Microbially produced electrically conductive protein nanowires (e-PNs) are a revolutionary 'green' electronic material with substantial sustainability and functional advantages over traditional materials such as silicon nanowires and carbon nanotubes. e-PNs are produced from renewable feedstocks, with 100-fold less energy demand than that required for producing silicon nanowires or carbon nanotubes. No toxic chemicals are required for e-PN fabrication and the final product is biocompatible, environmentally benign, and recyclable. Yet, e-PNs are remarkably robust, maintaining function even under harsh CMOS-compatible fabrication conditions. e-PNs can be processed into thin-film electronics, nanocables, and flexible conductive composites. However, development of applications has been slowed by the fact that bacteria and archaea known to naturally produce e-PNs are slow-growing anaerobes that are difficult to mass culture. We resolved this bottleneck by designing a nonpathogenic strain of *E. coli* (strain GPN) that expresses abundant e-PNs from synthetic variants of the e-PN monomer gene from *Geobacter* species (ACS Synthetic Biology 9:647-654 (2020)). Advantages of strain GPN for e-PN fabrication include: 1) rapid, and scalable mass-culture under aerobic conditions; 2) 'plug and play' simplicity for the design and expression of e-PNs with novel functionalities; and 3) a versatile *E. coli* genetic toolbox for the introduction of genetic circuits that control the expression of multiple monomer genes introduced into the same strain to fabricate e-PNs with advanced sensing and electronic features. When coupled with a newly developed, simplified filtration method for harvesting e-PNs, *E. coli* strain GPN ensures a ready supply of e-PNs for diverse electronics applications. Examples of recently developed novel applications for e-PNs include devices that generate electricity from the ambient humidity in air (Nature 578:550-554 (2020)); neuromorphic memory devices that operate at biological voltages (Nature Communications 11:1861 (2020)); and electronic sensors with high selectivity and sensitivity (Nano Research 13:1479-1484 (2020)). These and other applications are being further optimized by tailoring e-PN properties to specific applications. For example, e-PN conductivity has been tuned over a million-fold by designing genes for synthetic e-PNs with modified amino acid composition. Peptides can be displayed on the outer surface of e-PNs by expressing novel monomer genes designed to add the desired peptide to the carboxyl end of the e-PN monomer (ACS Synthetic Biology 8:1809-1817 (2019)). These peptide decorations can function as ligands to specifically bind analytes of interest for sensor applications or to enhance interactions of e-PNs with other materials. More than one ligand can be added to the same wire and the stoichiometry of the ligands on the wires can be controlled with genetic circuits. Newly designed e-PNs fabricated with *E. coli* strain GPN and their potential applications will be discussed.

6:00 AM F.SM04.02.07
Smart Nanostructured Multifunctional Biomaterials as Next Generation Cochlear Implant Serena Danti[1,2], Mario Milazzo[1], Bahareh Azimi[2], Andrea Lazzeri[2], Markus Buehler[1] and Stefano Berrettini[2]; [1]Massachusetts Institute of Technology, United States; [2]University of Pisa, Italy

About 466 million people are estimated to suffer from disabling hearing loss. When the transduction mechanism (i.e., sensory cells and/or neurons) is damaged, sensorineural hearing loss (SNHL) occurs. Up to now, severe SNHL is only possible using complex electronic implants, i.e., cochlear implants (CIs). Conventional CIs suffer from some important disadvantages impacting the quality of life and hearing after implantation and for such reasons a new class of CIs is desirable. The ear sensory cells, hair cells, act as biological transducers in the organ of Corti, where they convert the mechanical vibration of the basilar membrane into stimulation of the underlying spiral ganglion neurons. By exploiting the mechanical tonotopy still present in deaf cochleae, piezoelectric materials in contact with the basilar membrane could potentially enable a fine-tuning process of the sound vibrations, thus providing a better quality of hearing versus discretized electrodes in electronic CIs. Piezoelectric CIs would thus represent an innovative and smart solution: they work in a biomimetic fashion, are self-powered and fully implantable, less expensive (material-based) than bionic CIs and a-magnetic (i.e., MRI-compatible).
In our hypothesis, a tissue engineering-aided nanostructured piezoelectric device and its proper surgical implantation can promote direct contact with spiral ganglion neurons, thus reducing the necessary electric output for neural stimulation and finally achieving sufficient sensitivity. Specifically, we move forward the primitive concept of bulk-structured piezoelectric CIs by designing a new device based on ultrafine fibers produced via electrospinning to be precisely delivered and provided with a nano/microscale resolution to be intimately and efficiently integrated with the cochlear microenvironment.
Ceramic materials with a perovskite-like structure, possess higher piezoelectric properties than those of piezopolymers (e.g., polyvinylidene fluoride, PVDF), but are very rigid and difficult to process. To gain the multifunctionality of the nanofibrous device, we study the immunomodulatory and antibacterial properties of nanoceramics to be incorporated inside piezoelectric

polymeric fibers. In fact, reducing the fibrotic tissue formation would allow the best electric delivery by the piezoelectric materials.
We investigate lithium niobate as a potential candidate material for next-generation CIs. Lithium niobate nanoparticles resulted otocompatible *in vitro* with OC-k3 cells, enhanced human beta-defensin (HBD-2) in HaCaT epithelial cells, and also showed direct antibacterial activity against *P. aeruginosa*. The $LiNbO_3$ ability of modulating the expression of IL-6 and IL-8 could play a beneficial role *in vivo*, by reducing the extent or duration of a post-implant inflammatory response. These nanoparticles were efficiently incorporated into PVDF-trifuoroethylene P(VDF-TrFE) fibers via electrospinning. Aligned composite fibers at 20% (w/w%) of lithium niobate showed an enhanced piezoelectric response, namely 90 ± 2 mV, with respect to their random counterparts, namely 40 ± 4 mV, under an applied load of 2.12 N. These composite fibrous structures supported SHSY-5Y neural-like cell growth *in vitro*.
Electroactive materials combining nanotechnology and tissue engineering show promise for cochlear stimulation and otoprotection.
This study was supported by MISTI funds 2016 (MIT-UNIPI project NANOSPARKS).

Optimizing Synergy Between Materials and Cell Microenvironments Using Functional Polyesters Milica Radisic; University of Toronto, Canada

Material based technologies play an integral role in many medical treatment strategies, including joint replacements, vascular stents, drug delivery methods, contact lenses and medical sutures. The application of successful technologies continues to grow, with an estimated market size of $130 billion USD by 2020. Although successes are notable, a number of biomaterial-based devices are limited in application by non-specific material properties to tissue type and undesired inflammation at the device interface. In application, polyester materials have traditionally been an effective polymer strategy, with successes in tissue engineering scaffolds and a variety of biomedical devices. Leveraging advantageous polyester degradability and well understood chemical synthesis, these materials serve as a strong functional platform to further optimize material-cell microenvironments. In this talk, I will describe the development of polyesters that (a) exhibit controllable mechanical properties to mimic the elastic properties of cardiac tissue extracellular matrix (ECM) and (b) incorporate a biomimetic moiety of mammalian immunity to recapitulate mechanistic inflammation regulation at the material surface.
Development of engineered cardiac tissue requires material scaffolds that match the elastic behavior of cardiac ECM. Using polycondensation techniques to incorporate unsaturated carbonyl groups into elastic polyester material gels, we generated materials that can be molded into intricate designs with secondary crosslinking to generate constructs with highly tunable elasticity. By adapting material synthesis conditions (i.e. monomer ratios, reaction time), elastic mechanical behavior was highly tunable across a range of soft biomaterial applications. Material applicability was highlighted in a number of micro-designed elastomeric scaffold supports for engineered tissue, both for *in vitro* organ-on-a-chip and *in vivo* cardiac patch technologies, wherein the two-step synthesis process allowed for micro molding into intricate shapes prior to gelation.
With biomaterial application *in vivo*, inflammation at the biomaterial surface limits device application. To tackle this, we looked to itaconate, a powerful small molecule metabolite of innate immunity that has recently emerged as a regulator of innate immune inflammation. This molecule has been previously limited therapeutically by short circulation times. To circumvent this, itaconate was incorporated directly into material backbones to impart biomimetic small molecule modulation, with quantified hydrolytic degradation release from polyester chains. Harnessing hydrolytic degradation release from polyester backbones, itaconate polymers resulted in the mechanism specific immunoregulatory properties on macrophage polarization in vitro. In a functional assay, the polymer-released itaconate inhibited bacterial growth on acetate. Translation to an *in vivo* model of biomaterial associated inflammation, intraperitoneal injection of ITA polymers demonstrated a rapid resolution of inflammation in comparison to a control polymer silicone, demonstrating the value of sustained biomimetic presentation of itaconate. Using scalable polyester synthesis techniques, we have demonstrated the power of instructive biomaterial technologies as functional modulators of the cell microenvironment.

5:15 AM *F.SM04.03.02
Self-Assembled Bioinspired Nanostructures for Green Electronics Nurit Ashkenasy; Ben Gurion University of the

Negev, Israel

Self-assembling peptides that are inherently biodegradable and biocompatible are extremely suitable for use in devices that adhere on, or even implanted into, the human body in order to monitor and regulate biological functions. The challenge for incorporating these materials in bioelectronic devices is the optimization of their electronic properties for the desired application. In this talk I will present peptide design rules that can be used to prepare electron and/ or proton conducting peptide based materials. Specifically, I will discuss the influence of aromatic side chains (both natural and non-natural) on electron conductivity.[1,2] I will further present enhancement of proton conduction in these films by the incorporation of protonating side chains, which can lead to extremely high proton conductivity values in these materials.[3,4] I will finally discuss the control of conductivity, thermal stability and biodegradability of self-assembling peptide nanostructures by peptide backbone motifs. These studies demonstrate the great potential of using peptide building blocks for the fabrication of green electronic materials.

Electrical and Mechanical Self-Healing of Genetically Engineered Conductive Curli Fiber Films Daniel Modafferi, Catrina Huyer, Juliana Ferraro, Sophia Roy and Noemie-Manuelle Dorval Courchesne; McGill University, Canada

The expanding use of electronics in all aspects of society broadens their use towards novel medical applications but also raises new environmental and health concerns. Medical electronic devices need to be able to store, harvest and transfer electric charges, while benefitting from physical properties harmonious with their biological interface, such as flexibility, stretchability and self-healing. One strategy to obtain both electrical and biocompatible properties is to use biological materials, which have the added benefit of being biodegradable, while having a much lower carbon footprint than other electronic materials like metals and organic polymers. Evolution has already generated biological materials, proteins, able to transfer electronic charges over long distances. Drawing inspiration from theoretical understanding of how electrons can be transferred in some native protein fibers through aromatic amino acids, fibrous proteins have been genetically engineered to exhibit conductivity. Curli fibers, which are grown naturally in the ubiquitous and very scalable *Escherichia coli*, are formed by the self-assembly of beta-helical CsgA monomers. Mutating a row of amino acids along the helix to aromatic residues confers conductivity to the dry amyloid film.
These proteins' ability to self-assemble through non-covalent bonds and their dispersibility in water are good indicators for self-healing properties. Here, we tested the conductive and mechanical properties of genetically engineered conductive curli fiber films. Specifically, we evaluated whether they can regenerate from different tears and scratches, simply by rehydrating the film in water. We drop-cast conductive curli fibers between electrodes to form films of various thicknesses and cut at different sizes. We used SEM imaging to observe the mechanical healing of the drop-cast film. We further performed cycles of cuts and healing to observe longer-term reusability of the material. Next, to reveal the flexibility of a free-standing film, we performed tensile tests. We were able to reattach two pieces of film back together to determine the material's resistance to breaks, and to quantify the regeneration of the electrical properties in doing so. We found that the material can recover almost entirely with micron-scale cut sizes, even for protein films as thin as 2 µm. These self-healing properties we defined show potential for use of conductive curli fibers as composites, or even pure materials, in wearable medical devices.

5:40 AM F.SM04.03.04

Photovoltage Generation in Organic-Biological Hybrid Architectures Massimo Trotta[1], Michele Di Lauro[2], Gioacchino Calandra Sebastianella[3], Anna De Salvo[2], Gabriella Buscemi[4], Danilo Vona[4], Fabio Biscarini[2] and Gianluca M. Farinola[4]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Istituto Italiano di Tecnologia, Italy; [3]Universita di Modena e Reggio Emilia, Italy; [4]Università degli Studi di Bari Aldo Moro, Italy

Solar energy transduction performed by photosynthetic organisms is the paramount process that ensures power to all metabolic activities on planet Earth[1]. Exploiting the highly efficient capability of the photosynthetic organisms to convert

visible and near infrared radiations into energy forms viable to human beings is a dream that accompanies man-kind since the visionary and wishful speech by Giacomo Ciamician at the beginning of XX century[2].
In the last two decades, vast literature tackles the use of photosynthesis in energy conversion using several approaches ranging from the use of the isolated enzymatic machinery responsible of light photoconversion [3] to complex systems that exploit photosynthetic microorganisms[4].
The most recent advances regarding photovoltage generation and the subsequent current amplification in Light-modulated Electrolyte-gated organic transistors[5,6] will be presented. These hybrid systems, based on the unique coupling of photosynthetic materials or organisms with the peculiarities offered by the platform of organic electronics will be presented. The potential of these architectures will be discussed in view of the interaction of the photosynthetic apparatus employed in the voltage generation with the organic electronic device of choice.

Large-Area Printable and Flexible Electronic Biosensors for Label-Free Single-Molecule Detection Luisa Torsi[1,2]; [1]University of Bari A. Moro, Italy; [2]Åbo Akademi University, Finland

Detecting a marker or a pathogen at the physical limit is the new frontier in medical analysis as it endows the clinicians with the attacker's advantage over life-threatening diseases such as tumours and pandemics. It is also received that label-free and electronic transductions can be conveniently fast and wieldy. Within this field different transducing approaches are pursued. They involve a transducing interface functionalized with biological recognition elements, such as antibodies or DNA probes, that endow the device with recognition properties by selectively capturing the analyte e.g. an antigen or a genomic marker, respectively. One recently proposed approach involves a large interface hosting trillions of highly-packed bio-recognition elements. The challenge is indeed that of measuring one single molecule in a large volume such as for instance 100 ml. This means being able to deploy a technology that can detect 10 - 20 10^{-21} mole l^{-1} (zeptomolar).
Mimicking cell's behaviour, ecently proposed approach involves a large interface hosting trillions of highly-packed bio-recognition elements. This is called, the "**Si**ngle **Mo**lecule with a large **T**ransistor (SiMoT)" technology that was proposed to sense a solution with markers present at extremely low concentrations. It is based on an Electrolyte Gated Organic filed-effect transistor operated in deionized water, with a gate that has an area of ca. 0.5 cm^2, hosting 10^{12} antibodies or genomic probes. The SiMoT platform has been proven to perform label-free and selective detection at the physical limit in real biofluids of protein biomarkers such as: human Immunoglobulin G, Immunoglobulin M, C-reactive protein, MUC1 and HIV1 p24 antigen as well as genomic markers such as miR-182-5p and KRAS. Indeed, the widely applicable method used to conjugate the recognition elements to the gate electrode, makes the SiMoT platform suitable for the detection of different classes of markers and pathogens reaching world record detections limits for label-free protein detection.

5:15 AM *F.SM04.04.02
Pushing the Limits of Elasticity in Soft-Matter Electronics Carmel Majidi; Carnegie Mellon University, United States

In order for machines and electronics to interface with biological tissue, they should be soft and elastic – i.e. remain functional when stretched and then return to their natural length when unloaded. In recent years, there has been tremendous progress in creating conductive elastomers and gels that are capable of extreme stretchability and which have been successfully utilized as bioelectronic interfaces. These include material architectures that are self-healing and can restore electrical and/or mechanical functionality when torn or punctured.

In this talk, I will review recent efforts to create mechanically robust, stretchable electronics using a variety of soft material architectures. In particular, I will focus on the following approaches: (i) silver-hydrogel composites that exhibit an unprecedented combination of mechanical compliance and electrical conductivity; (ii) biphasic compositions of silver nanoparticles and eutectic gallium-indium (EGaIn) liquid metal alloy for ultrathin “epidermal" electronics; and (iii) EGaIn-polymer composites capable of high electrical conductivity, extreme stretchability, negligible electromechanical coupling, and a variety of self-healing properties. To demonstrate their potential role in future bioelectronic applications, I will present examples of how these soft material architectures are used as electrodes for physiological monitoring (e.g. EMG, ECG) and as electrical interconnects for highly stretchable digital circuits.

5:30 AM F.SM04.04.03
Organic Electrochemical Sensing Transistors Fabricated on Soft Bioresorbable Substrates Nicolas Fumeaux, Silvia Demuru and Danick Briand; EPFL, Switzerland

Transient electronics have gained attention in the recent years, showing great promise to reduce electronic waste, enabling devices that can disintegrate for data security purposes or novel biomedical implants which eliminate the need for re-operation. In this work, we focus on the latter, also called “bioresorbable electronics”, devices that will naturally dissolve or be degraded into benign byproducts in the body. Materials such as dissolvable metals, degradable semi-conductors, polymers and dielectrics have been proposed. However, due to their properties, these materials are often not compatible with processes that involve high temperature or harsh chemicals, making them challenging to pattern. Printing techniques show great promise to address this challenge and could pave the road to personalized implants based on digital additive manufacturing, but require joint optimization of the ink formulation, the printing conditions and the post-treatment. In this work, we leverage the potential of these techniques to deposit functional materials on bioresorbable elastomeric substrates, poly(glycerol sebacate) (PGS) and poly(octamethylene maleate (anhydride) citrate) (POMaC) as well as on a biopolymer derived from silkworms, silk fibroin. Bioresorbable elastomers are of particular interest, as they enable the development of low-profile transient bioelectronics, in that they can conform to the shape and curves of internal organs and minimize immune response. We focus on the manufacturing of poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS)-based organic electrochemical transistors (OECTs). OECTs, generally based on a conducting polymeric channel gated through an aqueous electrolyte, have generated a lot of attention recently for the detection of multiple biomolecules and ions and high signal-to-noise ratio electrophysiological recordings.
PGS and POMaC were synthetized as described in previous publications, spin-coated on silicon wafers onto sacrificial layers and formed into free-standing films after thermal curing. Silk fibroin was purified as described previously, blade-cast and treated with water vapor for 24h. The suitability of the transient polymers as substrates for printed electronics was assessed and compared with a conventional substrate, polyimide. Degradable inks based on respectively zinc and carbon pastes were developed and evaluated for the creation of contacts and interconnects and silk fibroin inks were formulated to be used as a dielectric layer. Various manufacturing methods such as screen printing and direct ink writing were investigated for the patterning of these inks, as well as post-treatments that are compatible with the relatively low thermal resistance of the bioresorbable substrates. The degradation behavior of the printed patterns was assessed in phosphate buffered saline (PBS). Inks based on aqueous dispersions of PEDOT:PSS were patterned using inkjet printing and the conductivity of the polymer was compared on the degradable substrates and polyimide. The behavior of the resulting OECTs on transient substrates was characterized in PBS and found to be in line with the state of the art considering channel dimensions. A preliminary test to demonstrate the ion sensing capabilities of the organic transistors was conducted with different concentrations of potassium chloride (KCl). The work presented here represents a step forward in the facile manufacturing of bioresorbable implantable sensors. The fabrication scheme used in this work leverages different methods of material deposition, and, while combining fabrication approaches may be advantageous in some cases, we aim to develop fully printed devices. This could allow to create personalizable implants made of bioresorbable materials, for example for regeneration or diagnosis applications, in a scalable and customized manner.

5:40 AM F.SM04.04.04
Tracking Anticancer Drug Activity at Attomolar Concentrations in Cellular Lysates with Bioinspired Electrochemical Devices Jason D. Slinker[1], Ashan Wettasinghe[1], Naveen Singh[2], David Boothman[2] and Edward Motea[2]; [1]The University of Texas at Dallas, United States; [2]Indiana University School of Medicine, United States

The immunotherapy market surpassed 75 billion USD in 2019, and many emerging drugs also leverage the body's immune system. Among these immunotherapies, many current and future cancer treatments utilize DNA damage. To follow these DNA damaging immunotherapies, we have applied bioinspired electrochemical devices for real-time measurements of DNA damaging drugs in cellular lysates. We have shown these devices to quantify concentration-dependent drug activity, identify therapeutic concentration windows of cancer-selective activity, and mechanistically correlate damage activity with cancer cell death. Recently, we have shown these devices to detect an onset of activity of a deoxyniboquinone derivative at 100 attomolar levels in approximately 100 microliters of cellular media. This device is ready to be implemented as a standard tool for analyzing the drug activity of cancer-selective treatments in the lab, enabling quantitative identification of effective drugs for patients while minimizing side effects.

Fabrication of 3D Monolithic Architecture Electrodes Based on Conducting Polymer Microstructures Youngseok Kim and Myung-Han Yoon; Gwangju Institute of Science and Technology, Korea (the Republic of)

The conventional bioelectronic interfaces have been based on either 2-D thin films or 1-D fibers/wires which limit 3-D scalability as well as volume-/mass-dependent performance. Moreover, biological tissues and organs typically exhibit 3D arbitrary curvatures with wet surface, which impeded the close physical contact between the target tissue/organ and bioelectronic interfaces, leading to the low efficiency in bioelectric signal recording and/or stimulation. In this research, we report on 3D monolithic architectures with arbitrary shapes by employing conducting polymer microstructures as building blocks. Such arbitrary 3D structures were constructed by performing the seamless fusion of separate conducting polymer microstructures without using binder or adhesive. The resultant 3D structures exhibited decent mechanical robustness, high water stability, and outstanding biocompatibility, while the sheet resistance was reduced below 1 Ohm/square and the gravimetric capacitance was increased up to 79 F/g by taking advantage of cumulative mass loading and structural fusion. Finally, we demonstrated that 3D conductive mesh electrodes could be attached to the wet surface of biological organs/tissues such as heart and sciatic nerves without glue or clamp and efficiently record/stimulate bioelectrical signals *in vivo*.

5:15 AM F.SM04.05.02
Multifunctional Biodegradable Films with Engineered Properties—A Kirigami-Inspired Approach Sayantan Pradhan and Vamsi Yadavalli; Virginia Commonwealth University, United States

Multifunctional surfaces that can conformally adhere to complex interfaces, degrade at a controllable rate and invoke minimal reaction within the body can be used for soft and implantable electronics, wound healing, tissue engineering, neural interfacing and *in vivo* disease diagnostics. Designing interfaces for applications at dynamic, non-planar biological environments is a problem of great interest. Recently, “kirigami”- the Japanese art of paper cutting has been proposed as a unique strategy to engineer flexibility and stretchabililty by introducing patterned defects or cuts.
We discuss how the concepts of kirigami can be applied to form photolithographically patterned cuts in flexible, mechanically robust silk proteins for the fabrication of biofunctional films.[1] These macroscale films are optically transparent and possess tuneable degradation and engineered flexibility with precisely defined microscale cuts. The kirigami cutting is formed using the technique of “protein photolithography” using silk fibroin as a route to multiscale fabrication.[2,3] Tensile tests performed on these films show a remarkable improvement in mechanical properties in comparison to pristine films. Using numerical modelling, the mechanical behavior of the silk kirigami films can be predicted as a function of different cut geometry. We show that these films can be used as multilayer, biodegradable cell culture substrates as a result of the biocompatibility of the substrate biomaterial. Finally, by incorporating the conducting polymer polyaniline (PANI) in the silk composite, we are able to make multifunctional conducting silk kirigami films. The films demonstrate excellent linear

conductive behavior (μS range) over a voltage range of -0.5 to +0.5 V. The films are able to maintain their conductivity under severe mechanical flexure and deformations. These results indicate that silk kirigami can provide exceptional bioinspired and biodegradable structures towards flexible and stretchable biodevices.

Hierarchically Structured Silver Nanosatellite Particles for Highly Conductive Healable Putty-Like Nanocomposites Faseela Kizhakke Palakkamkuzhiyil, Daewoo Suh, Wonjoon Kim, Chanyong Park, Jang Gyun Lim, Sungwon Seo, Moon Ki Kim, Hyungpil Moon and Seunghyun Baik; Sungkyunkwan University, Korea (the Republic of)

Healable and deformable conductive materials have received considerable attention for future electronics such as artificial human skin, internet of things, and bioelectronics. However, their practical applications are impeded by low electrical conductivity and irreversible conductivity degradation after breaking/healing cycles. Here we report a highly conductive completely reversible electron tunneling-assisted percolation network of silver nanosatellite particles for putty-like moldable and healable nanocomposites [1]. The hierarchically structured silver nanosatellite particles with a bimodal size (medium: 164 nm, small: 3.7 nm) distribution are generated by the radical and reactive oxygen species-mediated vigorous etching and reduction reaction of silver flakes using tetrahydrofuran peroxide in a healable silicone rubber matrix. The silver nanosatellite network dramatically increases electrical conductivity by ~5 orders of magnitude, achieving an unusually high conductivity (1020 S/cm) in putty-like nanocomposites with excellent moldability [1]. The silver nanosatellite particles are uniformly and densely distributed with an interparticle distance of 3.1 nm, and the close work function match between silver and silicone enables electron tunneling. This leads to a completely reversible reconstruction of the percolation network, achieving ~100% electrical healing efficiency after 1000 breaking/healing cycles [1]. Moreover, the conductivity is stable even after 1000 water immersion cycles and 6-month exposure to ambient air. An emergency electronics repair demonstration is also performed by a robot using the nanocomposites [1]. A recent progress in our laboratory will also be introduced. Self-Healing Tandem Repeat Proteins Inspired by Squid Ring Teeth Melik C. Demirel, Oguzhan Colak and Abdon Pena-Francesch; The Pennsylvania State University, United States

Production of repetitive polypeptides that comprise one or more tandem copies of a single unit with distinct amorphous and ordered regions have been an interest for the last couple of decades. The self-healing performance of tandem repeat polypeptides creates new opportunities for the design of bioinspired and biosynthetic materials that were not possible previously, and addresses current limitations in self-healing soft materials. In this talk, we review programmable design, structure, and properties of functional materials and composites from squid-inspired tandem repeat proteins, with applications in bioelectronics. Protein based self-healing materials provides a rich architecture that can micro-phase-separate to form periodic nanostructures with enhanced physicochemical properties via directed or natural evolution that often exceed those of conventional synthetic polymers. These materials show hydrogen-bonded nanostructure and network morphology, with programmable healing properties (2–23 MPa strength after 1 s of healing) that surpass by several orders of magnitude those of other natural and synthetic soft materials.

Programmable Photomechanical Jumping of Polymer Monoliths Jisoo Jeon[1], Jun-Chan Choi[2], Hyeok Lee[3], Woongbi Cho[1], Jae Gwang Kim[1], Jae-Won Lee[2], Kyung-Il Joo[2,4], M. Cho[3], Hak-Rin Kim[2] and Jeong Jae Wie[1]; [1]Inha University, Korea (the Republic of); [2]Kyungpook National University, Korea (the Republic of); [3]Seoul National University, Korea (the Republic of); [4]Electronics and Telecommunications Research Institute, Korea (the Republic of)

Controlled jumping is a unique motion in nature and robotics to achieve rapid mobility and to avoid obstacles as well as rough terrains. One key challenge is the introduction of a remote powering system for untethered miniaturized robots as they have to work to overcome their own body mass without an internal power system. Toward light-fueled jumping, we synthesize photo-responsive polymer monoliths where spring-like molecular geometry is implemented via self-assembly of liquid crystalline polymer networks (LCNs). Upon light irradiation, the spring-like self-assembled photo-responsive molecules induce non-isometric structures providing unprecedented photomechanical jumping by an instantaneous energy release. The experimental jumping behavior is supported by a finite element method (FEM) simulation for quantitative analysis. The jumping capability of the soft robotic LCN reaches 15.5 body length (BL) height, and 880 BL/s take-off velocity. In addition, we demonstrate rotational axis- and angle-controlled jumping by programming the molecular alignment and macroscopic design. Finally, the controlled light irradiation provides continuous and directional jumping of soft robotic LCNs.

A Protein Based Polymer Film for Bio-Electronic Interfacing Ramesh Nandi, Yuval Agam and Nadav Amdursky; Technion-Israel Institute of Technology, Israel

Human machine interfacing is a long challenge for researchers, in last few decades we have witnessed emerging of different materials and electrodes for the purpose. Successful interfacing of human body with machine involves coupling of ionic and electronic signal at the interface. In addition to the successful interfacing of the ionic and electronic signals, any conductive material for biological interfacing should be stretchable, flexible, stable in aqueous or humid environment, bio-compatible and bio-degradable. Developing a single material having all these properties is a challenge by itself. However, conductive polymers are one of the promising materials for this purpose due to their organic carbon-based nature. Over the years, many different types of conducting organic polymers have been emerged using different synthetic organic analogues, however, the development of a synthetic polymer that fits all the above-mentioned criteria is still consider a challenge for researchers. Inspired by natural electron and ion transfer processes mediated mainly by proteins, here we present a novel conductive polymer made out of 100% natural Bovine Serum Albumin (BSA) protein, which is a side product of bovine industry, cheap and available in large scale. The polymer film is free-standing, transparent, stretchable, and highly stable in aqueous environment. Moreover, it is bio-compatible and biodegradable due to its biological nature, the synthesis method is within one pot and energy-efficient process and there is no need for any post-synthetic purification. This polymer film can efficiently record brain (electroencephalogram) and heart signal (electroencephalogram) from the human body in a non-invasive way with several other potential applications. While considering its novelty, our polymer can be considered a new class of materials in the field of bioelectronics.

Diffusivity Modulation of Planer Lipid Bilayer Mediated by Self-Assembled Peptides Yoshiki Nakamura, Hironaga Noguchi, Mirano Tsukiiwa and Yuhei Hayamizu; Tokyo Institute of Technology, Japan

Two-dimensional (2D) materials represented by graphene have been studied for biosensor applications owing to their excellent electronic properties and high specific surface areas. Lipid bilayer biosensors based on the 2D materials as supporting substrates have gained wide interest as a platform for highly-sensitive biosensing with inserted membrane proteins. For stable formation of a lipid film on the surface of 2D materials, it is essential to control the hydrophobicity of the surface which is correlated to the affinity of the surface with the lipid film. Moreover, it is important to control the lateral diffusivity of the lipid membrane for understanding interaction dynamics of biomolecules embedded into the membrane. In this study, to address this, we utilized self-assembled peptides as an adhesive layer for immobilization of planar lipid bilayer on h-BN, an insulative 2D material which is transparent in visible region. In our recent research, we developed a series of peptides which have an ability to form uniform monomolecular thick peptide thin film in a self-assembly manner [1]. More recently, peptides with a repeated amino acid sequence of glycine (G) and alanine (A) inspired by silk proteins have been demonstrated to form stable β-sheet structures on the surface of two-dimensional materials [2]. In this study, we utilized three types of peptides containing additional hydrophilic amino acids with the GA repeat sequence. These peptides formed self-assembled structures on h-BN surface and act as an adhesive layer to form a planar lipid bilayer. Self-assembled peptides

were prepared by dropping an aqueous peptide solution onto the surface of transferred h-BN on a substrate of Si/SiO2 or cover glass, and it was incubated at room temperature for 1 hour. Then, planar lipid membranes were prepared by the rupture method, where DOPC vesicle suspension in 10 mM PB was placed on the sample with the self-assembled peptides,, and it was incubated at room temperature for 1 hour or more. The morphology of lipid membranes on the surface was observed by atomic force microscopy (AFM). Furthermore, to investigate the fluidity of lipid molecules in the membrane, DOPC was mixed with 1% 14:0 NBD PE (lipid molecule tagged with a fluorophore). The lateral diffusion constant of the lipid membrane was measured by the photobleaching after fluorescence recovery (FRAP) method. AFM observations showed that lipid bilayer can be formed on a h-BN surface with high coverage, indicating that self-assembled peptides support the lipid bilayer as a molecular scaffold with a controlled hydrophilicity. The FRAP results showed that the diffusion constants of lipid bilayers depend on peptide sequences. These results revealed the importance of the peptide design to control the physical properties of the planar lipid bilayer on 2D material, which could be essential to develop lipid-based biosensors with 2D materials.

The Porphyrin Ring Rather Than the Metal Ion Dictates Long-Range Electron Transport Across Proteins Suggesting Coherence-Assisted Mechanism Yuval Agam and Nadav Amdursky; Technion–Israel Institute of Technology, Israel

The fundamental biological process of electron transport (ET) takes place across proteins with common ET pathways of several nanometers. Recent discoveries from the bacterial world push this limit and show long-range extracellular ET over several micrometers. Here, we aim in deciphering how protein-bound intramolecular cofactors can facilitate such long-range ET. In contrast to natural systems, our protein-based platform enables us to modulate important factors associated with ET in a facile manner, such as the type of the cofactor and its quantity within the protein. We chose here the biologically-relevant porphyrin molecule as the electron mediator. We use electrochemical impedance measurements (EIS) as well as three-terminal field effect transistor (FET) measurements to explore the role of the porphyrin variant in mediating ET. Using different porphyrins with different metal centers, or lacking a metal center, we show that the metal redox center has no role in ET, and that ET is mediated solely by the conjugated backbone of the molecule. We further support these results with advanced density functional theory (DFT) calculations of the variants. We discuss several mechanisms accounting to possible contribution of coherent processes during the ET. Our results suggest that our high measured ET efficiency is probably due to coherence-assisted ET mechanism. Our work can help understand the participation of heme molecules in common long-range biological ET and introduce the possibility of using the protein-based platform as a tool for the investigation of different systems.

Improvement of Adhesion and Osseointegration of Nanocomposite Biomembranes for Medical Implants Soyeon Kim, youngjoon Han, Chungik Oh, Hojoon Lee and Seungbum Hong; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Medical societies dedicated to treating musculoskeletal diseases are facing challenges due to an unprecedented increase in the aging population around the globe. As such, it is getting more important to develop novel class of materials that could assist the self-healing process of rigid body tissues. Hydroxyapatite (HAp, $Ca_{10}(PO_4)_6(OH)_2$), one of the most common form of naturally-occurring calcium orthophosphates, is actively investigated as a viable candidate as it integrates easily with the surrounding tissue, induced by its similarity with the main components and structure of human bones and teeth. To this end, it is most desirable that we fabricate HAp-based ceramic-polymer medical nanocomposites that significantly improves the unique mechanical and electrical properties of the host filler particles. However, the interface between the ceramic filler and the polymer matrix is very unstable due to the large discrepancy in their dielectric and bonding characteristics, which leads to the agglomeration of the ceramic particles inside the mixture. In order to resolve this issue, we sought to modify the HAp surface using mussel-inspired adhesive protein layer known as polydopamine (PDA) to reduce the interfacial energy between the two materials. Based on the result of our surface modification, we incorporated the PDA-coated HAp particles into a ferroelectric polymer membrane known as poly(vinylidenefluoride-co-trifluoroethylene) a.k.a. P(VDF-TrFE) to form a biocompatible nanocomposite that promotes electrochemical stimulus without any external bias. Our measurements suggests that the P(VDF-TrFE)/HAp nanocomposite has a high potential as a coating agent for a wide range of medical implants

Transparent and Conductive F-Doped SnO_2 Nanostructured Thin Films by Sequential Nebulizer Spray Pyrolysis T. M. W. J. Bandara[1], A. A. A. P. Aththanayake[1], G. R. A. Kumara[2], P. Samarasekara[1], Ajith DeSilva[3] and K. Tennakone[2,4]; [1]University of Peradeniya, Sri Lanka; [2]National Institute of Fundamental Studies, Sri Lanka; [3]University of West Georgia, United States; [4]Georgia State University, United States

Transparent conductive oxides (TCO) are a key component in many optoelectronic applications such as solar cells, flat panel displays, sensors, touch screens, light-emitting diodes, frost-resistant surfaces, and smart windows. The high electronic conductivity and high optical transmission are essential properties of TCOs for these applications. Owing to chemical inertness and high-temperature tolerance of F- doped tin oxide (FTO) films, they also have much demand in a variety of electrochemical devices. In this work, transparent and electrically conductive FTO thin films are prepared on soda-lime glass substrates. The films are fabricated by sequential nebulized spray pyrolysis with the help of a homemade low-cost spray gun. The surface morphology of the films is analyzed using scanning electron microscopy (SEM). It is found that surface is homogeneous and FTO crystallite sizes are in the order of ~10 nm. XRD pattern of the FTO films exhibits 2θ peaks for corresponding SnO_2 crystal planes at 26.64° (110), 33.90° (101), 37.95° (200), 51.87° (211), 56.17° (200), 60.05° (310), 61.89° (301). The crystallite sizes calculated from XRD data are in agreement with that of SEM. Optical transparency and bandgap energies are evaluated by UV visible spectroscopy. The FTO films with 15 Ω cm^{-2} sheet resistance are used to prepare quasi-solid-state dye-sensitized solar cells with a TiO_2 photoelectrode. The solar cell showed a ~ 5% energy conversion efficiency with high short-term stability.

Autonomic Self-Healing of PEDOT:PSS Achieved via Polyethylene Glycol Addition Yang Li[1], Xinda Li[1], Shiming Zhang[2] and Fabio Cicoira[1]; [1]Polytechnique Montreal, Canada; [2]University of California, Los Angeles, United States

Self-healing electronic materials are of primary interest for bioelectronics and sustainable electronics. In this work we report autonomic self-healing of films obtained from mixtures of the conducting polymer poly (3,4-ethylenedioxythiophene) doped with polystyrene sulfonate (PEDOT:PSS) and polyethylene glycol (PEG). The presence of PEG in PEDOT:PSS films decreases the elastic modulus and increases the elongation at break, thus leading to a softer material with enhanced self-healing characteristics. In situ imaging of the cutting/healing process shows that the healing mechanism is likely due to flowing back of the material to the damaged area right after the cutting.

Comparative Analysis of Neurogenic Differentiation *In Vitro* from Human Dental Pulp Stem Cells Using PLA and P4VP Haijiao Liu, Kuan-Che Feng, Ya-Chen Chuang, Juyi Li, Marcia Simon and Miriam H. Rafailovich; Stony Brook University, The State University of New York, United States

Millions of people acquire spinal cord or traumatic brain injuries and over 5000 related deaths each year. There is currently no effective way to treat nervous system injuries. Besides, nerve cells do not regenerate in the body. Human dental pulp stem cells (hDPSCs) are important oral mesenchymal stem cells with strong proliferation and multidirectional differentiation functions. Due to their capability to differentiate into neurons, hDPSCs play an important role in dentin repair and regeneration, which provides a new approach for regeneration treatment of traumatic brain injuries in clinical applications. However, the specific mechanisms involved in the neurogenic differentiation process of hDPSCs are still unclear and require further research. To address the issue, hDPSCs were differentiated into neurons using two different polymers, PLA and P4VP. Using these two polymers, we cultured hDPSCs on substrates under eight different conditions, PLA, P4VP, flat flim, fiber, with Graphene and without Graphene. hDPSCs were cultured by neurobasal A media, consisting of 100 U/ml penicillin, 1 x B27 supplement, 100 µg/mL streptomycin, 20 ng/mL epidermal growth factor, and 40 ng/mL basic fibroblast growth factor (FGF) was used. After 7,14,21,28 days, we observed nerve cells numbers and differentiation by SEM and optical microscopy. For 28 days nerve cells, we used PCR technology to detect NES, TUBB3 and NEFM primer. Confocal Microscopy showed multiple layers on most substrates; more elongated cells directly on the substrate surface. SEM showed uniform fibers with no deformities, even with graphene. The results also show that greater elongation of DPSCs on PLA fibers, upregulation of neurogenic markers was slightly higher on flat surfaces than fibrous surfaces. Graphene was shown to be insignificant in neurogenic differentiation. Therefore, the substrates coated with PLA fibers with Graphene may help millions of people restore nerve cells injure cases annually.

Synthesis and Characterization of Cellulose Nanofiber Reinforced Aromatic Polyamide Membranes Rodolfo Cruz-Silva[1,1], Kazuo Izu[1], Jun Maeda[1], Shigeru Saito[1], Aaron Morelos-Gomez[1,1], Celia Aguilar[1,2], Yoshihiro Takizawa[1], Yamanaka

Ayaka[3], Syogo Tejima[3], Kazunori Fujisawa[1,1], Kenji Takeuchi[1,1], Takuya Hayashi[1,1], Toru Noguchi[1,1], Akira Isogai[4] and Morinobu Endo[1,1]; [1]Shinshu University, Japan; [2]Universidad Autonoma de Nuevo Leon, Mexico; [3]Research Organization for Information Science and Technology, Japan; [4]The University of Tokyo, Japan

Cellulose nanofibers have attracted great attention in recent years. Cellulose is an abundant biopolymer that combines not only structural functions with excellent mechanical properties and is also closely related to water transport functions in plants. Here, we show that aromatic polyamide reinforced with TEMPO-oxidized crystalline cellulose nanofibers shows better chlorine resistance, permeation, and antifouling as compared to plain polyamide membranes. Synthesis was carried out by interfacial polymerization over a supported polysulfone membrane. Membranes were conditioned and tested for desalination agains 3.5% sodium chloride salt solution. Fouling tests were carried out using bovine serum albumin as foulant model. Molecular dynamics studies show that cellulose nanofibers reduce the matrix mobility and improve the hydrophilicity without affecting the chemical composition of the surface layer of the membrane. Infrared and X-ray photoelectron spectroscopy results show a strong interaction between the carboxylic groups of the CNF surface and the m-phenylediamine monomer. Membrane morphology was studied by several microscopic techniques, such as SEM, TEM, AFM and laser confocal scanning microscopy. Molecular dynamics simulations show that m-phenylendiamine/cellulose nanofiber provides the matrix with higher water affinity improving the membrane permeation without affecting the salt rejection. CNF shows great potential as a novel nanoreinforcing material for the preparation of nanocomposite aromatic polyamide membranes with improved properties.

Synthesis was carried out by interfacial polymerization over a supported polysulfone membrane. Membranes were conditioned and tested for desalination agains 3.5% sodium chloride salt solution. Fouling tests were carried out using bovine serum albumin as foulant model. Molecular dynamics studies show that cellulose nanofibers reduce the matrix mobility and improve the hydrophilicity without affecting the chemical composition of the surface layer of the membrane. Infrared and X-ray photoelectron spectroscopy results show a strong interaction between the carboxylic groups of the CNF surface and the m-phenylediamine monomer. Membrane morphology was studied by several microscopic techniques, such as SEM, TEM, AFM and laser confocal scanning microscopy. Molecular dynamics simulations show that m-phenylendiamine/cellulose nanofiber provides the matrix with higher water affinity improving the membrane permeation without affecting the salt rejection. CNF shows great potential as a novel nanoreinforcing material for the preparation of nanocomposite aromatic polyamide membranes with improved properties.

F.SM05.06.03
Mood Identification by Facial Subtle Movement Analysis Fan Yang[1], Jordan Saadon[1], Ryan Burgert[1], Selma Mohammad[1], Miriam H. Rafailovich[1], Charles Mikell[1], Sima Mofakham[1], Wade Boohar[2], Sophia Cai[3] and Amisha Agrawal[4]; [1]Stony Brook University, United States; [2]Olathe North High School, United States; [3]Barrington High School, United States; [4]University High School, United States

Research into mood and emotion has often been dependent on self-report, highlighting the need for a more objective measure of mood state. However, until recently, it has been nearly impossible for machines to match the speed and accuracy of the

average person in interpreting faces. In this study, we used digital image speckle correlation (DISC), a technique which was originally used to study the mechanical properties of materials by tracking their deformations, to assess an individual's mood state based on the analysis of facial microexpressions. Ten healthy volunteers were shown a set of ten happy and ten sad images while being videotaped. Upon measuring facial movements in response to happy and sad images, we conducted detailed Shannon entropy and Principal Component Analysis (PCA) to identify facial maps for different mood states. Within and across subjects, happy and sad images elicited spatially distinct changes in facial expression. PCA and entropy calculations on facial movement reliably distinguished the subject's underlying mood. Furthermore, we characterized key changes in facial expression which reliably signal changes in mood state across all individuals. DISC-based analysis of the face was capable of determining an individual's mood with high specificity across multiple test subjects, suggesting that automated camera-based methods may be both robust and economical in clinical monitoring settings. It also showed promising potentials in brain study together with electroencephalogram as subtle facial movements were also found in epilepsy and comatose patients using DISC.

