
Facets of Multicomponent Halide Perovskites—How *In Situ* Experiments Can Help us to Understand Formation, Stability and Composition Ana F. Nogueira; University of Campinas, Brazil

Multicomponent perovskite solar cells have reached the recent efficiency breakthrough of 25.2%, higher than silicon polycrystalline photovoltaics. Such fantastic result was only possible due to a precise control and engineering of the morphology, interfaces and the use of multiple cations in perovskite A-site, as Rb, Cs, MA (methylamonnium) and FA (formamidinium). For tandem perovskite solar cells, a mixture of different anions, as Br and I is also desired to adjust the band gap. Such cocktail of different cations and anions influences the formation of intermediates, new phases, favours halide homogenization, etc; so that at the end, the efficiency of the device is closely related to not only the optical quality of the film (e.g. crystallinity), but morphology and composition.
In this presentation, we will summarize important results using *in situ* experiments to probe perovskite formation (2D and 3D), stability and composition. We employed time-resolved grazing incidence wide angle x-ray scattering (GIWAXS), small angle x-ray scattering (SAXS) and high-resolution XRD taken at the Brazilian Synchrotron National Laboratory and SSRL-Stanford.
In situ GIWAXS experiments allowed us to understand the influence of the relative humidity and time to drop the antisolvent during the preparation of perovskite films and get important information about final composition and morphology [1]. It is well known that a 2D layer on the top of a 3D bulk perovskite improves stability and performance. *In situ* GIWAXS revealed us that during thermal annealing the 2D layer transforms itself into a disorder layer, improving hole transfer and stability [2]. This technique was also employed to identify the first intermediates formed during the degradation of different Cs and Br perovskite compositions under ambient conditions [3].
In situ SAXS is another powerful technique to follow the first stages of the 2D perosvkite's formation. Our results suggest that the formation of the individual slabs in $BA_2[FAPbI_3]PbI_4$ is quite fast (within the first 10 s) and, then, these slabs self-assemble into bulk crystallites during the next 40 minutes [4].
Another topic of interest is the photoinduced phase segregation in FACs-based perovskite films. We investigated this

phenomenon by photoluminescence (PL) studies and *in situ* high-resolution XRD (dark and under illumination). We found out that cubic-tetragonal transition is able to stabilize the samples with higher Br and Cs content, however this is not true for the films with 17% Br. Thus, other mechanisms must be operating and ruling phase segregation [5].

Polyelemental, Multicomponent Perovskite Semiconductor Libraries Through Combinatorial Screening Michael Saliba; Technical University of Darmstadt, Germany

Perovskites have emerged as low-cost, high efficiency photovoltaics with certified efficiencies of 25.2% approaching already established technologies. The perovskites used for solar cells have an ABX3 structure where the cation A is methylammonium (MA), formamidinium (FA), or cesium (Cs); the metal B is Pb or Sn; and the halide X is Cl, Br or I. Unfortunately, single-cation perovskites often suffer from phase, temperature or humidity instabilities. This is particularly noteworthy for CsPbX3 and FAPbX3 which are stable at room temperature as a photoinactive “yellow phase”instead of the more desired photoactive “black phase”that is only stable at higher temperatures. Moreover, apart from phase stability, operating perovskite solar cells (PSCs) at elevated temperatures (of 85 °C) is required for passing industrial norms. Recently, double-cation perovskites (using MA, FA or Cs, FA) were shown to have a stable “black phase”at room temperature.(1,2) These perovskites also exhibit unexpected, novel properties. For example, Cs/FA mixtures supress halide segregation enabling band gaps for perovskite/silicon or perovskite/perovskite tandems.(3) In general, adding more components increases entropy that can stabilize unstable materials (such as the “yellow phase”of FAPbI3 that can be avoided using the also unstable CsPbI3). Here, we take the mixing approach further to investigate triple cation (with Cs, MA, FA) perovskites resulting in significantly improved reproducibility and stability.(4) We then use multiple cation engineering as a strategy to integrate the seemingly too small rubidium (Rb) (that never shows a black phase as a single-cation perovskite) to study novel multication perovskites.(5) One composition containing Rb, Cs, MA and FA resulted in a stabilized efficiency of 21.6% and an electroluminescence of 3.8%. The Voc of 1.24 V at a band gap of 1.63 eV leads to a very small loss-in-potential of 0.39 V, one of the lowest measured on any PV material indicating the almost recombination-free nature of the novel compound. Polymer-coated cells maintained 95% of their initial performance at 85°C for 500 hours under full illumination and maximum power point tracking. This is a crucial step towards industrialisation of perovskite solar cells. Lastly, to explore the theme of multicomponent perovskites further, molecular cations were revaluated using a globularity factor. With this, we calculated that ethylammonium (EA) has been misclassified as too large. Using the multication strategy, we studied an EA-containing compound that yielded an open-circuit voltage of 1.59 V, one of the highest to date. Moreover, using EA, we demonstrate a continuous fine-tuning for perovskites in the "green gap" which is highly relevant for lasers and display technology. The last part elaborates on a roadmap on how to extend the multication to multicomponent engineering providing a series of new compounds that are highly relevant candidates for the coming years.(6) (1) Jeon et al. Insight into Layered and Deficient Metal Halide Perovskites from First Principles and Symmetry Claudio Quarti[1], Mikaël Kepenekian[1], Pedesseau Laurent[2], Boubacar Traore[2], Nicolas Mercier[3], Mercouri G. Kanatzidis[4], Constantinos Stoumpos[5], Jacky Even[2] and Claudine Katan[1]; [1]Univ Rennes, ENSCR, INSA, CNRS, ISCR, France; [2]Univ Rennes, INSA Rennes, CNRS, Insttut Foton, France; [3]Université d’Angers, France; [4]Northwestern University, United States; [5]University of Crete, Greece

Currently, many different perovskite -with corner-sharing octahedra- as well as non-perovskite metal-halide solids are synthetized worldwide entailing the need for in-depth understanding of their structure/property relationships. In this regard, combining the huge accumulated knowledge over the last decades, on halide but also oxide perovskites, with modern atomic scale modeling as well as symmetry analysis has proved useful. Among others, new compositions such as A'_2A_{n-}

$_1M_nX_{3n+1}$ (where A and A' are cations, X is halide and M is metal) afford layered structures with a controlled number (n, currently ≤ 7) of octahedra in the perovskite layer. Those correspond to innate heterostructures that offer an ideal platform for fundamental understanding such as effect of quantum or dielectric confinement.[1]

Efforts have also been successful in building new perovskite structures with cations surpassing the Goldschmidt tolerance factor. For instance, this has been recently demonstrated for layered perovskites with the use of ethylammonium, isopropylammonium or dimethylammonium as perovskitizer, having a perovskite sheet retaining its continuous corner-sharing connectivity.[2] On another note, new three dimensional networks have been achieved by mixing larger cations (e.g., hydroxyethylammonium) with the standard ones (e.g. methylammonium, formamidinium) leading to the formation of voids in the perovskite lattice, either disordered (Hollow perovskites) or with structural signature of a periodic pattern (Deficient perovskites).[3]

In this talk, I will discuss some of our recent theoretical results paying attention on newly discovered halide perovskite phases and opportunities to further engineer their properties in connection with their use in devices.