F.SM06.05.02
The Effects of Bioprinting on the Structure, Function and Survival of Organotypic Skin Kimberly Lu, Olias Christie, Michael Cottone, Philip Cottone, Michael Gozelski, Juyi Li, Robert Wong and Miriam H. Rafailovich; Stony Brook University, United States

With the advancement of 3D printing in the 21st century, prospective treatments for regenerative medicine, cosmetology, and material science are actively being explored[1,2]. This research aims to investigate the feasibility of 3D bioprinting technology in producing viable skin tissue. In order to achieve this, a novel procedure for the construction of dermal and epidermal organotypics was developed. This evaluation was performed by comparing organotypic skin samples consisting of non-printed epidermal and dermal layers (NN), non-printed epidermal and printed dermal layers (NP), printed epidermal and non-printed dermal layers (PN), and printed epidermal and dermal layers (PP). The assessment of claudin and filaggrin immunohistochemical staining of the samples suggest a revision to the methodology in which printing the epidermal layer at a lower pressure while printing the dermal layer at a relatively higher pressure may lead to improved cellular function and overall integrity of the organotypic skin-equivalent. These results demonstrate the potential of bioprinting as a novel technique for producing a skin equivalent product, which may serve as an alternative to conventional tissue engineering methods.

Late News: Synthesis of Alginate Microgels with a Polymer Shell—A Simple Way to Protect Encapsulated Cells So Hyun Ahn, Srinivasa Raghavan and William E. Bentley; University of Maryland, United States

Microgels of biopolymers such as alginate are widely used to encapsulate cells and other biological payloads. Alginate is an attractive material for cell encapsulation because spherical gels are easily created by contacting aqueous droplets of sodium alginate with divalent cations such as Ca^{2+}. Alginate chains in the gel become crosslinked by Ca^{2+} cations into a 3-D network. When alginate gels are placed in a buffer, however, the Ca^{2+} crosslinks are eliminated by exchange with Na^{+}, thereby weakening and degrading the gels. With time, encapsulated cells are released into the external solution.

Here, we describe a simple solution to the above problem, which involves forming alginate gels enveloped by a thin shell of a covalently crosslinked gel. The shell is formed via free-radical polymerization using conventional monomers such as acrylamide (AAm) or acrylate derivatives, including polyethylene glycol-diacrylate (PEGDA). The entire process is performed in a single step at room temperature (or 37°C) under mild, aqueous conditions. It involves combining the alginate solution with a radical initiator, which is then introduced as droplets into a reservoir containing Ca^{2+} and monomers. Within minutes, the droplets are converted into alginate-polymer microcapsules with a core of alginate and a shell of the polymer (AAm or PEGDA). The stability of these microcapsules under physiological conditions is compared with that of conventional alginate/Ca^{2+} microgels. The latter swell and degrade when placed in buffer or in chelators like sodium citrate, whereas the former remain stable under all conditions.

We also show that a various types of cells can be safely encapsulated in these hybrid beads. We encapsulate both mammalian cell and different strains of genetically engineered bacteria in these microcapsules and find that the cells remain viable and

functional over time. In particular, engineered 'reporter' bacterial cells respond to different molecular signals from the external solution such as IPTG, AI-1 and hydrogen peroxide. The cells are retained in the hydrogel capsules throughout the study which is a crucial aspect for studying cell's response to molecular cues in a robust manner. Moreover, multiple sets of capsules each containing different strains can be synthesized and co-cultured to study cell-cell communication, providing an ideal platform for studying *in vitro* signaling events. Lastly, a variation of the synthesis technique is performed to generate multilayered microcapsules with a liquid core surrounded by concentric layers of alginate and AAm gels.

Late News: Analysis and Mechanical Compression Model of a Three-Component Scaffold Composed of Polycaprolactone-Hydroxyapatite-Graphene Oxide for Tissue Engineering Javier Ortiz Ortiz, Georgina Carbajal de la Torre, Marco Antonio Espinosa Medina, Nancy Nelly Zurita Méndez and Lourdes Ballesteros-Almanza; Universidad Michoacana de San Nicolas de Hidalgo, Mexico

The use of multiple materials has helped in the development of tissue engineering. The use of polymeric matrices and biomaterials added to particular materials offers specific solutions both due to the interaction of the biomaterials and the mechanical properties of the generated biomaterial. In this work, the mechanical properties of compression of a three-component scaffolds for tissue engineering composed of polycaprolactone (PCL), hydroxyapatite (HA), and graphene oxide (GO) are shown. Scaffolds were subjected to compression on the Cell Scale™ brand Univert™ testing machine. Once the experimental data had been obtained, the stress-strain curve was obtained, also the compression mechanical behavior model was performed using the Levenberg-Marquardt least-squares algorithm in the Comsol Multiphisics™ software. To explain the compression phenomenon, scanning electron microscopy analyzes are performed where scaffolds are observed before being compressed and also after compression.

F.SM06.05.07
Late News: Determination of the Physical and Mechanical Properties of the Nopal Fiber (Opuntia ficus-indica) and Availability as a Biopolymer Isaí Pérez Servín, Rosa E. Pérez Sánchez, Georgina Carbajal de la Torre, Ruy Ortíz Rodríguez, Héctor E. Martínez Flores and Javier Ortiz Ortiz; Universidad Michoacana de San Nicolás de Hidalgo, Mexico

Nopal is a cactus that is distributed in different agroclimatic zones in a wild and cultivated way, due to its high forage potential, it has been destined to be used in the food, agricultural and pharmaceutical industry, however, when the cladode nopal reaches certain maturity, its use in the previously mentioned scopes is no longer viable, due to its high availability of fiber and lignin; this content of fiber in nopal could be implemented in the cosmetic and medical scopes as a biopolymer. The present study shows the physical and mechanical properties of nopal fiber components, and its thermographic analysis as an approach to determine its suitability and availability to fulfill the function of a biopolymer. An acid/alkaline extraction with potassium hydroxide (KOH; 1%) at 50° C was performed on the nopal sample previously dried. After the extraction, the sample was dried in a vacuum oven and its size was reduced by grinding. Mechanical tests were performed on nopal fibers in the Cell Scale Univert testing machine to obtain stress-strain curves. From the thermographic analysis, the kinetic drying model describing the process necessary for finite element modeling was proposed. The evaluation of the physical and mechanical characteristics allows us to determine the use and viability of nopal fiber as a biomaterial.

F.SM07.05.04
Human Primary Macrophages Upregulate M1 Phenotype Markers in Response to Chemically Modified Alginates Erin O'Brien[1], Stephen T. Nestor[2], Arturo Vegas[2] and Kara Spiller[1]; [1]Drexel University, United States; [2]Boston University, United States

Introduction: Angiogenesis is largely directed by macrophages, immune cells that can change their phenotype in response to external stimuli. Macrophages precisely control the timing and dosage of angiogenic growth factors, and also direct the innate immune response to biomaterials. Therefore, biomaterial-mediated macrophage modulation is an attractive strategy to recover dysfunctional angiogenesis. Macrophage phenotypes encompass a wide spectrum, but in vitro are commonly categorized as M0 before activation, then M1 or M2 post-activation, with several identified subtypes under the M2 umbrella. Although each phenotype's exact role in angiogenesis is not well understood, there is a growing body of evidence suggesting that early M1 macrophages initiate blood vessel sprouting, and subsequent M2 activity stabilizes these structures. Recent studies also indicate that M1 macrophages that switch to an M2 phenotype may have enhanced angiogenic properties. Furthermore, in pathologies where angiogenesis is inhibited, such as chronic wounds, M1 macrophages are insufficiently activated and fail to switch to an M2 phenotype. Thus, biomaterial strategies that seek to recover dysfunctional angiogenesis should aim to initially promote a robust M1 macrophage phenotype.
Previous work from Vegas et al. established a library of alginate hydrogels modified with chemical functionalities, then

ranked it by inflammatory activity, as measured by levels of cathepsin activity in vivo. This study was conducted to test the capabilities of the inflammatory alginate hydrogels to promote an M1 phenotype in primary human macrophages in vitro. Here we seeded M0 macrophages onto alginate hydrogels, then used Nanostring, a high-throughput gene expression assay, to measure expression of M1 markers, M2 markers, and genes associated with angiogenesis or fibrosis.
Methods: 5 types of alginate hydrogels were fabricated by the Vegas lab at Boston University: 3 inflammatory, 1 anti-inflammatory, and 1 non-modified. Primary monocytes were purchased from the Human Immunology Core at the University of Pennsylvania and cultured with 20 ng/mL of macrophage colony stimulating factor (MCSF) to induce differentiation into macrophages. On day 5, 200,000 macrophages were seeded onto each 5 mm section of hydrogel in a 24-well plate. Samples were incubated for 1 hour at 37°C to allow cell attachment. 800 µL of complete media with MCSF was added to each scaffold-containing well. M0 and M1 control samples were refreshed with complete media with MCSF. 100 ng/mL of human recombinant IFNg and LPS were added to the M1 control samples to induce M1 activation. On day 7, media was removed and scaffolds were mechanically degraded and lysed. RNA was extracted and quantified. For samples with at least 20 ng/µL of RNA, 100 ng were hybridized with a 72-gene custom Nanostring Codeset targeting M1, M2, angiogenic, and fibrotic genes. Nanostring sample preparation and reading was conducted according to Nanostring's standard protocol.
Results: Nanostring gene counts were normalized to the Nanostring in-house controls and fold changes over the M0 controls were calculated. Of the M1 markers measured, two (CD80 and CCL2) were upregulated in macrophages seeded on the inflammatory alginate hydrogels. Interestingly, these genes were also highly upregulated in macrophages seeded on non-modified alginate, and were even upregulated in macrophages seeded on anti-inflammatory alginate, though to a lesser extent.
Conclusion: These findings show that alginate hydrogels may be able to induce an M1-like phenotype in macrophages, via upregulation of CD80 and CCL2. However, proinflammatory modification of these hydrogels did not seem to enhance this upregulation. Instead, the results of this study suggest that alginate may be a naturally inflammatory material. Further investigation of the inflammatory properties of alginate are necessary to explore its potential as an M1 phenotype-promoting biomaterial.

F.SM07.05.05
New Class of Biodegradable Drug Delivery Vehicles Eva Krakor, Isabel Gessner, Veronika W. Wulff, Astrid Schauss, Uwe Ruschewitz and Sanjay Mathur; University of Cologne, Germany

The field of nanoparticles for biomedical applications has become one of the most promising and most studied topics in the last years because it offers potential enhancement in pharmaceuticals, medical imaging and diagnosis, cancer treatment, implantable materials and tissue regeneration. In terms of therapeutic applications, especially drug delivery vehicles have been intensively studied. In this case, hollow particles have aroused tremendous interest due to their unique properties such as large surface areas, low densities and high loading capacities due to a protected hollow core. The transport of therapeutic, which can be either, encapsulated, covalently attached or adsorbed onto hollow particles, has been shown to be highly beneficial for multiple reasons compared to simple drug administration e.g., the cargo is protected against enzymatic degradation and the total drug administration can be reduced, which minimizes the risk of side effects.
HMSC were synthesized through a hard template-based method. First, ellipsoidal hematite particles were synthesized in a solvothermal process and coated with silica in a sol gel process afterwards. The iron oxide core was removed by etching resulting in HMSC. The porosity of as-prepared particles was analyzed using nitrogen adsorption-desorption method revealing a pore size of circa 4 nm and a high surface area of 308.8 m_2/g. Cytotoxicity was determined using cell viability test (MTT) towards human kidney cells (HEK293) which clearly demonstrates that no reduction of cell viability was observed even at high concentrations of 100 µg/ml. Uptake studies using confocal microscopy were carried out using human cervical cancer cells (HeLa) which could show the successful internalization over a period of 24 hours. For testing their capability as drug delivery vehicle, a hydrophilic antibiotic (ciprofloxacin) and a hydrophobic anticancer (curcumin) compound were loaded and a pH dependent release under physiological conditions at 37°C was monitored via UV-Vis spectroscopy. After the drug release a reduction in shell thickness of HMSC was confirmed via SEM and TEM images. This study demonstrates the suitability of as-prepared hollow silica capsules as drug delivery vehicles for a broad range of drugs, hydrophobic as well as hydrophilic. Furthermore, it would be possible to modify the surface of drug loaded HMSC with proteins, e.g. antibodies as they are often used in immunotherapeutic regimens.

Nanoparticle Synthesis by Engineered *E. coli* Cells Transformed with a Phytochelatin Synthase Gene Haley Hill, Manjula Bomma, Zhigang Xiao and Qunying Yuan; Alabama A&M University, United States

In this study, the phytochelatin synthase gene of *Rhizobium tropici* was assembled by PCR, inserted into pUC19 vector, and further transformed into *E coli* DH5α cells. Our preliminary data showed that these engineered *E coli* DH5α cells synthesized

more selenium nanoparticles than DH5α cells transformed with pUC19 vector. The scanning electron microscope (SEM) examination of the nanoparticles revealed that the nanoparticles produced by both groups of cells had a size of 100-200nm with a spherical conformation, compositional analysis using Energy-dispersive X-ray spectroscopy identified that the nanoparticles only contain selenium. The capacity of phytochelatin synthase gene transformed bacteria to produce other metallic nanoparticles, including silver and gold will be tested and the physical properties of the nanoparticles will be further analyzed using the transmission electron microscope (TEM) analysis. The research results will be reported in the MRS meeting.

F.SM07.05.08
Late News: Vitamin Lipid Nanoparticles Enable Adoptive Macrophage Transfer for the Treatment of Multidrug-Resistant Bacterial Sepsis Xucheng Hou and Xinfu Zhang; OSU college of pharmacy, United States

Sepsis, a condition caused by severe infections, affects more than 30 million people worldwide every year and remains the leading cause of death in hospitals. Moreover, antimicrobial resistance has become an additional challenge in the treatment of sepsis, and thus, alternative therapeutic approaches are urgently needed. Macrophages are one of the most efficient pathogen scavengers. Indeed, in septic patients, impaired macrophages seem to be primarily responsible for insufficient antimicrobial defense. Nevertheless, immunostimulatory agents for reversing deactivated macrophages did not significantly improve the patient survival in clinical trials. This may be attributed to that immunostimulatory agents are not able to completely restore the function of impaired macrophages. Moreover, many bacteria, such as *Staphylococcus aureus* and *Escherichia coli*, have evolved immune escape mechanisms for thwarting phagolysosomal killing, resulting in intracellular survival. In addition, the prevalence of antibiotic resistance contributes to recurrent infections. Based on these research findings, we hypothesized that adoptive transfer of macrophages containing antimicrobial peptides linked to cathepsin B in the lysosomes (MACs) may enable the immunocompromised sepsis host to boost innate immunity, prevent bacterial immune evasion, and eliminate multi-drug resistant (MDR) bacteria.

To test our hypothesis, we first designed the AMP-CatB mRNA encoding an antimicrobial peptide IB367 (AMP-IB367), a cathepsin B (CatB), and a CatB-sensitive linker. AMP-IB367 is a broad-spectrum AMP with rapid bactericidal activity. CatB, an endogenous lysosomal protein, is first translated as an inactive precursor in the cytoplasm. After translocation into the lysosome, the precursor is processed into mature CatB. Here, the CatB is incorporated to transport the AMP-IB367 into lysosomes, where the linker is cleaved by CatB and thus the APM-IB367 is released. When phagosomes encapsulating bacteria fuse with lysosomes, the ingested bacteria are exposed to both pre-stored AMP-IB367 and lysosomal antimicrobial components. Although immune evasion strategies may protect MDR bacteria from phagolysosomal killing mechanisms, the AMP-IB367 is able to kill these bacteria. In order to equip macrophages with the AMP-CatB mRNA, we synthesized a series of vitamin-derived lipid nanomaterials. We found that the mRNA delivery efficiency of V_CLNPs was 10-fold better than Lipofectamine 3000 and 50-fold better than electroporation in RAW264.7 macrophages. After optimizing the molar ratio of V_C-Lipid:DOPE:Cholesterol and the mass ratio of V_C-Lipid:mRNA, we identified the optimal V_CLNPs formulation with improved mRNA delivery efficiency over 7-fold than its initial formulation. Because V_CLNPs were also effective to deliver mRNA in bone-marrow-derived macrophages (BMDMs), we chose BMDMs for further antibacterial studies because of the clinical translatability. In vitro bactericidal results showed that MACs eliminated over 80% multi-drug resistant Staphylococcus aureus (MDRSA) or multi-drug resistant Escherichia coli (MDR E.coli) at 12 h. Next, we tested the therapeutic effects of MACs in MDRSA- and MDR E.coli-induced sepsis mice with immunosuppression. Analysis of blood at 24 h showed that MACs were more effective in cleaning bacteria than PBS-BMDMs. Furthermore, survival rate of MACs (83%) was significantly higher than that of PBS-BMDM group (40%).

In summary, we have developed macrophages containing antimicrobial peptides linked to cathepsin B in the lysosomes (MACs) via V_CLNPs-mediated delivery of mRNA. Our results prove the concept that adoptive transfer of MACs beneficially reduce bacterial burden and improve survival in MDR bacteria-induced sepsis mice with immunosuppression by restoring innate immune defense, preventing bacterial immune evasion, and eradicating infections.

F.SM07.05.09
Late News: TIO2 Increases Bacterial Infection by Altering the Distribution of Cholesterol on Cell Membrane Fan Yang[1], Yan Xu[1], Stephen Walker[1], Wonhwa Cho[2], Tatsiana Mironava[1] and Miriam H. Rafailovich[1]; [1]Stony Brook University, United States; [2]University of Illinois at Chicago, United States

According to the National Nanotechnology Initiative of America, titanium dioxide (TiO_2) is one of the most commonly manufactured nanoparticles. These nanoparticles are widely used in food, pharmaceutical, cosmetic and chemical industries

as pigments, catalysts, and photovoltaic sources. The latter property is also exploited in water purification where UV-irradiated TiO_2 is a common anti-bacterial agent. However, there is no consensus on the toxicological profile of TiO_2 nanoparticles (NPs), and multiple concerns have surfaced on the potential harmful effects on human health[1]. Experiments conducted on HeLa cells indicated that cells cultured with 0.1 mg/ml rutile and anatase TiO_2 NPs for 24 hrs prior to exposure to *Staphylococcus aureus* (*S. aureus*) had 350 and 250% respectively more bacteria per cell, while macrophages exposed to TiO_2 NPs ingested 40% fewer *S. aureus*, further increasing the risk of infection when present in vivo[2]. The particles were observed to sequester within the cytoplasm of phagocytes simply occupying space which would normally be used for ingesting bacteria. Ingestion of TiO_2 NPs in HeLa cells resulted in an increase in membrane rigidity and extracellular LDH which was attributed to the increase in bacteria[2].
Another possible explanation may be in the concentration distribution of membrane cholesterol. Specifically, we demonstrate an increase in cholesterol concentration of the outer plasma membrane leaflet accompanied by the decrease in cholesterol inner leaflet concentration. Alteration of the inner/outer leaflet cholesterol ratio may also explain the increase in bacterial infectivity NPs since *S. aureus* requires cholesterol for proper membrane attachment and virulence. This effect was absent in ABCA1 knockout HeLa cells suggesting an interaction between TiO_2 and the ABCA, a known cholesterol membrane efflux regulatory protein that facilitates cholesterol transport across the cellular membrane. The hypothesis has also been confirmed by the RT-PCR data detecting the RNA expressions of ABCA1 and ABCG1. We found that compared to the control group, cells exposed to TiO_2 for 24 hrs had higher RNA expression levels to 240% and 170% for ABCA1 and ABCG1, respectively. These data indicate that cells exposed to TiO_2 NPs have altered cholesterol distribution within their membranes, which results in increased rigidity and enhanced bacterial infection. Further work is in progress to evaluate this effect in cells obtained from healthy human tissue.

F.SM07.05.10
Late News: Influence of Surface Topography and Modulus on Fibrinogen Adsorption and Subsequent Cell Response Jie Li and Kyla Sask; McMaster University, Canada

Introduction: Protein adsorption to a material is a complex process which causes thrombus formation, infection, and inflammation and can lead to failure of devices[1]. Surface properties such as chemistry, topography, and mechanics influence protein adsorption and structural changes. Fibrinogen plays a dominant role in mediating platelet and leukocyte interactions with surfaces and its degree of unfolding can impact the extent of cell activation[2]. Macrophages are essential in the immune response to biomaterials and the effect of protein conformational changes on their activation is not fully understood. This work aims to characterize protein adsorption and conformational changes on planar and patterned polydimethylsiloxane (PDMS) with varying elastic moduli and determine the relationship to macrophage response.
Methods: Microscale patterns were designed with three sizes of the following height : groove width : ridge width ratio: (1) 20:20:10 μm; (2) 20:20:20 μm and; (3) 10:10:10 μm. Photolithography and soft lithography are used with PDMS substrates of varying mixing ratios of Sylgard 184 and 527 to investigate the combined effect of surface topography and elastic modulus on fibrinogen adsorption and degree of unfolding. A micro-BCA assay was used to determine the amounts of fibrinogen adsorption (2.0 mg/mL in PBS) on PDMS with the range of stiffnesses. An antibody binding assay using a primary antibody to the fibrinogen gamma chain was developed to quantify the amount of fibrinogen adsorbed with exposure of the gamma chain. This assay will be extended to determine RGD density and further conformational changes of protein on PDMS. We are in the process of further interrogating the role of protein conformation on immune cell interactions using the RAW 264.7 macrophage cell line.
Results: Micropattern designs of three dimensions were prepared for photolithography and soft lithography. Contact angle measurements of PDMS substrates with varying stiffnesses indicated that ratios had relatively similar surface wettabilities with the 1:5 ratio slightly more and the 1:1 ratio slightly less hydrophobic. According to the BCA assay results, the 1:1 ratio of Syl 184 & 527 PDMS polymers adsorbed the most fibrinogen with an average of 10.50 ± 0.26 μg/cm^2, while the 1:5 ratio of Syl 184 & 527 adsorbed the least with an average of 8.88 ± 0.48 μg/cm^2. The antibody binding assay was completed and is being optimized to compare absorbance values based on the amount of fibrinogen determined from the BCA assay. This will provide an indication of changes in orientation and conformation as a result of varying surface topography and modulus.
Discussion and Conclusions: This work focuses on understanding the mechanisms underlying protein adsorption and subsequent cellular regulation abilities of microstructures and elastic modulus. The designed micropatterns provide a way to investigate the combined effect of topography and stiffness on protein adsorption and macrophage adhesion. The BCA assay indicates that varying the surface modulus has an influence on fibrinogen adsorption. The antibody binding assay will

investigate whether protein conformational changes play a role in this varied amount. Future work is being completed to determine the establishment of macrophage focal adhesions and cytokine secretion profiles in response to micropatterned topography and elastic modulus. Controlling these surface properties provides a method to monitor macrophage activation and regulation of immune cell response.

Robust Immune Suppressing Nanoparticles to Overcome Multidrug Resistance in Breast Cancer Haneen Omar and Abdulaziz Almalik; King Abdulaziz City for Science and Technology, Saudi Arabia

Multidrug resistance (MDR), accounting for therapeutic failure, remains a major challenge to manage cancer effectively. Currently, there are only a few strategies that are executed to conquer MDR by restoring chemosensitivity. In this respect, we report an immune suppressing nanoparticle decorated with alpha-1 acid glycoprotein (AGP), an anti-inflammatory protein, to serve as an effective chemoresistant reversal agent to modulate MDR and resensitize aggressive breast tumour cells. Hyaluronic acid-chitosan nanoparticles decorated with AGP (AGP-HA NPs) were synthesized by a sequential ionic gelation method consisting of spray drying and AGP-surface adsorption. The morphology, size, surface charge density, and composition of the synthesized NPs were characterized by utilizing SEM, DLS, Zeta potential, and FTIR, respectively. We have investigated the potential efficacy of AGP-HA NPs in reversing the MDR phenotype of MDA-MB-231 in response to anti-cancer drug doxorubicin (DOX). Our findings showed synergistic antitumor effects between HA and AGP protein as evident from the significantly enhanced efficacy of DOX post switching drug resistance phenotype of the cells to chemo-sensitive phenotype. Overall, our results suggest that AGP-HA NPs represent a viable and effective treatment option to strengthen the anticancer effects of chemotherapeutic agents and potentially contribute to improving the survival rate of patients with metastatic breast cancer.

F.SM07.05.13

pH-sensitive Nanoparticles Based Oral Drug Delivery for the Treatment of Inflammatory Bowel Disease Eden M. Jacob and Sakthi Kumar; Toyo University, Japan

The role of nanomedicine as an enhanced pharmaceutical strategy to deliver drugs has been studied for quite a few decades. The emergence of pH-sensitive nanoscale particles is beneficial due to its ability to release its cargo only at a high pH environment of the colon, which helps for direct targeting of the inflamed tissues in inflammatory bowel disease (IBD). Hence, we have designed the formulation of biodegradable polymer poly (lactic-co-glycolic acid) nanoparticles coated with Eudragit® S100 (EPNPS) for the delivery of novel polyphenolic compounds to reduce the inflammation caused by proinflammatory cytokines. The EPNPs were prepared by a single emulsion solvent evaporation technique and were characterized for shape and surface morphology using a scanning electron microscope (SEM) and transmission electron microscopy (TEM). The *in vitro* drug release was investigated using phosphate buffer saline (PBS) simulating different gut pH. The *in vitro* cytotoxicity of the EPNPs also evaluated and found to be highly biocompatible in nature. The inhibition of proinflammatory cytokines production also conducted using lactate dehydrogenase (LDH) assay. The characterization of EPNPs using SEM and TEM revealed spherical shape and smooth surface of the nanoparticles and was found to be 200-300nm in size. The EPNPs showed substantial improvement in the release of the drug, specifically at colonic pH. Results suggested that pH-sensitive EPNP nanoparticles as a promising candidate in the oral delivery to the colonic inflamed tissues.

Two is Better Than One—A Comprehensive Study on the Synergistic Effects of Co-Delivery of Paclitaxel and Parthenolide in Discoidal Bicelle, *In Vitro* and *In Vivo* Armin Rad, Mu-Ping Nieh and Xiuling Lu; University of Connecticut, United States

Combinatory modulation of the physical and biochemical characteristics of nanocarrier delivery systems is an emergent topic in the field of nanomedicine. Here, using the combined effects of incorporation of active targeting moieties, nanoscale morphology and shape, and physical properties for anti-cancer drugs function. We investigated a novel complex made of lipid bicelles nanocarrier for the efficient delivery of a combination of Paclitaxel (PTX). In addition, we hypothesized that Parthenolide (PTL) can be used as a chemosensitizers to restore the proper apoptotic signaling and to overcome chemotherapy resistance in human lung and breast cancer cells. We synthesized and characterized self-assembled bicelles

(nanodiscs) and nanovesicles which were made up of short- (DHPC) and long-chain (DPPC) lipids encapsulating PTL and PTX molecules. By using simultaneous self-assembly encapsulation, we have encapsulated Parthenolide and Paclitaxel as two cancer drugs. Dynamic light scattering, small angle X-ray scattering (SAXS), Fluorescence-activated cell sorting (FACS), and fluorescence confocal optical microscopy (FCOM) were used to quantify and visualize the cellular uptake of folate-conjugated NPs, respectively and *in vivo* subcutaneous rat studies were performed to investigate the samples. Self-assembled lipid discoidal and vesicular nanoparticles with low-polydispersity ~30 nm size range and identical chemical compositions were synthesized, characterized, and correlated with in vitro cancer cellular internalization, in vivo tumor accumulation and cancer treatments. Folate targeted nanodiscs not only have shown a higher tumor uptake and therapeutic efficiency, but also exhibited well-defined size, robust formation, and high-efficiency encapsulation of hydrophobic molecules, which enable the scalable manufacturing of a generalized in vivo multimodal delivery platform. A comprehensive evaluation of different effective factors, such as loading rate, surface chemistry, nanocarriers shapes, and drug combination ratios were evaluated and a comprehensive regiment for an effective treatment is introduced. The negatively charged bicelles with a PTL:PTX:Lipid molar ratio of 2.5:1:500 yielded a discoidal shape with a uniform diameter of 30 nm and a bilayer thickness of 5 nm, indicated the best anti-cancer function against both regular and drug resistive lung and breast cancer cells. SAXS analysis was also performed to provide insight into how the hydrophobic PTL and PTX molecules interact within the bicelles. Further, flow cytometry followed by confocal microscopy analyses substantiates the superior transfection efficiency of bicelles. We further analyzed how the co-encapsulation and molar ratios of drug and nanocarrier may affect the anti-cancer efficiency *in vivo* and *in vitro*. Several important discoveries in this report are summarized below. Detailed structural analysis and loading capacity of bicelles with two hydrophobic drug molecules, PTX and PTL, are performed. The structural variation of discs strongly depends on the molecular size and shape of the payload. Generally speaking, bicelle shows great potential as a nanocarrier for hydrophobic drug molecules. Both in vitro and in vivo studies on A549 cell line using drug-loaded bicelles indicate high efficacy (high cellular uptake, low IC_{50} and MIC_{90}) for cancer treatment. Moreover, we demonstrate strong synergy with PTX and PTL with IC_{50} and MIC_{90} are magnitudes lower than those of the free drugs in DMSO or Cremophor El. The significant synergetic effect is observed in the MDR A549 cell line as well. The research outcome aims to provide an efficacious nanocarrier platform, which can potentially be generalized for transporting therapeutics and diagnostics to other types of cancers or diseased cells.

Microfabricated Porous PTFE Membrane for Separation in Biomedical Uses Masashi Maruyama, Mitsuya Yamamoto and Hirotaka Sakuma; Hitachi Ltd, Japan

Porous membranes with well-defined pore structures find plenty of uses in research and industrial areas. Well-defined pore structures afford sharp selectivity in filtration and thus applications in biomedical uses are also expected such as cell/spheroid separation and immunoprotection. Track-etching is a well-known technology to fabricate porous membranes with relatively defined pores, but undesired overlapped spots result in loss of selectivity. Against the background, we developed a novel microfabrication methodology to prepare porous membrane with strictly defined pores. We successfully developed porous PTFE membrane with 5-10 um thickness with tunable pore sizes. We will discuss the potential applications of microfabricated PTFE membranes in biomedical uses.

Designed Organization of Proteins in Multidimensional Arrays with Preserved Biological Functionality Shih-Ting Wang[1], Brian Minevich[2], Jianfang Liu[3], Honghu Zhang[1], Dmytro Nykypanchuk[1], James Byrnes[1], Wu Liu[1], Lev Bershadsky[1], Qun Liu[1], Tong Wang[4], Gang Ren[3] and Oleg Gang[1,2]; [1]Brookhaven National Laboratory, United States; [2]Columbia University, United States; [3]Lawrence Berkeley National Laboratory, United States; [4]The City College of New York, United States

An ability to control the assembly of functional proteins with designable organizations and an unpresented density in multidimensional space, provides routes to the next-generation nano-systems, biomaterials and complex biomolecular scaffolds. To achieve this, DNA nanotechnology offers exciting opportunities to modulate assembly processes with nano-scale resolution and spatial addressability. In this work, we developed a protein encapsulation strategy combined with the DNA programmable assembly for a bottom-up fabrication of biologically functional protein arrays with 2D and 3D prescribed organizations. We showed that ferritin, an iron storage protein, was integrated with DNA frames, of which each vertex and their internal space were encoded with addressable strands to program the protein position and vertex-to-vertex interconnection. Such designed arrays allow to maintain a biological activity of ferritin in the nanoscale lattices at relevant environments, and meanwhile, small molecules can access the iron core of ferritin within the 3D array and convert it into a core-less form, apoferritin. Our study, through the use of *in situ* small angle X-ray scattering, electron microscopy and

tomographic modelling, revealed the complex arrangement of designed protein arrays and their ability to perform functions within 3D arrays, thus confirming a new strategy for creating bio-active protein-containing materials.

Late News: Polymer-Ceramic Scaffold for Bone Tissue Applications Katia Mendoza-Calderón[1], Nancy Nelly Zurita Méndez[2], Javier Ortiz Ortiz[2], Marco Antonio Espinosa Medina[2] and Georgina Carbajal de la Torre[2]; [1]Tecnológico Nacional de México., Mexico; [2]Universidad Michoacana de San Nicolás de Hidalñgo, Mexico

Defects in bone tissue have been more common in recent years, based on this a section has been dedicated in the area of biomaterials for research. Currently, knowledge about new biomaterials has led to the discovery of sets of precursors that work effectively in the recovery of damaged tissue, which must meet certain requirements to be recognized as biomaterials, that is, they must be biocompatible, biodegradable, non-toxic, have mechanical resistance, as well as the appropriate density, weight, shape and size. Once these characteristics are known, it has been decided to experiment with three basic precursors in bone regeneration. The work that was carried out aims to manufacture three-dimensional matrices using precursors such as hydroxyapatite, polylactic acid and polycaprolactone. The characterizations were carried out to verify the purity of such biomaterials. Differential Scanning Calorimetry for both tests in a nitrogen/air atmosphere (80/20) at a temperature range of 100 °C to 1000 °C with a heating of 10 °C/min; on the other hand, for polylactic acid an analysis was carried out using Fourier Transform Infrared Spectrometry. Once the results were obtained, the scaffolding was manufactured using leaching and solvent casting techniques. With this, two groups of samples were developed with concentrations of 30% HAp -10% PLA -60% PCL and 10% HAp - 10% PLA - 80% PCL, they were mixed with an organic solvent and sodium chloride. The resulting scaffolds were subjected to mechanical compression and tension tests. Obtaining promising results for application in bone tissue.

A Study of Silver Nanoparticles Control with Three Biocompatible Reducing Substances Qixing Liu[1], Arthur McClelland[2] and Tingying (Helen) Zeng[3,4]; [1]Zhejiang University, China; [2]Harvard University, United States; [3]Academy for Advanced Research and Development, United States; [4]Massachusetts Institute of Technology, United States

Silver nanoparticles play a significant role in public health. They have been proven to be effective substrates for high-intensity surface-enhanced Raman spectroscopy (SERS) in biomedical applications. The nanoparticles are able to detect organic molecules at nanomolar concentration and has the potential for early disease detection or virus killing. Since SERS technology has gained traction in public health uses recently, the synthesis of AgNPs which is considered as the essential and fundamental key of applications, has attracted numerous researchers. In this study, we propose a green, wet-chemical way to control the synthesis of AgNPs and explore three different reducing agents under similar conditions. Sodium citrate, L-cysteine, and oxalic acid, all used as reducing agents, are respectively added into the $AgNO_3$ aqueous solution where the Ag^+ concentration is 2.5mmol/L in room temperature. L-cysteine, a specially selected amino acid, exists in every group acting as the capping agent to restrict the aggregation and control the size of nanoparticles. According to the surface-enhanced Raman spectrum and SEM images, sodium citrate demonstrates the best reducing ability under the same concentration of the carboxy group and can be used for a quick synthesis. On the other hand, the particle size of oxalic acid carpets is more controlled regardless of concentration. It is suitable for precise synthesis associated with the time when the surface-enhanced Raman spectrum indicates the size growth of silver nanoparticles as time increases. Some mechanisms during the process are revealed as well. After analyzing the spectrum, we deem that Ag^+ ion combines with carboxy groups more easily than sulfur in this system. Consequently, these three reducing agents exhibit their unique advantages which provide us with various selections for the synthesis of silver nanoparticles under different requirements for different applications in public health.

Polymer-Based Artificial Synapses—Using Protons and Electrons to Impart Plasticity to Semiconductors Alberto Salleo; Stanford University, United States

The brain can perform massively parallel information processing while consuming only ~1- 100 fJ per synaptic event. I will describe a novel electrochemical neuromorphic device (ENODe) that switches at record-low energy (<0.1 fJ projected, <10 pJ measured) as well as voltage (< 1mV, measured), and displays a large number of distinct, non-volatile conductance states within a ~1 V operating range. The tunable resistance behaves very linearly, allowing blind updates in a neural network when operated with the proper access device. ENODes also display outstanding endurance achieving over 10^9 switching events with very little degradation. I will describe our recent efforts at scaling and materials selection, allowing us to reach 20 ns write pulses and operation at high temperature (up to 120°C). These properties are very promising in terms of the ability to integrate with Si electronics to demonstrate online learning and inference. ENODes are electrochemical devices where gated proton drift induces changes in the electronic states of a semiconductor channel. The peculiarities of the physics of these devices will be discussed along with their consequences on device design and performance.

Electron Transport and Complex Dynamics in 2D Nanoparticle-Molecule Networks—A Platform for Reservoir Computing Dominique Vuillaume; IEMN-CNRS, France

2D networks of interconnected nano-objets (nanowires, nanoparticles, molecules) are experimentally and theoretically explored to implement unconventional computing machines, and especially reservoir computing [1-9]. 2D networks of molecularly functionalized nanoparticles (NPs) (hereafter called NMN : nanoparticle molecule network) have emerged as an interesting approach in molecular electronics to understand fundamental electron transport mechanisms [10].
I will describe the study of NMN approaches using functional molecules self-assembled in high density 2D networks with topological structures that are intrinsically similar to the structure of a "reservoir computing". NMNs equipped with molecules which can change their electronic properties upon a given excitation (optical, chemical, ionic) are interesting to study multifunctional systems at the nanoscale (<100 nm).
I will discuss several key features of the electronic properties of these 2D networks of molecularly functionalized nanoparticles to assess their possible use for reservoir computing: highly non-linear electron transport, variability, complex/rich dynamics (harmonic, interharmonic, intermodulation distortions), co-tunneling, noise and plasmonic response [9-12]. I will also discuss the electron transport properties of some molecules of interest for the chemical and biochemical sensing with these NMNs reservoir computing approaches, combining sensing and computing in a single nanoscale device. These approaches, without direct analogs in semiconductor nanoelectronics, would open new perspectives to molecular electronics in unconventional computing.

6:15 PM *F.SM05.07.03
Physically Flexible and Biological Compatible Demonstration of an Organic Electronics Axon-Hillock Neural Circuit Mohammad Javad Mirshojaeian Hosseini[1], Elisa Donati[2], Tomoyuki Yokota[3], Sunghoon Lee[3], Giacomo Indiveri[2], Takao Someya[3] and Robert A. Nawrocki[1]; [1]Purdue University, United States; [2]Institute of Neuroinformatics, Switzerland; [3]The University of Tokyo, Japan

Spiking Neural Networks (SNN) provide distributed computational capability and emulate the brain processing principles based on spike frequency and pulse width [1]. Because of being intrinsically compatible with brain signaling, one of the target applications of SNN hardware implementation, known as neuromorphic systems [2], are Brain-Computer Interfaces (BCI) [3]. With a handful of exceptions [4], such implementations have typically been implemented using silicon technology, which is physically hard and rigid, and non-biocompatible, resulting in a permanent damage to the brain's soft tissue. Organic electronics offer physical softness and flexibility, biocompatibility, and low-cost, large-area fabrication, to directly interface with biological tissues [5].

We report on the fabrication of a physically flexible, organic electronics, spiking integrate-and-fire Axon-Hillock (AH) neural circuit. Organic Field-Effect Transistors (OFETs) are fabricated on top of a flexible, 50 µm Polyimide substrate. OFETs' architecture is bottom-gate top-contact, and fabricated through thermal deposition of Ti (3 nm)/Au (50 nm) as the gate electrode, 60 nm of Parylene as the dielectric, 30 nm of dinaphtho[2,3b:2',3'-f]thieno[3,2-b]thiophene (DNTT) as the p-type and N,N'-bis(n-octyl)-x:y,dicyanoperylene3,4:9,10-bis(dicarboximide) (PDI8-CN2) as the n-type semiconductor. A 50 nm layer of Au serves as the source and the drain electrodes. A layer of Parylene encapsulates the structure. Non-circuit-integrated commercial resistors and capacitors are used to accelerate the characterization and the fabrication process. All integrated all-organic circuit is beyond the scope of this work and would increase the complexity of the process.

The results show that the AH circuit with 500 nA input current can produce spikes with a range of frequencies. Given the membrane capacitance (C_{mem}) of 15 nF and feedback capacitance ($C_{feedback}$) of 47 nF, the spiking frequency reaches 670 mHz. The frequency can be lowered by increasing capacitance values to C_{mem} = 33 nF and $C_{feedback}$ = 100 nF, respectively, to 370 mHz. Decreasing capacitance to C_{mem} = 2.2 nF and $C_{feedback}$ = 6.8 nF, will result in a higher spiking rate (5 Hz), but will also increase the influence of power line noise and parasitic capacitance. The frequency-current (*F-I*) transfer function shows the dynamics of the neuron. By increasing the input current, the *F-I* curve will saturate indicating an upper bound of frequency spikes. The computational ability of the neuron is also demonstrated with a basic summation of two unitary excitatory synaptic events. The static and dynamic power dissipation is recorded and is limited to 0.4 µW and 40 µW, respectively.

We believe that this work is the first demonstration of a functioning organic electronics integrate-and-fire spiking neuron, paving the way for future implantable BMIs. Beyond neuroscientific applications, this technology can also be used in slow processes, such as temperature measurement, which are intrinsically difficult for ultra-fast silicon devices to achieve, as well as physically flexible large-area applications.

Neuromorphic elements have been predominantly solid-state devices which simulate the resistive and capacitive behaviors needed for neural networks and brain-inspired computing, but in non-brain-like ways. This talk will describe ways we are integrating lipid and polymer bilayer membranes with micro- and nanofabrication to develop fundamentally new types of neuromorphic elements that have the composition (biomolecules), structure (biomembranes), and switching mechanism (voltage-sensitive ion channels) of real biological synapses, and operate at lower power than the current state-of-the-art. Our devices consist of insulating, nm-thick lipid or polymer-based bilayer membranes that assemble at the interfaces of two or more aqueous droplets in oil, and that have demonstrated both memristive and memcapacitive behaviors, including memory resistance and capacitance, synaptic functions such as paired-pulse facilitation and depression, spike rate dependent plasticity, voltage-dependent inactivation and recovery, and charging hysteresis. These behaviors are linked to electrostriction, an electromechanical phenomenon that encompasses both electrowetting and electrocompression in the membrane, which are changes in membrane area and thickness due to charging in the presence of electric fields. Electrostriction results in a voltage-dependent capacitive susceptibility that replaces the more familiar concept of static capacitance, which, up to now, has dominated electrophysiological descriptions and characterizations of biomembranes. In this picture, biomembranes are not just equivalent RC circuits dependent only on ionic currents controlled by the conductance (resistance) of ion channels. Large capacitive currents from small voltage inputs can be generated as well for the development of neuromorphic computing elements exhibiting both short-term and long-term synaptic plasticity.

Most of today’s strategies to interface biology with electronic hardware are based on layered architectures where the front-end of sensing is optimized separately from the back-end for processing/computing signals. Alternatively, biological systems are capitalizing on distributed architecture where both sensing and computing are mix together and co-optimized. In this talk, we will present our strategy to implement bio-sensing of electroactive cells in a neuromorphic perspective. We will present how organic electrochemical transistors can be used to record electrical signals from neural cells. We will show various strategies capitalizing on the versatility of organic materials synthesis and organic device fabrication to tune and adapt the functionalities of such bio-sensors. We will then present how these strategies can be efficiently used to realize computing functions directly at the interface with biology. Notably, we will illustrate how a network of ionic sensors can implement the

reservoir computing concept, a powerful neuromorphic computing approach of particular interest for dynamical signal processing.

Scalable, Soft and Stretchable Optoelectronics and Neuromorphic Sensing Architectures in Human-Machine Interfaces Benjamin C. Tee; National University of Singapore, Singapore

Human-machine interfaces will continue to be critical to advance applications in healthcare, robotics and consumer electronics. Having a cross-disciplinary approach to materials innovation, especially with regards to soft materials[1] will effectively address the mechanical constraints when interfacing with humans. In this talk, I will discuss some of the new material platforms we are developing for more robust human-machine interactions, such as self-healing stretchable optoelectronics devices[2]. Such optoelectronic devices might be employed in optogenetic neural interfaces . At the same time, I will also present our efforts in brain inspired scalable neuromorphic architectures for electronic skins[3]. Such system architectures can be broadly applied in various applications with high impact potential for wearables, brain-machine interfaces, prosthetics and robotics.

Designing Biomimetic Electronic Interfaces Francesca Santoro; Istituto Italiano di Tecnologia, Italy

The interface between biological cells and non-biological materials has profound influences on cellular activities, chronic tissue responses, and ultimately the success of medical implants and bioelectronic devices. The optimal coupling between cells, i.e. neurons, and materials is mainly based on surface interaction, electrical communication and sensing.
In the last years, many efforts have been devoted to the engineering of materials to recapitulate both the environment (i.e. dimensionality, curvature, dinamicity) and the functionalities (i.e. long and short term plasticity) of the neuronal tissue to ensure a better integration of the bioelectronic platform and cells.
On the one hand, here we explore how the transition from planar to pseudo-3D nanopatterned inorganic and organic materials have introduced a new strategy of integrating bioelectronic platforms with biological cells under static and dynamic conditions. Although a spontaneous penetration does not occur, adhesion processes are such that a very intimate contact can be achieved. On the other hand, we investigate how organic semiconductors can be exploited for recapitulating electrical neuronal functions such as long term and short term potentiation. In this way, both the topology and the material functionalities can be exploited for achieving in vitro biohybrid platforms for neuronal network interfacing.

1:00 PM *F.SM05.08.04
New Materials and Device Concepts for Organic Electrochemical Transistors Jonathan Rivnay; Northwestern University, United States

Organic electrochemical transistors (OECTs) have gained considerable interest for applications in bioelectronics, power electronics, circuits and neuromorphic computing. Their defining characteristic is the bulk-modulation of channel conductance owing to the facile penetration of ions into the (semi)conducting polymeric channel. For this reason, their device scaling relies on film thickness, enabling finer size scale devices, and unique form factors. Despite recent progress and a rapidly expanding library of new materials, the understanding of stability and transport/coupling of ionic and electronic carriers remain largely unexplored. We highlight recent synthetic and processing approaches used to tailor device properties and stability, as well as new opportunities enabled by such advances. We demonstrate how the reliance on bulk transport allows for relaxed fabrication demands and production of simple multi-device circuit concepts for analog signal processing. Finally, by studying the role of additives on charging, trapping, and structural re-arrangement, we can gain insight into the next generation of non-volatile organic mixed conductors for neuromorphic hardware. The implementation of OECT-based sensing and circuits holds particular promise in brain-inspired bioelectronics – the role of materials design and development is critical for their success.

Evolvable Organic Electrochemical Transistors for Neuromorphic Applications Simone Fabiano; Linköping University, Sweden

Organic electrochemical transistors (OECTs) are in a stage of rapid development as novel applications that make use of these versatile devices continue to emerge. OECTs are characterized by the coupling of both ionic and electronic inputs to modulate transistor channel conductance. This attribute renders OECTs ideal for interfacing electronics with biological systems, which make use of ionic and biochemical currents and gradients for signaling. Here we will present a new concept of OECT that evolves with use. The transistor channel can be formed, modulated, and obliterated under operation. The strength of the transistor response to a given stimulus can be modulated within a range that spans several orders of magnitude, introducing behaviors analogous to neuroplasticity into electronic systems. This evolvable transistor can be incorporated into a simple circuit that mimics classical conditioning. Also, we will present several biomimetic logic circuits that link sensory inputs to the growth of the transistor channel, thus to achieve higher order processes like self-regulation and coincidence detection. OECTs that physically and electronically evolve under operation will bring about a new paradigm of machine learning based on evolvable organic electronics.

Governing Conducting-Polymer Micro-Objects' Fractality for Unconventional Computing Ankush Kumar[1], Kamila Janzakova[1], Yannick Coffinier[1], David Guérin[1], Fabien Alibart[1,2] and Sébastien Pecqueur[1]; [1]Institut d'Électronique, Microélectronique et Nanotechnologie (IEMN), CNRS, UMR 8520, F-59652, France; [2]Laboratoire Nanotechnologies & Nanosystèmes (LN2), CNRS, Université de Sherbrooke, Canada

Electropolymerization is an interesting bottom-up strategy to structure conducting materials at the micro/nano-scale in liquid phase that offers a wide morphological versatility. Since the geometry of these structures governs their electrochemical properties, it is fundamental to decipher the mechanisms that rule the polymer assembling upon the electrically-programmed growth to use this phenomenon as a neuro-inspired building block for unconventional information processing.
Herein, we investigate various electrical parameters of electropolymerization affecting the conducting polymer network geometry. We find that various structures such as dendrites, trees, fractals as well as low-fractality cables can be obtained between the two-wire electrodes, based on applied voltage amplitude, biasing symmetry, bias frequency, the concentration of monomers and electrode configurations. We qualitatively and quantitatively study the relationship between the electrical parameters affecting geometrical parameters of the conducting polymer network as well as electropolymerization dynamics through video and image processing. The systematic analysis shows that an increase in applied voltage leads to higher growth rate, more branches, and lower surface to bulk ratio. At the other hand, an increase in bias frequency leads to higher growth rate, smaller number of branches, and higher surface to volume ratio.
In order to model the experimental phenomena, we simulate a simplified version of the problem with two bipolar metal electrodes and an electrolyte filled with dilute moving particles at random positions, reflecting the monomers in the liquid phase. The wire electrodes are biased with AC frequency and the spacio-temporal potential map is evaluated by solving the Laplace equation. The motion of the monomer particles is controlled by the electric field and by random Brownian motion. The particles that happen to touch the electrodes are stuck to the electrodes, with a certain probability of sticking. The stuck particles are incorporated into the electrode, and the potential is recalculated for the motion of the particles;. The simulations are tested for different AC applied voltages, frequency, duty cycles, and voltage offsets. The increase in applied voltage leads to higher sticking probability; resulting in a higher growth rate, multiple branches, and higher density, which goes well with the experiments. Further, the effect of frequency, which is not so intuitive, shows that higher AC frequency, favors linear cable like growth, while lower frequency leads to more isotropic growth, while voltage offset and non-equal duty cycle lead to asymmetrical growth, in accordance with experiments. In addition, the effect of electrode spacing, different electrode designs, electrical pulse shapes and the concentration of particles, are also studied. The study helps in visualizing the motion of particles in different electrical conditions, which is not possible to probe experimentally. Some subtle experimental features, such as the effect of preferential growth on the tips, and broadening of the electrode before touching, are observed in the modeling studies. Thus, we find that the different network architectures are associated with different Laplace end diffusion fields governing the monomers motion and in turn electropolymerized network geometry. Such unconventional engineering route could have a variety of applications from neuromorphic engineering to bottom-up computing strategies.

6:45 AM *F.SM05.01.06
Physically Flexible and Biological Compatible Demonstration of an Organic Electronics Axon-Hillock Neural Circuit Mohammad Javad Mirshojaeian Hosseini[1], Elisa Donati[2], Tomoyuki Yokota[3], Sunghoon Lee[3], Giacomo Indiveri[2], Takao Someya[3] and Robert A. Nawrocki[1]; [1]Purdue University, United States; [2]Institute of Neuroinformatics, Switzerland; [3]The University of Tokyo, Japan

Spiking Neural Networks (SNN) provide distributed computational capability and emulate the brain processing principles based on spike frequency and pulse width [1]. Because of being intrinsically compatible with brain signaling, one of the target applications of SNN hardware implementation, known as neuromorphic systems [2], are Brain-Computer Interfaces (BCI) [3]. With a handful of exceptions [4], such implementations have typically been implemented using silicon technology, which is physically hard and rigid, and non-biocompatible, resulting in a permanent damage to the brain's soft tissue. Organic electronics offer physical softness and flexibility, biocompatibility, and low-cost, large-area fabrication, to directly interface with biological tissues [5].

We report on the fabrication of a physically flexible, organic electronics, spiking integrate-and-fire Axon-Hillock (AH) neural circuit. Organic Field-Effect Transistors (OFETs) are fabricated on top of a flexible, 50 µm Polyimide substrate. OFETs' architecture is bottom-gate top-contact, and fabricated through thermal deposition of Ti (3 nm)/Au (50 nm) as the gate electrode, 60 nm of Parylene as the dielectric, 30 nm of dinaphtho[2,3b:2',3'-f]thieno[3,2-b]thiophene (DNTT) as the p-type and N,N'-bis(n-octyl)-x:y,dicyanoperylene3,4:9,10-bis(dicaroximide) (PDI8-CN2) as the n-type semiconductor. A 50 nm layer of Au serves as the source and the drain electrodes. A layer of Parylene encapsulates the structure. Non-circuit-integrated commercial resistors and capacitors are used to accelerate the characterization and the fabrication process. All integrated all-organic circuit is beyond the scope of this work and would increase the complexity of the process.

The results show that the AH circuit with 500 nA input current can produce spikes with a range of frequencies. Given the membrane capacitance (C_{mem}) of 15 nF and feedback capacitance ($C_{feedback}$) of 47 nF, the spiking frequency reaches 670 mHz. The frequency can be lowered by increasing capacitance values to C_{mem} = 33 nF and $C_{feedback}$ = 100 nF, respectively, to 370 mHz. Decreasing capacitance to C_{mem} = 2.2 nF and $C_{feedback}$ = 6.8 nF, will result in a higher spiking rate (5 Hz), but will also increase the influence of power line noise and parasitic capacitance. The frequency-current (*F-I*) transfer function shows the dynamics of the neuron. By increasing the input current, the *F-I* curve will saturate indicating an upper bound of frequency spikes. The computational ability of the neuron is also demonstrated with a basic summation of two unitary excitatory synaptic events. The static and dynamic power dissipation is recorded and is limited to 0.4 µW and 40 µW, respectively.

We believe that this work is the first demonstration of a functioning organic electronics integrate-and-fire spiking neuron, paving the way for future implantable BMIs. Beyond neuroscientific applications, this technology can also be used in slow processes, such as temperature measurement, which are intrinsically difficult for ultra-fast silicon devices to achieve, as well as physically flexible large-area applications.

Bio-Inspired Neuromorphic Electronics for Artificial Nervous Systems Tae-Woo Lee; Seoul National University, Korea (the Republic of)

Neuromorphic electronics have handled complex real-world problems such as visual information, speech recognition, and body motion control with compressibility, fault tolerance, and high energy efficiency. These neuromorphic electronics have been investigated to develop artificial nervous system systems that mimic biological nervous systems. Mimicking the learning and memory functions of the human brain has been a major focus so far in neurological electronics. Further, the functional integration of artificial synapses with sensing/motor elements would be a core technology for applications of

human-like robotics and neuroprosthetics, enabling the emulation of sensing and responding behaviors in biological systems. In biology, sensations such as vision, hearing, touch, taste, and smell and responding with muscles are related with peripheral nerves.
Herein, bio-inspired neuromorphic electronics for artificial nervous systems were covered. Artificial synapse-based sensory and motor electronic nerves are developed by integrating with sensory and motor organs. Firstly, pressure sensors (artificial mechanoreceptors), organic ring oscillators (artificial nerve fibers), and synaptic transistors were integrated to emulate the functions and operating principles of biological counterparts. By connecting this artificial pressure-sensory nerve to biological motor nerves in a detached cockroach leg, a hybrid reflex arc system was realized. In addition, a stretchable photo-sensitive sensorimotor nervous system composed of a photo-sensitive detector (an artificial photoreceptor) and a stretchable artificial synapse with a polymer actuator (an artificial muscle). In addition, a retina-inspired photo-sensitive synaptic transistor was developed by using ultraviolet-responsive 2-dimensional carbon nitride nanodot layers as a floating gate to selectively detect and process ultraviolet light exposure information. Lastly, for an artificial auditory system, organic artificial synapse was connected to a triboelectric sensor. Our bio-inspired neuromorphic systems can be used for neuromorphic computing, humanoid soft robots, and neural prostheses.

Memory and Learning in Biomolecular Soft Materials Charles P. Collier[1], Joseph S. Najem[2], Richard S. Williams[3], Graham Taylor[4], Md S. Hasan[5], Ryan Weiss[6], Stephen A. Sarles[6], Garrett Rose[6], Alex Belianinov[1] and Catherine Schuman[1]; [1]Oak Ridge National Laboratory, United States; [2]The Pennsylvania State University, United States; [3]Texas A&M University, United States; [4]T&T Scientific, United States; [5]The University of Mississippi, United States; [6]The University of Tennessee, Knoxville, United States

Neuromorphic elements have been predominantly solid-state devices which simulate the resistive and capacitive behaviors needed for neural networks and brain-inspired computing, but in non-brain-like ways. This talk will describe ways we are integrating lipid and polymer bilayer membranes with micro- and nanofabrication to develop fundamentally new types of neuromorphic elements that have the composition (biomolecules), structure (biomembranes), and switching mechanism (voltage-sensitive ion channels) of real biological synapses, and operate at lower power than the current state-of-the-art. Our devices consist of insulating, nm-thick lipid or polymer-based bilayer membranes that assemble at the interfaces of two or more aqueous droplets in oil, and that have demonstrated both memristive and memcapacitive behaviors, including memory resistance and capacitance, synaptic functions such as paired-pulse facilitation and depression, spike rate dependent plasticity, voltage-dependent inactivation and recovery, and charging hysteresis. These behaviors are linked to electrostriction, an electromechanical phenomenon that encompasses both electrowetting and electrocompression in the membrane, which are changes in membrane area and thickness due to charging in the presence of electric fields. Electrostriction results in a voltage-dependent capacitive susceptibility that replaces the more familiar concept of static capacitance, which, up to now, has dominated electrophysiological descriptions and characterizations of biomembranes. In this picture, biomembranes are not just equivalent RC circuits dependent only on ionic currents controlled by the conductance (resistance) of ion channels. Large capacitive currents from small voltage inputs can be generated as well for the development of neuromorphic computing elements exhibiting both short-term and long-term synaptic plasticity.

7:45 AM F.SM05.01.01
Late News: Self-Assembled Oligoethylene Glycols for Air-Stable Molecular Electronics and *In Operando* Modulation Xinkai Qiu and Ryan C. Chiechi; University of Groningen, Netherlands

Self-assembled monolayers (SAMs) are widely used to engineer the surface properties of metals. The relatively simple and versatile chemistry of metal-thiolate bonds makes thiolate SAMs the preferred option in a range of applications, yet fragility and a tendency to oxidize in air limit their long-term use. In our recently published paper in Nature Materials, we report the formation of thiol-free self-assembled mono- and bilayers of glycol ethers, which bind to the surface of coinage metals through the spontaneous chemisorption of glycol ether-functionalized fullerenes. As-prepared assemblies are bilayers presenting fullerene cages at both the substrate and ambient interface. Subsequent exposure to functionalized glycol ethers displaces the topmost layer of glycol ether-functionalized fullerenes, and the resulting assemblies expose functional groups to the ambient interface. These layers exhibit the key properties of thiolate SAMs, yet they are stable to ambient conditions for several weeks, as shown by the performance of tunneling junctions formed from SAMs of alkyl-functionalized glycol ethers. Glycol ether-functionalized spiropyrans incorporated into mixed monolayers lead to reversible, light-driven conductance switching. Self-assemblies of glycol ethers are drop-in replacements for thiolate SAMs that retain all of their useful properties while avoiding the drawbacks of metal-thiolate bonds.[1]
In a follow-up work, we demonstrate the reconfiguration of molecular tunneling junctions while in operation via the self-assembly of bilayers of glycol ethers. We use well-established functional groups to modulate the magnitude and direction of

rectification in assembled tunneling junctions by exposing them to solutions containing different glycol ethers. Variable temperature measurements reveal that rectification occurs by a bias-dependent tunneling-hopping mechanism and that glycol ethers, besides being unusually efficient tunneling medium, behave identically to alkanes. We fabricated memory bits from crossbar junctions prepared by injecting eutectic Ga-In in microfluidic channels. Two 8-bit registers were able to perform logical AND operations on bit strings encoded into chemical packets as microfluidic droplets that alter the composition of the crossbar junctions through self-assembly to effect memristor-like properties. This proof-of-concept work demonstrates the potential for fieldable molecular-electronic devices based on tunneling junctions of self-assembled monolayers and bilayers.[2]

One-Shot Regression and Classification with Crosspoint Memory Arrays Daniele Ielmini[1], Giacomo Pedretti[1], Piergiulio Mannocci[1] and Zhong Sun[2]; [1]Politecnico di Milano, Italy; [2]Peking University, China

As artificial intelligence (AI) becomes a popular feature in industry, social networks, smart homes and transportation, there is an increasing need for AI accelerators in edge computing, to solve for excessive traffic to the cloud and ensure privacy and security of the processed data. In this frame, in-memory computing (IMC) has risen as low-power processing approach for data intensive problems. Matrix-vector multiplication (MVM) can be accelerated in crosspoint arrays by leveraging the Kirchhoff's law for current summation and the Ohm's law for voltage-conductance multiplication, as well as taking advantage of the parallelism in the memory array. Connecting the crosspoint array in a feedback loop also allows to accelerate inverse operations, i.e., one-step solutions of linear systems such as Ax = b where the NxN matrix A is stored as conductance values in the array, vector b represents applied currents and solution vector x is the output voltage. O(1) complexity of eigenvector extraction and O(N) complexity of matrix inversion have been demonstrated, which outperforms classical digital computing and even quantum computing.
In this work, we show that the same circuit concept can serve to accelerate regression and classification problems, which are two key problems of AI. Linear regression is solved within two coupled crosspoint arrays by computing the pseudo-inverse matrix in one step. M-dimensional linear regression allows to make predictions based on an existing data set or temporal sequence, thus enabling fast, energy efficient machine learning on the edge. The same circuit enables logistic regression, hence one-step classification within the crosspoint array, which allows for one-shot training of multiple layer perceptrons (MLP). The implications of these novel concepts for AI acceleration and the best technological implementation for data-intensive computing will be discussed.

Atomic Memory and Computing Applications Deji Akinwande[1] and Mario Lanza[2]; [1]The University of Texas at Austin, United States; [2]Soochow University, China

This talk will present our latest research adventures on 2D atomic nanomaterials towards greater scientific understanding and computing applications. In particular, the talk will highlight our work on non-volatile memory (atomristors) that can be employed in various applications including information storage, brain-inspired computing, and zero-power RF switches. Non-volatile memory device based on atomically-thin materials is an application of defects, and is a rapidly advancing field with rich physics that can be attributed to metal ion binding to native defects. The promising 2D materials for neuromorphic computing include MoS2 and hBN. In particular, hBN memory devices feature very low switching energy, a relatively wide range of stable programmable resistance states, and good endurance and retention. Recent progress has also demonstrated wafer-scale integration of 2D memory devices with a prospect to leverage silicon electronics for fully integrated systems.

6:00 AM F.SM05.02/F.NM07.05.04
High-Throughput Computational Screening to Identify Novel Proton Conducting Electrolytes for All-Solid-State Neuromorphic Devices Konstantin Klyukin, Pjotrs Zguns, Ju Li and Bilge Yildiz; Massachusetts Institute of Technology, United States

Artificial electrochemical synapses based on the charge-driven proton intercalation demonstrate much promise toward brain-inspired neural computing [1]. Proton transport plays a critical role in these devices determining switching speed and reliability. Despite great attention and intensive experimental investigations, even the cutting-edge proton conductors still suffer from sluggish ion transport kinetics at low temperatures or are not compatible with current CMOS fabrication processes. Therefore, there is an urgent need for fast solid-state proton conductors operating below 100 °C, much required for rapidly growing proton-based neuromorphic computing applications.

In this work, we consider a large class of solid-state materials having hydrogen as a part of their nominal structure such as solid acids and inorganic hydrates. By considering different combinations of common acids and metal ions, it is possible to synthesize thousands of materials with widely varying structures and physicochemical properties, and yet many of them remain relatively unexplored for the ability to conduct protons. We performed a high-throughput computational screening of the available materials datasets to identify chemical compositions and structure types that are likely to have high proton mobility. To estimate proton conductivity, we used ab initio molecular dynamics simulations. We further correlated this data with simple structural features and built a classification model to preselect a small set of materials for more detailed investigations. Based on our simulations, we identified promising materials and suggested effective strategies for improving proton conductivity.

Metal-Insulator Transition Property for the Nano-Confined Electric Domain in the Strongly Correlated $NdNiO_3$ Azusa Hattori, Takashi Yamanaka, Akira Nanba and Hidekazu Tanaka; Osaka University, Japan

Strongly correlated metal oxide (SCMO), such as manganite, nickelate, and so on show first-order metal-insulator phase transition (MIT) with a change in conductivity by several orders magnitude. Since a discovery of the phase separation during MIT process, many researchers have been trying to capture a nanoscale electric domain and investigate its exotic properties. Typical SCMO material, rare earth Ni oxides ($ReNiO_3$, Re = Nd, Sm, and Eu) having a perovskite structure, show giant resistance change due to MIT at a wide temperature range of 150 K to 500 K. In this family, bulk neodymium nickelate: $NdNiO_3$ (NNO) shows 1-2 orders resistance change through MIT at around 200 K [1]. Very recently, the coexistence of insulator and metal domains with a few hundred nm size was observed during the MIT process for NNO system [2]. This phase-separated phenomenon is also observed in typical SCMOs, such as VO_2 and manganite. The overall observed MIT property, i.e., the resistance change for a sample, is considered to be dominated by competing nanoscale electronic phases. A step resistance change due to the electronic phase confinement effect: increase in resistance change rate has been reported in nanoscale samples comparable to domain size [3]. Therefore, it is expected that the nanoscale NNO sample shows a step resistance change due to MIT property of single nanoscale electronic phases. In this study, we fabricated NNO nanowire structures with 50-200 nm widths and measured their transport properties.
The NNO thin films were fabricated on $NdGaO_3$(110)(a_{pc} = 0.3858 nm), LSAT(100)(a = 0.3868 nm), and $SrTiO_3$(100)(a = 0.3858 nm) substrates by pulsed laser deposition method. NNO nanowires with different wire widths from 50 nm to 500 nm were fabricated by electron beam (EB) lithography and Ar ion milling process. All films and nanowire samples showed the resistance changes corresponding to MIT, but the RT curves shape were quite different. While the thin film sample showed gradual resistance change, the nanowire sample showed some step resistance changes both in cooling and heating processes. This step changes indicate that the nano electronic phases are confined in the NNO nanowire and a single electric domain shows first-order MIT with a single-step change in electrical transport property. For example, we found that the 50 nm width nanowire on $SrTiO_3$ substrate showed the intermittent step-resistance change, implying the further confine electronic phases to a nanometer space. Interestingly, the nanowires on $NdGaO_3$(110) and LSAT(100) substrates showed more prominent step resistance changes than that on $SrTiO_3$(100) substrate, which imply the nano-confinement condition were affected by the strain. The dR/dT vs. T plot showed that the transition temperature distribution of each electronic phase in the nanowires were different. This is probably because the strains depending on the three different substrate effect where on the Ni-O-Ni angular distribution, which affected the MIT properties of $NdNiO_3$ nano-electronic phase. In the presentation, we will present

the quantitative correlation between nano-spatial size and nano-confinement MIT properties. We will also discuss the revealed the MIT property for a single domain in a NNO nanowire and the strain effect for the nano-confined domains behaviors.

6:30 AM F.SM05.02/F.NM07.05.06
Ionic Liquid Regulated Silver Filament Formation in a Solid Polymer Electrolyte for Neuromorphic Applications Zhongmou Chao, Ke Xu and Susan Fullerton; University of Pittsburgh, United States

Much progress has been made over the past decade using conductive bridge random access memory (CBRAM) to emulate both artificial synapses and artificial neurons for neuromorphic applications. However, the intrinsically stochastic switching process of metal filament formation and dissolution results in unreliable analog synaptic weight updating, while the non-volatile characteristic of CBRAM prevents the leaky integrate-and-fire function—a hallmark characteristic of an artificial neuron. We have previously reported that silver nanofilament growth dynamics in a polymer electrolyte can be regulated by the addition of ionic liquid (IL) by: (1) reducing stochasticity of the filament switching (shifting its formation time distribution from power-law to Gaussian) and (2) creating a competition between the formation of IL electrical double layers (EDL) and silver electrodeposition. The competition enables the tuning of filament growth dynamics from abrupt to gradual, with gradual growth introducing multiple well-defined resistance states—a feature necessary for emulating the communications between neurons in an artificial neural network. We also observed a linear correspondence ($R^2 = 0.95$) between nanofilament resistance states and program pulses, which is essential to improve learning accuracy in Deep Neural Networks (DNNs). Here, we report on silver filament formation and dissolution in response to presynaptic programming biases and focus on benchmarking the performance against the requirements for artificial synapses. The temporal stability of "abrupt growth" silver filaments is also studied. Lastly, we demonstrate a system integrating both gradual and abrupt silver filaments to implement some key artificial neuron functionalities.

6:45 AM *F.SM05.02/F.NM07.05.07
Progress in Analog DNN Hardware Accelerators Using Phase Change Materials Charles Mackin, Hsinyu Tsai, Pritish Narayanan, Stefano Ambrogio, Katie Spoon, Andrea Fasoli, Alexander Friz, An Chen and Geoffrey W. Burr; IBM, United States

Neuromorphic computing with analog memory can accelerate deep neural networks (DNNs) by enabling multiply-accumulate (MAC) operations to occur within memory. Analog memory, however, presents a number of device-level challenges having macro-implications on the achievable accuracy and reliability of these artificial neural networks. This talk focuses on the adverse effects of conductance drift in phase-change memory (PCM) on network reliability. It is shown that conductance drift can be effectively compensated in a variety of networks by applying a 'slope correction' technique to the squashing functions to maintain accuracy/reliability for a period of ~1 year. In addition to conductance drift, PCM poses considerable variability challenges, which impact the accuracy of the initial weights. This talk summarizes recent advances in optimizing initial weight programming, and provides evidence suggesting that the combination of 'slope correction' and programming optimization techniques may allow DNN acceleration using analog memory while maintaining software-equivalent accuracy with reasonable reliability.

7:15 AM *F.SM05.02/F.NM07.05.08
Computing with Memristive and Memcapacitive Devices J. Joshua Yang; University of Southern California, United States

Memristive devices have become a promising candidate for unconventional computing(1) due to their attractive properties(2, 3). Computing can be implemented on a Resistive Neural Network (ResNN) with memristor synapses and neurons or a Capacitive Neural Network (CapNN) with memcapacitor synapses and neurons. For ResNNs as computing accelerators, we have built a dot-product engine based on a 128 x 64 1T1R crossbar array using traditional non-volatile memristors with 64 stable analog resistance levels(4). Accurate image compression and filtering have been demonstrated with such analog computing accelerator(4). In addition, we have demonstrated efficient and self-adaptive in-situ learning in a two-layer neural networks using such memristive arrays(5), which is expected to significantly improve the speed and energy efficiency of machine learning. A variety of neural networks based on such accelerators have been demonstrated, including reinforcement learning(6), LSTM(7), recurrent CNN(8) memristive networks. For ResNNs beyond accelerator applications, we developed diffusive memristors(9) with diffusion dynamics that is critical for neuromorphic functions. Based on the diffusive memristors, we have further developed artificial synapses(10) and neurons(11) to more faithfully emulate their bio-counterparts. We then integrated these artificial synapses and neurons into a small neural network, with which pattern

classification and unsupervised learning have been demonstrated(11). For CapNNs, we have developed pseudo-memcapacitive devices based on the diffusive memristors. Capacitive synapses and neurons enabled by these memcapacitive devices have been developed and used to form a fully integrated CapNN(12), which has shown spiking signal classification and Hebbian-like learning functions. Moreover, the diffusive memristors can be used for cybersecurity(13, 14) and robotics applications(15). The requirements on device properties, and thus the corresponding challenges and solutions, are different for ResNNs and CapNNs, which will be discussed in detail in this talk. J. J. Yang, D. B. Memristive Materials and Devices for Unconventional Computing J. Joshua Yang; University of Southern California, United States

Memristive devices[1] have become a promising candidate for energy-efficient and high-throughput unconventional computing[2], which is a key enabler for artificial intelligent systems in the big data and IoT era[3]. The computing can be implemented on a Resistive Neural Network[4] with memristive synapses[5] and neurons[6] or a Capacitive Neural Network[7,8] with memcapacitive synapses and neurons. In this talk, I will first briefly introduce the promises and challenges of memristive materials and devices for such applications. I will then discuss a few examples selected from our recent experimental demonstrations of unconventional computing using memristive networks with different levels of bio-inspiration: first, deep learning accelerators[9] with supervised online learning[10]; second, neuromorphic computing for pattern classification with unsupervised learning[6]; last, other computing applications, such as reinforcement learning[11] for decision making, artificial nociceptors for robotics[12], provable key destruction[13] and true random number generators[14] for cybersecurity.

Development of Neuristors and Synaptors Using Quantum Materials for Energy Efficient Neuromorphic Computing Ivan Schuller; University of California, San Diego, United States

The Quantum Materials for Energy Efficient Neuromorphic Computing (QMEENC) Energy Frontiers Research Center (EFRC) is a highly collaborative effort dedicated to the development of quantum materials based implementation of energy efficient devices that will form the basis for neuromorphic computing. This project is currently two parallel approaches based on charge, using highly correlated oxides, and spin, using spin torque oscillators. We are also developing hybrid concepts, which take advantage of the functional properties of both approaches.
In addition to the general description of the QMEENC approach, I will describe the first implementation of energy efficient neuristors (that emulates neuronal functionalities) and a synaptors (that emulates synaptic functionalities), based on heterostructures, which incorporate strongly correlated oxides.

This work was supports as part of the Quantum Materials for Energy Efficient Neuromorphic Computing an Energy Frontiers Research Center funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences under Award # DE-SC0019273.

Robust Resistive and Mem-Devices Using Organometallic Molecules- Ideal Candidates for Neuromorphic Devices Thirumalai Venkatesan[1,2], Sreetosh Goswami[3] and Sreebrata Goswami[3]; [1]Azometrix, United States; [2]National University of Singapore, Singapore; [3]NUS, Singapore

Artificial intelligence (AI) has been heralded as the flagbearer of the fourth industrial revolution. But it comes with a cost and that is computing power. It is projected that by 2040, we will need more computing energy than the total energy we can produce now. So, we need devices that can offer higher computing/ storage density with low energy consumption like neuronal computation. We are addressing these challenges using a molecular-electronic route. Historically, organic electronic devices have stimulated scientific excitements in OLEDs but are yet to make any other significant technological impact. The reasons behind their limited success are their poor robustness, stability, endurance and most importantly, the lack of mechanistic understanding that restricts the emergence of approaches to solve these problems. We have overcome each of these difficulties in our memristors based on transition metal complexes of azo-aromatic ligands that exhibit high reproducibility (~350 devices), fast switching (≤30 ns), excellent endurance (~10^{12} cycles), stability (>10^6 s) and scalability (down to ~60nm^2)[1-5]. Using *in-situ* Raman spectroscopy we are able to track the electronic changes in molecules *in-operando* at every point of our voltage sweep providing a clear picture of our molecular mechanism that enables us to do different molecular and device engineering to achieve targeted functionalities. Using devices of this genre we are addressing the existing computing challenges *via* three routes,
By designing devices with ultra-low power: We can design memristors with switching voltage as low as 70mV, with energy ~36aJ/ 60nm^2. The current and voltage levels of these devices meet the requirements specified in ITRS road map.
By designing memristors and memcapacitors with multiple discrete plateaus[3]: We have developed memristors with 3- 4 distinct conducting plateaus which also shows mem-capacitance. Their concomitant occurrence is enabled by symmetry breaking of our film-molecules driven by voltage, a new paradigm in condensed matter physics.
Brain inspired computing: Using devices that exhibit concomitant memristive and memcapacitive functions we can simulate biological actions such as neuronal action potential and even cardiac myocyte pulsing.

Acting Like a Synapse—A Biohybrid Neuromorphic Platform Combining Electronical and Optical Readouts Giovanni Maria Matrone[1], Claudia Lubrano[1], Valeria Criscuolo[1], Csaba Forro[2], Yoeri van de Burgt[3] and Francesca Santoro[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Stanford University, United States; [3]Technische Universiteit Eindhoven, Netherlands

In biological neural networks communication relies on electric signals in the form of action potentials (APs) that trigger the release of neurotransmitters at the synapses, thus influencing the mechanisms of synaptic plasticity that regulates over time the transmission efficiency across the synaptic cleft. Indeed, progress over the last few years designing artificial neuromorphic systems (ANS)[1] has paved the way to a rapid improvement of the current machine learning (MC) processes but, focusing mainly on replicating electrical signal transmission, has limited a direct communication with biological systems[2]. Electrical to chemical signal transduction is essential to fully replicate brain functions and establish in future an active interaction with biological tissues[3]. Biohybrid interfaces are emerging since they promise to couple the activity of biological neural cells with neuromorphic artificial devices, enabling sensing and stimulation through two ways communication.
In this context, the conductive polymer mixture PEDOT: PSS can be exploited for the electrochemical detection of electroactive neurotransmitters[4] (i.e. dopamine, norepinephrine, ascorbic acid) through redox reactions while providing a suitable biocompatible interface with cells and neurons[5]. Here, we present the design of a novel electrochemical neuromorphic organic device (ENODe) capable of identifying multiple neurotransmitters simultaneously present. Additionally, through modular microfluidic channels, different flow regimes are regulated in order to replicate the condition of exocytosis displayed by a real synapse. Hence, the platform allows to transduce the neurotransmitters-mediated chemical signal, eliciting an output that is stored and read as a change in the polymer's conductance, a neuromorphic phenomenon that replicates neuronal's short-term and long-term plasticity[6]. Moreover, by exploiting PEDOT:PSS electrochromism, the system's readout is alternatively monitored as a variation of the polymer's transmittance and since this is intimately related to its conductance modulation, a novel dual output system to refine feedback regulation in closed-loop operations is presented. Hence, this platform allows to fully recapitulate synaptic plasticity and being conceivable as a bio-hybrid interface through direct coupling with neural tissues, it promises to move from a mere recording of biological functions to a dynamic interactive control.[7]

Elucidating Microstructure-Dependent Synaptic Plasticity of Ion-Gel Gated Semi-Crystalline Polymer Synaptic Transistors Gyeong-Tak Go[1], Yeongjun Lee[1], Dae-Gyo Seo[1], Mingyuan Pei[2], Wanhee Lee[1], Hoichang Yang[2] and Tae-Woo Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Inha University, Korea (the Republic of)

Organic synaptic transistors using intrinsic organic semiconductors have emerged to overcome the limitation of conventional electronics by demonstrating various synaptic functions. Although organic synaptic transistors have succeeded in mimic biological synapses, especially short-term plasticity, devices emulated only limited long-term plasticity with short retention behaviors. The long-term retention behavior is essential for non-volatile and long-term memory characteristic in neuromorphic computing. Correlating the synaptic responses with the microstructures of polymer semiconductor is a crucial step to achieve long-term retention. The fundamental study on synaptic responses related to microstructures of organic materials has not been discovered yet. Here, we show that the long-term retention in ion-gel gated organic synaptic transistors (IGOSTs) can be achieved by controlling the microstructure of organic semiconductors. We controlled the crystallinity of

poly(3-hexylthiophene-2,5-diyl) (P3HT) in films spun-cast on bare and self-assembled monolayer, before and after thermal treatments. The long-term retention has been significantly prolonged in the IGOSTs, which tends to be elongated as the crystallinity of the semiconductor increased. The microstructure and crystallinity are determined by grazing-incidence X-ray diffraction, optical analyses, and atomic force microscopy. We also evaluate the synaptic current decay behaviors according to a de-doping mechanism of the polymer semiconductor over time. We simulated the recognition of handwritten digits of IGOSTs based on highly-crystalline P3HT, thus achieved higher classification accuracy (>92%) compared with IGOSTs based on low-crystalline P3HT. Our study provides fundamental information about the effects of microstructure on the synaptic responses and strategy to design the IGOSTs for neuromorphic electronics.

Designing Biomimetic Electronic Interfaces Francesca Santoro; Istituto Italiano di Tecnologia, Italy

The interface between biological cells and non-biological materials has profound influences on cellular activities, chronic tissue responses, and ultimately the success of medical implants and bioelectronic devices. The optimal coupling between cells, i.e. neurons, and materials is mainly based on surface interaction, electrical communication and sensing.
In the last years, many efforts have been devoted to the engineering of materials to recapitulate both the environment (i.e. dimensionality, curvature, dinamicity) and the functionalities (i.e. long and short term plasticity) of the neuronal tissue to ensure a better integration of the bioelectronic platform and cells.
On the one hand, here we explore how the transition from planar to pseudo-3D nanopatterned inorganic and organic materials have introduced a new strategy of integrating bioelectronic platforms with biological cells under static and dynamic conditions. Although a spontaneous penetration does not occur, adhesion processes are such that a very intimate contact can be achieved. On the other hand, we investigate how organic semiconductors can be exploited for recapitulating electrical neuronal functions such as long term and short term potentiation. In this way, both the topology and the material functionalities can be exploited for achieving in vitro biohybrid platforms for neuronal network interfacing.

Merging Bio-Sensing and Neuromorphic Computing with Organic Electro Chemical Transistors Fabien Alibart[1,2], Mahdi Ghazal[1], Kamila Janzakova[1], Ankush Kumar[1], Anna Susloparova[1], Sophie Halliez[3], Morvane Colin[3], Luc Buée[3], David Guérin[1], Thomas Dargent[1], Yannick Coffinier[1] and Sébastien Pecqueur[1]; [1]IEMN-CNRS, France; [2]LN2-3IT, Canada; [3]Jean Pierre Aubert Research Center, France

Most of today's strategies to interface biology with electronic hardware are based on layered architectures where the front-end of sensing is optimized separately from the back-end for processing/computing signals. Alternatively, biological systems are capitalizing on distributed architecture where both sensing and computing are mix together and co-optimized. In this talk, we will present our strategy to implement bio-sensing of electroactive cells in a neuromorphic perspective. We will present how organic electrochemical transistors can be used to record electrical signals from neural cells. We will show various strategies capitalizing on the versatility of organic materials synthesis and organic device fabrication to tune and adapt the functionalities of such bio-sensors. We will then present how these strategies can be efficiently used to realize computing functions directly at the interface with biology. Notably, we will illustrate how a network of ionic sensors can implement the reservoir computing concept, a powerful neuromorphic computing approach of particular interest for dynamical signal processing.

Organic Memristive Devices for Learning Mimicking and Interfacing with Nervous Cells Victor Erokhin; IMEM-CNR, Italy

Organic memristive devices contain a heterojunction of conducting polymer and solid electrolyte. Similarly to nervous systems, these elements combine memory and processing functions. Their working principle is based on the significant difference of the polyaniline resistance in reduced and oxidized states [1, 2]. These devices have been successfully applied for the construction of artificial neuron networks at the hardware level [3,4]. The device can be realized on flexible supports

and its properties are similar to synapse behavior, what has allowed realization of electrical circuits, mimicking learning of simple animals (pond snail) [5] and classical conditioning (Pavlov dog learning) according to STDP-like algorithm [6,7]. Its biocompatibility was demonstrated by the realization of hybrid systems, where slim mould Physarum polycephalum was interfaced with organic memristive devices [8].
Long- and short-term potentiation and depression of these devices depends not only on the number of passed pulses, but also on the frequency of their application [9].
Finally, we will consider a first step towards the realization of synapse prosthesis, describing experiments on the coupling of two live nervous cells from the rat cortex via organic memristive device [10]. Nervous cells were contacted by patch clamp electrodes, allowing to avoid artifacts. It has been demonstrated that the plasticity of the device electrical properties is similar to that of chemical synapses in living beings.

6:30 AM F.SM05.04.04
Engineering of Synaptic Plasticity of Ion-Gel Gated Synaptic Transistors for Neuromorphic Computing and Artificial Sensory Nerves Dae-Gyo Seo[1], Yeongjun Lee[1,2], Hoichang Yang[3], Changduk Yang[4], Sang-Woo Kim[5] and Tae-Woo Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Samsung Advanced Institute of Technology, Korea (the Republic of); [3]Inha University, Korea (the Republic of); [4]Ulsan National Institute of Science and Technology, Korea (the Republic of); [5]Sungkyunkwan University, Korea (the Republic of)

Unlike the inorganic neuromorphic electronics which can only implement the long-term plasticity, the organic neuromorphic electronics have paid attention due to promising applications from next-generation computing to neuroprosthetics by implementing not only the long-term potentiation (LTP) but also the short-term potentiation (STP). Recently, conjugated polymers such as poly(3-hexylthiophene-2,5-diyl) (P3HT) with electrolyte dielectrics have been studied to implement high-density computing and memory systems using less energy. Parallelly, diketopyrrolopyrroles (DPPs) based artificial synaptic devices have shown promising applications from neuroprosthetics to soft robotics. However, recently studied organic-based artificial synapses only focused on emulating the single function of the biological counterparts; either memory or signal transitions.
In this study, we introduce the engineering of synaptic properties by modulating morphological characteristics of organics semiconductors (OSCs) with fixed presynaptic spike forms in artificial synaptic devices without changing the OSCs. By achieving this, the relation between the morphology of the film and the synaptic property has been revealed. Changing the morphological property of the OSCs, resulted in the clear transition from STP dominant synaptic property to LTP dominant synaptic properties. Furthermore, artificial neural networks (ANNs) simulation and artificial auditory sensory nervous system were successfully demonstrated. This achievement is an imperative step toward the development of versatile neuromorphic electronics and promising for various neuromorphic electronics applications from neuromorphic computing to neural

prosthetics, bio-interface devices, and soft robotics which can immensely expand the field of neuromorphic electronics by providing an understanding of the mechanisms of synaptic properties.

Scalable, Soft and Stretchable Optoelectronics and Neuromorphic Sensing Architectures in Human-Machine Interfaces Benjamin C. Tee; National University of Singapore, Singapore

Human-machine interfaces will continue to be critical to advance applications in healthcare, robotics and consumer electronics. Having a cross-disciplinary approach to materials innovation, especially with regards to soft materials[1] will effectively address the mechanical constraints when interfacing with humans. In this talk, I will discuss some of the new material platforms we are developing for more robust human-machine interactions, such as self-healing stretchable optoelectronics devices[2]. Such optoelectronic devices might be employed in optogenetic neural interfaces . At the same time, I will also present our efforts in brain inspired scalable neuromorphic architectures for electronic skins[3]. Such system architectures can be broadly applied in various applications with high impact potential for wearables, brain-machine interfaces, prosthetics and robotics.

7:15 AM *F.SM05.04.06
New Materials and Device Concepts for Organic Electrochemical Transistors Jonathan Rivnay; Northwestern University, United States

Organic electrochemical transistors (OECTs) have gained considerable interest for applications in bioelectronics, power electronics, circuits and neuromorphic computing. Their defining characteristic is the bulk-modulation of channel conductance owing to the facile penetration of ions into the (semi)conducting polymeric channel. For this reason, their device scaling relies on film thickness, enabling finer size scale devices, and unique form factors. Despite recent progress and a rapidly expanding library of new materials, the understanding of stability and transport/coupling of ionic and electronic carriers remain largely unexplored. We highlight recent synthetic and processing approaches used to tailor device properties and stability, as well as new opportunities enabled by such advances. We demonstrate how the reliance on bulk transport allows for relaxed fabrication demands and production of simple multi-device circuit concepts for analog signal processing. Finally, by studying the role of additives on charging, trapping, and structural re-arrangement, we can gain insight into the next generation of non-volatile organic mixed conductors for neuromorphic hardware. The implementation of OECT-based sensing and circuits holds particular promise in brain-inspired bioelectronics – the role of materials design and development is critical for their success.

7:45 AM F.SM05.04.07
Cellular Lensing and Near Infrared Fluorescent Nanosensor Arrays for Real-Time Chemical Efflux Cytometry Sooyeon Cho, Xun Gong, Volodymyr Koman and Michael Strano; Massachusetts Institute of Technology, United States

Nanosensor arrays have proven to be powerful tools to measure single biological cells and organisms, achieving spatial and temporal precision even at the single molecule level. However, there has not been a way of extending this approach to statically relevant numbers of living cells and organisms. Herein, we design and fabricate a high throughput nanosensor array in a microfluidic channel that addresses this limitation, creating a Nanosensor Chemical Cytometry (NCC) for the first time. We show that one can utilize the cell itself as a lens and optical element to extract much more information from the nanosensor array on a per cell basis at high throughout. An array of nIR fluorescent single walled carbon nanotube (SWNT) sensors is deposited along a microfluidic channel through which a population of flowing cells is guided. As an example, the array can detect, in real time, the H_2O_2 efflux of monocytes at attomole sensitivity at a rate of 10 cells/min. We show that the cells themselves can function as Gaussian lenses, projecting informative excitation profiles onto the nanosensor array. This

allows for cross-correlation of the cellular diameter, effective refractive index, and eccentricity with chemical efflux and creates a chemical cytometer for the measurement of cellular heterogeneity with unprecedented precision. For example, we study distinct H_2O_2 efflux rates between 330 and 624 atmole/cell per min in cell size ranges of 271 and 263 μm^2, eccentricity values between 0.405 and 0.363 and RI values between 1.383 and 1.377 for pristine and activated monocytes, respectively. Hence, we show that this new nanotechnology based tool has significant potential to answer important questions in cellular immunology, cell manufacturing and biopharmaceutical research.