AI-Driven Design of Novel Halide Perovskites Arun Kumar Mannodi Kanakkithodi and Maria Chan; Argonne National Laboratory, United States

Halide perovskites have become increasingly popular semiconductors for application in photovoltaics, LEDs, transistors and electronics. While materials like methylammonium- or Cesium- lead halide perovskites are well studied, there remain vast regions of the ABX3 chemical space that are unexplored in terms of stability, electronic structure and defect behavior. There have been several attempts to tune the properties of halide perovskites by partial substitution at the A-site by Rb, K or other large organic cations, at the B-site by Sn, Ge or other divalent cations with similar ionic radii as Pb such as Ba, and at the X site by mixing of I, Br and Cl. To discover new perovskite compositions with improved properties, materials scientists would traditionally use an Edisonian approach to synthesize and test one composition after another until a candidate is found that is stable, robust, processable, and possesses the required properties. Data-driven approaches have rendered brute-force experimentation nearly a thing of the past; today, we can leverage better-than-ever-before computing power and increasingly optimal machine learning methodologies to develop a knowledgebase of semiconductor materials that allows instant access to properties of existing compounds and efficient design of novel compositions for applications in solar cells, infrared sensors, wearable electronics and quantum information sciences. In this work, we combine first principles computations and machine learning to develop a general prediction and design framework for mixed composition halide perovskites with tailored structural, energetic, optoelectronic and defect properties. We consider a chemical space of cubic ABX3 perovskites where A is selected from the set {FA, MA, Cs, Rb, K}, B from the set {Pb, Sn, Ge, Ba, Sr, Ca}, and X from {I, Br, Cl}. Density functional theory (DFT) computations are performed to generate a dataset of the pseudo-cubic crystal structure, formation and mixing energy, band gap, dielectric constant and cation/anion vacancy formation energy of several hundred known and hypothetical perovskite compositions. This compositionally diverse perovskite dataset along with a set of unique descriptors-based on tabulated elemental properties of constituent elements at the A, B and X site in the compound-serve as input to a neural network (NN) model with multiple output neurons to simultaneously predict each of the aforementioned properties. This model forms the material à properties 'forward prediction' half of the design framework and is applicable to any amount of mixing at the A, B and X sites, which opens up immediate access to extreme levels of alloying that are expensive to model computationally. Following this, the NN model is combined with a mathematical optimization scheme employing genetic algorithms (GA), Bayesian optimization (BO) and generative adversarial networks (GAN) to efficiently design novel compositions with a set of targeted structural, energetic, electronic and defect properties, completing the

properties à material 'inverse design' component. This AI-based design framework is used to quickly screen promising new perovskites which we study in greater detail using more expensive calculations at advanced levels of theory (eg. hybrid functionals that predict band gaps more accurately), and recommend such materials to experimental collaborators for synthesis, testing and characterization. With further expansions in terms of data, descriptors and learning strategies, this framework can lead to the definitive prediction and design methodology that covers the entire halide perovskite chemical universe and informs the creation of new materials that would have taken years of computation or experimentation to be discovered in the past. 5:40 AM F.EL08.04.05
Resolving Rotational Stacking Disorder and Electronic Level Alignment in a 2D Oligothiophene-Based Lead Iodide Perovskite Manoj K. Jana[1], Chi Liu[1], Sven Lidin[2], David J. Dirkes[3], Wei You[3], Volker Blum[1] and David Mitzi[1]; [1]Duke University, United States; [2]Lund University, Sweden; [3]University of North Carolina at Chapel Hill, United States

Two-dimensional (2D) hybrid organic-inorganic perovskites (HOIPs) represent diverse quantum well heterostructures composed of alternating inorganic and organic layers. While 2D HOIPs are nominally periodic in three dimensions for X-ray scattering, the inorganic layers can orient quasi-randomly, leading to rotational stacking disorder (RSD). RSD manifests as poorly resolved, diffuse X-ray scattering along the stacking direction, limiting the structural description to an apparently disordered subcell. However, local ordering preferences can still exist between adjacent unit cells and can considerably impact the properties, particularly the electronic structure. Here, we elucidate RSD and determine the preferred local ordering in the 2D [AE2T]PbI4 HOIP (AE2T: 5,5?-bis(ethylammonium)-[2,2?-bithiophene]). We use first-principles calculations to determine energy differences between a set of systematically generated supercells with different order patterns. We show that interlayer ordering tendencies are weak, explaining the observed RSD in terms of differing in-plane rotation of PbI6 octahedra in neighboring inorganic planes. In contrast, the ordering preference within a given organic layer is strong, favoring a herringbone-type arrangement of adjacent AE2T cations. The calculated electronic level alignments of proximal organic and inorganic frontier orbitals in the valence band vary significantly with the local arrangement of AE2T cations; only the most stable AE2T configuration leads to an interfacial type-Ib band alignment consistent with observed optical properties. The present study underscores the importance of resolving local structure arrangements in 2D HOIPs for reliable structure-property prediction.

5:50 AM F.EL08.04.06
Computational Design Rules for Novel Double Perovskites for Opto-Electronic Devices—The Analogy Between $Cs_2AgInCl_6$ and Ba_2AgIO_6. George Volonakis[1,2] and Feliciano Giustino[3,2]; [1]Université de Rennes 1, France; [2]University of Oxford, United Kingdom; [3]The University of Texas at Austin, United States

Recent computational design strategies towards designing new materials that do not contain Pb have been remarkably successful, and lead to the discovery of a series of novel compounds within the so-called halide double perovskites family. [1] Today there are five inorganic crystals that have been synthesized and characterized; Cs2BiAgCl6, Cs2BiAgBr6, Cs2SbAgCl6, Cs2SbAgBr6, and Cs2InAgCl6. Among these, Cs2BiAgBr6 has the narrower indirect band gap of 1.9 eV, and Cs2InAgCl6 is the only direct band gap semiconductor, yet with a large gap of 3.3 eV. All of them exhibit low carrier effective masses and consequently, are prominent candidates for opto-electronic applications including photovoltaics. Here, we probe oxide perovskites to look for potential promising oxide perovskites following our substitution-based computational design approach. We identify a new oxide double perovskite semiconductor: Ba2AgIO6 (BAIO), and report on its synthesis by low-temp solution process. BAIO has a band gap in the visible range (i.e. 1.9 eV), and a broad PL spectrum. Surprisingly, BAIO has an electronic band structure remarkably similar to that of our recently discovered perovskite Cs2AgInCl6. This allows us to further develop a universal analogy concept that can be used to identify links between oxide and halide perovskites. As such example, we show how BAIO and Cs2AgInCl6 are both analogs of the well-known transparent conductor BaSnO3, but the significantly lower band-gap of BAIO makes this new compound more promising for oxide-based optoelectronics and for novel monolithic halide/oxide devices.