8:00 AM F.SM05.04.08
3D Nanoarchitecture Materials for Synergistic Electrical/Optical Multimodal Sensing Capability Hyeuk Jin Han[1,2], Seunghee H. Cho[2], Sangjun Han[2], Ji-Soo Jang[2], Gyu Rac Lee[2], Eugene Cho[2], Il Doo Kim[2], Min Seok Jang[2], Harry Tuller[3], Judy Cha[1] and Yeon Sik Jung[2]; [1]Yale University, United States; [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]Massachusetts Institute of Technology, United States

To detect chemical or biological molecules, it is crucial that sensor devices can differentiate various target molecules. However, in general, each sensing methods are geared towards one aspect for sensing while sacrificing others due to their particular limitations. For example, gas sensors based on metal oxide have high sensitivity while having low identification ability. On the other hand, surface-enhanced Raman spectroscopy is a representative label-free and selective detection method that can identify target molecules but often lack quantitative sensing capability, especially for gaseous targets. Herein, we introduce a label-free electrical/optical multimodal sensor based on systematically assembled 3D nanoarchitecture with multifunctional materials for optimizing the structure effect. It combines several sensing modalities and sensing elements via the integration of semiconducting nanowire frameworks and dual-functioning metallic nanoparticles. Our multimodal sensor can successfully estimate the mixed gas compositions selectively and quantitatively in the sub-100 ppm level, even in a mixture of gaseous aromatic compounds with similar molecular structures by providing complementary information. Our approach not only provides the sensitivity but also has the ability to differentiate the target molecules. Potentially, a multimodal sensor could be an application to early diagnosis of many diseases and the rapid detection of toxic chemicals and explosives

Electron Transporting Polymers for Biological Interfacing Sahika Inal; King Abdullah University of Science and Technology (KAUST), Saudi Arabia

Fluidity, mobility, and resistivity are key characteristics of native membranes in our cells where cation channels regulate numerous molecular mechanisms (e.g., the excitation of neurons). Interfacing with biomimetic membranes via electronic devices promises to expand our understanding of the function of these membranes in disease states. The challenge is to form supported lipid bilayer (SLBs) on (semi)conducting films while sustaining high sensitivity and operational stability. In this talk, I will show the traits of n-type organic semiconductors for such biological interfaces. I will show the very first ion channel sensor based on an n-type, accumulation mode, microscale organic electrochemical transistor (OECT), which interfaces an SLB embedded with a pore-forming protein. The polymer is particularly sensitive to divalent cations, endowing the system with biomimetic properties. The side-chain engineering of semiconducting polymers prompts the development of next-generation bioelectronic hybrids where electron-transporting polymers establish bilateral electronic communication with living systems.

5:30 AM *F.SM05.05/F.FL01.06.02
Thin-Film Organic Electrochemical Devices for Applied Neural Control—Capacitive and Faradaic Effects Eric Glowacki; Linkoping University, Sweden

A great demand exists for minimally-invasive neuromodulation technologies to enable next-generation bioelectronic medicine. We report on our developments of ultrathin organic (opto)electronic devices for neurostimulation. All of these

devices rely on far red/near infrared irradiation in the tissue transparency window to actuate nanoscale organic semiconductor components. Our flagship technology is the organic electrolytic photocapacitor (OEPC) – a device that mimics biphasic current-pulse neurostimulation and thus transduces an optical signal into directly-evoked action potentials in neurons. These devices are not only wireless, but also 100-1000 times thinner than most existing technologies. We will discuss chronic implants capable of stimulating peripheral nerves (sciatic and vagus) when actuated from outside of the body using diode lasers. We have observed stable operation in rodent models for at least 100 days. As a different approach, we will report on favorable harnessing of DC electrochemistry effects, normally considered spurious and undesired. Specifically, we show how electrochemical generation of low doses of hydrogen peroxide can be used to reversibly stimulate M-type potassium channels, providing a novel method of controlling neural excitability.

6:00 AM F.SM05.05/F.FL01.06.03
Enhancement-Mode Ion-Based Transistors for *In Vivo* Electrophysiology and Real-Time Data Processing Claudia Cea, Georgios Spyropoulos, Jennifer Gelinas and Dion Khodagholy; Columbia University, United States

Bioelectronic devices must have high speed and high performance to interact with the often rapid, low amplitude signals generated by neural tissue. They should also be capable of forming complementary logic and analog circuits to allow acquisition, processing and manipulation of a biological environment. However, the lack of readily available p-type polymers for use in enhancement mode transistors and their complicated synthesis significantly limits the investigation and application of such devices in bioelectronics. Here, we develop an enhancement mode ion-gated transistor (e-IGT) that functions based on a reversible redox reaction and hydrated ion reservoirs within the conducting polymer channel to enable long-term stable operation and shortened ion transit time. We combined a highly conductive poly(3, 4-ethylenedioxythiophene) doped with polystyrene sulfonate (PEDOT:PSS) and a reducing agent polyethylenimine (PEI) to enable doping of the polymer in an aqueous environment. The transistor operates as following: (1) the protonated PEI bonds with the PSS- and de-dopes the PEDOT:PSS chain resulting in an initial off-state of the transistor, (2) a subsequent application of negative gate voltage dopes the PEDOT:PSS switching the channel on. To determine an optimal transistor configuration and material composition, we microfabricated transistor arrays of varying geometrical parameters. The high-transconductance and high-speed of the e-IGTs resulted in a gain bandwidth product that is several orders of magnitude above other ion-based transistors. We used these transistors to acquire a wide range of electrophysiological signals, including in vivo recording of neural action potentials. Furthermore, we combined E-IGTs with d-IGTs to create a real-time non-linear rectifier to accurately detect epileptic discharges in vivo. In conclusion, E-IGTs offer a safe, reliable, and high performance building block for chronically implanted bioelectronics, with spatiotemporal resolution to the scale of individual neurons.

Organic Electrochemical Transistors Based on Electropolymerized Dendritic Structures Kamila Janzakova[1], Mahdi Ghazal[1], Ankush Kumar[1], Yannick Coffinier[1], David Guérin[1], Sébastien Pecqueur[1] and Fabien Alibart[1,2]; [1]University of Lille, France; [2]Laboratoire Nanotechnologies & Nanosystèmes (LN2), Canada

One of the neuromorphic engineering aims is using nanoelectronics' materials and devices to reproduce key features that are used by the brain for computing. Currently, neuromorphic engineering has explored standard silicon-based technologies (i.e. such as complementary metal–oxide–semiconductor) or more emerging material and devices (iono-electronic materials and resistive memory devices, for example). Most of these technologies are still bounded to a top down approach. However, brain computing largely rely on bottom-up processes. For instance, interconnectivity between cells and formation of communication pathway in neural networks result principaly from bottom-up organization. Here, we show how dendritic growth of organic conductive polymers (PEDOT) can be used to mimic structural branching observed in neural network. Conducting-polymer based dendritic structures with different morphology are synthesized in a two-electrode setup by pulsed voltage-driven electropolymerization derived from state-of-the-art bipolar AC-electrochemical synthetic methods. We show how various AC signals can lead to a large variety of dendritic structures and PEDOT morphologies. In a second part, such dendritic structures are used to implement functionnal OECTs. More importantly, we focus on the transconductance and memory effects that can be obtained in such dendritic OECTs such as short tem plasticity. We report on the relationship between dendrites morphologies and STP time constant.
This work paves the way to new approaches for neuromorphic engineering, such as structural plasticity and neural network topology exploration.

Forming Input/Output (i/o) Interfaces with Excitable Cells And Tissue Using Nanocarbons Tzahi Cohen-Karni; Carnegie Mellon University, United States

We focus on developing a new class of nanoscale materials and novel strategies for the investigation of biological entities at multiple length scales, from the molecular level to complex cellular networks. Our highly flexible bottom-up nanomaterials synthesis capabilities allow us to form unique hybrid-nanomaterials that can be used in various input/output bioelectrical interfaces. For example, we have developed several bioelectrical platforms based on graphene, a two-dimensional (2D) atomically thin carbon allotrope. We have demonstrated recording of the electrical activity of excitable cells with graphene-based ultra-microelectrodes as small as the size as an axon ca. 2μm in size. Using graphene-based hybrid-nanomaterials, we have formed remote, non-genetic bioelectrical interfaces with excitable cells and modulated cellular and network activity with high precision and low needed power. We have also developed a breakthrough bioelectrical interface, a 3D self-rolled biosensor arrays (3D-SR-BAs) of either active field effect transistors or passive microelectrodes to measure both cardiac and neural spheroids electrophysiology in 3D. Our approach enables electrophysiological investigation and monitoring of the complex signal transduction in 3D cellular assemblies toward an organ-on-an-electronic-chip (organ-on-e-chip) platform for tissue maturation investigations and development of drugs for disease treatment. In summary, the exceptional synthetic control and flexible assembly of nanomaterials provide powerful tools for fundamental studies and applications in life science and open up the potential to seamlessly merge either nanomaterials-based platforms or unique nanosensor geometries and topologies with cells, fusing nonliving and living systems together.

7:00 AM *F.SM05.05/F.FL01.06.06
High-Resolution Bioelectronic Interfaces Enabled by Nanoscale Soft Conductors Flavia Vitale; University of Pennsylvania, United States

The rapid rise of bioelectronics has enabled a number of innovative approaches to treat neurological disorders, restore and repair lost functions, and modulate neural circuitry to control mood and behavior. The vast majority of bioelectronic interfaces, however, still rely on traditional noble metal and silicon materials, which are expensive to source and process and are intrinsically inadequate to address the mechanical, chemical, and electrical properties of excitable circuits in the body. To establish bioelectronic technologies as the clinical standard, significant innovations in materials and fabrication strategies are still required to achieve safety, softness, biocompatibility, and long-term stability. Nanostructured materials are uniquely positioned to address these challenges because they combine high electrical conductivity with intrinsically high mass-specific surface area and mechanical flexibility. Furthermore, they can interact with biological systems on a molecular scale and can be easily integrated within scalable solution-based processing, thus allowing easy modulation of their electronic and optical properties.
In this talk I will present the ongoing work in my lab to leverage the unique properties of nanostructured materials and engineer novel bioelectronic interfaces for sensing and stimulating neural and neuromuscular circuits. Specifically, I will describe the fundamental electronic, electrochemical, and mechanical properties of 2D transition metal carbides nanomaterials (a.k.a. MXenes) and how these translate into significant impedance and noise reduction when MXenes are integrated bioelectronic interfaces. Then, I will present *ad hoc,* scalable, rapid manufacturing processes developed in my lab to translate the exceptional material properties at the molecular scale into high-resolution, low impedance bioelectronic interfaces that are also compatible with clinical neuroimaging modalities, such a magnetic resonance imaging (MRI) and computerized tomography (CT). Finally, to illustrate the potential of MXene-based bioelectronics, I will present different example of applications in both implantable and wearable interfaces.

7:30 AM F.SM05.05/F.FL01.06.07
Late News: Spatiotemporal Response of Organic Electrochemical Transistors Dimitrios Koutsouras[1], Morteza Hassanpour Amiri[1], Katharina Lieberth[1], Kamal Asadi[1], Fabrizio Torricelli[2], Paul W. Blom[1] and Paschalis Gkoupidenis[1]; [1]Max Planck Institute for Polymer Research, Germany; [2]University of Brescia, Italy

Organic electrochemical transistors (OECTs) have recently attracted tremendous attention in the scientific community due to their unique set of features. Especially, the lack of an insulating layer that separates gate from channel, like in conventional field effect transistors, and their feature to support electrolyte gating open new pathways in the field of bioelectronics. In particular, they render the device ideal for measurements in the aqueous environments that dominate the biological world. Additionally, they provide extra possibilities in terms of the device architecture as the gating electrode can be patterned on the same plane as the conducting channel. In a set up like that, what is of extreme interest is the effect of the gate position with respect to the channel. In this work, the spatiotemporal response of a poly(3,4 ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) OECT is examined and its device physics is studied. This work opens new routes for exploiting the physics of multi terminal OECT devices in bioelectronics, sensing and neuromorphic electronics.

F.SM05.06.03
Mood Identification by Facial Subtle Movement Analysis Fan Yang[1], Jordan Saadon[1], Ryan Burgert[1], Selma Mohammad[1], Miriam H. Rafailovich[1], Charles Mikell[1], Sima Mofakham[1], Wade Boohar[2], Sophia Cai[3] and Amisha Agrawal[4]; [1]Stony Brook University, United States; [2]Olathe North High School, United States; [3]Barrington High School, United States; [4]University High School, United States

Research into mood and emotion has often been dependent on self-report, highlighting the need for a more objective measure of mood state. However, until recently, it has been nearly impossible for machines to match the speed and accuracy of the average person in interpreting faces. In this study, we used digital image speckle correlation (DISC), a technique which was originally used to study the mechanical properties of materials by tracking their deformations, to assess an individual's mood state based on the analysis of facial microexpressions. Ten healthy volunteers were shown a set of ten happy and ten sad images while being videotaped. Upon measuring facial movements in response to happy and sad images, we conducted detailed Shannon entropy and Principal Component Analysis (PCA) to identify facial maps for different mood states. Within and across subjects, happy and sad images elicited spatially distinct changes in facial expression. PCA and entropy calculations on facial movement reliably distinguished the subject's underlying mood. Furthermore, we characterized key changes in facial expression which reliably signal changes in mood state across all individuals. DISC-based analysis of the face was capable of determining an individual's mood with high specificity across multiple test subjects, suggesting that automated camera-based methods may be both robust and economical in clinical monitoring settings. It also showed promising potentials in brain study together with electroencephalogram as subtle facial movements were also found in epilepsy and comatose patients using DISC.

Converged Biofabrication Technologies for the Generation of Osteochondral Implants with Long-Term Functionality Jos Malda[1,2]; [1]UMC Utrecht, Netherlands; [2]Utrecht University, Netherlands

A major challenge in the application of regenerative medicine strategies is the replication of the complexity and functionality of living tissues. Biofabrication techniques, such as inkjet, extrusion, or light-assisted printing, can result in living structures that further replicate the 3D architecture and organization of native tissue. Recent developments have resulted in the availability of a plethora of bioinks, new printing approaches, and the technological advancement of established techniques However, it remains largely unknown which materials and technical parameters are essential for the fabrication of intrinsically hierarchical cell-material constructs that truly mimic biological function of tissues. Moreover, it is unlikely that any of these technologies used individually would be able to replicate this complexity and functionality. Hence, we previously urged the field to shift its focus from materials and technologies toward the biological development of the resulting constructs.
This is illustrated by an example from the field of orthopaedics, in particular the treatment of osteochondral defects in a large (equine) animal model. Driven by the observations that the collagen structure provides articular cartilage with its extraordinary mechanical properties and that this structure does not recover once damaged, we evaluated the performance of a biofabricated composite osteochondral implant designed to provide long-term mechanical resistance, comparing implants cell-seeded with cell-free implants. The implants were composed of a gelatin methacryloyl cartilage phase, reinforced with precisely patterned melt electro-written polycaprolactone micrometer-scale fibers and displaying a zonal, cartilage-mimetic architecture. This structure was firmly integrated with a room temperature-setting calcium phosphate cement-based bone anchor via a converged melt electrowriting-extrusion-based printing approach. Cell-containing implants were pre-cultured in vitro and samples were then implanted orthotopically in ponies for 6 months. The reinforcement of the cartilage phase enhanced both the compressive and shear properties of the implants considerably, closer to native values than achieved before.
Abundant deposition of glycosaminoglycan- and type II collagen-rich tissue was observed in vitro, which was maintained during the 6-month in vivo implantation period, showing that the composite architecture, comprising multi-scale printing of hydrogel, microfibers and ceramic materials had provided the required mechanical stability and integration of the implant within the subchondral bone to allow survival of the implant in the mechanically challenging environment of the equine knee joint over an extensive period of time while retaining its mechanical characteristics. Our findings underscore the hypothesis that the mechanical stability is more determining for the success of the implant than the presence of cells. This observation is of great translational importance and highlights the aptness of advanced (bio)fabrication and 3D printing technologies for functional tissue restoration in the harsh articular environment.

2:15 PM *F.SM06.03.01
Strategies to Engineer a Functional Kidney Proximal Tubule Rosalinde Masereeuw; University of Utrecht, Netherlands

In patients with severe kidney disease, renal clearance is compromised resulting in the accumulation of a plethora of endogenous waste molecules that cannot be removed by current dialysis techniques, the most often applied treatment. These uremic retention solutes, also named uremic toxins, are a heterogeneous group of organic compounds of which many are too large to be filtered and/or are protein-bound. Their renal excretion depends largely on renal tubular secretion by which the binding is shifted towards the free fraction that can be eliminated. To facilitate this process, kidney proximal tubule cells are equipped with a range of transport proteins that cooperate in cellular uptake and urinary excretion. In recent years, we and others have invested in the development of bioengineered kidney tubules that could potentially restore this essential function. For this, well characterized human kidney proximal tubule cells were combined with functionalized, living membranes. This presentation addresses these developments in the context of functional kidney tubule engineering. Furthermore, hurdles to take before a safe implementation of bioengineered kidneys in clinics becomes a realistic option will be discussed.

2:45 PM *F.SM06.01.01
Biomaterials for the Early Detection and Treatment of Disease Joyce Y. Wong; Boston University, United States

To engineer and build tissues, one requires an understanding of key relationships between cell behavior and the underlying substrate. In native tissues, extracellular matrix proteins are in the form of fibrous networks, sheets, and fibers. Our laboratory has been developing methods to form extracellular matrix fiber alloys and cell sheets. Over the past few years, we

have been investigating the role of composition and processing conditions of various extracellular matrix fibers and alloy fibers on mechanical properties and biological properties. These fibers are also critical components of tissues such as blood vessels. We have also determined the role of mechanical strain on binding of different antibodies and peptide-functionalized contrast agents to these fibers. Importantly, we discovered that composition can be tuned to stabilize extracellular matrix proteins in fiber forms, which is especially useful with compositions where it is difficult to process the proteins into fibers. Through an integrated computational and experimental approach, we have discovered relationships between hydrophobicity and protein fiber forming capability and stability. Moreover, we have verified that the protein alloy fibers support cell adhesion and allow one to tune the mechanical properties of the fiber. This is of significance as the mechanical properties of the substrate play an important role in modulating cell behavior, e.g. cell migration and proliferation. We have also developed several methods to generate a layered tissue patch that mimics the cellular organization of native vessels and a bioMEMS device that can be used to assess physiological function of these tissue-engineered constructs with patient data input.

3:15 PM *F.SM06.03.03
Engineering the Microenvironment That will Enable a Long-Term Bioprosthetic Ovary Transplant Monica M. Laronda[1,2]; [1]Ann and Robert H. Lurie Children's Hospital of Chicago, United States; [2]Northwestern University, United States

The ovaries contain a finite resource of potential eggs and sex hormone-producing cells, and therefore, life-saving cancer treatments that irradiate or chemically induce cell death within the ovaries will likely result in premature ovarian insufficiency (POI) with reduced ovarian hormones and infertility. The option to have biological children, is a key quality of life measure for cancer survivors. Women with POI will experience co-morbidities associated with loss of ovarian hormones and a shorter life expectancy. The only method for fertility preservation for pediatric patients, who do not yet make eggs, is ovarian tissue cryopreservation (OTC). This tissue can then be transplanted back to restore fertility and hormone function. However, only 20 – 30% of transplants result in livebirth and it produces an average of 2 – 5 years of hormone restoration, leaving many without biological children and decades of post-cancer survival without essential hormone production. One major contributor to the shortened function of transplanted ovarian tissue is the significant spike in activation of the ovarian reserve (primordial follicles, containing the oocytes and hormone-producing cells) and subsequent depletion, at least in part, due to the disruption in the microenvironment. Additionally, some patients have metastatic disease within the ovary and therefore cannot use that tissue in its current form. Therefore, a safe, long-term solution for fertility and hormone restoration would involve isolating the ovarian cells that are essential for function from potential cancer cells and housing them in a microenvironment that maintains the bank of potential eggs and prolongs hormone production. We have defined the architectures of a 3D printed scaffold that support the necessary cell-cell contacts between the oocyte and the surrounding hormone producing support cells. This bioprosthetic ovary of the 3D printed gelatin scaffold with isolated ovarian follicles restored fertility and hormone function and supported livebirths and rearing of offspring in mice. To advance this research through the next steps toward translation to the clinic, we must define the follicular microenvironment that will enable a regulated recruitment of eggs from the ovarian reserve and support a safe, effective and long-term transplant. We have mapped the matrisome composition across the ovarian compartments and the stiffness of tissue components in ovaries of large mammals. Our novel proteomics screen and analysis has enabled us to identify new matrisome proteins within the ovary and pinpoint proteins of interest that may control primordial follicle activation or quiescence. We have additionally defined the physical properties of the ovarian compartments, where the cortical (outer) region is denser and stiffer than the medullary (inner) region. We have developed decellularized ovary extracellular matrix inks and are investigating the roles of specific biochemical and physical cues on primordial follicle quiescence and activation. A bioprosthetic ovary, defined by these microenvironment properties, would improve current options for fertility and hormone restoration for women.

3:30 PM *F.SM06.02.03
Using Chaotic Advection for Facile High-Throughput Fabrication of Ordered Multilayer Micro- and Nanostructures—Continuous Chaotic Printing Grissel Trujillo de Santiago, Edna Johana Bolívar-Monsalve, Carlos Ceballos-González, Carolina Chávez-Madero, Mohamadmahdi Samandari, Diego Armando Sandoval Salaiza, Yu Shrike Zhang and Mario M. Alvarez; Tecnológico de Monterrey, Mexico

Today, tissue engineering evolves exponentially and provides real solutions to create biological models and solve clinical problems. However, we still face challenges that hinder its full potential to generate complex and large-size tissues and organs. Here we present advances in chaotic bioprinting, an additive manufacturing technique that enables the creation of complex biological structures at an unprecedented level of resolution and throughput.
Continuous chaotic printing uses chaotic advection for deterministic and continuous extrusion of fibers with internal multilayered structures. Two free-flowing materials are coextruded through a printhead containing a miniaturized Kenics static mixer (KSM) composed of multiple helicoidal elements. This produces a fiber with a well-defined internal multilayer

microarchitecture at high-throughput (>1.0 m min^{-1}). The number of mixing elements and the printhead diameter determine the number and thickness of the internal lamellae, which are generated according to successive bifurcations that yield a vast amount of inter-material surface area (~10^2 cm^2 cm^{-3}) at high resolution (~10 μm). This creates a new opportunity to produce structures with extremely high surface area to volume (SAV). Comparison of experimental and computational results demonstrates that continuous chaotic 3D printing is a robust process with predictable output. The simplicity and high resolution of continuous chaotic printing strongly supports its potential use in novel applications.
Here, we illustrate the application of continuous chaotic bioprinting into the fabrication of complex multi-layered bacterial microcosmoi. We demonstrate that the degree of resolution achieved within these constructs can be finely controlled up to the range of a few microns of separation between layers and that the degree of interface between bacterial layers greatly matters for competition.
We also demonstrate the application of tissue-like structures in which living layers of muscle cells evolve into a coherent segment of muscle. Lumina can be easily built into these constructs by using a combination of sacrificial and permanent inks and a multi-port modification to the chaotic printhead.
We are currently exploring more applications of chaotic printing into tissue engineering such as the fabrication of vascularized cancer models, and multi-cell type tissue-like architectures where distinctive mammalian cell layers share a high amount of common interface.
Different fields, outside biosciences and technologies, are also in pursuit of simple and robust ways to create multilayered and multi-material structures to attain functionalities that monolithic materials do not exhibit. We envision that chaotic printing may be applied to technological scenarios such as the fabrication of batteries, superconductors, super catalytic surfaces, and 3D microfluidic reactors.

5:15 PM *F.SM06.04.01
Growth, Characterization and Application of Self-Organized Microvascular Networks for Models of Disease Roger Kamm; Massachusetts Institute of Technology, United States

Methods now exist to create single- or multi-organ engineered living systems that can be used to model a variety of disease processes. Aside from providing new insights into disease mechanisms, these systems can also be used to screen new drugs to treat the disease, or even to identify different therapeutic strategies for sub-populations possessing different genetic profiles. Here we present several models that require a microvascular network, modeling different stages of metastatic cancer. In one set of studies, circulating tumor cells are introduced via side channels into the microvascular bed, where they arrest, become activated and undergo transendothelial migration. Model systems include the brain, muscle, placenta and bone marrow, each showing distinctive characteristics. These or others can be used to model drug delivery to a developing tumor, either primary or metastatic.
Microfluidic devices used in these studies are, for the most part, simple, single layer systems that can be cast in a single piece of PDMS, forming channels and gel compartments by bonding to a coverslip. Alternatively, systems can be injection molded in tissue culture plastics. Microphysiological systems MPS) can be ether ‘engineered’ or self-organize using the same capabilities of developing organisms. Our approach is to rely, as much as possible, on the innate capabilities of the cells to interact to form the structures of a particular organ. Cells or cell assemblies/organoids are mixed in hydrogel solution and injected into one or more adjacent compartments allowing for direct signaling or physical contact between the multiple different cell types. Many of these systems contain microvascular networks that can be perfused via side channels, with pumping by simple low-pressure diaphragm pumps, directly connected to the MPS to minimize media volumes. The role of circulating immune cells can also be studied, as these, too, arrest in the vascular beds and extravasate into the surrounding gel matrix.
Results will be shown first demonstrating the form and function of the microvascular beds. Then several examples will be taken from the systems mentioned above to illustrate different applications, and to demonstrate the flexibility of the underlying platform. Future directions will be discussed including the challenges ahead in generating perfusable organoids.

5:45 PM *F.SM06.03.02

Stem Cell-Derived Models to Study Human Neural System Development Jianping Fu; University of Michigan-Ann Arbor, United States

Neurulation is a key developmental process that gives rise to the neural tube (NT), the precursor structure of the central nervous system (CNS). Neurulation is initiated after the gastrulation by a neural induction process, during which the dorsal ectoderm is specified into a patterned tissue containing the neural plate (NP) and the non-neural ectoderm (NNE) separated by the neural plate border (NPB). After neural induction, the NP folds and fuses to form the tubular NT. The development of the NT continues with differentiation of distinct classes of neuronal progenitor cells located at defined positions within the NT along both the anterior-posterior (AP) and dorsal-ventral (DV) axes. In this talk, I will discuss the recent research activities in my group to leverage the developmental potential and self-organization property of human pluripotent stem cells (hPSCs) in conjunction with 2D and 3D bioengineering tools to achieve the development of spatially patterned multicellular tissues that mimic certain aspects of early human neurulation process, including neural induction, AP and DV patterning of the NT. These stem cell-derived models offer promising trackable systems to study neural development and disease.

6:15 PM *F.SM06.01.02
Bioelectronic Devices and Materials for Engineered, 3D Hybrid Tissues Brian Timko; Tufts University, United States

Hybrid bioelectronic systems offer unique advantages to achieve two-way electronic communication with living cells and tissues. Bioelectronic devices are readily multiplexed and form seamless, stable interfaces with surrounding cells and tissues, representing a distinct advantage over conventional systems such as patch clamp and optical dyes. First, we will present an overview of our recent heart-on-a-chip platform which integrated both extra- and intracellular devices for monitoring cardiac electrophysiology during episodes of acute hypoxia. This system allowed us to monitor not only cell-cell communication (e.g., wavefront propagation) but also action potentials at several spatially-distinct regions simultaneously. Next, we will discuss prospects for flexible bioelectronic scaffolds for achieving hybrid, 3D cardiac or brain systems. We developed a Photo-crosslinkable Silk Fibroin (PSF) derivative which was compatible with conventional photolithography processes and enabled flexible scaffolds with well-defined geometries and cm-scale uniformity. Our freestanding PSF-based scaffolds supported bioelectronic devices, provided excellent electrical passivation, and adhered both cardiac and neuron model cells. Finally, we will discuss recent work to develop stimulation elements for spatially-selective neural activation. Taken together, these research directions open new avenues for engineered, bioelectronics-innervated cardiac and brain systems. We will discuss prospects for merging our bioelectronic devices with state-of-the-art tissue engineering techniques.

6:30 PM *F.SM06.02.02
Extracellular Matrix-Derived Printable Biomaterials for Engineering Human Tissues Jinah Jang; Pohang University of Science and Technology, Korea (the Republic of)

The recent development of bioengineering enables to create human tissues by integrating various native microenvironments, including tissue-specific cells, biochemical and biophysical cues. A significant transition of 3D bioprinting technology into the biomedical field helps to improve the function of engineered tissues by recapitulating physiologically relevant geometry, complexity, and vascular network. Bioinks, used as printable biomaterials, facilitate dispensing of cells through a dispenser as well as support their viability and function by providing engineered extracellular matrix. The successful construction of functional human tissues requires accurate environments that are able to mimic the biochemical and biophysical properties of the target tissue. This talk will cover my research interests in building 3D human tissues and organs to understand, diagnose, and treat various intractable diseases, particularly for cardiovascular diseases and diebetes. A development of tissue-derived decellularized extracellular matrix bioink will be mainly discussed as a straightforward strategy to provide biological and biophysical phenomena into engineered tissues. I will also discuss the development of a 3D vascularized stem cell patch that is generated by integrating the concept of tissue engineering and the developed platform technologies. Combined with recent advances in human pluripotent stem cell technologies, printed human tissues could serve as an enabling platform for studying complex physiology in tissue and organ contexts of individuals.

7:00 PM *F.SM06.04.02
Microfluidic Organs-on-Chips Yuanjin Zhao; Southeast University, China

In biological research, the interaction of biomolecules, cells and materials is an eternal topic. Many technologies have been employed to construct three-dimensional micro-and nano- hierarchical structure of materials. However, it is still a challenge to combine the artificially controllable biomaterials and the complicated biomolecular interaction/cell living unit, and thus to realize the regulation and control of the cell culture by using these materials. Moreover, it is necessary to develop a biotechnology for cell research to real-time and accurately monitor the interaction of the biomolecules/cells and the

biomaterials, which could effectively reveal the biological mechanism of the cell behavior. In this point, we proposed to generate the desired functional materials by using microfluidic methods. Based on this technology, we have created a series of novel biomaterials, which showed demonstrated values in cells culture and organs-on-chips construction.

5:30 AM F.SM06.01.03
"All Electric" Ion Pumps as Artificial Cell Membranes Gideon Segev[1], Rylan J. Kautz[2], Shane Ardo[2,2,2], David Larson[3,3], Joel W. Ager[3,3,4] and Francesca Maria Toma[3,3]; [1]Tel Aviv University, Israel; [2]University of California, Irvine, United States; [3]Lawrence Berkeley National Laboratory, United States; [4]University of California, Berkeley, United States

Ion pumps are devices that use external power to introduce a net ionic flux. For example, in the photosynthetic process, light is used to pump protons up a concentration gradient which will be used in sequential steps to generate fuels. Although every cell membrane is essentially an ion pump, an artificial ion pump that can operate in steady state with no associated redox reactions is yet to be demonstrated. In this contribution we report a first of its kind "all electric", ion pump based on a ratcheting mechanism.

Electronic ratchets are devices that utilize modulation in a spatially varying electric field to drive steady state current. Similar to peristaltic pumps, where the pump mechanism is not in direct contact with the pumped fluid, electronic ratchets induce net ionic current with no direct charge transport between the power source and the pumped charge carriers. Thus, electronic ratchets can be used to pump ions in steady state with no electrochemical reactions between the power source and the pumped ions resulting in an "all electric" ion pump.
Porous capacitor based ion pumps were fabricated by coating the two surfaces of nano-porous alumina wafers with gold. The electric field within the nano-pores is modulated by oscillating the capacitors voltage. Thus, when immersed in solution, ions within the pores experience a modulating electric field resulting in ratchet based ion pumping. The device pumping performance was studied both theoretically and experimentally for various input signals, geometries and solutions. It is shown that different ions can be pumped selectively by tuning the input signal frequency.

Label-Free Monitoring and Manipulation of Microfluidic Water-in-Oil Droplets Christoph Frey[1,2], Jonas Pfeil[3], Tobias Neckernuss[3], Daniel Geiger[3], Klaus Weishaupt[1,2], Ilia Platzman[1,2], Othmar Marti[3] and Joachim Spatz[1,2,4]; [1]Max Planck Institute for Medical Research, Germany; [2]University of Heidelberg, Germany; [3]University of Ulm, Germany; [4]Max Planck School Matter to Life, Germany

The advantages of droplet-based microfluidics are evident: multiple lab functions can be integrated on a single chip, sample consumption is minimal and objects like cells can be studied in an isolated environment, thus offering high precision at high throughput. A key point for end-user applications is the availability of powerful but easy-to-implement methods for real-time analysis and automatized manipulation of the droplets. We developed an optical device, consisting of a fast camera with an integrated data processing unit that uses smart algorithms for label-free real-time monitoring and active manipulation of passing droplets. The device continuously analyzes up to 10000 frames per second in real-time. In bright-field images parameters like size, brightness, granularity, circumference and speed of the droplets and their content are analyzed and can be used to manipulate the passing droplets based on their properties. We demonstrate the capabilities of our device by measuring different droplet production parameters and the label-free detection of cells encapsulated in droplets. Furthermore, we performed field-mediated, label-free sorting of cell containing droplets from empty droplets. Therefore, peripheral electronics consisting of a function generator and high-voltage amplifier that are connected to a sorting electrode are controlled by our device. Decision making is based on predefined parameter ranges that are compared to the measurement results of the droplets right before the sorting gate. Similarly, in another experiment we demonstrate efficient separation of droplets of different size. We envision that our novel device will be a useful tool for the online monitoring of passing droplets, enhancing the possibilities and dissemination of label-free methods for screening and manipulation in lab-on-a-chip systems.

5:50 AM F.SM06.01.06
PEDOT:Hyaluronic Acid and Collagen-Based Scaffolds for Electroactive Monitoring of Cellular Processes Janire Saez[1], Antonio Dominguez-Alfaro[2,3], David Mecerreyes[3,4] and Roisin Owens[1]; [1]University of Cambridge, United Kingdom; [2]CIC biomaGUNE, Spain; [3]POLYMAT Research Centre, Spain; [4]IKERBASQUE, Spain

3D cell cultures to create biomimetic environments are finding numerous applications in drug discovery, regenerative medicine, and cancer research, among many other fields. 3D cultures often rely on scaffolds, typically made of polymeric and biopolymeric materials, which support cell attachment and favour tissue development. These scaffolds possess certain structural and mechanical properties, such as porosity and stiffness, that mimic the extracellular matrix providing a similar microenvironment to that found in vivo. However, these scaffolds are typically passive, merely providing a templated support. We have been focusing on electroactive scaffolds capable of electrically monitoring cellular processes (eg. cell growth, migration) by following a synthetic biology approach. Porous conducting polymer scaffolds made of PEDOT (poly(3,4-ethylenedioxythiophene): HA (Hyaluronic acid) and/or collagen dispersions were obtained by the freeze-drying method, fine-tuning the chemicophysical and mechanical properties of the scaffold to render the system suitable for a variety of biological applications. We demonstrate that these scaffolds, apart from being a cell growth support, are capable of electrically monitoring cell growth. Current work is focusing on understanding the role of cancer cell migration through the scaffolds, in addition to the typical mechanical and biochemical cues present in 3D scaffolds.

Converged Biofabrication Technologies for the Generation of Osteochondral Implants with Long-Term Functionality Jos Malda[1,2]; [1]UMC Utrecht, Netherlands; [2]Utrecht University, Netherlands

A major challenge in the application of regenerative medicine strategies is the replication of the complexity and functionality of living tissues. Biofabrication techniques, such as inkjet, extrusion, or light-assisted printing, can result in living structures that further replicate the 3D architecture and organization of native tissue. Recent developments have resulted in the availability of a plethora of bioinks, new printing approaches, and the technological advancement of established techniques However, it remains largely unknown which materials and technical parameters are essential for the fabrication of intrinsically hierarchical cell-material constructs that truly mimic biological function of tissues. Moreover, it is unlikely that any of these technologies used individually would be able to replicate this complexity and functionality. Hence, we previously urged the field to shift its focus from materials and technologies toward the biological development of the resulting constructs.
This is illustrated by an example from the field of orthopaedics, in particular the treatment of osteochondral defects in a large (equine) animal model. Driven by the observations that the collagen structure provides articular cartilage with its extraordinary mechanical properties and that this structure does not recover once damaged, we evaluated the performance of a biofabricated composite osteochondral implant designed to provide long-term mechanical resistance, comparing implants cell-seeded with cell-free implants. The implants were composed of a gelatin methacryloyl cartilage phase, reinforced with precisely patterned melt electro-written polycaprolactone micrometer-scale fibers and displaying a zonal, cartilage-mimetic architecture. This structure was firmly integrated with a room temperature-setting calcium phosphate cement-based bone anchor via a converged melt electrowriting-extrusion-based printing approach. Cell-containing implants were pre-cultured in vitro and samples were then implanted orthotopically in ponies for 6 months. The reinforcement of the cartilage phase enhanced both the compressive and shear properties of the implants considerably, closer to native values than achieved before.
Abundant deposition of glycosaminoglycan- and type II collagen-rich tissue was observed in vitro, which was maintained during the 6-month in vivo implantation period, showing that the composite architecture, comprising multi-scale printing of hydrogel, microfibers and ceramic materials had provided the required mechanical stability and integration of the implant within the subchondral bone to allow survival of the implant in the mechanically challenging environment of the equine knee joint over an extensive period of time while retaining its mechanical characteristics. Our findings underscore the hypothesis that the mechanical stability is more determining for the success of the implant than the presence of cells. This observation is of great translational importance and highlights the aptness of advanced (bio)fabrication and 3D printing technologies for functional tissue restoration in the harsh articular environment.

Extracellular Matrix-Derived Printable Biomaterials for Engineering Human Tissues Jinah Jang; Pohang University of Science and Technology, Korea (the Republic of)

The recent development of bioengineering enables to create human tissues by integrating various native microenvironments, including tissue-specific cells, biochemical and biophysical cues. A significant transition of 3D bioprinting technology into the biomedical field helps to improve the function of engineered tissues by recapitulating physiologically relevant geometry, complexity, and vascular network. Bioinks, used as printable biomaterials, facilitate dispensing of cells through a dispenser as well as support their viability and function by providing engineered extracellular matrix. The successful construction of functional human tissues requires accurate environments that are able to mimic the biochemical and biophysical properties of the target tissue. This talk will cover my research interests in building 3D human tissues and organs to understand, diagnose, and treat various intractable diseases, particularly for cardiovascular diseases and diebetes. A development of tissue-derived decellularized extracellular matrix bioink will be mainly discussed as a straightforward strategy to provide biological and biophysical phenomena into engineered tissues. I will also discuss the development of a 3D vascularized stem cell patch that is generated by integrating the concept of tissue engineering and the developed platform technologies. Combined with recent advances in human pluripotent stem cell technologies, printed human tissues could serve as an enabling platform for studying complex physiology in tissue and organ contexts of individuals.

Using Chaotic Advection for Facile High-Throughput Fabrication of Ordered Multilayer Micro- and Nanostructures—Continuous Chaotic Printing Grissel Trujillo de Santiago, Edna Johana Bolívar-Monsalve, Carlos Ceballos-González, Carolina Chávez-Madero, Mohamadmahdi Samandari, Diego Armando Sandoval Salaiza, Yu Shrike

Zhang and Mario M. Alvarez; Tecnológico de Monterrey, Mexico

Today, tissue engineering evolves exponentially and provides real solutions to create biological models and solve clinical problems. However, we still face challenges that hinder its full potential to generate complex and large-size tissues and organs. Here we present advances in chaotic bioprinting, an additive manufacturing technique that enables the creation of complex biological structures at an unprecedented level of resolution and throughput.
Continuous chaotic printing uses chaotic advection for deterministic and continuous extrusion of fibers with internal multilayered structures. Two free-flowing materials are coextruded through a printhead containing a miniaturized Kenics static mixer (KSM) composed of multiple helicoidal elements. This produces a fiber with a well-defined internal multilayer microarchitecture at high-throughput (>1.0 m min^{-1}). The number of mixing elements and the printhead diameter determine the number and thickness of the internal lamellae, which are generated according to successive bifurcations that yield a vast amount of inter-material surface area (~10^2 cm^2 cm^{-3}) at high resolution (~10 μm). This creates a new opportunity to produce structures with extremely high surface area to volume (SAV). Comparison of experimental and computational results demonstrates that continuous chaotic 3D printing is a robust process with predictable output. The simplicity and high resolution of continuous chaotic printing strongly supports its potential use in novel applications.
Here, we illustrate the application of continuous chaotic bioprinting into the fabrication of complex multi-layered bacterial microcosmoi. We demonstrate that the degree of resolution achieved within these constructs can be finely controlled up to the range of a few microns of separation between layers and that the degree of interface between bacterial layers greatly matters for competition.
We also demonstrate the application of tissue-like structures in which living layers of muscle cells evolve into a coherent segment of muscle. Lumina can be easily built into these constructs by using a combination of sacrificial and permanent inks and a multi-port modification to the chaotic printhead.
We are currently exploring more applications of chaotic printing into tissue engineering such as the fabrication of vascularized cancer models, and multi-cell type tissue-like architectures where distinctive mammalian cell layers share a high amount of common interface.
Different fields, outside biosciences and technologies, are also in pursuit of simple and robust ways to create multilayered and multi-material structures to attain functionalities that monolithic materials do not exhibit. We envision that chaotic printing may be applied to technological scenarios such as the fabrication of batteries, superconductors, super catalytic surfaces, and 3D microfluidic reactors.

5:45 AM F.SM06.02.04
***In Situ* Printing of Nanoengineered Osteogenic Hybrid Materials for the Treatment of Bone Defects** Adnan Memic[1], Azadeh Mostafavi[2], Tuerdimaimaiti Abudula[1], Carina Russell[2], Ebrahim Mostafavi[3], Tyrell Williams[2], Numan Salah[1], Ahmed Alshahrie[1], Seth Harris[2], Seyed Masoud M. Basri[4], Yogendra Mishra[5], Thomas J. Webster[3] and Ali Tamayol[6]; [1]King Abdulaziz University, Saudi Arabia; [2]University of Nebraska–Lincoln, United States; [3]Northeastern University, United States; [4]American University of Sharjah, United Arab Emirates; [5]University of Southern Denmark, Denmark; [6]University of Connecticut, United States

Bone defects are commonly caused by traumatic injuries and tumor removal and critically sized defects overwhelm the regenerative capacity of the native tissue. Reparative strategies such as auto, xeno, and allografts have proven to be insufficient to cure these defects. For the first time, we introduce the use of handheld melt spun three dimensional printers that can deposit scaffolding materials directly within the defect site to properly fill the cavity. Engineered composite filaments were generated from poly(caprolactone) doped with zinc oxide nanoparticles and hydroxyapatite microparticles. The use of PCL-based materials allowed low-temperature printing to avoid overheating of the surrounding tissues. The *in situ* printed scaffolds showed moderate adhesion to the bone tissue, which can prevent scaffold dislocation. The printed scaffolds showed to be osteoconductive and supported the osteodifferentiation of mesenchymal stem cells. Biocompatibility of the scaffolds upon *in situ* printing subcutaneously in mice showed promising results.

Strategies to Engineer a Functional Kidney Proximal Tubule Rosalinde Masereeuw; University of Utrecht, Netherlands

In patients with severe kidney disease, renal clearance is compromised resulting in the accumulation of a plethora of endogenous waste molecules that cannot be removed by current dialysis techniques, the most often applied treatment. These uremic retention solutes, also named uremic toxins, are a heterogeneous group of organic compounds of which many are too large to be filtered and/or are protein-bound. Their renal excretion depends largely on renal tubular secretion by which the binding is shifted towards the free fraction that can be eliminated. To facilitate this process, kidney proximal tubule cells are equipped with a range of transport proteins that cooperate in cellular uptake and urinary excretion. In recent years, we and others have invested in the development of bioengineered kidney tubules that could potentially restore this essential function. For this, well characterized human kidney proximal tubule cells were combined with functionalized, living membranes. This presentation addresses these developments in the context of functional kidney tubule engineering. Furthermore, hurdles to take before a safe implementation of bioengineered kidneys in clinics becomes a realistic option will be discussed.

5:15 AM *F.SM06.03.02
Stem Cell-Derived Models to Study Human Neural System Development Jianping Fu; University of Michigan-Ann Arbor, United States

Neurulation is a key developmental process that gives rise to the neural tube (NT), the precursor structure of the central nervous system (CNS). Neurulation is initiated after the gastrulation by a neural induction process, during which the dorsal ectoderm is specified into a patterned tissue containing the neural plate (NP) and the non-neural ectoderm (NNE) separated by the neural plate border (NPB). After neural induction, the NP folds and fuses to form the tubular NT. The development of the NT continues with differentiation of distinct classes of neuronal progenitor cells located at defined positions within the NT along both the anterior-posterior (AP) and dorsal-ventral (DV) axes. In this talk, I will discuss the recent research activities in my group to leverage the developmental potential and self-organization property of human pluripotent stem cells (hPSCs) in conjunction with 2D and 3D bioengineering tools to achieve the development of spatially patterned multicellular tissues that mimic certain aspects of early human neurulation process, including neural induction, AP and DV patterning of the NT. These stem cell-derived models offer promising trackable systems to study neural development and disease.

Engineering the Microenvironment That will Enable a Long-Term Bioprosthetic Ovary Transplant Monica M. Laronda[1,2]; [1]Ann and Robert H. Lurie Children's Hospital of Chicago, United States; [2]Northwestern University, United States

The ovaries contain a finite resource of potential eggs and sex hormone-producing cells, and therefore, life-saving cancer treatments that irradiate or chemically induce cell death within the ovaries will likely result in premature ovarian insufficiency (POI) with reduced ovarian hormones and infertility. The option to have biological children, is a key quality of life measure for cancer survivors. Women with POI will experience co-morbidities associated with loss of ovarian hormones and a shorter life expectancy. The only method for fertility preservation for pediatric patients, who do not yet make eggs, is ovarian tissue cryopreservation (OTC). This tissue can then be transplanted back to restore fertility and hormone function. However, only 20 – 30% of transplants result in livebirth and it produces an average of 2 – 5 years of hormone restoration, leaving many without biological children and decades of post-cancer survival without essential hormone production. One major contributor to the shortened function of transplanted ovarian tissue is the significant spike in activation of the ovarian reserve (primordial follicles, containing the oocytes and hormone-producing cells) and subsequent depletion, at least in part, due to the disruption in the microenvironment. Additionally, some patients have metastatic disease within the ovary and therefore cannot use that tissue in its current form. Therefore, a safe, long-term solution for fertility and hormone restoration would involve isolating the ovarian cells that are essential for function from potential cancer cells and housing them in a microenvironment that maintains the bank of potential eggs and prolongs hormone production. We have defined the architectures of a 3D printed scaffold that support the necessary cell-cell contacts between the oocyte and the surrounding hormone producing support cells. This bioprosthetic ovary of the 3D printed gelatin scaffold with isolated ovarian follicles restored fertility and hormone function and supported livebirths and rearing of offspring in mice. To advance this research through the next steps toward translation to the clinic, we must define the follicular microenvironment that will enable a regulated recruitment of eggs from the ovarian reserve and support a safe, effective and long-term transplant. We have mapped the matrisome composition across the ovarian compartments and the stiffness of tissue components in ovaries of large mammals. Our novel proteomics screen and analysis has enabled us to identify new matrisome proteins within the ovary and pinpoint proteins of interest that may control primordial follicle activation or quiescence. We have additionally defined the physical properties of the ovarian compartments, where the cortical (outer) region is denser and stiffer than the medullary (inner) region. We have developed decellularized ovary extracellular matrix inks and are investigating the roles of specific biochemical and physical cues on primordial follicle quiescence and activation. A bioprosthetic ovary, defined by these microenvironment properties, would improve current options for fertility and hormone restoration for women.

5:45 AM F.SM06.03.04
Impact of Drying Time and Temperature on Lyophilized Silk Fibroin Scaffold Structural Properties Alycia Abbott, Mattea E. Gravina and Jeannine M. Coburn; Worcester Polytechnic Institute, United States

Lyophilized silk fibroin (silk) scaffolds have been used to develop 3D models for multiple disease states.[1] Silk is a natural, biocompatible, FDA approved biomaterial that allows a high degree of control over physical properties.[2] Lyophilization of different silk solutions produces porous scaffolds with varying pore sizes and Young's moduli.[3] However, the effect of varying the drying time and temperature during lyophilization on pore size, pore shape, and bulk modulus is not well described. Understanding the impact of drying time and temperature conditioning on silk scaffold structural properties will allow better definition of lyophilization protocols and tailoring of silk scaffolds to specific disease states.
Silk fibroin was extracted from *B. Mori* silkworm cocoons as previously described.[1] Solutions of 3, 6, 9, and 12% silk (w/v) were created by concentrating silk solution or diluting with water. Rate-controlled lyophilization cycles were used to create porous scaffolds (15.6 mm diameter). Primary drying times (18 h – 1 week) and drying temperatures (-45°C to -15°C) were explored to determine the impact on pore size, pore shape, and Young's modulus. Shelf and sample temperatures were recorded during lyophilization. Pores were evaluated through fluorescent and scanning electron microscopy of scaffolds cut into 200 µm thick sections. An ImageJ protocol was developed to evaluate pore size and shape. Scaffolds were hydrated (impact on secondary structures was examined through FTIR), biopsied (6 mm) and compressed between two parallel plates. The Young's modulus of the scaffolds was determined through uniaxial compression testing on an Instron (2mm/min to 50% strain). Young's modulus was calculated from the stress-strain curve.
Not all lyophilization runs produced viable scaffolds from all silk concentrations. Higher silk percentages (9 and 12%) were shown to require longer drying times than lower silk percentages (3 and 6%). A gradient of pore sizes was seen throughout scaffolds with smaller pores being present in the outermost regions. Pore size was non-normally distributed when imaged at low magnifications (4x) but was normally distributed at high magnifications (500x) suggesting multiple scales may be important for pore evaluation. Due to low average circularity values, Feret diameter, area, and perimeter were used to compare scaffolds instead of treating pores as spheres. Preliminary data suggests silk concentration had a greater impact on pore size and shape than drying time and temperature. Young's moduli values increased as silk concentration increased in agreement with previous literature.[3] Young's moduli values for each silk concentration were significantly different from each other silk concentration ($p < 0.01$). Scaffolds fabricated from the same silk concentration but with stepwise temperature drying had significantly lower Young's moduli (6%, $p<0.001$; 12%, $p < 0.0001$) than scaffolds dried at a constant temperature.
The impact of lyophilization parameters on Young's modulus, and pore size and shape for four different silk formulations were evaluated. The Young's moduli of scaffolds increased as silk concentration increased. Drying temperature significantly affected the Young's moduli of scaffolds with the same silk concentration. Changes in silk concentration had a larger impact on pore size and shape than lyophilization parameters, although analysis is still ongoing. These results begin to demonstrate the impact of drying time and temperature on silk scaffold properties. This knowledge can be used to tailor lyophilization protocols to produce silk scaffolds with specific properties, such as a soft matrix with a desired pore range for tissue engineering applications.

Growth, Characterization and Application of Self-Organized Microvascular Networks for Models of Disease Roger Kamm; Massachusetts Institute of Technology, United States

Methods now exist to create single- or multi-organ engineered living systems that can be used to model a variety of disease processes. Aside from providing new insights into disease mechanisms, these systems can also be used to screen new drugs to treat the disease, or even to identify different therapeutic strategies for sub-populations possessing different genetic profiles. Here we present several models that require a microvascular network, modeling different stages of metastatic cancer. In one set of studies, circulating tumor cells are introduced via side channels into the microvascular bed, where they arrest,

become activated and undergo transendothelial migration. Model systems include the brain, muscle, placenta and bone marrow, each showing distinctive characteristics. These or others can be used to model drug delivery to a developing tumor, either primary or metastatic.
Microfluidic devices used in these studies are, for the most part, simple, single layer systems that can be cast in a single piece of PDMS, forming channels and gel compartments by bonding to a coverslip. Alternatively, systems can be injection molded in tissue culture plastics. Microphysiological systems MPS) can be ether 'engineered' or self-organize using the same capabilities of developing organisms. Our approach is to rely, as much as possible, on the innate capabilities of the cells to interact to form the structures of a particular organ. Cells or cell assemblies/organoids are mixed in hydrogel solution and injected into one or more adjacent compartments allowing for direct signaling or physical contact between the multiple different cell types. Many of these systems contain microvascular networks that can be perfused via side channels, with pumping by simple low-pressure diaphragm pumps, directly connected to the MPS to minimize media volumes. The role of circulating immune cells can also be studied, as these, too, arrest in the vascular beds and extravasate into the surrounding gel matrix.
Results will be shown first demonstrating the form and function of the microvascular beds. Then several examples will be taken from the systems mentioned above to illustrate different applications, and to demonstrate the flexibility of the underlying platform. Future directions will be discussed including the challenges ahead in generating perfusable organoids.

Microfluidic Organs-on-Chips Yuanjin Zhao; Southeast University, China

In biological research, the interaction of biomolecules, cells and materials is an eternal topic. Many technologies have been employed to construct three-dimensional micro-and nano- hierarchical structure of materials. However, it is still a challenge to combine the artificially controllable biomaterials and the complicated biomolecular interaction/cell living unit, and thus to realize the regulation and control of the cell culture by using these materials. Moreover, it is necessary to develop a biotechnology for cell research to real-time and accurately monitor the interaction of the biomolecules/cells and the biomaterials, which could effectively reveal the biological mechanism of the cell behavior. In this point, we proposed to generate the desired functional materials by using microfluidic methods. Based on this technology, we have created a series of novel biomaterials, which showed demonstrated values in cells culture and organs-on-chips construction.

5:30 AM F.SM06.04.03
Heart-on-a-Chip Model with Integrated Extra- and Intracellular Bioelectronics for Monitoring Cardiac Electrophysiology Under Acute Hypoxia Olurotimi A. Bolonduro and Brian Timko; Tufts University, United States

Cardiovascular disease is the leading cause of death in the US, with many cases attributed to cardiac ischemia. Cardiac ischemia occurs when an artery supplying blood to the heart is partially or fully blocked. This results in reduced blood flow to downstream tissue, gradually transforming normoxic blood (21% O_2) into hypoxic blood (<5% O_2). If hypoxic conditions are present for an extended period of time, a myocardial infarction (MI) may occur, leading to abnormal cardiac electrophysiology, loss of function, and tissue death. Despite the effects of ischemic stresses on cardiac electrophysiology, there are few tools that enable multiplexed, real-time studies of cardiac function under ischemia-like conditions.

Herein, we present a heart-on-a-chip model with integrated bioelectronics for studying the effects of acute hypoxia on cardiac function. This model consisted of a PDMS microfluidic channel, cell culture area, and extra- and intracellular recording elements that provided complementary electrophysiological readouts from cardiac model cells. The microfluidic channel enabled rapid modulation of medium oxygenation within the reservoir, which mimicked oxygenation regimes induced by an onset or removal of a coronary occlusion. Basic functionality of the microfluidic channel was confirmed with immunohistochemistry; reversibly-activated hypoxia-related transduction pathways were activated and visualized within the cardiomyocytes.

Our platform provided multiplexed bioelectronic readouts from up to 16 spatially-distinct locations. Extracellular recording elements consisted of 30-micron Au pads and provided stable, continuous readouts of wavefront propagation. Intracellular recording elements penetrated the cytosol following highly-localized electroporation, providing readouts that followed the action potential. A hypoxic regime applied over a 6-hour window caused an initial period of tachycardia followed by a reduction in beat rate and eventually arrhythmia; disruption of wavefronts and continuous reduction in propagation speed from 19 ± 5 mm/s to $< 13 \pm 8$ mm/s; and narrowing of the AP. Moreover, multiplexed recordings of APs allowed us to observe heterogeneities between cells under both normoxic and hypoxic conditions, highlighting a clear advantage of our platform over tradtional techniques such as patch clamp.

The noninvasive nature of our platform enables a wide range of studies relevant to MI and could also be extended to incorporate other elements of ischemia including acidosis, hyperkalemia, nutrient deprivation, and waste accumulation. Moreover, our multiplexing capabilities could be expanded to larger and denser arrays for more complex biological systems including hypoxic gradients. Ultimately, our platform could yield fundamental insights into cardiac signaling pathways and/or provide a high-throughput platform for assessing therapeutics.

5:40 AM F.SM06.04.04
Perfusion Bioreactor Enabled Bone Metastasis Prostate Cancer Testbed Haneesh Jasuja, Kalpana Katti and Dinesh Katti; North Dakota State University, United States

The International Agency for Research on Cancer (IARC) of the World Health Organization reports 1,276,106 incidences and 358,989 fatalities resulting from prostate cancer world wide in 2018. Prostate cancer is the second leading cause of cancer death among men in the United States. Prostate cancer has the propensity to migrate to or metastasize to bone. Although curative treatments are available for primary prostate cancer tumors, advanced-stage prostate cancer that has metastasized to bone often results in a poor prognosis. The primary cause of morbidity due to prostate cancer is the metastasis to bone. The effects of various biochemical factors in the bone microenvironment have been demonstrated in the disease progression to metastasis; however, the role of physical factors such as mechanical cues induced by the interstitial fluid flow around the bone is poorly explored. It has been established that interstitial flow has a pro-migratory and biomechanical stimulatory effect on cancer cell invasion. To address this issue, we designed a 3D *in-vitro* model to evaluate the progression of prostate cancer cells at metastasis condition, colonizing the bone site under dynamic conditions. In this study, we developed a 3D dynamic *in-vitro* model employing nanoclay-polycaprolactone-hydroxyapatite scaffolds and a specially designed perfusion bioreactor. Initially, we differentiated human mesenchymal stem cells (hMSCs) on scaffolds under dynamic culturing conditions to duplicate an accurate bone-like microenvironment. Next, we utilized these bone mimetic scaffolds to grow prostate cancer cells under identical dynamic conditions to recapitulate prostate cancer metastasis to bone. Finally, we performed various cellular assays and immunocytochemistry studies to establish the feasibility of dynamic culture. We observed a significant increase in bone growth under dynamic culture conditions evaluated by bone-related biomarkers (ALP, RUNX2, and OCN) compared to static culture. We also noticed upregulation in E-cadherin and downregulation of vimentin levels under dynamic conditions that confirms the occurrence of mesenchymal to epithelial (MET) transition of prostate cancer cells at the metastatic bone site. We further examined the influence of fluid-induced mechanical cues on cells by monitoring alteration in orientation and morphology of hMSCs and prostate cancer cells. Overall, we observed significant differences in cellular morphology and gene expressions of bone cells and prostate tumors grown under flow conditions. The established perfusion bioreactor based 3D dynamic *in-vitro* model can be further utilized to elucidate the mechanisms of prostate cancer metastasis and screen novel drug therapies geared towards bone metastasis prostate cancer.

5:50 AM F.SM06.04.05
Spatially Controlled Stem Cell Differentiation via Morphogen Gradients—A Comparison of Static and Dynamic Microfluidic Platforms Kiara W. Cui, Leeya Engel, Carolyn Dundes, Tina Nguyen, Kyle Loh and Alexander Dunn; Stanford University, United States

The ability to harness the processes by which complex tissues arise during embryonic development would improve our ability to engineer complex tissue-like constructs *in vitro*—a long-standing goal of tissue engineering and regenerative medicine. In embryos, uniform populations of stem cells are exposed to spatial gradients of diffusible extracellular signaling proteins, known as morphogens. Varying levels of these signaling proteins induce stem cells to differentiate into distinct cell types at different positions along the gradient, thus creating spatially patterned tissues.

Here, we describe two straightforward and easy-to-adopt microfluidic strategies to expose human pluripotent stem cells (hPSCs) *in vitro* to spatial gradients of desired differentiation-inducing extracellular signals. Both approaches afford a high degree of control over the distribution of extracellular signals while preserving the viability of the cultured stem cells. The first microfluidic platform is commercially available and entails static culture, whereas the second microfluidic platform requires fabrication and dynamic fluid exchange. In each platform, we first computationally modeled the spatial distribution of differentiation-inducing extracellular signals. Then, we used each platform to expose hPSCs to a gradient of these signals (in this case, inducing a cell type known as the primitive streak), resulting in a regionalized culture with differentiated primitive streak (PS) cells predominately localized on one side and undifferentiated stem cells at the other side of the device. By combining this approach with a fluorescent reporter for differentiated cells and live-cell fluorescence imaging, we characterized the spatial and temporal dynamics of primitive streak differentiation within the induced signaling gradients. We

envision that microfluidic approaches to create precisely controlled morphogen gradients will add to the stem cell and developmental biology toolkit, and may eventually pave the way to create increasingly spatially patterned tissue-like constructs *in vitro*.

The Effects of Bioprinting on the Structure, Function and Survival of Organotypic Skin Kimberly Lu, Olias Christie, Michael Cottone, Philip Cottone, Michael Gozelski, Juyi Li, Robert Wong and Miriam H. Rafailovich; Stony Brook University, United States

With the advancement of 3D printing in the 21st century, prospective treatments for regenerative medicine, cosmetology, and material science are actively being explored[1,2]. This research aims to investigate the feasibility of 3D bioprinting technology in producing viable skin tissue. In order to achieve this, a novel procedure for the construction of dermal and epidermal organotypics was developed. This evaluation was performed by comparing organotypic skin samples consisting of non-printed epidermal and dermal layers (NN), non-printed epidermal and printed dermal layers (NP), printed epidermal and non-printed dermal layers (PN), and printed epidermal and dermal layers (PP). The assessment of claudin and filaggrin immunohistochemical staining of the samples suggest a revision to the methodology in which printing the epidermal layer at a lower pressure while printing the dermal layer at a relatively higher pressure may lead to improved cellular function and overall integrity of the organotypic skin-equivalent. These results demonstrate the potential of bioprinting as a novel technique for producing a skin equivalent product, which may serve as an alternative to conventional tissue engineering methods.

Late News: Synthesis of Alginate Microgels with a Polymer Shell—A Simple Way to Protect Encapsulated Cells So Hyun Ahn, Srinivasa Raghavan and William E. Bentley; University of Maryland, United States

Microgels of biopolymers such as alginate are widely used to encapsulate cells and other biological payloads. Alginate is an attractive material for cell encapsulation because spherical gels are easily created by contacting aqueous droplets of sodium alginate with divalent cations such as Ca^{2+}. Alginate chains in the gel become crosslinked by Ca^{2+} cations into a 3-D network. When alginate gels are placed in a buffer, however, the Ca^{2+} crosslinks are eliminated by exchange with Na^{+}, thereby weakening and degrading the gels. With time, encapsulated cells are released into the external solution.

Here, we describe a simple solution to the above problem, which involves forming alginate gels enveloped by a thin shell of a covalently crosslinked gel. The shell is formed via free-radical polymerization using conventional monomers such as acrylamide (AAm) or acrylate derivatives, including polyethylene glycol-diacrylate (PEGDA). The entire process is performed in a single step at room temperature (or 37°C) under mild, aqueous conditions. It involves combining the alginate solution with a radical initiator, which is then introduced as droplets into a reservoir containing Ca^{2+} and monomers. Within minutes, the droplets are converted into alginate-polymer microcapsules with a core of alginate and a shell of the polymer (AAm or PEGDA). The stability of these microcapsules under physiological conditions is compared with that of conventional alginate/Ca^{2+} microgels. The latter swell and degrade when placed in buffer or in chelators like sodium citrate, whereas the former remain stable under all conditions.

We also show that a various types of cells can be safely encapsulated in these hybrid beads. We encapsulate both mammalian cell and different strains of genetically engineered bacteria in these microcapsules and find that the cells remain viable and functional over time. In particular, engineered 'reporter' bacterial cells respond to different molecular signals from the external solution such as IPTG, AI-1 and hydrogen peroxide. The cells are retained in the hydrogel capsules throughout the

study which is a crucial aspect for studying cell's response to molecular cues in a robust manner. Moreover, multiple sets of capsules each containing different strains can be synthesized and co-cultured to study cell-cell communication, providing an ideal platform for studying *in vitro* signaling events. Lastly, a variation of the synthesis technique is performed to generate multilayered microcapsules with a liquid core surrounded by concentric layers of alginate and AAm gels.

Late News: Analysis and Mechanical Compression Model of a Three-Component Scaffold Composed of Polycaprolactone-Hydroxyapatite-Graphene Oxide for Tissue Engineering Javier Ortiz Ortiz, Georgina Carbajal de la Torre, Marco Antonio Espinosa Medina, Nancy Nelly Zurita Méndez and Lourdes Ballesteros-Almanza; Universidad Michoacana de San Nicolas de Hidalgo, Mexico

The use of multiple materials has helped in the development of tissue engineering. The use of polymeric matrices and biomaterials added to particular materials offers specific solutions both due to the interaction of the biomaterials and the mechanical properties of the generated biomaterial. In this work, the mechanical properties of compression of a three-component scaffolds for tissue engineering composed of polycaprolactone (PCL), hydroxyapatite (HA), and graphene oxide (GO) are shown. Scaffolds were subjected to compression on the Cell Scale™ brand Univert™ testing machine. Once the experimental data had been obtained, the stress-strain curve was obtained, also the compression mechanical behavior model was performed using the Levenberg-Marquardt least-squares algorithm in the Comsol Multiphisics™ software. To explain the compression phenomenon, scanning electron microscopy analyzes are performed where scaffolds are observed before being compressed and also after compression.

F.SM06.05.07
Late News: Determination of the Physical and Mechanical Properties of the Nopal Fiber (Opuntia ficus-indica) and Availability as a Biopolymer Isaí Pérez Servín, Rosa E. Pérez Sánchez, Georgina Carbajal de la Torre, Ruy Ortíz Rodríguez, Héctor E. Martínez Flores and Javier Ortiz Ortiz; Universidad Michoacana de San Nicolás de Hidalgo, Mexico

Nopal is a cactus that is distributed in different agroclimatic zones in a wild and cultivated way, due to its high forage potential, it has been destined to be used in the food, agricultural and pharmaceutical industry, however, when the cladode nopal reaches certain maturity, its use in the previously mentioned scopes is no longer viable, due to its high availability of fiber and lignin; this content of fiber in nopal could be implemented in the cosmetic and medical scopes as a biopolymer. The present study shows the physical and mechanical properties of nopal fiber components, and its thermographic analysis as an approach to determine its suitability and availability to fulfill the function of a biopolymer. An acid/alkaline extraction with potassium hydroxide (KOH; 1%) at 50° C was performed on the nopal sample previously dried. After the extraction, the sample was dried in a vacuum oven and its size was reduced by grinding. Mechanical tests were performed on nopal fibers in the Cell Scale Univert testing machine to obtain stress-strain curves. From the thermographic analysis, the kinetic drying model describing the process necessary for finite element modeling was proposed. The evaluation of the physical and mechanical characteristics allows us to determine the use and viability of nopal fiber as a biomaterial.

Enhancing Vaccine Immunity via a Nanoparticle Adjuvant That Alters Lymph Flow and Lymph Node Permeability Darrell Irvine; Massachusetts Institute of Technology, United States

Adjuvants play critical roles in shaping the immune response to vaccines. Here we describe a novel nanoparticle adjuvant, saponin-MPLA nanoparticles (SMNP), formed by the immunostimulatory compound saponin, the Toll like receptor (TLR)-4 agonist monophosphoryl lipid A (MPLA), cholesterol, and phospholipids. These components self-assemble into striking ~40 nm diam. cage-like structures reminiscent of ISCOMs (Immunostimulatory complexes) previously reported for saponin/phospholipid complexes, but have synergistic immunostimulatory properties from the combined action of saponins and MPLA. SMNP exhibited striking potency in both mouse and non-human primate (NHP) preclinical animal models of vaccination with a variety of subunit vaccines. Protein vaccines adjuvanted with SMNP elicited robust germinal center B cell and Tfh responses, leading to strong serum IgG responses and (in NHPs) HIV tier 2 neutralizing antibody responses. Strikingly, SMNP exhibited distinctive mechanisms of action, altering lymph flow and promoting antigen entry into draining lymph nodes, in a manner dependent on co-assembly of MPLA and saponin together in the same nanoparticle. Altogether, these findings suggest SMNP may be a promising novel adjuvant for subunit vaccines in settings of HIV, COVID-19, and other infectious diseases.

Microenvironmental Control of Bioengineered Immune Tissues with Microfluidics Rebecca R. Pompano; University of

Virginia, United States

A critical element of the immune system is tissue-level spatial organization. Cells and extracellular matrix elements are all highly organized in the lymph node, spleen, and thymus, as well as in the peripheral organs where immune cells infiltrate. Furthermore, secreted molecules are arranged in local patterns that depend on diffusion and interstitial flow. To begin to probe the functional outcomes of this intricate organizational structure, our laboratory has focused on combining live tissues and engineered biomaterials with microfluidic and micropatterning for fluidic and spatial control. We have developed microsystems to deliver drugs locally to specific regions of spatially structured tissues, to co-culture multiple structured organs under recirculating flow, and to begin to build a micropatterned lymph node. Here we will discuss our recent progress towards modeling complex immune function outside the body, to gain insight into the spatiotemporal dynamics of inflammation and immunity.

Biomaterials as Tools to Study and Manipulate Immune Signaling Christopher M. Jewell; University of Maryland, United States

Our research combines immunology and biomaterials to understand the interactions between synthetic materials and immune tissues, and to design more selective therapeutic vaccines for cancer and autoimmunity. This presentation will highlight our recent efforts toward these goals combining materials science and bioengineering tools, cell culture, animal models, and samples from human patients. In one example I will discuss new degradable polymer depots that could improve the selectivity of therapies for autoimmune diseases such as multiple sclerosis and diabetes by locally reprogramming the function of lymph nodes – tissues that coordinate immune function. A second area will present the lab's efforts to self-assemble immune signals into modular nanostructures. This rational design approach allows activation of programmable combinations and levels of immune pathways triggered. Modular control over these aspects of immune signaling could help improve the efficacy of vaccines for cancer and infectious disease, and enhance the efficiency of vaccine translation.

5:15 AM *F.SM07.01.02
Intravenous Nanoparticle Delivery for Reprogramming Immune Cells and Modulating Inflammatory Disease Lonnie Shea[1,1], Eiji Saito[1], Yining Zhang[1] and Jonghyuck Park[2]; [1]University of Michigan–Ann Arbor, United States; [2]University of Kentucky, United States

Introduction: Inflammatory monocytes and neutrophils contribute to deleterious inflammatory disease and tissue damage in a number of pathological conditions, such as trauma, viral infection, autoimmune disease, sepsis, and cancer. Tissue destruction results from the influx of these inflammatory monocytes and neutrophils, which secrete pro-inflammatory cytokines, reactive oxygen species (ROS). Critically, a number of agents such as steroids or cytokine-depleting antibodies are associated with unfavorable side effects, such as sepsis, gastrointestinal bleeding, and thromboembolism, indicating that improved methods are needed. Systemic depletion of neutrophils or monocytes has either not altered or has had a small effect on outcomes. Because monocytes and neutrophils are necessary for wound healing and tissue regeneration after injury, reprogramming the immune response could be a more effective strategy to minimize loss of function and enable repair.
Results: Herein, we describe our efforts at employing NPs to reprogram inflammatory cells intravascularly, which can alter their trafficking and polarization. NPs (500 nm diameter, zeta potential < -30 mV) and intercept the immune cells prior to their extravasation and redirect some to the spleen, with a fraction trafficking to the site of trauma or disease. Importantly, the NPs are attenuating the innate response yet do not alter the adaptive immune response and also support enhanced regeneration and functional recovery at sites of trauma or disease. These particles have been applied to models of viral infection and spinal cord injury to limit injury and tissue degeneration, and in models of metastatic cancer to alter metastasis.
Conclusions: NP infusion can reduce inflammation resulting in increasing tissue regeneration and normal tissue function. NPs-mediated rapid reprogramming of innate immune cells has a sustained impact on microenvironment modulation, which initiates a cascade of events, including induction of gene expression profiles associated with regeneration. Collectively, this strategy of targeting the innate immune cells in the vasculature prior to their extravasation to a injury or disease site may have broad applications to attenuating inflammation-mediated tissue damage.

Tissue-Anchored Enzyme for Immuno-Metabolic Suppression Benjamin Keselowsky; University of Florida, United States

This presentation highlights results from our molecular based approaches to direct the immune system toward tolerance and suppression. We have developed tissue-anchored enzymes – chimeric enzyme-carbohydrate binding fusion proteins in order to direct localized immunometabolism toward suppression. Specifically, indoleamine 2,3 dioxygenase, which depletes tryptophan through the kynurenine pathway, is fused to galectin 3, which binds extracellular glycans and affords prolonged tissue retention. This approach has provided potent, confined metabolic programming promoting tissue homeostasis in multiple inflammation models including osteoarthritis and periodontal disease.

5:45 AM F.SM07.01.05
The Plasticity of Primary Human Macrophages When Interacting with Tissue-Engineered Blood Vessels Beatriz Hernaez Estrada[1,2], Edorta Santos Vizcaino[2,3], Rosa M. Hernandez[2,3] and Kara Spiller[1]; [1]Drexel University, United States; [2]University of the Basque Country, Spain; [3]Biomedical Research Networking, Spain

Introduction: Deficient vascularization of engineered tissues is one of the major causes of inadequate tissue integration and function *in vivo*. A potential solution to this problem is the implantation of pre-vascularized biomaterials, such as those prepared from human adipose microvascular endothelial cells (HAMECS) and adipose-derived mesenchymal stromal cells (MSC) [1-2]. However, these pre-vascularized constructs will encounter an inflammatory environment upon implantation, and it is not known how this will affect the engineered blood vessels. Macrophages, the primary cells of the inflammatory response, are key regulators of tissue vascularization and integration of implanted biomaterials. Even though macrophages can exist as different phenotypes, each with distinct effects on blood vessels, they are also very plastic cells that are able to switch phenotypes depending on microenvironmental stimuli [3]. In the first phase of wound healing, macrophages are primarily pro-inflammatory (M1), whereas the second stage is characterized by a pro-wound resolution phenotype (M2). M2 macrophages can be derived from non-activated (M0) macrophages or they may switch from M1 (resulting in M1-M2). The diversity of these populations and their crosstalk with blood vessels are not known. Therefore, the purpose of this study was to assess the phenotypic subsets of primary human macrophages polarized to pro-inflammatory (M1) and pro-wound

resolution (M2 and M1-M2) phenotypes, and how they change when cultured with 3D tissue-engineered human blood vessels *in vitro*.
Methods: Tissue-engineered blood vessels were formed by co-culturing HAMECs and MSCs within porous gelatin scaffolds (Surgifoam®). M0, M1, M2 and M1-M2 primary macrophages were seeded alone on the scaffolds or in co-culture with the engineered blood vessels as previously described [3]. Then, the scaffolds were digested to generate a single cell suspension and stained with a 10-marker flow cytometry panel: macrophage general marker (CD45), M1 macrophage markers (CCR7, HLA-DR, CD83, CD38 and PD-L1), and M2 macrophage markers (CD206, CD209, CD163 and CXCR4). Data were acquired on BD Fortessa™ flow cytometer. Live, single and CD45 positive cells from all the different conditions were down sampled and merged into a single expression matrix prior to dimensionality reduction analysis in FlowJo®. Cluster analysis was done using manual gating or different plugins such as FlowSom.
Results: Using this approach, we were able to differentiate the effect of the biomaterial itself from the effects of interactions with blood vessels on macrophage phenotype. While macrophages polarized to the different phenotypes were relatively homogenous in 2D culture, after 24 hours in 3D culture, even without tissue-engineered blood vessels, they became a heterogeneous population comprising 3-4 main clusters, each comprising cells that expressed varying levels of each marker. Following crosstalk with tissue-engineered blood vessels, the prior polarization states of the macrophages affected their response. In particular, M1 and M1-M2 macrophages became enriched in clusters characterized by high levels of M1 markers (such as CD38, CD80 and CD38), while M2 and M0 macrophages became enriched in clusters that were predominant in M2 markers (such as CD206, CD163 and CXCR4).
Conclusions: These findings suggest that macrophage phenotype is strongly affected by co-culture with tissue-engineered blood vessels in a way that depends on the prior polarization state of the macrophages.

5:55 AM F.SM07.01.06
De novo Design of Functional Zwitterionic Biomimetic Material for Immunomodulation Bowen Li[1] and Shaoyi Jiang[2]; [1]Massachusetts Institute of Technology, United States; [2]Cornell University, United States

Super-hydrophilic zwitterionic polymers are a class of non-fouling materials capable of effectively resisting any nonspecific interactions with biological systems. Beyond conventional zwitterionic polymers that are biologically inert, we have designed a functional zwitterionic polymer by achieving a tradeoff between the non-specific interaction for non-fouling property and the specific interaction for bioactive functionality. Built from phosphoserine, an immune-signaling molecule in nature, this zwitterionic polymer exhibits both non-fouling and immunomodulatory properties. Conjugation of this zwitterionic polymer to uricase, a highly immunogenic enzyme, shows to proactively eradicate all the unwanted immune response, outperforming the inert zwitterionic polymers. On the other hand, this polymer could significantly prolong the half-life of uricase in vivo, overcoming the innate drawback of phosphoserine in inducing accelerated clearance. As the first demonstration of a non-fouling zwitterionic material with build-in immunomodulatory functionality, this work not only provides new insights into the fundamental design of biomaterials, but also contains far-reaching implications for broad biomedical applications including drug delivery, implants and cell therapy.

Materials-Based Organoids to Model Immunity in Aged and Young Individuals Against Antibiotic–Resistant Bacteria Ankur Singh; Georgia Institute of Technology, United States

Antibiotic–resistant bacteria are a major and rising global health threat. Although this threat affects all ages, pediatric patients, and aged individuals are at increased risk of antibiotic–resistant bacterial infections. Of concern are *Klebsiella*

pneumoniae (*K. pneumoniae*) that fail to induce in vivo germinal center B cell responses, which facilitate antibody production to fight infection. Immunotherapies using antibodies targeting antibiotic–resistant bacteria are emerging as promising alternatives, however, they cannot be efficiently derived ex vivo, necessitating the need for immune technologies to develop therapeutics. In this talk, I will discuss how organoid polymer functionality and mode of *Klebsiella pneumoniae* membrane antigen presentation regulates ex vivo germinal center epigenetics in young and aged B cells. In this work, polyethylene glycol (PEG)–based immune organoids are developed to elucidate the effects of polymer endpoint chemistry, integrin ligands, and mode of *K. pneumoniae* antigen presentation on germinal center B cell phenotype and epigenetics, to better define the lymph node microenvironment factors regulating ex vivo germinal center dynamics. Notably, both PEG vinyl sulfone or acrylate fail to sustain primary immune cells, but functionalization with maleimide (PEG–4MAL) leads to B cell expansion and germinal center–like induction. Single cell RNA sequencing analysis of lymph node stromal and bulk sequencing of germinal center B cells show niche associated heterogeneity of integrin–related genes. Incorporation of niche–mimicking peptides reveals that collagen–1 promotes germinal center–like dynamics and epigenetics. PEG–4MAL organoids elucidate the impact of *K. pneumoniae* outer membrane–embedded protein antigen versus soluble antigen presentation on germinal centers and preserve the response across young and aged mice. Finally, I will discuss ongoing efforts to engineer immune organoids from primary B cells from non–human primates and humans.

Cell- and Fluid-Sampling Microneedle Arrays for Minimally Invasive Monitoring of Tissue-Resident Immunity Sasan Jalili-Firoozinezhad[1], Coralie M. Backlund[1], Daniel Garafola[1,1,1], Mariane Melo[2], Paula T. Hammond[1,1,3] and Darrell Irvine[1,4,3]; [1]Massachusetts Institute of Technology, United States; [2]Massachusetts Institute of Technology and Harvard University, United States; [3]Institute for Soldier Nanotechnologies, MIT, United States; [4]Department of Biological Engineering, MIT, United States

Immune monitoring approaches in human patients and animal models primarily rely on peripheral blood analysis, as the standard method for immunophenotyping. Although this strategy mirrors important information of the immune responses of the host, blood draws fail to track major immune cell populations preferentially residing in peripheral tissues, including barrier tissues such as the skin. Moreover, invasive approaches for sampling and analyzing immune cell populations from lymph nodes or skin are apparatus intensive and require special training for use. On the other hand, minimally invasive methods for quantitative monitoring of the immune status of the skin or other barrier tissues could provide valuable information in the context of patients with genetic and acquired immunodeficiency disorders, organ transplants, and vaccination, but such approaches are currently lacking. To overcome these challenges, we developed microneedle (MN) skin patches, coated with an ionically-crosslinked biocompatible polymer, which swells upon skin insertion, absorbing interstitial fluid (ISF) and enabling migration of cells into the patch in a minimally invasive, cost-effective manner. These MN arrays were used to monitor antigen-specific tissue-resident lymphocytes in the OVA-vaccinated and LPS-infected C57Bl/6 mice skin. We demonstrated that by applying the patches to skin for 12 hours, several thousand live cells are recovered without immunizing or altering pre-existing T cell or B cell responses against target antigens. In response to local intradermal LPS injection, without prior vaccination, MN arrays were able to sample more abundant lymphocytes and inflammatory cytokines compared to naïve, untreated mice. Our data strongly suggest that the sampling MN skin patches could be harnessed as a powerful tool to quantitatively elucidate immune signatures of infectious or autoimmune diseases in the future.

5:40 AM F.SM07.02.04
Detecting Cancer Biomarkers Using Single-Molecule Techniques for Future Liquid Biopsy Applications Keshani G.

Pattiya Arachchillage, Subrata Chandra and Juan M. Artes Vivancos; University of Massachusetts, Lowell, United States

Cancer is one of the most frequent causes of death globally, and cancer biomarkers are promising for detecting cancers early.[1] This disease kills more than 8 million people per year, and most probably, we may need to expect this number to increase by more than 50% in the coming decades.[1] Early diagnosed cancers are relatively easier to treat and cure. There are various techniques to screen cancers as early as possible. Liquid biopsy is a promising approach since it is used to diagnose tumor-specific biomarkers non-invasively.[2] Moreover, it can detect genetic material (circulating tumor nucleic acids, ctNA), which is important in various applications, including cancer screening.[3,2] Detecting ctNA in the blood is challenging, because of the low ctNA concentration and the low frequency of mutations compared to wild-type sequences.[2] Nanotechnology methods can help to address this challenge. In particular, the Scanning Tunneling Microscopic (STM)-assisted break junctions method (STM-BJ)[4] has recently allowed the first demonstration of detection and identification of RNA via single-molecule conductance.[3] This is an ideal method for liquid biopsy since it is non-invasive and could be helpful to detect cancers without the use of surgery.[2] Early detection of the genetic material in cancer biomarkers, such as ctDNA and ctRNA[2], through liquid biopsy using nanotechnology may help save many lives from cancer patients.
In this work, we focus on characterizing ctNAs and investigate an effective method for their ultra-sensitive detection in complex samples. The main hypothesis of the study is that the sequences of ctNAs can be used to detect cancers as the literature supports.[5] The selected biomarkers are KRAS, BRAF, and Nras, in agreement with data from the Pan-Cancer Analysis of Whole Genomes (PCAWG) Consortium of the International Cancer Genome Consortium (ICGC) and The Cancer Genome Atlas (TCGA).[5,6] We use STMBJ to measure and compare the conductivity of these ctNAs, comparing the conductivity of wild type and mutated biomarker sequences of different lengths. Detecting electrical fingerprints from biomarkers will greatly impact the early detection of cancers, allowing beginning treatments early, potentially saving many lives.

5:50 AM F.SM07.02.05

Late News: Engineering a Dynamic Host-Guest Substrate for Cytotoxic T Cell Activation Rui Li[1], Yingrui Deng[2], Boguang Yang[2], Cai Liang[2], Oi Lan Kathy Lui[2] and Liming Bian[2]; [1]New York University, United States; [2]The Chinese University of Hong Kong, Hong Kong

In immunotherapy, cytotoxic T cells orchestrate an organized macromolecular assembly of T cell receptors (TCRs) in the immunological synapse (IS) to successfully commit antigen recognition and effector functions. Shortly after the contact of T cells with the APCs or cancer cells, the complex of the ligated TCR and costimulatory molecules will dynamically cluster in the IS. Initially, the TCR-CD3-pMHC complexation would generate biochemical and mechano-cues, augmented by the CD28 co-stimulation through the PI3K signaling pathway. Then the ligated TCRs transfer to the central SMAC to trigger the downstream tyrosine kinase cascades. Eventually, the dynamic interactions between the TCR clusters and the actomyosin cytoskeleton lead to the maturation of the IS and the full activation of T cells. Recent researches have shown that the enhanced flexibility of the immunoreceptors would improve the T cell activation and proliferation through an enhanced mechanosensing of the TCR. Lambert et al. showed that the CD4+/CD8+ T cell populations showed an elevated proliferation and robust cytokine production with a decrease in the rigidity of PDMS stimulating microsphere. Moreover, an artificial T cell-stimulating matrix with two stimulating signals and low mechanical stiffness was reported to better promote the CD3 clustering, T cell proliferation, and cytotoxic functionality of the CD8+ T cells. Though not yet fully proven, the high flexibility and mobility of the stimulating ligands should contribute to the augmented outcomes of the activated T cell. Inspired by this idea, we emulated the dynamic process of TCR ligation and clustering by utilizing the supramolecular host-

guest interactions to conjugate the activating ligands onto an APC-mimetic substrate, where the cyclodextrin-modified ligands are likely to be relocated under the retrograde actin flow-mediated force during the TCR clustering. First, we synthesized the adamantane-modified methacrylated hyaluronic acid (MeHA-ADA) macromers and separately conjugated the anti-CD3ε (stimulation signal 1) and anti-CD28 (co-stimulation signal 2) antibodies to the b-cyclodextrins. Then both signal molecules attach to the backbones of MeHA-ADA through the non-covalent reversible interactions between the b-cyclodextrins and adamantanes. Control substrates were fabricated by chemically crosslinking the antibodies onto the macromer through thiol-ene reactions. The dynamic host-guest T cell activating substrate was characterized to have similar mechanical stiffness and to bear the non-significantly different amounts of antibodies and RGD peptides compared with those of the control substrates. Then the freshly isolated murine naïve CD8+ T cells were cultured on all substrates for 7 days before the verification of their effects on T cell activation and proliferation. The RT-qPCR results showed that the expression levels of IFNγ, IL-2, TNFα, and NFATc1 were significantly promoted in the CD8+ T cells cultured on the dynamic host-guest substrate compared to those of the control substrates and free-adding antibodies. Besides, the flow cytometry results showed that the surface markers of activated T cells, CD44 and CD69, were significantly elevated on the T cells cultured on dynamic host-guest substrates. Furthermore, over 68% of the naïve T cells cultured on the dynamic host-guest substrates differentiate into the CD45R+ effector T cells and CD45R+/CD62L+ effector memory T cells, accompanied by robust proliferation and cytokine secretion. These results indicate that the reversible nature of supramolecular interactions offers great prospects for the design of T cell-activating platforms, combining the soft mechanical properties of the lymphoid tissues and complex ligand presentation of the APC membrane to promote the activation of cytotoxic T cells for the future clinical use. Our work provides valuable insights for the biomimetic design of platforms with wide therapeutic applications in immunotherapy.

Late News: Spatial Organization of CpG-Nanoconstructs Influences Targeting of Toll-Like Receptors Kwahun Lee and Teri W. Odom; Northwestern University, United States

Nanoparticle-based constructs have shown enhanced performance when delivering immunostimulatory molecules in cancer immunotherapy – an emerging approach to treat cancer. Their endosomal organization, however, has received little attention for targeting intracellular receptors. This talk will describe how the spatial organization of endosome-targeted constructs can influence their ability to induce downstream cell signaling. As a model system, Toll-like receptor 9 activation of macrophage induced by CpG-constructs will be examined. First, we will discuss how endosomal organizations of these constructs can be controlled by the surface curvature. Second, the spatial organizations will be correlated with immunostimulatory activity of the constructs. Finally, we will describe the implications and promises of these results for different targeted-delivery systems.