Pronounced Nonlinear Bandgap Behavior in Mixed $Cs_2Ag(Sb_xBi_{1-x})Br_6$ Double Perovskite Alloys Zewei Li[1], Seán Kavanagh[2,3,2], Mari Napari[4], Robert Palgrave[2], Mojtaba A. Jalebi[2], Zahra A. Garmaroudi[1], Mikko Laitinen[5], Jaakko Julin[5],

Richard Friend[1], David O. Scanlon[2,2,6], Aron Walsh[3,7] and Robert Hoye[3]; [1]University of Cambridge, United Kingdom; [2]University College London, United Kingdom; [3]Imperial College London, United Kingdom; [4]University of Southampton, United Kingdom; [5]University of Jyväskylä, Finland; [6]Harwell Science and Innovation Campus, United Kingdom; [7]Yonsei University, Korea (the Republic of)

Halide-based double perovskites have gained significant attention in recent years, owing to the ability to replace the toxic Pb^{2+} cation with a pair of more benign cations (e.g. Ag^{+} and Bi^{3+}) while preserving the perovskite crystal structure. However, most double perovskites, including the prototypical $Cs_2AgBiBr_6$, have wide bandgaps, limiting photoconversion efficiencies. Recently, it has been demonstrated that the bandgap of $Cs_2AgBiBr_6$ can be reduced through alloying with Sb^{3+}. But the bandgap of the pure Sb-based compound ($Cs_2AgSbBr_6$) is also wide. A particular challenge with the Sb-Bi double perovskite alloy system is that materials with high Sb content are difficult to synthesize phase-pure due to the high formation energy of $Cs_2AgSbBr_6$. In this talk, we show a solution-based route we developed to achieve phase-pure $Cs_2Ag(Sb_xBi_{1-x})Br_6$ thin films with the mixing parameter x tunable over the entire composition range. In doing so, we reveal this system to disobey Vegard's law, exhibiting significant bandgap bowing, such that the mixed alloys (x between 0.5 and 0.9) demonstrate smaller bandgaps (down to 2.08 eV) than the pure Sb- (2.18 eV) and Bi-based (2.25 eV) double perovskites. Based on the calculated electronic band alignment, the origin of bandgap bowing in this double perovskite alloy is found to be electronic, rather than structural, in nature. The staggered bandgap alignment between $Cs_2AgBiBr_6$ and $Cs_2AgSbBr_6$, in combination with non-linear mixing of electronic states, via either short-range ordering or spin-orbit effects, produces a bandgap lower than that of either pure material. This work demonstrates a method to reduce the bandgap of $Cs_2AgBiBr_6$ double perovskites, such that it is better suited to photovoltaic or photocatalytic applications. More broadly, our results suggest that bandgap bowing could be found in other lead-free double perovskite alloys by pairing together materials with band positions forming a Type II heterojunction, thus offering a new route to engineer the bandgaps of these materials.

6:10 AM F.EL08.04.09
Efficient Lead-Free Perovskite Solar Cells Enabled by Polymer Induced Trap Passivation for $FA_xPEA_{1-x}SnI_3$ Layer Wenzhan Xu, Yu Gao, Feiyu Kang and Guodan Wei; Tsinghua University, China

Tin-based perovskites with excellent optoelectronic properties are promising candidates for fabricating efficient lead-free perovskite solar cells (PSCs). Unfortunately, Tin-based PSCs exhibited a low efficiency, which mainly arises from serious traps-induced non-radiative recombination, leading into large energy loss with a low voltage, more seriously, Sn^{2+} is leasily oxizated to Sn^{4+}, which leads into p-type self-doping with devices having high dark current denisty. Herein, the polymer poly(ethylene glycol) diacrylate (PEGDA) is employed as a template-agent in $FASnI_3$ to control nucleation and growth is reported. This $FASnI_3$ layer showed a compact crystal with large grain size and reduced defects. As a result, the fabricated planar heterojunction device of ITO/PEDOT:PSS/$FA_xPEA_{1-x}SnI_3$ /ICBA/BCP/Ag showed the power conversion efficiency (PCE) of 9.35% with voltage of 0.75 V. Moreover, corresponding pervoskite solar cells exhibit an enhanced stability.

6:20 AM F.EL08.04.10
Compositional Optimization Strategies for Multi-Cation Perovskites Against Thin-Film Degradation Shijing Sun[1], Armi Tiihonen[1], Felipe Oviedo[1], Zhe Liu[1], Janak Thapa[1], Noor Titan Putri Hartono[1], Anuj Goyal[2], Jason J. Yoo[1], Ruipeng Li[3], Moungi Bawendi[1], Vladan Stevanovic[2], John W. Fisher[1] and Tonio Buonassisi[1]; [1]Massachusetts Institute of Technology, United States; [2]National Renewable Energy Laboratory, United States; [3]Brookhaven National Laboratory, United States

Improving the heat–moisture–light stability of organic–inorganic perovskites, an outstanding semiconductor material class, is a critical challenge.[1] To identify the most stable multi-cation lead iodide perovskites containing Cs, formamidinium (FA) and methylammonium (MA), we fuse results from density functional theory (DFT) calculations and high-throughput *in situ* thin-film degradation test within a singular machine learning (ML) algorithm to inform the compositional optimization of $Cs_xMA_yFA_{1-x-y}PbI_3$.[2] We identify thin-film compositions centred at $Cs_{0.17}MA_{0.03}FA_{0.80}PbI_3$ that achieve a 3x delay in macroscopic degradation onset under elevated temperature, humidity and light compared with the more complex $Cs_{0.05}(MA_{0.17}FA_{0.83})_{0.95}Pb(I_{0.83}Br_{0.17})_3$. [3] We find up to 8% of MA can be incorporated into the perovskite structure before stability is significantly compromised. Cs is beneficial at low concentrations, however beyond 17% is found to contribute to reduced stability**.** Synchrotron-based grazing-incidence wide-angle X-ray scattering (GIWAXS) further reveals that the $CsPbI_3$ minority phase is both a degradation product and an accelerator for chemical decomposition in hot and humid environments, and our findings highlight this detrimental effect can be kinetically suppressed by co-optimising Cs and MA content. Our findings highlight the detrimental effect of $CsPbI_3$ in hot and humid environments both as a degradation product and an accelerator for further chemical decomposition even in top-performing multi-cation compositions.[4] This indicates a limitation of Cs as a perovskite-stabilizing agent, despite it has been to date one of the most widely used cations for environmental stability and performance enhancement in perovskite optoelectronics.