6:10 AM F.SM07.02.07
Late News: Antigen Functionalized Nanomaterials for the Study and Regulation of the Mechanical Activity of NK Cells and T Cells Mark Schvartzman; Ben-Gurion University of the Negev, Israel

The immune activity of cytotoxic lymphocytes cells is regulated by many chemical and physical cues, whose integration mechanism is still obscure. As other lymphocytes, Cytotoxic lymphocytes act in a highly heterogeneous and diverse environment, with rapidly and abruptly changing physical properties and chemical compositions. Here, we engineered a new nanoscale platform which allows to control and integrate chemical, mechanical, and spatial stimuli for Natural Killer (NK) cells, and screen the individual and cumulative effect of these stimuli on NK cell morphology and cytotoxic activity. This platform is based on nanowires produced from the bottom-up, which are confined within micron-scale stimulating domains. These domains mimic to a certain extent professional antigen-presenting cells, such as dendritic cells. The nanowires within the domains provide the mechanical stimulation of NK cells, as we recently reported [1]. Whether the enhanced activation is due to the high compliance of the ultra-flexible nanowires to the mechanical forces, or to the nanoscale topography that the nanowires impose on the cell membrane, is still unclear.
To address this question here, we compared NK cells stimulated on domains of nanowires with different diameters. These nanowires comply differently to the mechanical forces applied by NK cells while producing similar topographical environments. In our platform, we also mimicked the spatial discontinuity of antigens into nanosized clusters, by selective immobilization onto the nanowire tips. We seeded primary NK cells on these heterogeneous surfaces and found two distinct subpopulations split by physical location: either on the top of the nanowire islands or between the islands. The two subpopulations vastly differed in morphological features of the cells, including circularity, length, spreading, and orientation. Furthermore, the cells in the two subpopulations were different in their activation levels, which we quantified *via* expression of lysosomal Lysosomal-associated membrane protein 1 (LAMP-1): only cells belonging to the subpopulation sitting on atop the nanowire islands showed enhanced activation. Finally, we showed that by independently varying nanowire flexibility *via* their diameter, as well as the presence of stimulating antigens, the degree of activation of NK cells could be

fine-tuned.
To further explore the effect of the nanowire flexibility on the activation of cytotoxic lymphocytes, we synthesized nanowires with systematically varied length – from 2 microns to 20 microns, chemically coated them with antigens, and used them as a stimulation platform for primary NK cells and T cells. In both cases, we found that the activation of these cells assessed via the expression of LAMP-1 and the release of interferon-gamma increased with the increase in the nanowire length. These results confirm that the nanoscale mechanical compliance of the interface between NK cells and T cells plays a critical role in their immune stimulation.
Our novel platform demonstrates an unprecedented level of simultaneous control over chemical and physical stimuli, with an unparalleled spatial resolution at the nanometric scale. The observed immune response of NK cells to the fine variations in both physical and chemical stimuli provides an important insight into the mechanism of their cytotoxic activity. Besides, the demonstrated microenvironment for NK cell stimulation, which is engineered with features that independently tune chemical and physical stimuli, paves the way to future technologies for the *ex vivo* expansion and activation of cytotoxic lymphocytes in immunotherapy.

Delivering Molecular Self-Assemblies for Immunotherapies—Tabletization and Mucosal Delivery Sean H. Kelly, Emmanuel Opolot, Yaoying Wu, Ajay K. Varadhan and Joel Collier; Duke University, United States

The control or eradication of numerous infectious diseases relies on widespread vaccination, which in turn currently depends on cold chain continuity and the availability of trained medical personnel across the globe. Supramolecular vaccines based on short peptides have been previously found to be highly thermally stable, potentially reducing requirements for a continuous cold chain. Here we describe recent efforts to render peptide self-assemblies immunogenic when delivered via mucosal routes, along with additional strategies for designing easily administered and stable tabletized forms that are immunogenic sublingually (under the tongue). Combinations of self-assembly, modification with the mucus-inert polymers polyethylene glycol (PEG) or proline-alanine-serine peptides (PAS), mucosal adjuvants, and sublingual delivery enabled systemic immune responses against short peptide epitopes, which otherwise are poorly immunogenic sublingually. Stabilized self-assemblies were formulated into highly porous, thermally stable, and easily administered tablets which rapidly dissolved under the tongue to deliver peptide self-assemblies and elicit systemic immune responses. In mice, sublingual immunizations with tabletized self-assembling peptides elicited antibody responses against both model epitopes and an epitope from *M. tuberculosis*. Further, the tablets' immunogenicity was not diminished after being heated for 1 week at 45 degrees C, in contrast to traditional carrier-based vaccines that were thermally sensitive. Together these strategies are aimed at reducing barriers for global vaccine distribution and administration by reducing dependence on continuous cold chains and highly trained medical personnel.

5:15 AM *F.SM07.03.02
Enhancing Vaccine Immunity via a Nanoparticle Adjuvant That Alters Lymph Flow and Lymph Node Permeability Darrell Irvine; Massachusetts Institute of Technology, United States

Adjuvants play critical roles in shaping the immune response to vaccines. Here we describe a novel nanoparticle adjuvant, saponin-MPLA nanoparticles (SMNP), formed by the immunostimulatory compound saponin, the Toll like receptor (TLR)-4 agonist monophosphoryl lipid A (MPLA), cholesterol, and phospholipids. These components self-assemble into striking ~40 nm diam. cage-like structures reminiscent of ISCOMs (Immunostimulatory complexes) previously reported for saponin/phospholipid complexes, but have synergistic immunostimulatory properties from the combined action of saponins and MPLA. SMNP exhibited striking potency in both mouse and non-human primate (NHP) preclinical animal models of vaccination with a variety of subunit vaccines. Protein vaccines adjuvanted with SMNP elicited robust germinal center B cell and Tfh responses, leading to strong serum IgG responses and (in NHPs) HIV tier 2 neutralizing antibody responses. Strikingly, SMNP exhibited distinctive mechanisms of action, altering lymph flow and promoting antigen entry into draining lymph nodes, in a manner dependent on co-assembly of MPLA and saponin together in the same nanoparticle. Altogether,

these findings suggest SMNP may be a promising novel adjuvant for subunit vaccines in settings of HIV, COVID-19, and other infectious diseases.

5:30 AM F.SM07.03.03
Enhancing the Stability and Potency of Innate Activators Through Polymeric Nanoparticle Delivery Emily Gale, Gillie Roth, Anton Smith and Eric A. Appel; Stanford University, United States

Immunomodulatory therapies such as cancer immunotherapies and prophylactic vaccines often depend on adjuvants to drive potent and directed immune responses. Innate immune receptor agonists have become a popular category of adjuvants due to their specificity and robust effects. A subset of these agonists (e.g. CpG ODN, poly(I:C), and cyclic dinucleotides) are nucleic acid derivatives that activate cytosolic or endosomal receptors in immune cells, including several classes of dendritic cells (DCs). Stimulated DCs can then present antigen and stimulate naïve T cells for generation of the appropriate adaptive immune response. Unfortunately, these agonists are susceptible to degradation by nucleases *in vivo*, and thus enhanced stabilization and targeting should prolong their function and enhance their effect. We hypothesized that encapsulation of these negatively charged agonists in cationic polymeric nanoparticles would provide an increased agonist half-life and promote targeting to intracellular compartments of immune cells. Here, I discuss the development of methods to encapsulate nucleic acid agonists in biodegradable cationic poly(beta amino-ester) (PBAEs) nanoparticles as well as the specific particle properties (*i.e.*, size, surface charge, polymer chemistry) that lead to a 13-fold increase in innate immune cell activation as measured by type I interferon production. By controlling stability, targeting, and release profiles of this promising class of nucleic acid agonists, we were able to direct the downstream adaptive immune response to a subunit vaccine, significantly enhancing both antibody concentration (1.5-fold) and affinity (14-fold). This nanoparticle platform can be used for the delivery of a range of therapeutic and stimulatory nucleic acids for improved cancer immunotherapies and infectious disease vaccines.

Cancer immunotherapy can also be augmented with innate immune cell-targeting adjuvants to elicit potent immune activation and a strong anti-cancer response. Despite their potential in both vaccines and as part of cancer immunotherapies, many small molecule toll-like receptor (TLR) agonists have been limited clinically due to their extreme potency and lack of pharmacokinetic control, causing systemic toxicity from unregulated systemic cytokine release. In this work, we overcome these shortcomings by generating PEG-PLA nanoparticles presenting potent TLR7/8a moieties on their surface. The NP platform allows precise control of TLR7/8a valency and resulting surface presentation through self-assembly using nanoprecipitation. We hypothesized that the pharmacokinetic profile of the nanoparticles would minimize systemic toxicity, localizing TLR7/8a presentation to the tumor bed and tumor draining lymph nodes. In conjunction with anti-programmed death-ligand 1 (anti-PD-L1) checkpoint blockade, peritumoral injection of TLR7/8a nanoparticles slowed tumor growth, extended survival, and decreased systemic toxicity in comparison to the free TLR7/8a in a murine colon adenocarcinoma model. These nanoparticles constitute a modular platform for controlling pharmacokinetics of small molecule immunostimulatory molecules, resulting in increased potency and decreased toxicity. Together both of these studies demonstrate the value of polymer nanoparticle delivery systems for targeted delivery of different adjuvants (many of which have not made it to the clinic due to toxicity or poor stability) to enhance safety and efficacy for use in either prophylactic vaccines or as part of cancer immunotherapies.

5:40 AM *F.SM07.03.04
Spatial Control Over Innate Immune Activation by Imidazoquinoline TLR7/8 Agonists Through Lipid Polymer Amphiple Conjugation Bruno G. De Geest; Ghent University, Belgium

Uncontrolled systemic inflammatory immune triggering has hampered the clinical translation of several classes of small-molecule immunomodulators, such as imidazoquinoline TLR7/8 agonists for vaccine design and cancer immunotherapy. By taking advantage of the inherent serum-protein-binding property of lipid motifs and their tendency to accumulate in lymphoid tissue, we designed amphiphilic lipid-polymer conjugates that suppress systemic inflammation but provoke potent lymph-node immune activation. This work provides a rational basis for the design of lipid-polymer amphiphiles for optimized lymphoid targeting.

Microneedle Based Vaccines for Viral Infections Divakara SSM Uppu[1], Michelle Turvey[1], Abdul RM Sharif[1], Katell Bidet[1], Yanpu He[2], Jianzhu Chen[1,2,2] and Paula T. Hammond[1,2,2]; [1]Singapore-MIT Alliance for Research and Technology (SMART), Singapore; [2]Massachusetts Institute of Technology, United States

In the current era of the COVID-19 pandemic, there is no greater need than vaccines. Dengue, a mosquito-borne viral disease,

is a neglected disease in the tropical world, where an estimated 2.5 billion people live at risk of infection each year[1]. To date, no safe and effective vaccine exists for Dengue. Most virus vaccines are live-attenuated vaccines (LAVs) containing a weakened virus that produce an effective immune response. However, LAVs typically suffer from safety limitations and, more importantly, require cold chain storage[2]. In contrast to LAVs, protein-based subunit vaccines are considered safer. However, subunit proteins as vaccine antigens are typically poorly immunogenic and require adjuvants that require both co-delivery and controlled release for maximum efficacy[3]. In this talk, I will describe our efforts to achieve cold chain independence and vaccine delivery using biomaterials.

Here, we design and formulate microneedle-based intradermal vaccines based on the live virus as well as subunit proteins for protection against the Dengue virus. Microneedles are miniaturized needles (100 μm to 1mm) typically assembled as an array and applied onto the skin. Specifically, I will talk about the design and development of (i) LAV[2] and (ii) protein subunit[3] microneedle-based vaccines using the Dengue virus as a model system. In the first part of my talk, I will discuss the development of polymeric matrix to formulate the LAV vaccine on microneedles for improving the viability at room temperature for up to 4 weeks without loss of efficacy. During the second part, I will talk about developing polymeric multilayer thin films on microneedles encapsulating a subunit vaccine (protein antigen and two adjuvants) for achieving controlled release from days to weeks.

Mimicry of Glycoprotein-Independent HIV Targeting of Myeloid Cells with Lipid-Wrapped Polymer Nanoparticles Behnaz Eshaghi[1], Suryaram Gummuluru[2] and Bjoern Reinhard[1]; [1]Boston University, United States; [2]Boston University Medical School, United States

Human Immunodeficiency Virus (HIV) transfers from special, non-endolysosomal compartments in myeloid dendritic cells and macrophages to T cells in a process called trans-infection. It has been demonstrated that lipid-wrapped gold nanoparticles that contain the ganglioside, GM3, can recapitulate viral segregation in non-endolysosomal compartments in CD169-expressing dendritic cells and macrophages, and some findings suggest that GM3-presenting nanoparticles can even reconstitute a virological synapse after addition of T cells. However, for a number of reasons, including low payload and their non-degradable nature, gold nanoparticles are not ideal for exploiting the GM3-CD169 mediated accumulation of nanoparticles at the contact between antigen presenting cells and T cells for important applications. In this presentation, we will provide an overview of our recent progress in utilizing lipid-wrapped polymer nanoparticles as HIV-mimicking nanoparticles. We have assembled GM3-presenting, lipid-wrapped polymer nanoparticles with different polymer cores. Due to differences in the core composition, the NP had different glass transition temperatures that resulted in different stiffnesses at physiological temperatures. We mapped the intracellular distribution of the nanoparticles in CD169-expressing macrophages through confocal microscopy. Our findings suggest that in addition to the presentation of the ganglioside GM3 in the membrane around the nanoparticle core, the stiffness of the core plays an important role for successfully mimicking viral behavior. We found that while soft nanoparticles (Young's modulus of < 100 MPa) exclusively enter an endolysosomal pathway, for nanoparticles with a stiff core (Young's modulus ≈1.4 GPA) a significant fraction of cells shows a different trafficking pattern that results in a segregation in non-endolysosomal compartments. The staining patterns of these compartments resemble those of virus containing compartments (VCCs) known to be reservoir sites for HIV.

SESSION F.SM07.04: Materials Approaches for Improving Cancer Immunotherapies

Engineering Smart Technologies for Next-Generation Vaccines and Immunotherapies John T. Wilson; Vanderbilt University, United States

Interventions that engage the power and specificity of the immune system have enormous potential to improve human health, yet the efficacy, safety, and utility of many promising immunomodulatory agents is limited by critical drug delivery barriers. This talk will describe current research in my laboratory focused on engineering nanostructured polymeric materials for intracellular delivery of immunomodulatory proteins, nucleic acids, and small molecules. Specifically, I will discuss our recent efforts in developing environmentally-responsive "smart" materials that open access cytosolic immunoregulatory machinery and how these materials can be leveraged to improve responses to cancer immunotherapy and infectious disease vaccines.

5:15 AM *F.SM07.04.02
Polymeric, Microparticle-Loaded Hydrogels Serve as Depots for Lactate and Mimic the 'Cold' Tumor Microenvironment Jamal Lewis; University of California, Davis, United States

Immunotherapeutic approaches are effective by either harnessing the ability of the host immune system to recognize and eliminate cells that display tumor antigens, providing external stimuli to ramp up the destruction of tumor cells in an antigen-specific manner, or by negating the ability of the tumor cells to inhibit host immune cell activation. The latter option is particularly attractive as it avoids constitutive activation of immune cells, which can result in collateral damage to healthy tissues. This can be accomplished by exploiting molecular signals within the tumor microenvironment (TME), so that the tumor shifts from being "immunologically cold" and imune-evasive to "immunologically hot" and susceptible to immune elimination (e.g. checkpoint inhibitor - Keytruda®; anti-PD-1). Although these new immunotherapeutic approaches are a significant improvement on more conventional therapies, they still fail to rid the patient of tumor burden in most cases. As such, active research is underway to uncover other molecules that engender the 'cold' climate of the TME. One molecule that is ubiquitous in the TME and now emerging as a major source of immune suppression is lactate. Lactic acid is an intermediate in glucose metabolism and at physiological pHs is found as the conjugate base, lactate. Lactate is surprisingly both a byproduct and energy source for cancer cells, depending on the availability of oxygen. Within the TME, lactate drives the differentiation of immunosuppressive cell subsets, such as myeloid derived suppressor cells, which have the ability to prevent the maturation of dendritic cells (DCs), thereby halting subsequent anti-tumor adaptive immune responses. Lactate also impairs the differentiation of monocytes into macrophages (MΦ) and DCs and the LPS maturation of MΦs and DCs in the TME. Evidently, lactate immunometabolism is critical to the host's immune response to cancer. However, we lack a defined model to replicate lactate conditions seen in the TME. *In vitro* models of solid tumors vary in complexity and range from tumor-derived cell lines to 3D models of the tumor microenvironment. More often than not, these models fail to recapitulate the complex milieu of immune factors and immune cells that are present in the *in vivo* setting and crucial to evaluating the efficacy of immunotherapies. Moreover, current cancer models fail to isolate the effects of lactate alone, which can conflate interpretation of results and leaves the efficacy of therapeutic strategies targeting lactate unanswered. Moreover, a combinatorial model, where lactate can be incorporated in combination with other molecules/ conditions of interest (e.g. hypoxia) is highly desired. Biomaterials offer a potential strategy to recapitulate the biochemistry of the TME, including lactate bioavailibility. Here, we engineered a TME-mimicking system that is able to replicate one critical component of the TME, endogenous lactate levels, to understand the direct effect of localized lactate concentrations on immune cells. This system utilizes peptide hydrogels loaded with GM-CSF and degradable lactate-based polymeric microparticles. The hydrogel environment encapsulates the microparticles in a hydrated peptide mesh which allows for its hydrolysis into monomeric lactate and the subsequent accumulation of lactate in the hydrogel. Additionally, GM-CSF, a suppressive secretory chemokine produced by many tumors, serves to recruit innate immune cells to the hydrogel. Such a platform is expandable, where lactate and other immunogenic moieties can be investigated together. Moreover, the isolated effects of lactate on immune cells *in vivo* can provide evidence for targeting this molecule in immunotherapies.

Engineered Biomaterials for Overcoming Transport Barriers in the Tumor Immune Microenvironment to Enhance Cancer Immunotherapy Susan N. Thomas; Georgia Institute of Technology, United States

The transport of fluids, biomolecules and cells from the tumor microenvironment to draining lymph nodes and into the circulation is facilitated by the concerted influence of the blood and lymphatic vascular systems. Our efforts to characterize the impact of these transport processes on disease progression, in particular by regulating both metastasis and adaptive immunity, as well as to develop therapeutic approaches for tumor therapy that mitigate these effects by leveraging engineered biomaterials, will be described.

5:45 AM F.SM07.04.04
Injectable Hydrogel Reservoirs Alter CD40 Agonist Antibody Pharmacokinetics to Improve Safety and Efficacy Santiago Correa, Emily Gale, Aaron T. Mayer, Zunyu Xiao, Joseph L. Mann and Eric A. Appel; Stanford, United

States

Immunotherapy can be made safer and more effective by using materials approaches to control the spatial and temporal exposure to immuno-stimulants. We previously described a polymer-nanoparticle (PNP) based hydrogel that is biocompatible, long lasting, and injectable<!--[endif]---->[1, 2], traits that we hypothesized would improve controlled local delivery of immunotherapy. Here, we report that PNP hydrogels prolong the local exposure to CD40 agonist antibody (CD40 mAb), improving tolerability and therapeutic efficacy in the B16 model of melanoma.<!--![endif]---->
<!--[endif]---->
We used positron emission tomography (PET) imaging to confirm hydrogel delivery altered CD40 mAb pharmacokinetics over the course of 12 days. Compared to dose-matched local bolus injections, hydrogels redistributed antibody exposure to the injection site and the tumor draining lymph node, increasing CD40 mAb AUC by 96% and 35%, respectively. As anticipated, hydrogel delivery reduced CD40 mAb loss to off-target antigen sinks such as the liver and the spleen, where CD40 mAb AUC decreased by 15% and 23%, respectively.

Consistent with these findings, we observed reduced toxicity in mice treated with hydrogels. In particular, mice treated with CD40 hydrogels had attenuated weight loss and recovered their weight more quickly than bolus controls. Serum cytokine analyses confirmed that hydrogels mitigated cytokine storm compared to dose-matched local bolus controls. Toxic side effects were further diminished by reducing the dose of CD40 mAb in the hydrogels, but reduced dose did not impair antitumor efficacy. Overall, these results indicate that delivery via PNP gel improves safety and maintains efficacy of CD4 mAb at low doses.

This approach did not require modifying cargo in any way, thus we anticipate hydrogel delivery will also improve the safety of other potent biologics, including cytokines and bispecific antibodies. Overall, PNP hydrogels may provide a highly translatable solution to the problem of immune-related adverse effects.

5:55 AM F.SM07.04.05
Noninvasive Imaging of Tumor-Infiltrating Immune Cells Using Rare-Earth Nanoparticles to Monitor Response to Cancer Immunotherapy Swati Kataria[1,2] and Angela Belcher[1,2]; [1]Massachusetts Institute of Technology, United States; [2]Koch Institute for Integrative Cancer Research at MIT, United States

Cancer immunotherapy is fast emerging as the most promising treatment approach for a number of cancers, fueled by the breakthrough success of immune checkpoint inhibitors which promote immune-mediated clearance of tumors. However, the response rates to checkpoint inhibitors remain limited to 10-40% of patients, and it is a significant clinical challenge to identify candidates for treatment to minimize immunotherapy-related adverse events. Studies have shown that the presence of tumor-infiltrating lymphocytes (such as CD8+ T-cells, which drive tumor-cell killing) is one of the strongest prognostic factors predicting overall survival across a large number of cancers. Tumor biopsies have shown that during immunotherapy, responders exhibit an influx of activated CD8+ T-cells to the tumor site, while non-responding tumors continue to exclude them. Thus, the ability to visualize the distribution of tumor-infiltrating lymphocytes before and during treatment will allow us to observe and monitor the response status to therapy. However, it is a significant challenge to image and track immune cells in-vivo because they are relatively sparse and highly mobile. There is a need to develop new tools that can non-invasively assess the evolving immune composition of the tumor microenvironment, allowing evaluation of therapy-induced responses in real time.

Imaging in the near-infrared window (NIR-II 1000nm-1700nm) has generated growing excitement in recent years for deep-tissue optical imaging approaches. Biological tissue in this spectral range exhibits reduced scattering of photons and autofluorescence, enabling for high resolution imaging of deep tissue structures. Rare-earth nanoparticles (RENPs) have emerged as superior imaging agents due to their emission bands in regions of near-zero tissue autofluorescence (1300-1700nm), high photostability, and low intrinsic toxicity in a variety of animal models. We leverage advances in near-infrared imaging technologies using rare-earth nanoparticles to target and image immune cells in tumors as markers for therapeutic response. To achieve this, we synthesized small but ultra-bright rare-earth nanoparticles (sodium ytterbium fluoride doped

with erbium, cerium and zinc), and tailored the size and brightness during synthesis to enable observation of microscale features in-vivo. We then used a custom PEG-rich lipid formulation to make the nanoparticles serum-stable, and conjugated targeting antibodies on the surface to target immune cells of interest. We then performed both ex-vivo and in-situ labeling of immune cells in a murine melanoma tumor model, known for its poor response to immunotherapy. We demonstrate the ability of these nanoparticles to non-invasively image trafficking of labeled immune cells to the tumor in subsets of mice undergoing checkpoint inhibitor therapy (anti-PD1), indicating immune-mediated anti-tumor activity. Our work focuses on one key immune-cell sub-type (CD8+ T-cells), but the modularity of rare-earth nanoparticles makes them ideal tools for multiplexing, allowing future studies that simultaneously image multiple cell types in tumors for a more complex understanding of tumor-immune dynamics.

6:05 AM *F.SM07.04.06
Making Cold Tumors Hot—Nano-Layered Particles for Systemic Cytokine Delivery Antonio Barberio, Sean Smith, Darrell Irvine and Paula T. Hammond; Massachusetts Institute of Technology, United States

Although immunotherapies have been highly effective for some forms of cancer, it has generally worked best in tumors in which there are significant numbers of leukocytes present that enable immune activation. Unfortunately, there are numerous aggressive cancer types which do not present with significant immune cell infiltration. These tumors tend to show little or no response to check point inhibitors or other therapies that block the regulatory response of the immune system; furthermore, such tumors are often also poor responders to Car-T and other more established immuno-therapeutic approaches. Cytokines can be potent immune stimulators that upregulate the innate immune response within a tumor microenvironment, causing a cascade of inflammatory signaling that can lead to activation of antigen presenting cells, and ultimately, the infiltration of tumor-specific CD8+ T cells and NK cells to the tumor site. This effect of creating a localized cytokine storm within the tumor can lead to a much more effective immune response against tumor cells; however delivery of cytokines, particularly highly potent and effective ones such as IL-12 can be difficult due to patient safety concerns. Release of cytokine to the blood stream can lead to harmful off-target effects, and these kinds of effects have made these proteins difficult to introduce as promising immunotherapies for patients. We have developed a modular nanoparticle approach using liposomal core particles and layering them with an electrostatic layer-by-layer (LBL) process in a simple and elegant method of constructing highly tailored ultrathin polymer coatings. The resulting LbL nanoparticles (NPs) have negatively charged outer layers that present polyelectrolytes such as dextran sulfate or hyaluronic acid in a hydrated brush arrangement that enables hydration, steric repulsion, colloidal and serum stability, and specific or non-specific targeting. We have determined a subset of polyanion outer layers that have high affinity and selectivity for ovarian cancer cells and, based on the polyanion composition, will cause trafficking either to the outer surface or to intracellular compartments in ovarian cancer cells. We have used this unique ability to control trafficking to create LbL NPs that can deliver IL-12 from the outer surfaces of ovarian cancer cells, thus generating highly localized depots that efficiently release cytokine and upregulate the immune response in high grade serous ovarian cancer, a cancer which has not previously benefitted from immunotherapeutic approaches. In vitro and in vivo results will be discussed, as well as release mechanisms, toxicity studies and clinical outlook for these targeted systems.

6:20 AM *F.SM07.04.07
Metabolic and Chemical Immunoengineering Enhances Anti-Tumor Immunity Li Tang; École polytechnique fédérale de Lausanne (EPFL), Switzerland

Cancer immunotherapy represented by immune checkpoint blockades has achieved remarkable clinical success. However, an outstanding challenge is that a great majority of patients fail to respond to this therapy. This is in part due to the fact that tumor infiltrating lymphocytes (TILs) become exhausted and eventually incapable to control tumor progression. Among exhausted $CD8^+$ TILs, a subpopulation, termed terminally exhausted $CD8^+$ T-cells, have superior cytotoxicity but largely reduced proliferation capacity, and are known to be the direct contributors to the anti-tumor cytotoxicity. However, this subpopulation does not respond to immune checkpoint blockades or most current immunotherapies and are difficult to expand and maintain with their cytotoxicity. In the first part of the talk, I will discuss a new metabolic immunoengineering approach that expands the terminally exhausted $CD8^+$ TILs and sustains their cytotoxic functions leading to eradication of established solid tumors and durable cures in a majority of treated mice when combined with adoptive T-cell transfer immunotherapies. Next, I will discuss a new cancer vaccine platform we developed recently for personalized neoantigen vaccine delivery, termed polycondensate neoepitope (PNE). PNE is a redox-responsive vaccine made through a reversible polycondensation reaction of peptide neoantigens and adjuvants together with a tracelessly responsive linker-monomer. Peptide-based neoantigens with diverse sequences and structures could be co-polymerized with molecular adjuvants to form PNEs of high loading capacity for vaccine delivery without adding any carriers. The redox-responsive PNEs with controlled molecular weights and sizes efficiently targeted and accumulated in draining lymph nodes, and greatly promoted the antigen capture and cross-presentation by professional antigen presenting cells. Mice immunized with PNEs showed markedly

enhanced antigen-specific T cell response and the protective immunity against the tumor cell challenge.

6:35 AM F.SM07.04.08
Engineering Biomaterials to Overcome Hypoxia-Driven Immunosuppression and Boost Cytotoxic T Cells Thibault Colombani[1], Loek Eggermont[1], Stephen Hatfield[1], Mahboobeh Rezaeeyazdi[1], Adnan Memic[1,2], Michail Stikovsky[1] and Sidi A. Bencherif[1,3]; [1]Northeastern University, United States; [2]King Abdulaziz University, Saudi Arabia; [3]Harvard University, United States

Hypoxia, a state of low oxygen tension, is one of the major obstacles in the treatment of solid tumors due to its inhibitory potential on cytotoxic immune cells. Targeting hypoxia-driven immunosuppression is a promising approach to prevent tumor escape from immunosurveillance. Biomaterials with a capacity to produce oxygen and be delivered near a tumor bed represent a viable strategy for reversing local hypoxia. This approach could boost effector functions of antitumor T cells, and potentially reinforce current cancer immunotherapies. Recently, we engineered injectable oxygen-generating biomaterials, known as cryogels. Oxygen-generating cryogels (O_2-cryogels), with their unique physical features, including mechanical robustness and syringe injectability, were designed to release oxygen in a controlled and sustained fashion. We found that local oxygenation from O_2-cryogels downregulated hypoxia-inducible gene expression in hypoxic murine melanoma and reduced the accumulation of immunosuppressive metabolites such as extracellular adenosine. Strikingly, O_2-cryogels released the break on the tumoricidal function of hypoxic T cells against melanoma in a very short time (< 4h). Mechanistically, O_2-cryogels *i*) enhanced T cell–tumor cell interactions; *ii*) increased T cell-mediated production of cytotoxic proteins (perforin and granzyme B) fatal to tumor cells; and, as a result, *iii*) restored the killing ability of antigen-specific T cells. Collectively, O_2-cryogels provide a unique platform to expand our understanding on how hypoxia affects immune cells and may leverage emergent cancer immunotherapies to circumvent hypoxia-driven immunosuppressive mechanisms and achieve more predictable and favorable outcomes.

Establishing the Role of Matrix Viscoelasticity on Cancer-Macrophage Migration and Phenotype Kolade Adebowale and Ovijit Chaudhuri; Stanford University, United States

Increased tumor stiffness and alterations in viscoelasticity has been implicated in cancer progression. Viscoelastic materials exhibit stress relaxation, which results in resistance to a deformation relaxing over time.Emerging evidence indicates that macrophage immune cells play a key role in regulating cancer progression and can constitute up to 50% of the tumor mass. Macrophages migrate into the tumor microenvironment where they can polarize to a cancer supporting (anti-inflammatory) or cancer inhibiting (pro-inflammatory) phenotype. Current work has demonstrated the impact of 2D elastic substrates on macrophage phenotype. However, the impact of viscoelasticity on macrophage polarization and migration in 3D is unknown. Here, we develop an alginate-collagen based matrix that has tunable viscoelastic properties to examine how matrix viscoelasticity impacts macrophage migration and phenotype. The choice of collagen as the biochemical ligand is to mimic the stromal matrix where immune cells are typically found. Importantly, the viscoelastic properties are tuned independent of polymer concentration and Young's modulus by varying the molecular weight and crosslinking of the gels, allowing for the impact of matrix viscoelasticity to be specifically demonstrated. Specifically, we can tune the characteristic stress relaxation times from ~100 to 5,000 seconds while keeping the initial Young's modulus of all the materials at ~2kPa. U937 pro-monocytic cells lines were encapsulated in the 3D alginate-collagen matrix and cell migration was assessed using confocal time-lapse microscopy. The results demonstrate enhanced cell migration with faster matrix stress relaxation. Ongoing studies are examining the impact of matrix viscoelasticity on U937 polarization as well as elucidate the biophysical mechanisms of U937 immune cell migration.

Engineering Innate Immune Mediated Cancer Cell Killing by Antibody Recruiting Macromolecules Bruno G. De Geest and Annemiek Uvyn; Ghent University, Belgium

Binding of monoclonal antibodies (mAbs) onto a cell surface triggers antibody-mediated effector killing by innate immune cells through complement activation (CDC), antibody-dependent cellular cytotoxicity (ADCC) and antibody-dependent phagocytosis (ADCP). As an alternative to mAbs, synthetic systems that can recruit endogenous antibodies from the blood stream to a cancer cell surface could be of great relevance. Herein, we explore antibody-recruiting polymers (ARmacro) as a

novel class of immunotherapy. ARmacro consist of a cell-binding motif linked to a polymer that contains multiple small molecule antibody-binding motifs such as dinitrophenol and rhamnose along its backbone or at dangling chain ends. As a proof of concept, we employ a lipid anchor that inserts into the phospholipid cell membrane or a ctclooctyne that covalently conjugates to the glycocalyx of metabolically azide-labeled cells. We demonstrate that macro allow for high avidity antibody binding and drive antibody recruitment to treated cells for several days. Furthermore, we show that macro-treated cancer cells are prone to antibody-mediated killing through phagocytosis by macrophages.

Development of Platelet-Based Drug Delivery System Brian Schnoor and Anne-Laure Papa; George Washington University, United States

Introduction: The interactions between platelets and circulating tumor cells (CTCs) facilitate the survival and dissemination of these cells during the metastatic cascade by cushioning the CTCs and thus protecting them from both shear stress and the immune response [1-3]. We recently demonstrated that drug free-platelet decoys display an anti-metastatic effect on disseminating cancer cells *in vivo* by providing an anti-platelet effect [4]. The goal of this current study is to design a platelet-based drug delivery system capable of targeting CTC clusters, which are multicellular assemblies of CTCs and platelets, consolidated by fibrin. Developing novel therapeutic strategies to abate the enhanced metastatic potential of these clusters (as opposed to single CTCs) is essential to limit metastatic dissemination and increase CTC vulnerability in the circulation. A system leveraging the effect of decoy platelets while incorporating a drug delivery component could effectively target and dissociate CTC clusters.
Materials and Methods: For the development of this cellular engineering system, the FDA-approved therapeutic agent Tissue Plasminogen Activator (TPA) was immobilized on the surface of a Lyophilized Platelet (LP) carrier. The LP carrier was chosen because it preserves platelet surface structures while inhibiting platelet function. This system was characterized by flow cytometry and a fluorescence assay to determine the carrier decoration level and drug loading. The loading method was optimized for incubation time and component concentration. Flow cytometry was used to determine the availability of GP IIb/IIIa receptors, integral to the system's interaction with CTCs. Finally, fibrinolytic and clot lysis activity of the system was measured using a fluorescent assay and an absorbance assay, respectively.
Results and Discussion: The results demonstrated that TPA was successfully loaded onto the LP carrier with a high level of decoration (97.8% decorated LP) and loading efficiency (38.5%). Flow cytometry confirmed that the GP IIb/IIIa receptors needed for the system to interact with cancer cells were available for CTC binding. The fibrinolytic assessment demonstrated that TPA retained its effectiveness when loaded onto the system. The fluorescent assay indicated that the rate of fibrinolysis was maintained for loaded TPA and the clot lysis assay showed almost identical curves for absorbance. These results demonstrate that the loading was successful, and the system components retained their functionality.
Conclusions: Through an optimized loading procedure, a platelet-based delivery system for TPA targeting CTC clusters was created. This is an important step in developing a method to delay metastasis by targeting CTC clusters. Moreover, this system can be adapted toward other conditions requiring a fibrinolytic response. With minor alterations, this system could treat strokes by targeting and lysing dangerous clots. To create a viable system, the effectiveness of the system will need to be assessed *in vitro* and *in vivo*, however, these results demonstrate the viability of this approach for multiple medical applications.
Acknowledgments: This work has been supported by the George Washington University startup funds and the Department of Defense Breast Cancer Research Program Expansion Award (W81XWH-19-1-0667).

Human Primary Macrophages Upregulate M1 Phenotype Markers in Response to Chemically Modified Alginates Erin O'Brien[1], Stephen T. Nestor[2], Arturo Vegas[2] and Kara Spiller[1]; [1]Drexel University, United States; [2]Boston University, United States

Introduction: Angiogenesis is largely directed by macrophages, immune cells that can change their phenotype in response to external stimuli. Macrophages precisely control the timing and dosage of angiogenic growth factors, and also direct the innate immune response to biomaterials. Therefore, biomaterial-mediated macrophage modulation is an attractive strategy to recover dysfunctional angiogenesis. Macrophage phenotypes encompass a wide spectrum, but in vitro are commonly categorized as M0 before activation, then M1 or M2 post-activation, with several identified subtypes under the M2 umbrella. Although each phenotype's exact role in angiogenesis is not well understood, there is a growing body of evidence suggesting that early M1 macrophages initiate blood vessel sprouting, and subsequent M2 activity stabilizes these structures. Recent studies also indicate that M1 macrophages that switch to an M2 phenotype may have enhanced angiogenic properties. Furthermore, in pathologies where angiogenesis is inhibited, such as chronic wounds, M1 macrophages are insufficiently activated and fail to switch to an M2 phenotype. Thus, biomaterial strategies that seek to recover dysfunctional angiogenesis should aim to initially promote a robust M1 macrophage phenotype.
Previous work from Vegas et al. established a library of alginate hydrogels modified with chemical functionalities, then ranked it by inflammatory activity, as measured by levels of cathepsin activity in vivo. This study was conducted to test the capabilities of the inflammatory alginate hydrogels to promote an M1 phenotype in primary human macrophages in vitro. Here we seeded M0 macrophages onto alginate hydrogels, then used Nanostring, a high-throughput gene expression assay, to measure expression of M1 markers, M2 markers, and genes associated with angiogenesis or fibrosis.
Methods: 5 types of alginate hydrogels were fabricated by the Vegas lab at Boston University: 3 inflammatory, 1 anti-inflammatory, and 1 non-modified. Primary monocytes were purchased from the Human Immunology Core at the University of Pennsylvania and cultured with 20 ng/mL of macrophage colony stimulating factor (MCSF) to induce differentiation into macrophages. On day 5, 200,000 macrophages were seeded onto each 5 mm section of hydrogel in a 24-well plate. Samples were incubated for 1 hour at 37°C to allow cell attachment. 800 µL of complete media with MCSF was added to each scaffold-containing well. M0 and M1 control samples were refreshed with complete media with MCSF. 100 ng/mL of human recombinant IFNg and LPS were added to the M1 control samples to induce M1 activation. On day 7, media was removed and scaffolds were mechanically degraded and lysed. RNA was extracted and quantified. For samples with at least 20 ng/µL of RNA, 100 ng were hybridized with a 72-gene custom Nanostring Codeset targeting M1, M2, angiogenic, and fibrotic genes. Nanostring sample preparation and reading was conducted according to Nanostring's standard protocol.
Results: Nanostring gene counts were normalized to the Nanostring in-house controls and fold changes over the M0 controls were calculated. Of the M1 markers measured, two (CD80 and CCL2) were upregulated in macrophages seeded on the inflammatory alginate hydrogels. Interestingly, these genes were also highly upregulated in macrophages seeded on non-modified alginate, and were even upregulated in macrophages seeded on anti-inflammatory alginate, though to a lesser extent.
Conclusion: These findings show that alginate hydrogels may be able to induce an M1-like phenotype in macrophages, via upregulation of CD80 and CCL2. However, proinflammatory modification of these hydrogels did not seem to enhance this upregulation. Instead, the results of this study suggest that alginate may be a naturally inflammatory material. Further investigation of the inflammatory properties of alginate are necessary to explore its potential as an M1 phenotype-promoting biomaterial.

New Class of Biodegradable Drug Delivery Vehicles Eva Krakor, Isabel Gessner, Veronika W. Wulff, Astrid Schauss, Uwe Ruschewitz and Sanjay Mathur; University of Cologne, Germany

The field of nanoparticles for biomedical applications has become one of the most promising and most studied topics in the last years because it offers potential enhancement in pharmaceuticals, medical imaging and diagnosis, cancer treatment, implantable materials and tissue regeneration. In terms of therapeutic applications, especially drug delivery vehicles have been intensively studied. In this case, hollow particles have aroused tremendous interest due to their unique properties such as large surface areas, low densities and high loading capacities due to a protected hollow core. The transport of therapeutic, which can be either, encapsulated, covalently attached or adsorbed onto hollow particles, has been shown to be highly beneficial for multiple reasons compared to simple drug administration e.g., the cargo is protected against enzymatic degradation and the total drug administration can be reduced, which minimizes the risk of side effects.
HMSC were synthesized through a hard template-based method. First, ellipsoidal hematite particles were synthesized in a

solvothermal process and coated with silica in a sol gel process afterwards. The iron oxide core was removed by etching resulting in HMSC. The porosity of as-prepared particles was analyzed using nitrogen adsorption-desorption method revealing a pore size of circa 4 nm and a high surface area of 308.8 m_2/g. Cytotoxicity was determined using cell viability test (MTT) towards human kidney cells (HEK293) which clearly demonstrates that no reduction of cell viability was observed even at high concentrations of 100 µg/ml. Uptake studies using confocal microscopy were carried out using human cervical cancer cells (HeLa) which could show the successful internalization over a period of 24 hours. For testing their capability as drug delivery vehicle, a hydrophilic antibiotic (ciprofloxacin) and a hydrophobic anticancer (curcumin) compound were loaded and a pH dependent release under physiological conditions at 37°C was monitored via UV-Vis spectroscopy. After the drug release a reduction in shell thickness of HMSC was confirmed via SEM and TEM images. This study demonstrates the suitability of as-prepared hollow silica capsules as drug delivery vehicles for a broad range of drugs, hydrophobic as well as hydrophilic. Furthermore, it would be possible to modify the surface of drug loaded HMSC with proteins, e.g. antibodies as they are often used in immunotherapeutic regimens.

Nanoparticle Synthesis by Engineered *E. coli* Cells Transformed with a Phytochelatin Synthase Gene Haley Hill, Manjula Bomma, Zhigang Xiao and Qunying Yuan; Alabama A&M University, United States

In this study, the phytochelatin synthase gene of *Rhizobium tropici* was assembled by PCR, inserted into pUC19 vector, and further transformed into *E coli* DH5α cells. Our preliminary data showed that these engineered *E coli* DH5α cells synthesized more selenium nanoparticles than DH5α cells transformed with pUC19 vector. The scanning electron microscope (SEM) examination of the nanoparticles revealed that the nanoparticles produced by both groups of cells had a size of 100-200nm with a spherical conformation, compositional analysis using Energy-dispersive X-ray spectroscopy identified that the nanoparticles only contain selenium. The capacity of phytochelatin synthase gene transformed bacteria to produce other metallic nanoparticles, including silver and gold will be tested and the physical properties of the nanoparticles will be further analyzed using the transmission electron microscope (TEM) analysis. The research results will be reported in the MRS meeting.

F.SM07.05.08
Late News: Vitamin Lipid Nanoparticles Enable Adoptive Macrophage Transfer for the Treatment of Multidrug-Resistant Bacterial Sepsis Xucheng Hou and Xinfu Zhang; OSU college of pharmacy, United States

Sepsis, a condition caused by severe infections, affects more than 30 million people worldwide every year and remains the leading cause of death in hospitals. Moreover, antimicrobial resistance has become an additional challenge in the treatment of sepsis, and thus, alternative therapeutic approaches are urgently needed. Macrophages are one of the most efficient pathogen scavengers. Indeed, in septic patients, impaired macrophages seem to be primarily responsible for insufficient antimicrobial defense. Nevertheless, immunostimulatory agents for reversing deactivated macrophages did not significantly improve the patient survival in clinical trials. This may be attributed to that immunostimulatory agents are not able to completely restore the function of impaired macrophages. Moreover, many bacteria, such as *Staphylococcus aureus* and *Escherichia coli*, have evolved immune escape mechanisms for thwarting phagolysosomal killing, resulting in intracellular survival. In addition, the prevalence of antibiotic resistance contributes to recurrent infections. Based on these research findings, we hypothesized that adoptive transfer of macrophages containing antimicrobial peptides linked to cathepsin B in the lysosomes (MACs) may enable the immunocompromised sepsis host to boost innate immunity, prevent bacterial immune evasion, and eliminate multi-drug resistant (MDR) bacteria.