Predicting Optoelectronic Failure in Hybrid Perovskites Using Machine Learning and Simple Optical Techniques Wiley A. Dunlap-Shohl, Ryan Stoddard, Hongbo Qiao, Yuhuan Meng, Wylie Kau and Hugh W. Hillhouse; University of Washington, United States

Stability is one of the most pressing issues facing commercialization of hybrid perovskite solar cells. While there have been encouraging recent improvements in the longevity of efficient perovskite devices,[1, 2] researchers have yet to demonstrate their ability to reach useful lifetimes on the order of decades, or even years. Key steps in reaching this goal include identifying behaviors that appear early in the life cycle of a perovskite film or device that are indicative of future failure, and developing quantitative links between these early-time features and metrics of sample lifetime. Accurate and general lifetime models that can bridge the gap between accelerated testing and normal operating conditions will enable more efficient troubleshooting of problems in state-of-the-art perovskite solar cells and hence be of great value to the photovoltaics community.
To address this challenge, we have developed techniques that monitor *in situ* the evolution of key optoelectronic figures of merit of perovskite thin films in response to varied environmental stresses. By combining measurements of photoluminescence, photoconductivity, and optical transmittance, we gather time-resolved information into carrier generation (quantified by quasi-Fermi level splitting/QFLS), carrier transport (quantified by mean carrier diffusion length L_D), and material integrity, respectively.[3] We show that carrier transport failure is the primary mechanism curtailing photovoltaic performance of hybrid perovskites, evidenced by a rapid drop in L_D that, in most cases, occurs before the QFLS has reached a maximum. The time t_{LD75} at which L_D has decreased to 75% of its starting value is therefore a useful measure of the perovskite film’s effective lifetime. Machine learning models employing a greedy feature selection algorithm predict $\ln(t_{LD75})$ for $MAPbI_3$ to within about 12%, with a dataset spanning a wide range of environmental stress conditions. The initial time derivative of transmittance has high predictive weight in these models, illustrating the importance of the connection between the material’s initial physical degradation rate and its eventual loss of connectivity between undegraded domains within the film. As an alternative means of characterizing material integrity, we have employed dark-field optical microscopy, which is sensitive to scattered light due to roughness or secondary phases, and unlike transmittance is compatible with *in situ* observations of devices with a metal back contact. Heterogeneity of the dark field images of degrading perovskite films evolves in a way that is highly correlated with their transmittance, showing that this technique can be used to connect changes in solar cell operating characteristics (such as shunt resistance) with local failure of the absorber material. These early successes demonstrate that simple *in situ* optical techniques provide extremely useful physical information that aids the task of forecasting perovskite failure.

6:40 AM F.EL08.04.12
Late News: Efficient Lone Pair-Driven Luminescence: Structure-Property Relationships in Emissive 5s2 Metal Halides Kyle M. McCall[1,2], Viktoriia Morad[1,2], Bogdan M. Benin[1,2] and Maksym V. Kovalenko[1,2]; [1]ETH Zürich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Low-dimensional metal halides have been the focus of intense investigations in recent years following the success of the three-dimensional (3D) hybrid lead halide perovskites as optoelectronic materials for solar cells, semiconductor radiation detectors, and narrow emitters. In particular, the light emission of zero-dimensional (0D) metal halides based on the $5s^2$ cations Sn^{II} and Sb^{III} have found utility in a variety of applications (including X-ray scintillation and remote thermometry) that are complementary to those of the 3D halide perovskites, thanks to their unusual properties including intrinsic broadband emission and highly temperature-dependent lifetimes. These properties derive from the exceptional chemistry of the $5s^2$ lone pair, which generates the appropriate atomic environments for efficient emission as it lies on the cusp of the static $4s^2$ lone pair and the dynamic but less pronounced $6s^2$ lone pair. However, the descriptions and terminology of this unusual emission vary significantly, complicating efforts of various researchers to build a cohesive understanding and enable the design such emissive materials.

Here, we provide a structural overview of these materials with a focus on the dynamics driven by the stereoactivity of the $5s^2$ lone pair to identify the structural features that enable strong emission. The chemistry of the $5s^2$ lone pairs in various halide environments is described and compared to those of the neighboring $4s^2$ and $6s^2$ cations to highlight the unique combination of stereoactivity and structural flexibility of these main group metals. We relate the different theoretical models which have been able to explain the success of these bright $5s^2$ emission centers into a cohesive framework, which is then applied to the array of compounds recently developed by our group and other researchers, demonstrating its utility and generating a holistic picture of the field from the point of view of a materials chemist. We summarize the most promising materials to identify the common trends among them, finding that Sn(II) bromides and Sb(III) chlorides lead the field with the highest efficiencies, highlighting the importance of metal-halogen overlap in the lone pair dynamics. We highlight the state-of-the-art applications which demonstrate the unique capabilities of these versatile emissive centers, describing the current progress and challenges for each application to identify promising future directions in the field. This work introduces the field of low-dimensional $5s^2$ metal halides, pointing the way towards an understanding that will enable the design of such materials for optoelectronic devices that deliver on the promise of these applications.

Late News: How Defect Tolerant are Halide Perovskites? Xie Zhang, Mark E. Turiansky, Jimmy-Xuan Shen and Chris G. Van de Walle; University of California, Santa Barbara, United States

“Defect tolerance” has been commonly considered as the origin of the high photovoltaic performance of halide perovskites. However, a rigorous assessment of this concept is still lacking. Based on accurate first-principles calculations, we quantitatively show that halide perovskites are not “defect tolerant”; defect-assisted nonradiative recombination is actually a key limitation of perovskite solar cells. The conventional wisdom suggests that only defects with charge-state transition levels deep in the band gap can be efficient nonradiative recombination center. We demonstrate that the presence of charge-state transition levels in the band gap is a prerequisite for being a nonradiative recombination center, but unlike in many conventional semiconductors the position of the level does not directly imply high or low capture rates because of exceptionally strong lattice coupling and anharmonicity in halide perovskites. Explicit calculations of the nonradiative capture rates are essential. We emphasize that accurate calculations, based on hybrid density functional theory and including spin-orbit coupling, are essential for obtaining reliable results. Our results show that iodine interstitials, although their transition levels are close to the band edges, can actually act as efficient nonradiative recombination centers in methylammonium-lead iodide, and are likely responsible for the experimentally observed nonradiative recombination rates. We also address the impact of impurities. The Bi impurity has been commonly believed to be an efficient recombination center. Our rigorous calculations show that while the Bi impurity does have a transition level in the band gap, it is, in fact, not a recombination center on its own. The observed impact on device performance occurs indirectly, via promoting the formation of iodine interstitials. These insights clarify misconceptions in the field, and point to fruitful directions for defect engineering toward enhanced performance.

SESSION F.EL08.05: Toward Pb-Free Perovskite Absorbers

Is There Any Hope for Efficient Sn-Based Perovskite Solar Cells? Maria Antonietta Loi; University of Groningen,

Netherlands

Organic lead halide perovskite based solar cells (HPSCs) have achieved certified power conversion efficiency (PCE) over 25.0%. Despite the high efficiency achieved, there are still many concerns about the large-scale applicability of this solar cells because of the water soluble toxic Pb2+. The simpler approach to address this issue is to find a benign or less toxic metal to replace the lead atom in the perovskite structure, with the resulting perovskite still showing the excellent optical and electrical properties. Theoretically, tin based perovskite holds the promise to produce similar or even higher PCE compared to their Pb counterpart. However, for relatively long time the tin-based HPSCs held a PCE lower than 7% though intensive research efforts were devoted to their investigation. The facile formation of tin vacancies and easy oxidation of Sn2+ have been identified as the main reason determining the low PCE. In my presentation I will report as a small amount of 2D tin perovskite templates the growth of highly crystalline and oriented 3D FASnI3 grains (2D/3D mixtures), suppressing effectively the appearance of tin vacancies and Sn2+ oxidation. As a consequence of the reduced background charge carrier density and trap assisted charge recombination, the device showed a 50% improvement in the PCE (up to 9%) compared to that using pure 3D tin perovskite. We further succeeded reducing the defects in the 2D/3D tin perovskite films by adding ethylammonium iodide (EAI) into the corresponding perovskite precursor solution. These films display larger crystalline grains and a more compact and uniform film morphology when compared to their counterparts without EA cation. These features lead to a much lower trap density, background charge carrier density and charge recombination loss in the corresponding devices. Results, which allow hopping for future highly efficient Sn-based hybrid perovskite solar cells.

Data-Science Methods Enable Perovskite Stability and Performance Improvements Tonio Buonassisi, Shijing Sun, Clio Batali, Antonio Buscemi, Alex Encinas, Janak Thapa, Noor Titan Putri Hartono, Felipe Oviedo and Armi Tiihonen; Massachusetts Institute of Technology, United States

Data-sceince methods, including advanced statistics and machine learning, can help researchers diagnose, optimize, and design more efficiently. In this talk, I'll summarize the MIT PVLab's recent progress optimizing bare films and record-efficiency perovskite devices with capping layers using data-science methods. These include combining density-functional theory (DFT) and Bayesian inference to accelerate the search for stable compositions, and optimizing capping layers for combined performance and stability. Lastly, I'll highlight our progress searching for lead-free perovskite-inspired, defect-tolerant semiconductors.

5:30 AM *F.EL08.05.05
Bismuth-Based Colloidal Nanocrystals—Lead-Free Materials for Solution-Processed Solar Cells Maria Bernechea; INA - Institute of Nanoscience of Aragon, Spain

In the last years, the field of solution-processed solar cells based on inorganic semiconductors has seen a great progress, showing the highest efficiencies among the emerging photovoltaic technologies. Indeed, of quantum dot solar cells have reached an efficiency over 16%, and solar cells based on perovskites have surpassed 25% efficiency. However, the future development of these cells could be limited due to the presence of highly toxic elements in their composition, more specifically lead (Pb). Efforts are thus required in searching for earth-abundant, and non-toxic materials. Inorganic colloidal nanocrystals (NCs) are attractive materials for their use as active layers in quantum dot solar cells. They are generally composed of earth-abundant elements, and they can be processed from solutions, allowing an easy and cheap fabrication of devices. Moreover, they have additional attractive properties, like high absorption coefficients, tunable bandgaps, and band energy level engineering through ligand exchange. In this context, bismuth-based colloidal NCs, appear as an attractive alternative for environmentally friendly, low cost solar cells. We have developed ways to modify the size and shape of the bismuth-based nanocrystals, and we have observed how this affects their optoelectronic properties. We have studied the modulation of Fermi level and energy bands introducing different ligands on the surface of the NCs. We have employed these NCs to fabricate solution-processed solar cells, focusing on completely non-toxic devices, achieving a certified efficiency of more than 6%, employing very thin layers (~35 nm) of AgBiS2 NCs. A summary of these results will be presented and future directions will be discussed.

5:45 AM F.EL08.05.06
Enhancement of Efficiency for Pb Free Perovskite Solar Cells Consisting of Sn2+ Doped with Ge2+ Shuzi Hayase[1], Kohei Nishimura[1], Muhammad Akmal Kamarudin[1], Daisuke Hirotani[2], Kengo Hamada[2], Qing Shen[1], Satoshi Iikubo[2], Takashi Minemoto[3] and Kenji Yoshino[4]; [1]The University of Elector-Communications, Japan; [2]Kyushu Institute of Technology, Japan; [3]Ritsumeikan University, Japan; [4]Miyazaki University, Japan

The certified efficiency of Pb-perovskite solar cells with more than 1 cm2 area is reported to be 20.9%(1). In the smaller cell, the cell efficiency with 25.2% has been reported, which is close to 22.3 % of multi Si solar cells (2). However, the use of Pb in electronic devices is limited according to the EU RoHS Directive. Thus, it is needed to develop Pb-free perovskite solar cells. Among Pb-free perovskite candidates, Sn perovskite is one of the most promising candidates for the light harvesting layer for the Pb-free perovskite, because they have perovskite structure similar to Pb-perovskite. However, the efficiency iwas not as high as those for Pb-perovslite solar cells. We have already reported that the efficiency was enhanced by Ge2+ doping to the Sn-perovskite layer, because the carrier density in the Sn-perovskite layer was reduced (3,4). Now, we discuss the further enhancement of the Sn-perovskite solar cells from the view point of the lattice strain (disordering) relaxation and the surface passivation on the perovskite slayer to show the direction of the research. We report post-treatment of Sn-perovskite layer with Lewis base (NH2-CH2-CH2-NH2) to suppress the recombination reaction in Sn-perovskite solar cells resulting in efficiencies of 10.2 %. Upon analyzing the X-ray photoelectron spectroscopy and impedance spectroscopy data, we came to the conclusion that the amine-group bonded the under-coordinated tin, passivating the dangling bonds and defects resulting in suppressed charge carrier recombination (5). This also has the effect of prolonged lifetime and higher charge carrier mobility. These findings provide the groundwork for improving the efficiency of Sn-halide PSCs to compete with that of lead-based PSCs by simple post-treatment with organic molecules (6). We and other research groups have reported that the efficiency of Sn-perovskite solar cells increases spontaneously during the storage, which we explained by the perovskite lattice strain (disordering) relaxation. This prompted us to examine the relationship between between relative lattice strain and photovoltaic performances. It is shown that the efficiency of the Sn-perovskite solar cells has good relationship with the lattice strain (disordering). By decreasing the lattice strain (disordering), Ge doped Sn-perovskite solar cells with 11.7% was prepared. The mechanism wil be discussed. 1. 5:55 AM F.EL08.05.07
Carrier Dynamics and Recombination in Low-Dimensional Halide Perovskites—Role of Structural Fluctuations Dibyajyoti Ghosh; University of Bath, United Kingdom