To test our hypothesis, we first designed the AMP-CatB mRNA encoding an antimicrobial peptide IB367 (AMP-IB367), a cathepsin B (CatB), and a CatB-sensitive linker. AMP-IB367 is a broad-spectrum AMP with rapid bactericidal activity. CatB, an endogenous lysosomal protein, is first translated as an inactive precursor in the cytoplasm. After translocation into the lysosome, the precursor is processed into mature CatB. Here, the CatB is incorporated to transport the AMP-IB367 into lysosomes, where the linker is cleaved by CatB and thus the APM-IB367 is released. When phagosomes encapsulating bacteria fuse with lysosomes, the ingested bacteria are exposed to both pre-stored AMP-IB367 and lysosomal antimicrobial components. Although immune evasion strategies may protect MDR bacteria from phagolysosomal killing mechanisms, the AMP-IB367 is able to kill these bacteria. In order to equip macrophages with the AMP-CatB mRNA, we synthesized a series of vitamin-derived lipid nanomaterials. We found that the mRNA delivery efficiency of V_CLNPs was 10-fold better than Lipofectamine 3000 and 50-fold better than electroporation in RAW264.7 macrophages. After optimizing the molar ratio of V_C-Lipid:DOPE:Cholesterol and the mass ratio of V_C-Lipid:mRNA, we identified the optimal V_CLNPs formulation with improved mRNA delivery efficiency over 7-fold than its initial formulation. Because V_CLNPs were also effective to deliver mRNA in bone-marrow-derived macrophages (BMDMs), we chose BMDMs for further antibacterial studies because of the

clinical translatability. In vitro bactericidal results showed that MACs eliminated over 80% multi-drug resistant Staphylococcus aureus (MDRSA) or multi-drug resistant Escherichia coli (MDR E.coli) at 12 h. Next, we tested the therapeutic effects of MACs in MDRSA- and MDR E.coli-induced sepsis mice with immunosuppression. Analysis of blood at 24 h showed that MACs were more effective in cleaning bacteria than PBS-BMDMs. Furthermore, survival rate of MACs (83%) was significantly higher than that of PBS-BMDM group (40%).

In summary, we have developed macrophages containing antimicrobial peptides linked to cathepsin B in the lysosomes (MACs) via V_CLNPs-mediated delivery of mRNA. Our results prove the concept that adoptive transfer of MACs beneficially reduce bacterial burden and improve survival in MDR bacteria-induced sepsis mice with immunosuppression by restoring innate immune defense, preventing bacterial immune evasion, and eradicating infections.

F.SM07.05.09
Late News: TIO2 Increases Bacterial Infection by Altering the Distribution of Cholesterol on Cell Membrane Fan Yang[1], Yan Xu[1], Stephen Walker[1], Wonhwa Cho[2], Tatsiana Mironava[1] and Miriam H. Rafailovich[1]; [1]Stony Brook University, United States; [2]University of Illinois at Chicago, United States

According to the National Nanotechnology Initiative of America, titanium dioxide (TiO_2) is one of the most commonly manufactured nanoparticles. These nanoparticles are widely used in food, pharmaceutical, cosmetic and chemical industries as pigments, catalysts, and photovoltaic sources. The latter property is also exploited in water purification where UV-irradiated TiO_2 is a common anti-bacterial agent. However, there is no consensus on the toxicological profile of TiO_2 nanoparticles (NPs), and multiple concerns have surfaced on the potential harmful effects on human health[1]. Experiments conducted on HeLa cells indicated that cells cultured with 0.1 mg/ml rutile and anatase TiO_2 NPs for 24 hrs prior to exposure to *Staphylococcus aureus* (*S. aureus*) had 350 and 250% respectively more bacteria per cell, while macrophages exposed to TiO_2 NPs ingested 40% fewer *S. aureus*, further increasing the risk of infection when present in vivo[2]. The particles were observed to sequester within the cytoplasm of phagocytes simply occupying space which would normally be used for ingesting bacteria. Ingestion of TiO_2 NPs in HeLa cells resulted in an increase in membrane rigidity and extracellular LDH which was attributed to the increase in bacteria[2].
Another possible explanation may be in the concentration distribution of membrane cholesterol. Specifically, we demonstrate an increase in cholesterol concentration of the outer plasma membrane leaflet accompanied by the decrease in cholesterol inner leaflet concentration. Alteration of the inner/outer leaflet cholesterol ratio may also explain the increase in bacterial infectivity NPs since *S. aureus* requires cholesterol for proper membrane attachment and virulence. This effect was absent in ABCA1 knockout HeLa cells suggesting an interaction between TiO_2 and the ABCA, a known cholesterol membrane efflux regulatory protein that facilitates cholesterol transport across the cellular membrane. The hypothesis has also been confirmed by the RT-PCR data detecting the RNA expressions of ABCA1 and ABCG1. We found that compared to the control group, cells exposed to TiO_2 for 24 hrs had higher RNA expression levels to 240% and 170% for ABCA1 and ABCG1, respectively. These data indicate that cells exposed to TiO_2 NPs have altered cholesterol distribution within their membranes, which results in increased rigidity and enhanced bacterial infection. Further work is in progress to evaluate this effect in cells obtained from healthy human tissue.

F.SM07.05.10
Late News: Influence of Surface Topography and Modulus on Fibrinogen Adsorption and Subsequent Cell Response Jie Li and Kyla Sask; McMaster University, Canada

Introduction: Protein adsorption to a material is a complex process which causes thrombus formation, infection, and inflammation and can lead to failure of devices[1]. Surface properties such as chemistry, topography, and mechanics influence protein adsorption and structural changes. Fibrinogen plays a dominant role in mediating platelet and leukocyte interactions with surfaces and its degree of unfolding can impact the extent of cell activation[2]. Macrophages are essential in the immune response to biomaterials and the effect of protein conformational changes on their activation is not fully understood. This work aims to characterize protein adsorption and conformational changes on planar and patterned polydimethylsiloxane (PDMS) with varying elastic moduli and determine the relationship to macrophage response.
Methods: Microscale patterns were designed with three sizes of the following height : groove width : ridge width ratio: (1)

20:20:10 μm; (2) 20:20:20 μm and; (3) 10:10:10 μm. Photolithography and soft lithography are used with PDMS substrates of varying mixing ratios of Sylgard 184 and 527 to investigate the combined effect of surface topography and elastic modulus on fibrinogen adsorption and degree of unfolding. A micro-BCA assay was used to determine the amounts of fibrinogen adsorption (2.0 mg/mL in PBS) on PDMS with the range of stiffnesses. An antibody binding assay using a primary antibody to the fibrinogen gamma chain was developed to quantify the amount of fibrinogen adsorbed with exposure of the gamma chain. This assay will be extended to determine RGD density and further conformational changes of protein on PDMS. We are in the process of further interrogating the role of protein conformation on immune cell interactions using the RAW 264.7 macrophage cell line.
Results: Micropattern designs of three dimensions were prepared for photolithography and soft lithography. Contact angle measurements of PDMS substrates with varying stiffnesses indicated that ratios had relatively similar surface wettabilities with the 1:5 ratio slightly more and the 1:1 ratio slightly less hydrophobic. According to the BCA assay results, the 1:1 ratio of Syl 184 & 527 PDMS polymers adsorbed the most fibrinogen with an average of 10.50 ± 0.26 μg/cm^2, while the 1:5 ratio of Syl 184 & 527 adsorbed the least with an average of 8.88 ± 0.48 μg/cm^2. The antibody binding assay was completed and is being optimized to compare absorbance values based on the amount of fibrinogen determined from the BCA assay. This will provide an indication of changes in orientation and conformation as a result of varying surface topography and modulus.
Discussion and Conclusions: This work focuses on understanding the mechanisms underlying protein adsorption and subsequent cellular regulation abilities of microstructures and elastic modulus. The designed micropatterns provide a way to investigate the combined effect of topography and stiffness on protein adsorption and macrophage adhesion. The BCA assay indicates that varying the surface modulus has an influence on fibrinogen adsorption. The antibody binding assay will investigate whether protein conformational changes play a role in this varied amount. Future work is being completed to determine the establishment of macrophage focal adhesions and cytokine secretion profiles in response to micropatterned topography and elastic modulus. Controlling these surface properties provides a method to monitor macrophage activation and regulation of immune cell response.

Robust Immune Suppressing Nanoparticles to Overcome Multidrug Resistance in Breast Cancer Haneen Omar and Abdulaziz Almalik; King Abdulaziz City for Science and Technology, Saudi Arabia

Multidrug resistance (MDR), accounting for therapeutic failure, remains a major challenge to manage cancer effectively. Currently, there are only a few strategies that are executed to conquer MDR by restoring chemosensitivity. In this respect, we report an immune suppressing nanoparticle decorated with alpha-1 acid glycoprotein (AGP), an anti-inflammatory protein, to serve as an effective chemoresistant reversal agent to modulate MDR and resensitize aggressive breast tumour cells. Hyaluronic acid-chitosan nanoparticles decorated with AGP (AGP-HA NPs) were synthesized by a sequential ionic gelation method consisting of spray drying and AGP-surface adsorption. The morphology, size, surface charge density, and composition of the synthesized NPs were characterized by utilizing SEM, DLS, Zeta potential, and FTIR, respectively. We have investigated the potential efficacy of AGP-HA NPs in reversing the MDR phenotype of MDA-MB-231 in response to anti-cancer drug doxorubicin (DOX). Our findings showed synergistic antitumor effects between HA and AGP protein as evident from the significantly enhanced efficacy of DOX post switching drug resistance phenotype of the cells to chemo-sensitive phenotype. Overall, our results suggest that AGP-HA NPs represent a viable and effective treatment option to strengthen the anticancer effects of chemotherapeutic agents and potentially contribute to improving the survival rate of patients with metastatic breast cancer.

F.SM07.05.13
pH-sensitive Nanoparticles Based Oral Drug Delivery for the Treatment of Inflammatory Bowel Disease Eden M. Jacob and Sakthi Kumar; Toyo University, Japan

The role of nanomedicine as an enhanced pharmaceutical strategy to deliver drugs has been studied for quite a few decades. The emergence of pH-sensitive nanoscale particles is beneficial due to its ability to release its cargo only at a high pH environment of the colon, which helps for direct targeting of the inflamed tissues in inflammatory bowel disease (IBD). Hence, we have designed the formulation of biodegradable polymer poly (lactic-co-glycolic acid) nanoparticles coated with Eudragit® S100 (EPNPS) for the delivery of novel polyphenolic compounds to reduce the inflammation caused by proinflammatory cytokines. The EPNPs were prepared by a single emulsion solvent evaporation technique and were characterized for shape and surface morphology using a scanning electron microscope (SEM) and transmission electron

microscopy (TEM). The *in vitro* drug release was investigated using phosphate buffer saline (PBS) simulating different gut pH. The *in vitro* cytotoxicity of the EPNPs also evaluated and found to be highly biocompatible in nature. The inhibition of proinflammatory cytokines production also conducted using lactate dehydrogenase (LDH) assay. The characterization of EPNPs using SEM and TEM revealed spherical shape and smooth surface of the nanoparticles and was found to be 200-300nm in size. The EPNPs showed substantial improvement in the release of the drug, specifically at colonic pH. Results suggested that pH-sensitive EPNP nanoparticles as a promising candidate in the oral delivery to the colonic inflamed tissues.

Two is Better Than One—A Comprehensive Study on the Synergistic Effects of Co-Delivery of Paclitaxel and Parthenolide in Discoidal Bicelle, *In Vitro* and *In Vivo* Armin Rad, Mu-Ping Nieh and Xiuling Lu; University of Connecticut, United States

Combinatory modulation of the physical and biochemical characteristics of nanocarrier delivery systems is an emergent topic in the field of nanomedicine. Here, using the combined effects of incorporation of active targeting moieties, nanoscale morphology and shape, and physical properties for anti-cancer drugs function. We investigated a novel complex made of lipid bicelles nanocarrier for the efficient delivery of a combination of Paclitaxel (PTX). In addition, we hypothesized that Parthenolide (PTL) can be used as a chemosensitizers to restore the proper apoptotic signaling and to overcome chemotherapy resistance in human lung and breast cancer cells. We synthesized and characterized self-assembled bicelles (nanodiscs) and nanovesicles which were made up of short- (DHPC) and long-chain (DPPC) lipids encapsulating PTL and PTX molecules. By using simultaneous self-assembly encapsulation, we have encapsulated Parthenolide and Paclitaxel as two cancer drugs. Dynamic light scattering, small angle X-ray scattering (SAXS), Fluorescence-activated cell sorting (FACS), and fluorescence confocal optical microscopy (FCOM) were used to quantify and visualize the cellular uptake of folate-conjugated NPs, respectively and *in vivo* subcutaneous rat studies were performed to investigate the samples. Self-assembled lipid discoidal and vesicular nanoparticles with low-polydispersity ~30 nm size range and identical chemical compositions were synthesized, characterized, and correlated with in vitro cancer cellular internalization, in vivo tumor accumulation and cancer treatments. Folate targeted nanodiscs not only have shown a higher tumor uptake and therapeutic efficiency, but also exhibited well-defined size, robust formation, and high-efficiency encapsulation of hydrophobic molecules, which enable the scalable manufacturing of a generalized in vivo multimodal delivery platform. A comprehensive evaluation of different effective factors, such as loading rate, surface chemistry, nanocarriers shapes, and drug combination ratios were evaluated and a comprehensive regiment for an effective treatment is introduced. The negatively charged bicelles with a PTL:PTX:Lipid molar ratio of 2.5:1:500 yielded a discoidal shape with a uniform diameter of 30 nm and a bilayer thickness of 5 nm, indicated the best anti-cancer function against both regular and drug resistive lung and breast cancer cells. SAXS analysis was also performed to provide insight into how the hydrophobic PTL and PTX molecules interact within the bicelles. Further, flow cytometry followed by confocal microscopy analyses substantiates the superior transfection efficiency of bicelles. We further analyzed how the co-encapsulation and molar ratios of drug and nanocarrier may affect the anti-cancer efficiency *in vivo* and *in vitro*. Several important discoveries in this report are summarized below. Detailed structural analysis and loading capacity of bicelles with two hydrophobic drug molecules, PTX and PTL, are performed. The structural variation of discs strongly depends on the molecular size and shape of the payload. Generally speaking, bicelle shows great potential as a nanocarrier for hydrophobic drug molecules. Both in vitro and in vivo studies on A549 cell line using drug-loaded bicelles indicate high efficacy (high cellular uptake, low IC_{50} and MIC_{90}) for cancer treatment. Moreover, we demonstrate strong synergy with PTX and PTL with IC_{50} and MIC_{90} are magnitudes lower than those of the free drugs in DMSO or Cremophor El. The significant synergetic effect is observed in the MDR A549 cell line as well. The research outcome aims to provide an efficacious nanocarrier platform, which can potentially be generalized for transporting therapeutics and diagnostics to other types of cancers or diseased cells.

Harnessing the Secreted Extracellular Matrix to Direct Cell Responses for Percutaneous Devices Nicholas G. Fischer, David De Jong and Conrado Aparicio; University of Minnesota, United States

Native extracellular matrixes (ECM) acts as signaling repositories to regulate cell behavior and function. Installation of implantable medical devices disrupts these matrices and destroys spatiotemporal presentation and interaction of cells with microenvironmental cues. Regeneration of tissue niches is critical for long-term stability and integration of medical devices in patients. Here, we present a new, broadly-applicable physicochemical strategy for percutaneous devices to leverage secreted, nascent ECM for instructing epithelial cell behavior. We synthesized a set of photopolymerizable polymers with catechol and structurally-similar moieties, easily applied to percutaneous device surfaces like catheters, dental restorative materials, or orthopaedic implants, with systematically varied physicochemical properties but similar bulk mechanical properties. Tuning surface physicochemical properties, specifically charge and polarity, enabled us to tune keratinocyte hemidesmosome formation, adhesive structures that anchor cells to ECM, formation and downstream signaling. A series of inhibitor and knock-down experiments demonstrated the bioinstructive effect of our materials on elaborated ECM, laminin332 in particular, in an integrin-dependent manner. We propose our biostructure polymers direct cell responses via modulation of laminin332's structure in the pericellular ECM. Finally, we challenged our engineered materials in a course of experiments, including *ex vivo*, meant to reflect the harsh environment experienced during clinical therapeutic use and showed our materials retain their mechanical and bioinstructive properties. Taken together, we present a strategy to leverage the secreted matrix, via surface physicochemical properties, for control of ECM-mediated signals toward enhancing biological responses critical for long-term stability and integration of percutaneous medical devices.

12:46 PM F.SM08.04.02
Shifting Macrophage Phenotype to Encourage Angiogenesis in Murine Hindlimb Ischemia Model Greg Risser[1], Dong

Li[2], Samuel Sung[1] and Kara Spiller[1]; [1]Drexel University, United States; [2]Shanghai Jiao Tong University, China

Introduction: Therapeutic angiogenesis is a promising treatment for ischemic tissue disorders and for vascularizing biomaterials in regenerative medicine. Macrophages are important regulators of angiogenesis, playing distinct roles in different stages of angiogenesis due to their diverse phenotypes. Interleukin 4 (IL-4)-stimulated macrophages (M2) play a role in the later stage of angiogenesis, likely by stabilizing and supporting new blood vessels, although their precise functions are not known. Biomaterials that control macrophages may be advantageous compared to strategies targeting other cell types because macrophages regulate many different cell types involved in angiogenesis and tissue repair. However, macrophages are highly plastic cells that can easily change their phenotype upon encountering different stimuli at a wound site. Consequently, a localized drug delivery system is necessary to release polarizing signals to macrophages in a sustained manner to maintain and promote phenotype. As a potent stimulator of the pro-angiogenic M2 phenotype, IL-4 was encapsulated in poly(lactic-co-glycolic acid) (PLGA) microparticles for sustained release. To test their effects on macrophage phenotype and angiogenesis, the microparticles were co-delivered with fluorescent macrophages into a murine model of hindlimb ischemia three days post-surgery.

Materials and Methods: Using double emulsion, IL-4 was encapsulated into PLGA microparticles (30-40 μm). Green fluorescent protein-labeled (GFP+) murine bone marrow derived macrophages were gathered and cultured to an M2 phenotype via stimulation with IL-4. These macrophages and microparticles were injected intramuscularly into the calf of a hindlimb ischemia murine model 3 days post injury. Mice were sacrificed two days later, and their calves harvested for flow cytometry analysis and immunohistochemistry (IHC). Using collagenase to digest the muscle, a single cell solution of the calf was stained with multiple macrophage phenotype markers (F4/80, CD206, ARG1, CD38, CD86) and Live/ Dead (L/D) markers. Separately, the solution was also stained with F4/80 and endothelial cell marker CD31. Flow data were analyzed using tSNE dimensionality reduction and Phenograph and FlowSOM clustering algorithms. Calf muscle sections were stained with DAPI and CD31, and images were analyzed with CellProfiler for CD31+ structures. All animal studies were approved by the Drexel Institutional Animal Use and Care Committee.

Results and Discussion: The number of GFP- macrophages was very high while the number of recovered GFP+ macrophages was exceedingly low, indicating that any effects of microparticles on angiogenesis and macrophage phenotype was caused by host macrophages. IL-4 releasing microparticles caused macrophages to take on a complex phenotypic profile. IL-4 affected macrophages were highest in clusters expressing both M1 and M2 markers. Additionally, treatment with IL-4 releasing microparticles increased the amount of endothelial cells (F4/80-CD31+), suggesting angiogenesis. Analysis of CD31+ structures showed that IL-4-releasing microparticles increased the density of vessels of 5-18 μm in diameter, while small capillaries (2-5 μm diameter) were unaffected. IL-4 release from the microparticles may have cause the M2 macrophages to help support recently created blood vessels, thereby increasing the number of larger structures.

Conclusions: This study shows that IL-4 releasing microparticles can control macrophage phenotype to support the development of blood vessels *in vivo*.

Naturally-Derived, Powder-Based Lung Tissue Sealant for Pleural Defects Utilizing a Murine Model Patrick N. Charron, Spencer Fenn, Minara Aliyeva, Nirav Daphtary and Rachael Oldinski; University of Vermont, United States

Introduction: Damage to the pleural tissue lining the lungs can occur in a multitude of ways, resulting in fluid leak into the pleural cavity, which, left untreated, can result in mortality. Historically such cases were treated via pleurodesis. Recent developments of lung tissue sealants serve as alternatives, but few options are available. While popular sealant tests can deliver qualitative pass/fail data, there is lack of quantitative *in vivo* methods to characterize sealing capabilities of these materials, particularly for pleural applications. In addition, commercial products have failed due to poor design and administration. Herein, we describe our development of a powder sealant capable of adhering to tissue and crosslinking to form an elastic hydrogel, circumventing limitations of current tissue sealants.

Experimental methods: Methacrylated alginate (AMA) was synthesized and characterized via ^{1}H-NMR spectroscopy. To enable gelation, visible green light crosslinkers were incorporated into the polymer solution. A sodium ion exchange was performed, the solution was lyophilized, and the product was processed into a powder. To investigate physical material properties, gelation kinetics and the viscosities of reconstituted solutions were collected at 37C, via an oscillatory time sweep at 10% radial strain and 1 Hz during exposure to green light. Quantitative *in vitro* experiments: dynamic burst pressure experiments were conducted using a custom-built burst pressure testing device, using a modified ASTM F2392 standard. Quantitative *in vivo* experiments: a murine model was developed in which we controlled respiratory dynamics to

test sealant mechanics. Mice were anesthetized with pentobarbital sodium, tracheostomized, and paralized using pancuronium. Body temperature was maintained by keeping the animal under a lamp. Mice were connected to a computer-controlled small animal mechanical ventilator (flexiVent, Scireq) and ventilated. A series of deep inflation maneuvers (Total Lung Capacity and Trapezoidal deep inflation waveform) and a composite signal comprising of mutually prime frequencies ranging from 0-20 Hz were performed to establish baseline for the animal prior to injury. The thoracic cavity of the animal was opened and lungs were punctured, followed by another series of baseline measurements to calibrate testing mechanics and verify injury. The injury was treated by the application of the AMA powder and tests were repeated to compare lung mechanics pre-injury and post-repair, allowing for real-time pressure data collection of lung mechanics during sealant testing. After testing, animals underwent euthanasia.

Results: After acute traumatic injury using a murine model, there was a loss in pressure, confirming the injury model. Successful post-repair (i.e., application of the AMA powder, hydration and crosslinking) tests indicated that the sealant maintained physiologically-relevant lung pressure and returned lung capacity to pre-injury values, and that the sealant did not fail. A failure in the patch would result in a failure to hold pressure. Initial results show physiologically relevant burst pressure values (i.e. 30 cmH2O) for the powder sealant collected during in vitro testing.

Conclusions: The data indicates efficacy of a novel powder-based elastic sealant for recapitulating lung mechanics post injury. During an *in vitro* burst pressure experiment, the powder formed an crosslinked sealant capable of maintaining physiological pressure before failure. The powder-based sealant has the advantages of adhering to tissue upon application *in situ* and subsequent hydration, remaining in place while crosslinking via light exposure took place. Future work will explore long term in vivo studies to investigate lung tissue healing after repair with the novel powder sealant material.

Late News: Microbial Biofactories—Production of Nanomaterials with Biomedical Applications Catherine P. O'Connell, David Medina and Thomas J. Webster; Northeastern University, United States

Antimicrobial resistance to antibiotics (AMR) and drug-resistant cancer are two of the main concerns that the healthcare system is facing nowadays [1,2]. Current chemotherapy treatments and antibiotic-based therapies are becoming ineffective or have plenty of drawbacks that are increasing the prevalence of resistance in both hospital and community settings. Therefore, new alternatives are needed, and nanotechnology might offer a suitable answer.

Although different nanomaterials are being used as a method to fight pathogens and cancer, traditionally synthesized nanoparticles present drawbacks, such as the production of toxic by-products, increased cytotoxicity in the cell and lack of selectivity. Consequently, green nanotechnology appears as an alternative approach, which employs living organisms and biomolecules as raw materials in a cost-effective and environmentally-friendly approach [3]. Among all these methods, microbially-produced nanomaterials have presented a significant potential, rendering nanomaterials with a powerful antimicrobial activity that can be tailored to the infection.

With the objective to demonstrate the antimicrobial and biocompatibility efficacy of bacterial-produced nanoparticles in skin bacterial infections, top pathogenic strains found in cutaneous wounds were employed for the synthesis of metalloid selenium nanoparticles (SeNPs), including Methicillin-resistant *Staphylococcus aureus* or *Pseudomonas aeruginosa*. Once generated, the SeNPs were analyzed in terms of their physicochemical features and the composition was extensively studied. After purification, the SeNPs were used as antimicrobial and anticancer agents through colony counting unit and MTS assays, respectively, as well as characterized for the mechanisms of death associated to their activities. At the same time, low cytotoxicity was demonstrated over the same range of antimicrobial efficiency.

Consequently, microbiological agents were successfully used as a biofactories for the generation of SeNPs of different compositions with biomedical properties. Therefore, bacteria were presented as a suitable approach for the synthesis of nanomaterials in a green fashion, overcoming the limitations of traditional nanotechnology.

Biomaterial-Guided Recruitment of Endothelial Progenitor Cells for Vascular Regeneration Mohamed A. Elkhodiry[1], Omar Bashth[1], Gaetan Laroche[2,3], Jean-François Tanguay[4,5] and Corinne A. Hoesli[1]; [1]McGill University, Canada; [2]Université Laval, Canada; [3]Centre de Recherche du CHU de Québec, Canada; [4]Montreal Heart Institute, Canada; [5]Université de Montréal, Canada

Endogenous endothelial progenitor cell (EPC) recruitment to sites of vascular injury is a multi-step process mediated by selectins, chemokines, and extracellular matrix (ECM) proteins. New vascular implants with surface-immobilized capture antibodies targeting circulating EPCs have shown clinical promise in accelerating the formation of neo-endothelium to cover the implant. The absence of subsequent adhesion-based signaling needed for EPC proliferation and differentiation could explain the lack of long-term improvement in vascular re-stenosis and overall vascular recovery. Antibodies can mimic the cell tethering effect of selectins but lack necessary EPC signaling effects introduced by cytokines and ECM proteins. We have previously shown that ECM-derived peptides, such as RGD, can promote the adhesion and enhance the clonal expansion of EPC-derived endothelial colony forming cells (ECFCs) via integrin based signaling. In this study, we developed a novel bifunctional surface modification strategy to produce surfaces that combine immobilized capture-antibodies and surface grafted ECM-derived peptides with controlled surface concentrations and ligand orientation. We hypothesize that this bifunctional strategy would further accelerate the re-endothelialization process while maximizing downstream endothelial function and vascular recovery via an integrin-dependent process.
Peripheral blood from 22 adult human donors was used to obtain donor-specific ECFCs. Aminated culture surfaces were modified by either the covalent conjugation of a customized RGD peptide, immobilization of vascular endothelial growth factor receptor-2 (VEGFR-2) antibody, or combining both biomolecules at different ratios using an optimized process. Unmodified surfaces were used as a negative control. Surface concentration of the peptide and antibody were analyzed using fluorescence microscopy and an enzyme-linked immunosorbent assay. First, the expanded ECFCs were seeded under static conditions and cell adhesion was studied using immunocytochemistry. ECFC interactions with the bifunctional surfaces were then interrogated under more physiologically relevant dynamic flow conditions in a microchannel perfusion loop at 1 dyn/cm^2 wall shear stress and analyzed through live cell imaging followed by immunocytochemistry.
Surfaces with immobilized anti-VEGFR-2 antibodies displayed significantly enhanced ECFC capture potential compared to RGD and unmodified controls as quantified by the number of adhered cells under both static and dynamic conditions. Average ECFC spreading and focal adhesion formation were significantly increased on RGD surfaces compared to the anti-VEGFR-2 and unmodified controls under both static and dynamic conditions. Total endothelial coverage and the total number of focal adhesions were maximized on the bifunctional surfaces combining the anti-VEGFR-2 and RGD due to a combined increase in both cell number and cell spreading. By increasing the peptide concentration on the bifunctional surfaces, ECFC spreading was increased without significantly affecting the number of adhered cells. These results suggest an additive (i.e. independent) effect of capture antibodies on ECFC tethering vs. RGD peptides on subsequent ECFC spreading and integrin-dependent cell signaling.
To our knowledge, this is the first study showcasing the ability of a bifunctional antibody/peptide surface modification strategy in promoting ECFC capture and adhesion. Our results also display a clear distinction between the mechanisms by which human-derived ECFCs react to immobilized capture antibodies and conjugated ECM-peptides. This strategy creates sequential steps of EPC trafficking to mimic endogenous processes of vascular healing which can potentially create an effective regenerative capacity for vascular implants.

Designing Soft Biomaterials with Multiscale Properties as Instructive Synthetic Extracellular Matrices April M. Kloxin; University of Delaware, United States

The biophysical and biochemical properties of the extracellular matrix (ECM) (e.g., mechanics, multiscale structure, receptor-binding sites) are essential for the function and regeneration of connective tissues throughout the body, from the collagen-rich loose irregular connective tissue of the lung to the dense regular connective tissue of tendon and ligament. To study the complex process of connective tissue healing outside of the body toward ultimately directing it in vivo, we have designed soft biomaterials, engineered synthetic hydrogels, that mimic key aspects of the collagen-rich ECM found in the early stages of tissue healing. These materials are constructed by bottom-up assembly of multifunctional collagen mimetic peptides (mfCMPs) designed with hydrogen bonding blocks and sticky ends for the formation of nano- and micro-fibrils and decorated with reactive handles for covalent crosslinking and labeling to control mechanical properties and bioactivity. We have established robust, scalable workflows for synthesis of these materials to facilitate their use in translational applications. Wound healing human mesenchymal stem cells (hMSCs) encapsulated within these materials exhibit good viability (over 85%) and significant elongation during 3D culture, with deposition of cell-secreted collagen I. Further, in response to a

chemokine gradient, hMSCs exhibit directional invasion and increased motility within these materials relative to hydrogels without mfCMPs. Our on-going investigations demonstrate the relevance of these collagen mimetic materials for fundamental studies to examine cell responses in fibrous wound-healing microenvironments and for translational studies to implement these materials as scaffolds for enhanced tissue regeneration.

Investigation of How Cell-Cell Communication in Regulating Dental Pulp Stem Cells Proliferation and Differentiation Ya-Chen Chuang[1], Haijiao Liu[1], Marcia Simon[1], Chang-Yong Nam[2] and Miriam H. Rafailovich[1]; [1]Stony Brook University, The State University of New York, United States; [2]Brookhaven National Laboratory, United States

Stem cells isolated from the dental pulp (dental pulp stem cells (DPSCs)) were shown the pluripotent differentiation properties, where the differentiation lineage can be regulated by both soluble and non-soluble factors. In our previous studies, we have shown that substrate modulus can trigger DPSCs to biomineralize when the modulus is higher than a critical value. However, the incomplete differentiation and amorphous particle-like mineral deposits were observed on flat hard substrates. Surface coating with TiO_2, on the other hand, was found to be able to induce osteogenic differentiation and hard tissue formation, regardless of substrate moduli. Instead of directly inducing the differentiation by substrate properties, lateral signals, cell-cell communication was also found to be important to regulate cell functions. Therefore, half-coating the polybutadiene (PB) substrates with TiO_2 by atomic layer deposition (ALD) were used to study DPSCs communication between cultures on TiO_2 coating and non-coating region of the substrate. The results showed that the cell proliferation was improved and biomineralization was induced from the cultures on the non-coating region, indicating the ability of lateral signal transduction in DPSCs. However, amorphous particle-like mineral deposits were present on the non-coating region while collagen fibers templated minerals were observed on the TiO_2 coating region. Hence, even though proliferation and biomineralization could be induced without directly contact with TiO_2-coated surface, while the ability to form fibers templated minerals, the structure required for bone or dentin tissue formation, is a function of surface properties, particularly the role of TiO_2 to nucleate banded collage fibers in enabling hard tissue formation.
This study address the importance of both integrin signals from substrate properties and transmembrane signals from cell-cell contact are important to investigate due to the dynamic *in vivo* environment, and was found to be able to regulate DPSCs proliferation and differentiation.

5:25 AM F.SM08.01.03
Harnessing the Secreted Extracellular Matrix to Direct Cell Responses for Percutaneous Devices Nicholas G. Fischer, David De Jong and Conrado Aparicio; University of Minnesota, United States

Native extracellular matrixes (ECM) acts as signaling repositories to regulate cell behavior and function. Installation of implantable medical devices disrupts these matrices and destroys spatiotemporal presentation and interaction of cells with microenvironmental cues. Regeneration of tissue niches is critical for long-term stability and integration of medical devices in patients. Here, we present a new, broadly-applicable physicochemical strategy for percutaneous devices to leverage secreted, nascent ECM for instructing epithelial cell behavior. We synthesized a set of photopolymerizable polymers with catechol and structurally-similar moieties, easily applied to percutaneous device surfaces like catheters, dental restorative materials, or orthopaedic implants, with systematically varied physicochemical properties but similar bulk mechanical properties. Tuning surface physicochemical properties, specifically charge and polarity, enabled us to tune keratinocyte hemidesmosome formation, adhesive structures that anchor cells to ECM, formation and downstream signaling. A series of inhibitor and knock-down experiments demonstrated the bioinstructive effect of our materials on elaborated ECM, laminin332 in particular, in an integrin-dependent manner. We propose our biostructure polymers direct cell responses via modulation of laminin332's structure in the pericellular ECM. Finally, we challenged our engineered materials in a course of experiments, including *ex vivo*, meant to reflect the harsh environment experienced during clinical therapeutic use and showed our materials retain their mechanical and bioinstructive properties. Taken together, we present a strategy to leverage the secreted matrix, via surface physicochemical properties, for control of ECM-mediated signals toward enhancing biological responses critical for long-term stability and integration of percutaneous medical devices.

5:35 AM *F.SM08.01.04
Functional Biomaterials from Functionalized Proteins—User-Programmable Hydrogels to Probe and Direct 4D Stem Cell Fate Cole DeForest; University of Washington, United States

The extracellular matrix directs stem cell function through a complex choreography of biomacromolecular interactions in a tissue-dependent manner. Far from static, this hierarchical milieu of biochemical and biophysical cues presented within the native cellular niche is both spatially complex and ever changing. As these pericellular reconfigurations are vital for tissue

morphogenesis, disease regulation, and healing, *in vitro* culture platforms that recapitulate such dynamic environmental phenomena would be invaluable for fundamental studies in stem cell biology, as well as in the eventual engineering of functional human tissue. In this talk, I will discuss some of our group's recent success in reversibly modifying both the chemical and physical aspects of synthetic cell culture platforms with user-defined spatiotemporal control, emphasizing new material strategies that are genetically encoded. Results will highlight our ability to modulate intricate cellular behavior including stem cell differentiation, protein secretion, and cell-cell interactions in 4D.

5:50 AM F.SM08.01.05
Vibrational Spectroscopy of the Electropolymerization of Poly(3,4-ethylenedioxythiophene) Copolymers Shrirang S. Chhatre, David Bruce Chase and David C. Martin; University of Delaware, United States

Various functionalized polythiophenes, particularly poly(3,4-ethylenedioxythophene) (PEDOT), have been investigated as tissue interfacing materials in medical devices and implants. Polythiophenes have the ability to communicate both electronically and ionically; thus, allowing it to communicate both with implanted electronic devices and electrolytically-active organs. They possess mechanical properties intermediate to hard inorganic electronics and soft wet tissue. Additionally, they are mechanically and chemically stable. These features make PEDOTs prime candidates for neural regeneration applications. However, despite the continued interest in PEDOT, there are still many unanswered questions. A major challenge is the relative insolubility of PEDOTs in most major solvents which prevents an accurate analysis of the degree of polymerization.
PEDOT and its copolymers, including the polymer formed from the carboxyl-substituted monomer P(EDOT-acid), have received specific attention because of their chemical stability and excellent charge transport properties. We have been investigating the use of vibrational spectroscopic techniques along with Gaussian molecular simulations to obtain a better understanding of the polymerization process. This complements ongoing research in our laboratory using in-situ Transmission Electron Microscopy (TEM) and hot stage optical microscopy (OM).
We were able to collect a Gel Permeation Chromatogram of P(EDOT-acid) thus allowing us for the first time to associate the vibrational spectra of a polymer with its molecular weight. Complimenting this with Density Functional Theory calculations and experimental vibrational spectroscopy (Raman and FTIR) data for various oligomers we are able to develop a deeper understanding about the chemistry and the material properties of these materials. We are examining the influence of chain length and conformation on the experimental and simulated vibrational spectra of PEDOT and P(EDOT-acid) oligomers. We have identified characteristic peaks associated with the reactive hydrogens on the thiophene ring that allow us to monitor the process of polymerization. We have specifically studied the vibrational modes associated with the reactive protons and conjugation of the thiophene network. The 3110 cm^{-1} thiophene C-H stretch peak is of particular interest, since it decreases with intensity as the monomers react. In addition, we have monitored the peak at 1422 cm^{-1} associated with the C=C stretch and the peaks at 835-1184 cm^{-1} associated with backbone conjugation. The peaks at 1540 cm^{-1} and 1570 cm^{-1} are associated with the quinoidal structure of the PEDOT. These clues provide insight into the changes occurring during the polymerization reaction. By correlating these spectroscopic results with data using microscopy, we are developing a deeper understanding of the thiophene electropolymerization reaction.

Biomaterial Approaches to Endogenous Tissue Repair in the Heart Jason Burdick; University of Pennsylvania, United States

Heart disease is the leading cause of mortality across the world and myocardial infarctions (MIs) are individually linked to at least 50% of deaths. During MI, blood supply to cardiac tissue is compromised, initiating a tissue remodeling response, which includes the loss of contractile cardiomyocytes and the replacement of healthy tissue with non-contractile fibrotic tissue. One goal in the treatment of MI is the replacement of these lost cardiomyocytes to improve cardiac function; however, cell-based therapies have not been successful to do this. An alternative to cell delivery is to promote endogenous cardiomyocyte proliferation using growth factors, small molecules, and gene transfer. Specifically, microRNA-based therapies that target cardiomyocyte proliferation have great potential for the treatment of MI, including the miR-302/367 cluster.

We developed an injectable hyaluronic acid (HA) hydrogel for the local and sustained delivery of miR-302 mimics to the heart. The hydrogel is based on the assembly of HA through modification with host-guest chemical groups, namely cyclodextrin (host) and adamantane (guest). These modifications permit the fabrication of shear-thinning and self-healing hydrogels that can be injected into cardiac tissue. The miR-302 mimics released from hydrogels in vitro over a week and promoted cardiomyocyte proliferation and a single injection of the hydrogel in the mouse heart led to local and sustained cardiomyocyte proliferation for two weeks. After MI, miR-302 hydrogel delivery caused local clonal proliferation and increased cardiomyocyte numbers in the border zone of Confetti mice. Further, the hydrogel delivered miR-302 decreased cardiac end-diastolic (39%) and end-systolic (50%) volumes and improved ejection fraction (32%) and fractional shortening (64%) four weeks after MI and injection, compared to controls. This is quite promising towards the development of new therapies in cardiac regeneration and we are currently investigating other delivered therapeutics, such as extracellular vesicles.

To better understand the action of molecules on tissues, in vitro models are needed. However, current models are limited in the engineering of functional tissue models with requisite cell densities and heterogeneity to appropriately model cell and tissue behaviors, such as cardiac tissue after MI. To address this, we developed a new bioprinting approach to transfer cellular spheroids into self-healing support hydrogels at high resolution, enabling their patterning and fusion into high-cell density microtissues of prescribed spatial organization. We bioprinted induced pluripotent stem cell-derived cardiac microtissue models with spatially controlled cardiomyocyte and fibroblast cell ratios to replicate the structural and functional features of scarred cardiac tissue that arise following MI, including reduced contractility and irregular electrical activity. The bioprinted *in vitro* model was then combined with functional readouts to probe how various pro-regenerative microRNA treatment regimes influenced tissue regeneration and recovery of function as a result of cardiomyocyte proliferation. This method is useful for a range of biomedical applications, including the development of precision models to mimic diseases and for the screening of drugs, particularly where high cell densities and heterogeneity are important.

5:15 AM F.SM08.02.03
Late News: Influence of Composition of β-TCP and Borate Bioglass Scaffolds on Cell Proliferation of Adipose Tissue-Derived Mesenchymal Stem Cells—Osteogenic Differentiation Carlos Paucar, Natalia Jaramillo, Ana I. Moreno, Valentina Ospina and Claudia Garcia; National University of Colombia, Colombia

Cell proliferation and osteogenic differentiation of mesenchymal stem cells were evaluated in contact with biodegradable and bioactive ceramic scaffolds. These structures were generated by 3D printing with Schwarz D geometry based on periodic minimum surfaces (TPMS). For its printing, composition by weight of the ceramic paste was used was 66.5% calcium phosphate β-TCP or 66.5% calcium phosphate with Magnesium β-TCP / Mg, 28.5% Bioglass Borate (BGBS), 3% Atapulgite and 2% of water. The osteogenic differentiation of mesenchymal stem cells (hMSC) from human adipose tissue (ADSCs) was performed. The scaffolds were characterized by X-ray diffraction (XRD) and infrared spectroscopy (FTIR), morphology, porosity and interconnectivity of the pores by scanning electron microscopy (SEM), degradability was tested by ISO 10993-14 standard, in vitro bioactivity by means of immersion tests in SBF by Kokubo test in different time intervals, cell proliferation and osteogenic differentiation by means of alkaline phosphatase activity.
The structural results showed calcium phosphate associated with its respective crystalline phases (β –TCP) and (β –TCP)/ Mg, in addition to the amorphous character of Bioglass Borate (BGBS). Calcium phosphate scaffold with Magnesium (β –TCP)/Mg showed better degradability and bioactivity compared to the (β –TCP) scaffold. Both scaffolds showed porosity and interconnectivity of pores. As for the mesenchymal stem cells from adipose tissue, they showed good adhesion and cell proliferation in contact with the scaffolds, being the scaffolds doped with Mg a better promoter of cell proliferation, in addition to this; they do not generate any cytotoxic effect in the cells, and finally the differentiation to an osteogenic environment was verified by means of alkaline phosphatase activity. As a result of this study, the 3D printed scaffolds showed good performance on cells proliferation of adipose tissue derived mesenchymal stem cells and the influence of magnesium is crucial for the development of osteogenic differentiation

5:25 AM *F.SM08.02.04
Annealed Hydrogel Microparticle (MAP) Scaffolds, Immune Response, and Regenerative Wound Healing Tatiana Segura; Duke University, United States

Injectable materials that can conform to the shape of a desired space are used in a variety of fields including medicine. The ability to fill a tissue defect with an injectable material can be used for example to deliver drugs, augment tissue volume, or

promote repair of an injury. This talk will explore the development of injectable materials that are based on assembled particle building blocks, for tissue repair. We find that using microparticle building blocks to build the scaffold generates a porous network by the space left behind between adjacent building blocks. Due to the injecability of this microporous material we have explored its wide applicability to tissue repair applicatins ranging from skin to brain wounds. In this talk, I will describe how MAP scaffolds can modulate the wound healing immune response and lead to regenerative wound healing.

Development of Biomimetic Models of Intestinal Tissue—Guiding Cellular Self-Organization Through Biofabrication Techniques Elena Martinez; University of Barcelona, Barcelona, Spain

Epithelial tissues contain three-dimensional (3D) microstructures that guide cell self-organization at the tissue level. In the small intestine, crypts and finger-like villi microstructures improve its absorbance function, provide specific microenvironments and compartmentalize cell types [1–3]. Despite its physiological relevance, tissue architecture and multicellular population are neglected in the standard in vitro models, thus compromising their predictive capabilities [4]. Our efforts in addressing these shortcomings by including key elements to mimic the native tissue in vitro will be discussed in this talk. First, this will include strategies to promote cell's self-organization capabilities giving rise to crypt-villus domains on 2D monolayers [5], and strategies to engineer cell spatial positioning through micropatterning. Then, our approach to include the 3D architecture of the tissue will be addressed. In here, light-based biofabrication techniques to produce 3D villus-like structures [6,7] will be discussed. Finally, I will introduce our biofabrication proposal to produce tissue engineered models that include the epithelial and the stromal compartments [8]. Improving the prediction capabilities of cell-based assays is a growing strategy to lead to more efficient drug development processes. As 2D-based systems are showing their limits, new 3D strategies are gaining acceptance among the scientific community [9]. Our approaches aim to further accelerate this trend by providing feasible strategies to routinely incorporate 3D multicellular structures at the tissue level in cell culture systems.