Low-dimensional halide perovskites have demonstrated promising luminescence properties for light-emitting diodes due to their high radiative recombination rate.[1] However, the lack of a complete understanding of the structure-property relationship hinders the systematic design of these materials to enhance their luminescence efficiency. Combining state-of-the-art nonadiabatic molecular dynamics and time-domain density functional theory, we explore the substantial effects of structural fluctuations on the excited state dynamics and carrier recombination in these perovskites. Here, I will demonstrate how structurally rigid perovskites experience weaker electron-phonon interactions, resulting in suppressed non-radiative carrier recombination and enhanced photoluminescence quantum yield (PLQY).[2,3] Our work revealed that stacking of the spacer cations, and halogen composition of the inorganic layers substantially tune the PLQY of these materials. Based on these understanding, we further propose a combination of suitable spacer cations and inorganic layer compositions to improve the PLQY of low-dimensional halide perovskites. References: 1. Smith et al. Chem. Rev. 2019, 119, 3104 2. Ghosh et al. Submitted, 2019 3. Leveillee et al. Under final review, Nano Lett. 2019

6:05 AM F.EL08.05.08
Late News: Enhanced Optical Absorption via Mixed-Valent Doping of Vacancy-Ordered A3B2X9 Triple Perovskites Seán Kavanagh[1,2,3], David O. Scanlon[1,4], Aron Walsh[2,5] and Robert Palgrave[1]; [1]University College London, United Kingdom; [2]Imperial College London, United Kingdom; [3]Centre for Doctoral Training in the Advanced Characterisation of Materials (CDT-ACM), United Kingdom; [4]Diamond Light Source, United Kingdom; [5]Yonsei University, Korea (the Republic of)

Vacancy-ordered triple perovskites have recently come under the scientific spotlight as promising materials for high-performance next-generation optoelectronic technologies.[1,2] Their $A_3B_2X_9$ stoichiometry facilitates the replacement of the toxic Pb^{2+} cation with a benign isoelectronic B^{3+} cation (e.g. Bi^{3+} or Sb^{3+}) while preserving the perovskite crystal structure. Unfortunately, however, these materials tend to exhibit large bandgaps (> 2 eV), impeding their application in many photo-catalytic/voltaic devices.[3,4]
In this work, we demonstrate a drastic shift of over 1 eV in the optical absorption onset of $Cs_3Bi_2Br_9$ (from 2.58 eV to 1.39 eV), upon doping with tin. Through a combination of detailed theoretical and experimental characterization of this novel material, we elucidate the origin of broadband absorption. Sn is found to disproportionate in the doped material, inducing a

strong intervalence charge transfer (IVCT) transition, whilst preserving the structural integrity of the perovskite framework. Our work provides valuable insight regarding the effects of mixed-valency and structure-property relationships in perovskite-inspired materials, guiding design strategies and expanding the compositional space of candidate materials. Moreover, we anticipate that this massive reduction in absorption onset could aid charge transport and/or photo-catalytic performance, opening the door to unexplored applications of this material class.

6:15 AM F.EL08.05.09
High Efficiency Pb-Free Cs2PtI6 Halide Perovskite Photovoltaic Devices with > 2 Microseconds Carrier Lifetime Shubhra Bansal, Dakota Schwartz and Curtis Walkons; University of Nevada, Las Vegas, United States

Organic-inorganic hybrid halide perovskite solar cells (HPSCs) have attracted immense attention because of excellent optoelectronic properties and record power conversion efficiency (PCE) has reached 24.2% from 3.8% within a few years. Despite the very high efficiency already attained by HPSCs (ABX3; A = MA, FA, Cs; B = Pb, Sn; X=I, Br, Cl) resulting from high absorption coefficient and electron-hole diffusion lengths; toxicity of Pb and stability of these materials are veritable issues. Replacing MA+ and FA+ with PEA+, BA+, Cs+ has shown to enhance the stability of hybrid perovskite solar cells against thermal and moisture related degradation. The superior optoelectronic properties of Pb-based halide perovskites are attributed to the inactive Pb 6s orbitals, and can be replaced by Ge2+, Sn2+, Sb3+, Bi3+, Cu2+ with inactive s orbitals. Replacement of Pb2+ with Sn2+ and Ge2+ seems to be a logical solution for addressing the toxicity issues and results in excellent optoelectronic properties such as high absorption coefficient, high hole mobility resulting in PCE of 9.6% for (GA,FA)SnI3 and 7.9% for mixed (FA,MA)GeSnI3 and 7.11% for CsSn0.5Ge0.5I3. However, a major challenge for Sn and Ge based Pb-free perovskites is poor power conversion efficiencies as divalent Sn2+ and Ge2+ tend to oxidize into 4+ oxidation state, generating excessive defects (Sn and Ge vacancies), and resultant short carrier diffusion lengths. The 2D structure Cs2SnI6 has received attention as a more stable alternative to CsSnI3 based halide-perovskites for photovoltaic applications due to stable Sn4+ oxidation state and the strong covalency of Sn-I bonds in the [SnI6]2- octahedral. Cs2PdBr6, Cs2TiBr6, Cs2AgBiX6, CsGe0.5Sn0.5I3, AgBiI4, (MA,Cs,Rb)3Sb2I9 have been shown to be unsuitable for PV applications due to many reasons such as bandgap > 2 eV, low minority carrier diffusion lengths, deep level defects, etc. We have reproducibly created high quality thin-films of Pb-free perovskite Cs2PtI6 via atmospheric solution process with experimentally determined bandgap of ~ 1.4 eV. Cs2PtI6 crystallizes in a cubic crystal structure with the space group with high {111} peak intensities. SEM analysis shows well-formed micron-sized crystallites with improved film density with the use of ethylene diamine treatment. These atmospherically processed films contains low oxygen levels (mostly surface CsOx) and Cl impurity from PtI4 precursors as determined by EDS, ToFSIMS and XPS. Cs2PtI6 shows enhanced stability and excellent optical absorption, hole mobility and minority carrier lifetimes. For the first time we have demonstrated a Pb-free halide perovskite material, Cs2PtI6, with high absorption coefficient compared to MAPbI3 and minority carrier lifetime > 2 ?s. The high absorption coefficient in Cs2PtI6 results from the stronger d-p transitions as compared to the p-p transitions in MAPbI3. The combination of high absorption coefficient and high minority carrier diffusion lifetime in Cs2PtI6 suggests presence of direct-indirect transition behavior similar to MAPbI3, perhaps due to high Z of Pt. Superstrate n-i-p devices with FTO/CdS/Cs2PtI6/carbon/Cu have been reported for the first time, with maximum PCE of 13.88% and low Voc deficit. Further improvement in device efficiency is envisioned with the improvement of Cs2PtI6 film quality and better selection of ETL and HTL materials. It is noted that cost of Pt-based precursors is higher compared to Pb-based precursors, however, Pt offers a model system for Pb-free perovskite materials and may offer a pathway to ultra-thin wide bandgap top cells for tandem solar cells. The key advantages of Cs2PtI6 over MAPbI3 include high stability, absorption coefficient, minority carrier lifetimes and tunable bandgap for applications beyond photovoltaics such as water splitting, photocatalytic CO2 reduction, and other optoelectronic devices.

Understanding Defect Physics to Stabilize Metal-Halide Perovskite Semiconductors for Optoelectronic Applications Annamaria Petrozza; Istituto Italiano di Tecnologia, Italy

Semiconducting metal-halide perovskites present various types of chemical interactions which give them a characteristic fluctuating structure sensitive to the operating conditions of the device, to which they adjust. This makes the control of structure-properties relationship, especially at interfaces where the device realizes its function, the crucial step in order to control devices operation. In particular, given their simple processability at relatively low temperature, one can expect an intrinsic level of structural/chemical disorder of the semiconductor which results in the formation of defects. Here, first I will summarize our understanding of the nature of defects and their photo-chemistry, which leverages on the cooperative action of density functional theory investigations and accurate experimental design. Then, I will show the correlation between the nature of defects and the observed semiconductor instabilities. Instabilities are manifested as light-induced ion migration and segregation, eventually leading to material degradation under prolonged exposure to light. Understanding, controlling and eventually blocking such material instabilities are fundamental steps towards large scale exploitation of perovskite in optoelectronic devices. Finally, based on such knowledge, I will discuss different synthetic and passivation strategies which are able to stabilize the perovskite layer towards photo, thermal and electrical instabilities, leading to improved optoelectronic material quality and enhanced device reliability

Tools to Reveal the Energetic Losses in Perovskite Solar Cells Pablo P. Boix; University De Valencia, Spain

The rapid development of perovskite solar cells has been based on improvements in materials and device architectures, yet further progress towards their theoretical limit will require a detailed study of the main physical processes determining the photovoltaic performance. In this talk, we combine optical and electrical spectroscopy measurements to gain insight into the main loses in perovskite solar cells. The analysis of solution-processed devices with controlled precursor concentrations is the prefect platform to develop an impedance spectroscopy equivalent circuit.[1] The model provides a tool to evaluate the processes directly affecting the device performance, including charge recombination and charge transport. In-situ absolute photoluminescence measured during cell operation enables an alternative way to probe the device recombination mechanisms. Applied to vacuum deposited perovskite solar cells, it can directly assess radiative recombination, as well as the variation of the relative radiative /non-radiative along the measured potentials. Altogether, we provide a complete view of the main loss mechanisms in perovskite solar cells, yet in a pragmatic way which allows its application as a device evaluation tool. [1] Yoo et al., Joule 3, 2535-2549

5:30 AM *F.EL08.06.03
Bulk and Interface Engineering for Defect Passivation in Perovskites Kai Zhu; National Renewable Energy Laboratory, United States

Perovskite solar cells (PSCs) have become a competitive photovoltaic (PV) technology with rapid progress of efficiencies reaching a certified 25.2% for single-junction devices. The bandgap tunability through perovskite composition engineering is attractive for developing ultrahigh-efficiency tandem solar cells, including perovskite/perovskite, perovskite/silicon, or perovskite/thin-film absorber (e.g., CIGS). Toward this end, highly efficient wide-bandgap and low-bandgap perovskites solar cells need to be development. In this talk, I will discuss our recent progress on suppressing defects in perovskites covering both the wide-bandgap (~1.7–1.8 eV) and low-bandgap (~1.2–1.3 eV) perovskite compositions. Strategies on reducing the bulk defects by utilizing 2D perovskite passivation agents (2D-PPA) will be discussed. The precursor chemistry and growth conditions affect significantly the physical and optoelectronic properties of perovskites. Surface recombination at an interface in a device is also critical to device operation. Characterization and strategies to reduce surface recombination will be presented. Applications of perovskite absorbers in highly efficient tandem devices will be discussed. Finally, the potential toxicity issue of Pb and the corresponding mitigation approaches will be discussed.

5:45 AM *F.EL08.06.04
Intricacy of Photoinduced Halide Ion Segregation and Dark Remixing in Mixed Halide Perovskites Prashant Kamat; University of Notre Dame, United States

The intrinsic ionic defects, specifically halide ion vacancies, often dictate the mobility of halide species within the perovskite film during the operation of solar cells. Of particular interest is the halide ion mobility in metal halide perovskites, which

plays an important role in determining the performance of perovskite solar cells. Photoinduced phase segregation seen in mixed halide perovskite films under steady state irradiation offers a convenient way to visualize halide ion segregation. Interestingly, upon storage in dark, the process is reversed and the original mixed halide composition gets restored. Whereas entropy of mixing explain the thermally activated mixing of halide ions to yield mixed halide perovskite, the opposite trend observed during photoirradiation remains an intriguing phenomenon. The threshold energy of incident light to observe halide segregation increases with increasing temperature. The diffusion of these halide species, which is tracked through changes in the absorption spectra at different temperatures, offers a direct measurement of thermally activated halide diffusion in perovskite films. The increase in the rate constant of halide diffusion with increasing temperature (from 5×10^{-5} s^{-1} at 23 °C to 2.2×10^{-3} s^{-1} at 140 °C) follows an Arrhenius relationship with activation energy of 51 kJ/mole. The thermally activated halide exchange shows the challenges of employing layers of different metal halide perovskites in stable tandem solar cells

Unravelling the Impacts of Mobile Ions on Perovskite Solar Cell Performance Rebecca Belisle; Wellesley College, United States

Defect tolerance has emerged as a central theme for the success of halide perovskites as photovoltaics. Some current estimates put the number of mobile ionic defects in common halide perovskites above 1017 cm-3, yet the halide perovskite band structure and resulting shallow nature of the hypothesized dominant defects limits their ability to act as recombination centers in these materials. However, this defect tolerance does not imply that these ionic defects have no impact on device performance. Current-voltage hysteresis, reverse-bias breakdown, photo-brightening, photodegradation, thermal stability, and other behaviors related to perovskite performance have all been attributed to the appreciably ionic transport in perovskites made possible by this large defect population. In this work I will present recent advances in both the development of experimental methods for analyzing the formation and behavior of mobile ions in halide perovskites, and our understanding of the effects of these mobile ions on device performance. I will discuss methods to investigate defect formation and transport, including our results using in situ photoluminescence and X-ray diffraction techniques to track ion movement and correlate that with the optoelectronic properties of methylammonium perovskites. Additionally, I will share our work looking at the impacts of mobile ions on device performance, particularly with regards to limits on the open-circuit voltage of perovskite solar cells. Finally, I will highlight the unique roles that contacts and surfaces can play in optimizing the performance and stability of perovskite solar cells in light of these mobile ionic defects.

Mechanism of Surface Passivation of Methylammonium Lead Tribromide Single Crystals by Benzylamine Herman Duim[1], Hong-Hua Fang[1], Sampson Adjokatse[1], Gert H. Ten Brink[1], Miguel A. Marques[2], Bart J. Kooi[1], Graeme R. Blake[1], Silvana Botti[3] and Maria Antonietta Loi[1]; [1]University of Groningen, Netherlands; [2]Martin-Luther-Universität-Halle-Wittenberg, Germany; [3]Friedrich-Alexander-Universität Jena, Germany

Solar cells, light-emitting diodes and photodetectors are amongst the promising examples of the use of hybrid organic-inorganic perovskite semiconductors in optoelectronic applications. The surface of these materials plays a crucial role in the performance and stability of such devices as the presence of surface trap states strongly affects the recombination rate of excited charge carriers. It has previously been reported that molecular ligands, such as benzylamine, are capable of significantly reducing the amount of surface trap states in thin films. In this work, we aim to clarify the mechanisms that govern the surface passivation of hybrid perovskites by benzylamine. We use freshly cleaved single crystal to investigate the influence of benzylamine on a well-defined perovskite surface. We demonstrate that benzylamine permanently passivates surface trap states in these single crystals which results in enhanced photoluminescence and charge carrier lifetimes. Additionally, we show that, when exposed to benzylamine, the methylammonium cations are replaced by benzylammonium, thereby creating a thermodynamically more stable two-dimensional (2D) perovskite (BA)2PbBr4 on the surface of the three-dimensional crystal. The formation of this 2D perovskite phase drives a highly anisotropic etching of the underlying crystal surface, with the {100} planes being most prone to etching. Initially, isolated square etching pits appear spread over the surface. As time elapses, these etching pits broaden and eventually merge to give rise to large flat terraces that are oriented normally to the cleaving plane. These results highlight that even a simple passivation procedure can have a marked effect on the morphology and composition of the perovskite material. A thorough understanding of the mechanisms governing the surface passivation is thus crucially important to optimize and design novel passivation schemes, with the ultimate goal of further advancing the efficiency of optoelectronic devices based on hybrid perovskites.

Multi-Messenger Stability Testing Using Environmental X-Ray Photoelectron Spectroscopy Anthony Donakowski[1], Wes Miller[2], Nicholas Anderson[2], Erin Sanehira[2], Joseph J. Berry[3], Michael Irwin[2], Angus Rockett[1] and Xerxes

Steirer[1]; [1]Colorado School of Mines, United States; [2]HEE Solar LLC, United States; [3]National Renewable Energy Laboratory, United States

Using Environmental X-ray Photoelectron Spectroscopy (EXPS), we evaluate the solid and gas phase products from degradation of metal halide perovskites (MHPs) during interaction with water and light. The stability of novel MHPs is traditionally assessed under accelerated stress conditions in complete photovoltaic devices but the associated trial and error approach provides little insight into the chemical origin of device or material failure. Alternatively, EXPS addresses MHP instability head on, testing resilience against water and other stimuli monitored by surface chemistry and electronic structure. With the environmental chamber of the EXPS we control sample temperature, atmosphere, and illumination. A quadrupole mass spectrometer allows identification and quantification of gaseous products. We report time-resolved chemical information about interface reactions, changes to surface bonding, activation energies, and chemical pathways to determine degradation pathways in situ. Using the multi-messenger EXPS approach, we observe significant chemical changes under accelerated stress factor degradation tests within one working day and compare these results to MHPs degraded under standard water and light stress conditions. These results provide insight into previous studies describing the high defect tolerance of MHPs in juxtaposition to their instability under operating conditions after certain chemical thresholds are met. Late News: Approaching the Limits of Optoelectronic Performance in Mixed Cation Mixed Halide Perovskites by Controlling Surface Recombination Sarthak Jariwala[1], Sven Burke[1], Sean P. Dunfield[2], R. C. Shallcross[3], Margherita Taddei[1], Jian Wang[1], Giles Eperon[2], Neal R. Armstrong[3], Joseph J. Berry[2] and David S. Ginger[1]; [1]University of Washington, Seattle, United States; [2]National Renewable Energy Laboratory, United States; [3]The University of Arizona, United States

We demonstrate the critical role of surface recombination in mixed-cation, mixed-halide perovskite, $FA_{0.83}Cs_{0.17}Pb(I_{0.85}Br_{0.15})_3$. By passivating non-radiative defects with the polymerizable Lewis base (3-aminopropyl)trimethoxysilane (APTMS) we transform these thin films. We demonstrate average minority carrier lifetimes > 4 μs, nearly single exponential monomolecular PL decays, and concomitantly high external photoluminescence quantum efficiencies (>20%, corresponding to ~97% of the maximum theoretical quasi-Fermi-level splitting) at low excitation fluence. We confirm both the composition and valence band edge position of the $FA_{0.83}Cs_{0.17}Pb(I_{0.85}Br_{0.15})_3$ perovskite using multi-institution, cross-validated, XPS and UPS measurements. We extend the APTMS surface passivation to higher bandgap double cation (FA,Cs) compositions (1.7 eV, 1.75 eV and 1.8 eV) as well as the widely used triple cation (FA,MA,Cs) composition and observe significant PL and PL lifetime improvements after surface passivation. Finally, we demonstrate that the average surface recombination velocity (SRV) decreases from ~1000 cm/s to ~10 cm/s post APTMS passivation for $FA_{0.83}Cs_{0.17}Pb(I_{0.85}Br_{0.15})_3$. Our results demonstrate that surface-mediated recombination is the primary non-radiative loss pathway in MA-free mixed-cation mixed-halide films with a range of different bandgaps, which is a problem observed for a wide range of perovskite active layers and reactive electrical contacts. This study indicates that surface passivation and contact engineering will enable near-theoretical device efficiencies with these materials.

SESSION F.EL08.07: Devices—Perovskite Photovoltaics

Metal Halide Perovskite Materials Development at Hunt Perovskite Technologies, LLC Michael Irwin; Hunt Perovskite Technologies, LLC, United States

An overview of Hunt Perovskite Technologies, LLC (HPT) metal halide perovskite (MHP) PV research program will be presented. Founded in 2013, HPT has focused their research on stabilizing the MHP material through better chemistry, as highlighted by stabilizing the pure alpha-phase $FAPbI_3$ MHP material in 2015. In this materials study, we have come to appreciate the unique defect structure of the MHP material by way of its ionic composition. Descriptions of MHP macro and molecular defect structure will be discussed, as well as their effect on the material's durability and PV device performance.