Engineering Epithelial Development Celeste Nelson; Princeton Univ, United States

The morphogenetic patterning that generates three-dimensional (3D) tissues requires dynamic concerted rearrangements of individual cells with respect to each other. We have developed microfluidic approaches to investigate the mechanical forces and downstream signaling responsible for generating the airways of the lung. I will discuss how we combine these experimental techniques with computational models to uncover the physical forces that drive development of complex epithelial geometries. I will also describe efforts to uncover and actuate the different physical mechanisms used to build the airways in lungs from birds, mammals, and reptiles.

5:30 AM F.SM08.03.03
Late News: Au Patterned Arrays and Spatially Controlled Bacterial Cell Organization Reveal Filamentous Cell

Interconnections in Multicellular Assemblies of Xylella Fastidiosa Silambarasan Anbumani[1], Richard Jannisen[2], Aldeliane M. da Silva[1], Mariana de Souza e. Silva[3], A. A. von Zuben[1], Hernandes F. Carvalho[1], Alessandra Alves de Souza[3] and Monica A. Cotta[1]; [1]University of Campinas, Brazil; [2]Delft University of Technology, Netherlands; [3]Agronomic Institute of Campinas, Brazil

Spatially controlled arrangement of bacterial adhesion and microcolonies (clusters of cells) has the great potential to unveil the dynamics of multicellular systems and especially complex biological phenomena such as cell-cell communication[1]. We present here a simple Au/SiO_2 device to spatially control bacterial cluster formation so that the basic biofilm framework can be studied in detail. Gold (Au) surfaces are biocompatible, chemically inert, and commonly used in diverse biomedical applications. On the other hand, thiol groups, which strongly interact with Au, are key functional molecules involved in adhesion mechanisms of several bacteria[2], including a plant pathogen *Xylella fastidiosa*.

In this work, Au patterned SiO_2 substrates have been prepared with direct laser writing lithography for selective bacterial adhesion of *X. fastidiosa*. The bacterial adhesion and aggregation were specifically tuned with well-defined geometry of Au array and different disk spacings. Ordered nucleated clusters on the Au patterned samples allowed us an extensive analysis for cell length populations with different growth time that represent unambiguous length distribution of typical cells (~3-4 μm) and filamentous cells (>9 μm) of *X. fastidiosa*[3]. Two filamentous cell populations are observed which relate well to the geometric distances between first and second neighbors in the disk array. Further, Au arrays with smaller spacings and closely organized clusters present larger fractions of filamented cells, when compared to Au arrays with larger spacings. We readily observed adjacent bacterial clusters interconnected by filamentous cells which predominantly depend on cluster sizes and disk distances. Upon continued growth, the clusters were interconnected by multiple filamentous cells that facilitate the macro-scale biofilm architecture of *X. fastidiosa*[3]. The results indirectly confirm quorum sensing based chemical signaling involved in the formation of filamentous cells associated with bacterial clusters of *X. fastidiosa*. The present approach based on Au patterned arrays is not only promising to understand various complex phenomenon of multicellular assembly but also offers new directions to engineering biological system.

Advances in Engineering Particles for Immunotherapy of Autoimmune Disease Jamal Lewis; University of California, Davis, United States

Current paradigms for the treatment of autoimmune diseases (e.g. rheumatoid arthritis [RA]) are woefully inadequate, often missing the mark on desired physiological responses and not targeting the root cause of the disease. Predictably, novel approaches to re-establish immune homeostasis in patients afflicted by autoimmune conditions are now under intense investigation. Notably, we are developing an array of multifunctional, biomaterial-based 'anti-vaccines' that can be easily administered to remediate some of the prevalent autoimmune diseases. In this talk, I will focus on two particulate systems currently under development in my lab, which attempt to control critical cellular and humoral mediators that engender conditions such as RA and autoimmune autism. Previously, our group demonstrated that subcutaneous injection of a dual-sized, biodegradable PLGA MP regulatory vaccine (REGvac), comprising two ~1 μm phagocytosable MPs (Vit D3 and collagen-II (coll-II)-loaded MPs) and two ~30 μm non-phagocytosable MPs (TGF-β1-loaded MPs and GM-CSF-loaded MPs), resulted in remission of the characteristic symptoms of RA. In this iteration, we used a singly encapsulated formulation of the REGvac, meaning each microparticle had one agent. To increase the translatability of this system we re-engineered this REGvac and applied it to a more rigorous model of RA, the collagen-induced arthritis/citrullinated fibrinogen induced

arthritis model (CIA/FIA). Further, we co-encapsulated each factor previously described in the REGvac into one small microparticle containing coll-II, citrullinated fibrinogen (cit fib) and Vit D3, and one large particle containing TGF-β1 and GM-CSF (*Duo* REGvac). Additionally, we tuned the release of each of the factors, fabricating the small MP from an increased molecular weight PLGA polymer and the large MP from a lower molecular weight PLGA polymer. This co-encapsulated formulation allows for the spatiotemporal control over delivery of each factor. The quick release of GM-CSF and TGF-β1 allows for rapid infiltration and recruitment of DCs to the injection site hours after the injection. The slower release of encapsulated factors from the small MP allows for a higher therapeutic payload to be delivered inside the cell. Moreover, Vit D3 co-encapsulation with antigen allows for tolerogenic cues to be delivered directly with antigen in a spatiotemporal context. We describe our efforts to improve the REGvac system and assess its ability to intervene in late stage RA in the CIA/FIA model. We are also heavily invested in developing a nanoparticle-based prophylactic for Maternal Autoantibody-related (MAR) autism. We previously demonstrated that LDH B peptide-functionalized citrate-coated dextran iron oxide nanoparticles (DIONPs) [Systems for Nanoparticle-based Autoantibody Reception and Entrapment (SNARE)] are capable of capturing LDH B autoantibodies from mothers of children with MAR autism *in vitro*. Further, we found that SNAREs intravenously injected in C57BL/6j pregnant dams demonstrated slow clearance from the blood (24 hours) and deposited in the liver and the lungs confirmed via histology and magnetic resonance imaging (MRI) analyses. Here, we investigated the ability of SNAREs to capture MAR autoantibodies in immunized pregnant dams. Remarkably, a single injection of 100 mg/kg SNAREs led to a 62% reduction of LDH B autoantibody maternal blood titer within 4 hours and 54% within 24 hours of injection with dampened titer levels for 5 days thereafter. The ability of SNAREs to capture MAR LDH B autoantibodies *in vivo* sets the basis for investigating its efficacy to prevent disease in a MAR autism mouse model.

Shifting Macrophage Phenotype to Encourage Angiogenesis in Murine Hindlimb Ischemia Model Greg Risser[1], Dong Li[2], Samuel Sung[1] and Kara Spiller[1]; [1]Drexel University, United States; [2]Shanghai Jiao Tong University, China

Introduction: Therapeutic angiogenesis is a promising treatment for ischemic tissue disorders and for vascularizing biomaterials in regenerative medicine. Macrophages are important regulators of angiogenesis, playing distinct roles in different stages of angiogenesis due to their diverse phenotypes. Interleukin 4 (IL-4)-stimulated macrophages (M2) play a role in the later stage of angiogenesis, likely by stabilizing and supporting new blood vessels, although their precise functions are not known. Biomaterials that control macrophages may be advantageous compared to strategies targeting other cell types because macrophages regulate many different cell types involved in angiogenesis and tissue repair. However, macrophages are highly plastic cells that can easily change their phenotype upon encountering different stimuli at a wound site. Consequently, a localized drug delivery system is necessary to release polarizing signals to macrophages in a sustained manner to maintain and promote phenotype. As a potent stimulator of the pro-angiogenic M2 phenotype, IL-4 was encapsulated in poly(lactic-co-glycolic acid) (PLGA) microparticles for sustained release. To test their effects on macrophage phenotype and angiogenesis, the microparticles were co-delivered with fluorescent macrophages into a murine model of hindlimb ischemia three days post-surgery.

Materials and Methods: Using double emulsion, IL-4 was encapsulated into PLGA microparticles (30-40 μm). Green fluorescent protein-labeled (GFP+) murine bone marrow derived macrophages were gathered and cultured to an M2 phenotype via stimulation with IL-4. These macrophages and microparticles were injected intramuscularly into the calf of a hindlimb ischemia murine model 3 days post injury. Mice were sacrificed two days later, and their calves harvested for flow cytometry analysis and immunohistochemistry (IHC). Using collagenase to digest the muscle, a single cell solution of the calf was stained with multiple macrophage phenotype markers (F4/80, CD206, ARG1, CD38, CD86) and Live/ Dead (L/D) markers. Separately, the solution was also stained with F4/80 and endothelial cell marker CD31. Flow data were analyzed using tSNE dimensionality reduction and Phenograph and FlowSOM clustering algorithms. Calf muscle sections were stained with DAPI and CD31, and images were analyzed with CellProfiler for CD31+ structures. All animal studies were approved by the Drexel Institutional Animal Use and Care Committee.

Results and Discussion: The number of GFP- macrophages was very high while the number of recovered GFP+ macrophages was exceedingly low, indicating that any effects of microparticles on angiogenesis and macrophage phenotype was caused by host macrophages. IL-4 releasing microparticles caused macrophages to take on a complex phenotypic profile. IL-4 affected macrophages were highest in clusters expressing both M1 and M2 markers. Additionally, treatment with IL-4 releasing microparticles increased the amount of endothelial cells (F4/80-CD31+), suggesting angiogenesis. Analysis of CD31+ structures showed that IL-4-releasing microparticles increased the density of vessels of 5-18 μm in diameter, while small capillaries (2-5 μm diameter) were unaffected. IL-4 release from the microparticles may have cause the M2 macrophages to help support recently created blood vessels, thereby increasing the number of larger structures.

Conclusions: This study shows that IL-4 releasing microparticles can control macrophage phenotype to support the development of blood vessels *in vivo*.

Immunomodulatory Biomaterials for Limb Salvage Kara Spiller; Drexel University, United States

Lower limb amputations are a major source of morbidity and mortality throughout the world. They principally result from a trifecta of atherosclerosis, limb ischemia, and the formation of non-healing chronic wounds. At the core of these afflictions is dysregulated behavior of macrophages, which are critical regulators of homeostatic tissue turnover and the healing of injured tissues. Therefore, biomaterials that can correct dysfunctional macrophage behavior hold promise for promoting wound healing in patients at risk for amputation.
In successful wound healing, macrophages transition from a population that is largely pro-inflammatory (M1) to a heterogeneous population of macrophages associated with the resolution of inflammation and wound healing (M2), although the extent of the diversity of this M2 population is not known. Because M1 macrophages normally switch to M2, and because chronic wounds are characterized by deficiencies in M1 as well as M2 activation, we investigated the consequences of prior M1 polarization on subsequent M2 polarization. M2 macrophages that were derived from M1 macrophages exhibited a distinct gene, protein, and functional signature compared to M2 macrophages derived directly from unactivated macrophages, suggesting that M1 polarization is an important regulator of M2 activation. These findings, in combination with our previous work describing important roles for M1 macrophages in initiating angiogenesis, indicate that immunomodulatory biomaterials should allow for a robust M1 phase prior to mediating a transition to M2. To investigate this concept, we developed PLGA microparticles that released IL4, a main cytokine responsible for promoting a key M2 subtype. When administered locally to the site of injury at 3 days following injury in a murine hindlimb ischemia model, these microparticles increased the number of larger blood vessels without affecting the number of small blood vessels. These findings support a potential role for M2 macrophages in the maturation stage of angiogenesis. Then, because patients at risk for amputation may suffer from impaired immune cell trafficking, we designed a biomaterial-mediated macrophage cell therapy strategy to control the phenotype of macrophages following their administration, a long-standing problem in macrophage cell therapy due to the inherent plasticity of these cells. In a proof-of-concept study, the anti-inflammatory drug dexamethasone was incorporated into PLGA microparticles and loaded into human peripheral blood-derived monocytes via phagocytosis. The microparticles were retained intracellularly for several weeks in vitro and they did not interfere with monocyte-to-macrophage differentiation nor subsequent phagocytosis of tissue debris or bacteria. After 7 days in pro-inflammatory media, macrophages containing dexamethasone-loaded microparticles decreased expression of pro-inflammatory genes, increased expression of M2 genes associated with dexamethasone treatment, and decreased secretion of the potent pro-inflammatory cytokine tumor necrosis factor-alpha (TNFa), even in the presence of pro-inflammatory stimuli.
Collectively, these studies highlight the importance of temporal control over macrophage phenotype, and suggest that immunomodulatory biomaterials that target macrophages may be effective in treatments designed to rescue angiogenesis and wound repair.

C-MEMS Based Label-Free Electrochemical Aptasensors for Turn-on and Turn-off Detections of Cancer Biomarkers Shahrzad Forouzanfar, Fahmida Alam, Nezih Pala and Chunlei Wang; Florida International University, United States

Cancer is referred to as a group of diseases in which abnormal growth of cells interferes with the function of vital organs and finally stops the body from functioning. Cancer patients have higher chances of survival if their cancer diseases are diagnosed in the early stage of development. Detection of cancer via cancer biomarkers is one of the well-established ways for early diagnosis of cancer diseases. Cancer biomarker is referred to as any substance that can indicate the presence of cancer in a body. Thus far, many cancer biomarkers have been discovered, which can be collected from tissue, blood, and urine. Among the cancer biomarkers detectable from blood, platelet-derived growth factor-BB (PDGF-BB) has been associated with development and metastasis of various malignant tumors in vital organs including breast, brain, ovarian, pancreas, and liver. A feasible means for early detection of cancers is developing point-of-care biosensors based on DNA aptamers, which are referred to as aptasensors. Various advanced technologies have been investigated for developing cancer biomarker aptasensors, including optical, piezoelectric, and electrochemical based techniques. Among the developed technologies,

label-free electrochemical aptasensors are highly compelling since they can reduce the cost and complications of sample preparation, and the electrochemical cells can be efficiently miniaturized and integrated with available lab-on-chips and MEMS technologies. Nevertheless, the sensing performance of the label-free electrochemical cancer aptasensors, including selectivity, limit of detection, and dynamic range requires further enhancements to be at similar levels to clinical testing. In the light of the importance of PDGF-BB detection and demanded enhancements for label-free electrochemical aptasensors, we have developed label-free electrochemical aptasensors based on photoresist derived carbon microelectrodes. The active electrode of this aptasensor was synthesized via well-established C-MEMS (carbon microelectromechanical systems) fabrication technology. C-MEMS platforms have unique features such as high resolution, low background capacitance, high stability when they exposed to different physical/chemical treatments, biocompatibility, and good electrical conductivity. The applied C-MEMS fabrication in this study includes photopatterning of SU-8 25 negative photoresist-based microelectrodes and carbonization of the developed microelectrodes at high temperatures and oxygen-free tube furnaces. The carbonized microelectrodes were functionalized utilizing oxygen plasma oxidation pretreatment to introduce carboxyl groups to the surfaces of the carbon microelectrodes. The PDGF-BB affinity aptamers were covalently immobilized via amid binding of amino-tag terminated aptamers and carboxyl groups covered carbon surfaces. The Fourier-transform infrared spectroscopy (FTIR) confirmed the successful carboxyl group functionalization of the C-MEMS microelectrodes and covalent immobilization of affinity aptamers via amide biding. Cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS) were used for characterizing the C-MEMS based aptasensors in different stages of development and sensing performances. The turn-on sensing strategy was implemented via measuring the charge transfer resistance (R_{CT}) from EIS Nyquist plots, which yielded to wide sensing linear range of 0.005 – 50 nM with a high sensitivity of 14.82×10^3 Ω.$(\text{Log (M)})^{-1}$ and low limit of detection of 1.9 pM (S/N=3). The turn-off sensing strategy was applied via measuring capacitance from CV curves, which conceded to a wide linear response range of 0.01 – 50 nM with a high sensitivity of 29.97 $\text{mF.cm}^{-2}.(\text{Log (M)})^{-1}$ and low limit of detection of 7 pM (S/N=3) toward the PDGF-BB. The developed label-free electrochemical aptasensor exhibited good selectivity, stability, and repeatability, which is highly promising for point-of-care cancer diagnosis technologies.

Light-Driven *In Situ* Gelation of Self-Assembled Hydrogels for Drug Delivery Hung Pang Lee and Akhilesh K. Gaharwar; Texas A&M University, United States

In situ gelation of hydrogels via near-infrared (NIR) light can implant drug reservoirs at deep tumor tissues with minimal invasion. Ultraviolet or visible light is often used for photocrosslinking but has limited application for deep tissue therapy due to the shallow penetration depths. NIR is of particular interest because of the therapeutic window where light has its maximum depth of penetration in tissue. However, NIR-triggered formation of hydrogels is rarely reported due to limited tools of NIR photochemistry. In this study, we demonstrate in situ gelation by combining with a NIR-responsive photothermal agent, molybdenum disulfide (MoS_2), with a temperature-responsive phase transition polymer, poly(N-isopropyl acrylamide) (PNIPAm). Molybdenum is thiophilic, and sulfur has a strong affinity toward forming disulfide bonds, together they offer facile binding centers for thiolated molecules. Therefore, thiolated-PNIPAm is synthesized to form crosslinks with defect-rich MoS_2 nanosheets. Moreover, dynamic polymer-nanoparticle interactions can be leveraged to control the formation of hydrogels spatiotemporally. With the increase in temperature by the photothermal effect of MoS_2, the hydrophobic interactions of MoS_2 nanosheets and PNIPAm chains are strengthened, and thus facilitate the gelation. Further, the combinatorial chemo-photothermal therapy of the MoS_2 hydrogels showed significant inhibition of cancer cells, indicating its effective role in chemotherapy. Overall, the hazardous-free gelling behavior of the MoS_2 hydrogels has strong potential for a range of biomedical applications, including phototherapy, 3D printing, and therapeutic delivery.

Maximizing Magnetic Heating of Iron Oxide Nanoparticle for Wireless Neuromodulation Gloria Lesly J. Miranda, Rohini Trevi G., Jason Giuliani and Gabriela Romero Uribe; University of Texas atSan Antonio, United States

Neurological disorders such as Epilepsy and Parkinson's (PD) are associated with the alteration of neural signals. Current techniques to modulate neural activity such as implantable microelectronic devices, pharmacological agents or optical stimulation, are nonspecific to cell-type and damaging to biological tissues [1–3]. Recently, magnetic hyperthermia has been proposed in neuromodulation as a wireless technology that could reach deep into brain due to the weak magnetic properties and low electrical conductivity of brain tissues [4]. This technology is highly dependent of the hysteresis power loss of magnetic nanoparticles (MNPs) under an applied alternating magnetic field (AMF). Thus, maximizing magnetic heating of MNPs will allow a more efficient energy conversion with lower cytotoxic effects.

Here, we investigate the magnetic heating properties of core and core-shell cubic MNPs for neuromodulation applications. Core MNPs are composed of Fe and Zn (Fe_2O_4Zn) at different molar compositions were synthesized to obtain nanoparticles (NPs) with different sizes (28 to 89 nm). It was observed that Fe_2O_4Zn NPs coercivity (H_c) increases with NPs size up to a saturation point due to a change in the multi-magnetic domains. On the other hand, it was found that the hybridization of Fe_2O_4Zn NPs with a Fe-Co shell ($CoFe_2O_4$) allowed us to control their H_c. Hybridization with Fe-Co shell can enhance Fe_2O_4Zn NPs H_c from 13 to 170 times depending on the shell molar composition. After optimization, Fe_2O_4Zn NPs (28, 35 and 55 nm) and Fe_2O_4Zn-$CoFe_2O_4$ NPs (with different Co concentration) were functionalized with polyacrylic acid (PAA) to stabilize them in biological fluids. Calorimetry studies were done to evaluate the specific power loss (SLP) of these MNPs when exposed to an AMF. SLP measurements were consistent with H_c values (dependent on size and Co concentration). Electrokinetic potential and polydispersity of MNPs in different biological fluids was assed using dynamic light scattering, and reveling high colloidal stability in phosphate buffer and media with high concentration of proteins. The cytotoxicity of these MNPs with and without AMFs was evaluated with a MTT Assay, where it was observed that MNPs functionalized with PAA (MNPs/PAA) with or without AMF cause no cytotoxic effects.

Finally, we tested our MNPs/PAA with the highest SLP and H_c to evoke neural activity in neurons expressing the heat-sensitive ion channel TRPV1. We isolated primary hippocampal neurons from new-born rats. After 1 week of culturing, we label the neurons with the Calcium indicator Fluo-4 in order to monitor neural activity through Calcium influx. Hippocampal neurons were exposed to cubic MNPs (with and without shell) and AMFs. Neural activity was recorded in real time using a calcium fluorescence imaging. We were able to evoke neural activity with all the MNPs tested. The heat dissipated by our MNPs was enough to trigger the response of the heat-sensitive transmembrane ion channels expressed on hippocampal neurons. The most remarkable achievement from this preliminary stimulation results was our ability to excite neural activity using 50X and 100X less the amount of MNPs in comparison with previously reported work [4]. This finding corroborates our hypothesis for maximizing hysteretic losses by magnetic anisotropy. Moreover, the optimized MNPs phase transfer procedure allowed us to reduce the possibility of agglomeration and bulk heating.

Engineered Tissues—Replacement Parts or Germs of Regeneration? Ivan Martin; University Hospital Basel, Switzerland

Cellular grafts for the regeneration of cartilage and bone have been engineered using a variety of cell sources, scaffolds and manufacturing systems. Clinical implementation of some of these approaches by the own group has led to promising outcome results (Fulco+, Lancet 2014; Mumme+, Lancet 2016; Saxer+, Stem Cells 2016), but is still associated with manufacturing and robustness challenges. Alternative strategies have been conceived to gain repeatability of processes, by delivering signals capable to recapitulate developmental events, with proofs of principle in the context of bone and cartilage regeneration (Scotti+, PNAS 2013; Occhetta+, PNAS 2018). Along this line, it was identified that regeneration-inductive signals may not require living cells to be efficiently delivered, but could be encoded in cell-laid and subsequently devitalized extracellular matrices (Bourgine+, PNAS 2014; Bourgine+, Adv Funct Mater 2017). The combination of multiple cytokines and morphogens, physiologically presented by a set of extracellular matrix molecules, would synergistically potentiate their effects. This new class of off-the-shelf biomaterials, which would function by offering the primordial template for the

development of the target tissue, may offer an alternative strategy to synthetic matrices. These cell-free extracellular matrices, as germs for de novo tissue development, could be generated based on highly standardized processes, thanks to the use of cell lines and bioreactor-based systems, and at the same time customized to address specific disease stages and patient profiles, in a perspective of personalized medicine (Haumer+, Adv Drug Del Rev 2017).

5:15 AM F.SM08.06.02
Naturally-Derived, Powder-Based Lung Tissue Sealant for Pleural Defects Utilizing a Murine Model Patrick N. Charron, Spencer Fenn, Minara Aliyeva, Nirav Daphtary and Rachael Oldinski; University of Vermont, United States

Introduction: Damage to the pleural tissue lining the lungs can occur in a multitude of ways, resulting in fluid leak into the pleural cavity, which, left untreated, can result in mortality. Historically such cases were treated via pleurodesis. Recent developments of lung tissue sealants serve as alternatives, but few options are available. While popular sealant tests can deliver qualitative pass/fail data, there is lack of quantitative *in vivo* methods to characterize sealing capabilities of these materials, particularly for pleural applications. In addition, commercial products have failed due to poor design and administration. Herein, we describe our development of a powder sealant capable of adhering to tissue and crosslinking to form an elastic hydrogel, circumventing limitations of current tissue sealants.

Experimental methods: Methacrylated alginate (AMA) was synthesized and characterized via ^{1}H-NMR spectroscopy. To enable gelation, visible green light crosslinkers were incorporated into the polymer solution. A sodium ion exchange was performed, the solution was lyophilized, and the product was processed into a powder. To investigate physical material properties, gelation kinetics and the viscosities of reconstituted solutions were collected at 37C, via an oscillatory time sweep at 10% radial strain and 1 Hz during exposure to green light. Quantitative *in vitro* experiments: dynamic burst pressure experiments were conducted using a custom-built burst pressure testing device, using a modified ASTM F2392 standard. Quantitative *in vivo* experiments: a murine model was developed in which we controlled respiratory dynamics to test sealant mechanics. Mice were anesthetized with pentobarbital sodium, tracheostomized, and paralized using pancuronium. Body temperature was maintained by keeping the animal under a lamp. Mice were connected to a computer-controlled small animal mechanical ventilator (flexiVent, Scireq) and ventilated. A series of deep inflation maneuvers (Total Lung Capacity and Trapezoidal deep inflation waveform) and a composite signal comprising of mutually prime frequencies ranging from 0-20 Hz were performed to establish baseline for the animal prior to injury. The thoracic cavity of the animal was opened and lungs were punctured, followed by another series of baseline measurements to calibrate testing mechanics and verify injury. The injury was treated by the application of the AMA powder and tests were repeated to compare lung mechanics pre-injury and post-repair, allowing for real-time pressure data collection of lung mechanics during sealant testing. After testing, animals underwent euthanasia.

Results: After acute traumatic injury using a murine model, there was a loss in pressure, confirming the injury model. Successful post-repair (i.e., application of the AMA powder, hydration and crosslinking) tests indicated that the sealant maintained physiologically-relevant lung pressure and returned lung capacity to pre-injury values, and that the sealant did not fail. A failure in the patch would result in a failure to hold pressure. Initial results show physiologically relevant burst pressure values (i.e. 30 cmH2O) for the powder sealant collected during in vitro testing.

Conclusions: The data indicates efficacy of a novel powder-based elastic sealant for recapitulating lung mechanics post injury. During an *in vitro* burst pressure experiment, the powder formed an crosslinked sealant capable of maintaining physiological pressure before failure. The powder-based sealant has the advantages of adhering to tissue upon application *in situ* and subsequent hydration, remaining in place while crosslinking via light exposure took place. Future work will explore long term in vivo studies to investigate lung tissue healing after repair with the novel powder sealant material.

5:25 AM F.SM08.06.04
Late News: The Influence of Conductivity and Mechanical Properties on the Neurogenic Differentiation of Dental Pulp Stem Cells Samuel Liu[1], Shivek Narang[2], Kuan-Che Feng[3], Haijiao Liu[3], Marcia Simon[4] and Miriam H. Rafailovich[3]; [1]Olathe North High School, United States; [2]Stanford Online High School, United States; [3]Stony Brook University, United States; [4]Stony Brook University, The State University of New York, United States

Currently, the central nervous system is unable to effectively repair itself or regenerate neurons when affected by damage. Dental pulp stem cells (DPSCs) are pluripotent stem cells which are promising candidates in

neuroregenerative medicine due to their ability to differentiate into functional neurons and accessibility via human third molars. Polybutadiene (PB) is a biocompatible polymer, whose modulus can be regulated by changing film thickness or adding inorganic particles. We have shown that when DPSCs are cultured in biomineralizing media containing beta glycerol phosphate and plated on PB they can adjust their modulus to follow that of the underlying substrate such that when the modulus exceeded a critical value, upregulation of the mineralizing gene, OCN, and hydroxyapatite deposition was observed . Further differentiation along a biomineralizing lineage was observed with the addition of titania nanoparticles [1]. Here we wish to explore whether these factors are also important in determining differentiation when the DPSCs are cultured in neurogenic media with and without graphene (G) and graphene oxide (GO) platelets. PB films, 250 nm (thin) and 2500 nm (thick) films with and without G were spun cast out of toluene onto silicon wafers. GO was floated onto the spun cast films from the air/water interface. The samples were annealed at 180C in ultra-high vacuum. Atomic Force Microscopy (AFM) analysis indicated that the G platelets were encapsulated and well distributed within the thick PB films. Aggregation of the graphene platelets, protruding from the film surfaces, were observed in the thin films. The GO films uniformly coated the thin and thick PB substrates. The relative modulus of the cells and substrates were also measured using scanning modulated force microscopy (SMFM). The results indicated that as previously observed, the thin films were 4.7 times harder than the thick films, and the addition of graphene increased their moduli approx. 6 fold, while maintaining the ratio. The modulus of the cells was also measured after 3 days in culture. Surprisingly the cells plated on the soft PB substrates, with and without graphene, were 1.5 times as hard as those plated on the harder thin PB and PB+G substrates, in contrast to previous results on DPSCs in osteogenic media. After 21 days, Real-Time Polymerase Chain Reaction (RT-PCR) was used to identify mRNA levels of neuronal markers which were compared to those measured for the culture after one day in culture. The results indicated no significant differences between hard and soft PB overlaid with GO, despite the significant differences in substrate and cell modulus, indicating that mechanical differences of either the substrate or the cells were not a factor in inducing differentiation. A significant result was observed only on the thick PB plus graphene substrate where the cells showed downregulation of early and intermediate neuronal markers NES and TUBB3, and upregulation of mature neuronal marker NEFM, suggesting that the presence of graphene enhanced neurogenic differentiation. Since graphene is highly conductive, while graphene oxide is not, these results indicate that the enhanced conductivity of the substrate due to the encapsulated particles may be the determining factor in enabling differentiation which is consistent with previous observations that graphene enhanced neuronal communication.

Tools for Controlling and Observing Complex Biological Systems Ed Boyden; Massachusetts Institute of Technology, United States

To enable the understanding and repair of complex biological systems such as the brain, we are creating novel optical tools that enable molecular-resolution maps of large scale systems, as well as technologies for observing and controlling high-speed physiological dynamics in such systems. First, we have developed a method for imaging large 3-D specimens with nanoscale precision, by embedding them in a swellable polymer, homogenizing their mechanical properties, and exposing them to water – which causes them to expand isotropically manyfold. This method, which we call expansion microscopy (ExM), enables scalable, inexpensive diffraction-limited microscopes to do large-volume nanoscopy, in a multiplexed fashion – important, for example, for brain mapping. Second, we have developed a set of genetically-encoded reagents, known as optogenetic tools, that when expressed in specific neurons, enable their electrical activities to be precisely driven or silenced in response to millisecond timescale pulses of light. Finally, we are developing novel reagents, such as fluorescent voltage indicators, and systems, such as novel microscope architectures, to enable the imaging of fast physiological processes in 3-D with millisecond precision. In this way we aim to enable the systematic mapping, control, and dynamical observation of complex biological systems like the brain.

Late News: Microbial Biofactories—Production of Nanomaterials with Biomedical Applications Catherine P. O'Connell, David Medina and Thomas J. Webster; Northeastern University, United States

Antimicrobial resistance to antibiotics (AMR) and drug-resistant cancer are two of the main concerns that the healthcare system is facing nowadays [1,2]. Current chemotherapy treatments and antibiotic-based therapies are becoming ineffective or have plenty of drawbacks that are increasing the prevalence of resistance in both hospital and community settings. Therefore, new alternatives are needed, and nanotechnology might offer a suitable answer.

Although different nanomaterials are being used as a method to fight pathogens and cancer, traditionally synthesized nanoparticles present drawbacks, such as the production of toxic by-products, increased cytotoxicity in the cell and lack of selectivity. Consequently, green nanotechnology appears as an alternative approach, which employs living organisms and biomolecules as raw materials in a cost-effective and environmentally-friendly approach [3]. Among all these methods, microbially-produced nanomaterials have presented a significant potential, rendering nanomaterials with a powerful antimicrobial activity that can be tailored to the infection.

With the objective to demonstrate the antimicrobial and biocompatibility efficacy of bacterial-produced nanoparticles in skin bacterial infections, top pathogenic strains found in cutaneous wounds were employed for the synthesis of metalloid selenium nanoparticles (SeNPs), including Methicillin-resistant *Staphylococcus aureus* or *Pseudomonas aeruginosa*. Once generated, the SeNPs were analyzed in terms of their physicochemical features and the composition was extensively studied. After purification, the SeNPs were used as antimicrobial and anticancer agents through colony counting unit and MTS assays, respectively, as well as characterized for the mechanisms of death associated to their activities. At the same time, low cytotoxicity was demonstrated over the same range of antimicrobial efficiency.

Consequently, microbiological agents were successfully used as a biofactories for the generation of SeNPs of different compositions with biomedical properties. Therefore, bacteria were presented as a suitable approach for the synthesis of nanomaterials in a green fashion, overcoming the limitations of traditional nanotechnology.

SESSION F.SM08.08: Vascular Engineering
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-SM08

5:00 AM *F.SM08.08.01
Engineering Vasculature Using Physical and Structural Cues Christopher Chen; Boston University, United States

A major barrier in tissue engineering is a lack of understanding of how to integrate vascular networks into 3D tissue constructs. Without perfusable vascular networks, large constructs containing living cells develop necrotic cores due to nutrient, oxygen, and waste diffusion limitations. To address this challenge, we have developed approaches to generate perfusable vascular networks that support 3D culture of assembled constructs, provide a means to study how to regulate vascular remodeling and angiogenesis, and improve the integration of such vasculature to host circulation in implanted constructs. We demonstrate a critical role for material properties such as stiffness or degradability, and also an important role for the organization of materials and cells to provide functional perfusable vasculature. Ultimately, these approaches will inform how we establish solutions to generate functional vascular beds for engineered tissues both in vitro and in vivo.

5:15 AM F.SM08.08.02
Biomaterial-Guided Recruitment of Endothelial Progenitor Cells for Vascular Regeneration Mohamed A. Elkhodiry[1],

Omar Bashth[1], Gaetan Laroche[2,3], Jean-François Tanguay[4,5] and Corinne A. Hoesli[1]; [1]McGill University, Canada; [2]Université Laval, Canada; [3]Centre de Recherche du CHU de Québec, Canada; [4]Montreal Heart Institute, Canada; [5]Université de Montréal, Canada

Endogenous endothelial progenitor cell (EPC) recruitment to sites of vascular injury is a multi-step process mediated by selectins, chemokines, and extracellular matrix (ECM) proteins. New vascular implants with surface-immobilized capture antibodies targeting circulating EPCs have shown clinical promise in accelerating the formation of neo-endothelium to cover the implant. The absence of subsequent adhesion-based signaling needed for EPC proliferation and differentiation could explain the lack of long-term improvement in vascular re-stenosis and overall vascular recovery. Antibodies can mimic the cell tethering effect of selectins but lack necessary EPC signaling effects introduced by cytokines and ECM proteins. We have previously shown that ECM-derived peptides, such as RGD, can promote the adhesion and enhance the clonal expansion of EPC-derived endothelial colony forming cells (ECFCs) via integrin based signaling. In this study, we developed a novel bifunctional surface modification strategy to produce surfaces that combine immobilized capture-antibodies and surface grafted ECM-derived peptides with controlled surface concentrations and ligand orientation. We hypothesize that this bifunctional strategy would further accelerate the re-endothelialization process while maximizing downstream endothelial function and vascular recovery via an integrin-dependent process.
Peripheral blood from 22 adult human donors was used to obtain donor-specific ECFCs. Aminated culture surfaces were modified by either the covalent conjugation of a customized RGD peptide, immobilization of vascular endothelial growth factor receptor-2 (VEGFR-2) antibody, or combining both biomolecules at different ratios using an optimized process. Unmodified surfaces were used as a negative control. Surface concentration of the peptide and antibody were analyzed using fluorescence microscopy and an enzyme-linked immunosorbent assay. First, the expanded ECFCs were seeded under static conditions and cell adhesion was studied using immunocytochemistry. ECFC interactions with the bifunctional surfaces were then interrogated under more physiologically relevant dynamic flow conditions in a microchannel perfusion loop at 1 dyn/cm^2 wall shear stress and analyzed through live cell imaging followed by immunocytochemistry.
Surfaces with immobilized anti-VEGFR-2 antibodies displayed significantly enhanced ECFC capture potential compared to RGD and unmodified controls as quantified by the number of adhered cells under both static and dynamic conditions. Average ECFC spreading and focal adhesion formation were significantly increased on RGD surfaces compared to the anti-VEGFR-2 and unmodified controls under both static and dynamic conditions. Total endothelial coverage and the total number of focal adhesions were maximized on the bifunctional surfaces combining the anti-VEGFR-2 and RGD due to a combined increase in both cell number and cell spreading. By increasing the peptide concentration on the bifunctional surfaces, ECFC spreading was increased without significantly affecting the number of adhered cells. These results suggest an additive (i.e. independent) effect of capture antibodies on ECFC tethering vs. RGD peptides on subsequent ECFC spreading and integrin-dependent cell signaling.
To our knowledge, this is the first study showcasing the ability of a bifunctional antibody/peptide surface modification strategy in promoting ECFC capture and adhesion. Our results also display a clear distinction between the mechanisms by which human-derived ECFCs react to immobilized capture antibodies and conjugated ECM-peptides. This strategy creates sequential steps of EPC trafficking to mimic endogenous processes of vascular healing which can potentially create an effective regenerative capacity for vascular implants.

5:25 AM F.SM08.08.03
Bioelectronic Tissue Engineered Vasculature for Monitoring Cell Behavior Alexander J. Boys, Charalampos Pitsalidis and Roisin Owens; University of Cambridge, United Kingdom

Monitoring vascular permeability represents a significant challenge in materials science. The study of vascular permeabilization is of great interest to the scientific community in its relevance to extravasation during tumor growth, transport across the blood-brain barrier, etc. However, studying vascular permeability *in vitro* requires development of materials systems that not only support cell growth but also produce real-time data on cell behavior. Native vasculature consists of a tube with an interior lining of barrier-forming cells called endothelial cells. These cells selectively allow transport of different factors, of which small molecules and ions primarily pass through intercellular junctions. In this study, we developed a bioelectronic platform for vascular tissue engineering to actively monitor the integrity of the vascular membrane during culture.
Previously, we developed bioelectronic monitoring systems for gauging various cellular phenomena. These systems have frequently used conductive polymers, such as poly(ethylene dioxythiophene):poly(styrene sulfonate) (PEDOT:PSS), which are biocompatible and ion-sensitive. These polymers can be designed for use as electrodes or transistors to monitor local ion flux. As cells deposit extracellular matrix (ECM) and form intercellular junctions, these structures inhibit ion flow, which can be sensed using conductive polymeric devices. These polymers can also be fabricated as porous scaffolds through ice templating to support cell growth.

To produce this vascular monitoring system, we constructed a bioelectronic device, which can simultaneously promote and monitor the development of a vascular membrane. This device was constructed using a porous, electroactive PEDOT:PSS scaffold to support cell culture with surrounding electrical architecture to monitor ion flux into the scaffolds. We produced tissue engineered vasculature by seeding fibroblasts onto the top of the scaffold. These cells were allowed to proliferate, producing a bed of ECM on top of and within the pores of the scaffold. Subsequently, vascular endothelial cells were deposited on top of this culture and allowed to proliferate. After a period of static culture, the devices were placed on an orbital shaker to mimic blood flow. During the following culture period, the devices were monitored using impedance spectroscopy to gauge the formation of a vascular membrane.
Over the course of the culture period, we observed a continuous increase in impedance, indicative of the deposition of ECM and the formation of vascular junctions. At the termination of culture, we found the scaffolds showed complete coverage and junctional formation across the entirety of the 6 mm scaffolds. We will now seek to apply biological factors that affect vascular permeability, such as TNF-α, to promote extravasation in the tissue engineered cultures allowing for determination of the efficacy of using this system to monitor vascular permeabilization. This system provides a platform for studying various physiological phenomena associated with transport through the vascular wall and highlights the capabilities of *in vitro* bioelectronic tissue engineering.

Superparamagnetic Iron Oxide Nanoparticles Modulate Platelet Functions Regina K. Kottana[1], Lionel Maurizi[2], Brian Schnoor[1], Kenise Morris[1], Nadine Millot[2] and Anne-Laure Papa[1]; [1]The George Washington University, United States; [2]University of Bourgogne Franche-Comté, France

Introduction: Platelets play a role in hemostasis and are the first responders to arrest bleeding during an injury [1]. Therefore, any aberration in their function can cause bleeding or thrombus formation. Nanoparticles (NPs) when present in the bloodstream interact with the different components of blood and have been shown to modulate platelet functions [2,3]. However, these interactions are not well understood. In this study, we are using six formulations of PVA (polyvinyl alcohol) coated-SPIONs based on differences in molecular weight (M.W.) and charge of the polymer coating to study the effect caused by their presence on platelet function of activation and aggregation, and additionally, we have explored possible mechanisms to explain the observed effect.
Materials and Methods: Human platelet-rich plasma was obtained from healthy donor blood. Platelet activation and aggregation were assessed in the presence of PVA-SPIONs with 12 kDa and 31 kDa PVA, as well as positive, neutral, or negative surface charges, by using flow cytometry and light transmission aggregometry. The agonist adenosine diphosphate was used to induce platelet activation and aggregation. Platelets were incubated with up to 500 ug/mL PVA-SPIONs. ELISAs were used to quantify the presence of plasma proteins fibrinogen and von-Willebrand factor (vWF) in platelet-poor plasma incubated with SPIONs. Fibrinogen and vWF binding to platelet GPIIb-IIIa was also studied using flow cytometry, while their structural integrity with SPION incubation was assessed by UV-vis.
Results and Discussion: Platelets were activated in the presence of positively charged SPIONs at 500 ug/mL, irrespective of M.W. of PVA. A dose-dependent inhibitory effect was also observed on platelet aggregation when platelets were incubated with SPIONs. This antiplatelet effect was independent of the M.W. and surface charge of the PVA-SPIONs. Therefore, we tested three hypotheses to explain this antiplatelet effect. Based on the important role of plasma proteins fibrinogen and vWF in platelet aggregation and the formation of protein corona due to the adsorption of proteins on the surface of NPs [4], we tested if the proteins were significantly adsorbed on the surface of the NP, thus depleting them from the plasma for potential platelet aggregation. Although adsorption of proteins was observed, there was no significant decrease in the concentration of available proteins for platelet aggregation. Next, we tested if the NPs interfere with the normal process of fibrinogen and/or vWF binding to platelet GPIIb-IIIa. In agreement with our platelet activation study, there was an increase in binding of fibrinogen to the receptor GPIIb-IIIa when the PRP was incubated with positively charged SPIONs. In addition, there was no change in the binding efficiency for both fibrinogen and vWF with other SPION formulations. Lastly, we investigated whether the PVA-SPIONs would interfere with the protein structure, and thus with their role in platelet aggregation.
Conclusions: PVA-SPIONs induced an inhibitory effect on platelet aggregation regardless of their size and charge. Our results suggest that the inhibitory effect could be ascribed to a change in fibrinogen conformation, induced by the presence of these nanoparticles, thus impairing the platelet-platelet bridging ability of the protein.
Acknowledgments: This work has been supported by the George Washington University startup funds.

Microfabricated Porous PTFE Membrane for Separation in Biomedical Uses Masashi Maruyama, Mitsuya Yamamoto and Hirotaka Sakuma; Hitachi Ltd, Japan

Porous membranes with well-defined pore structures find plenty of uses in research and industrial areas. Well-defined pore structures afford sharp selectivity in filtration and thus applications in biomedical uses are also expected such as cell/spheroid separation and immunoprotection. Track-etching is a well-known technology to fabricate porous membranes with relatively defined pores, but undesired overlapped spots result in loss of selectivity. Against the background, we developed a novel microfabrication methodology to prepare porous membrane with strictly defined pores. We successfully developed porous PTFE membrane with 5-10 um thickness with tunable pore sizes. We will discuss the potential applications of microfabricated PTFE membranes in biomedical uses.

F.SM08.09.03
Designed Organization of Proteins in Multidimensional Arrays with Preserved Biological Functionality Shih-Ting Wang[1], Brian Minevich[2], Jianfang Liu[3], Honghu Zhang[1], Dmytro Nykypanchuk[1], James Byrnes[1], Wu Liu[1], Lev Bershadsky[1], Qun Liu[1], Tong Wang[4], Gang Ren[3] and Oleg Gang[1,2]; [1]Brookhaven National Laboratory, United States; [2]Columbia University, United States; [3]Lawrence Berkeley National Laboratory, United States; [4]The City College of New York, United States

An ability to control the assembly of functional proteins with designable organizations and an unpresented density in multidimensional space, provides routes to the next-generation nano-systems, biomaterials and complex biomolecular scaffolds. To achieve this, DNA nanotechnology offers exciting opportunities to modulate assembly processes with nano-scale resolution and spatial addressability. In this work, we developed a protein encapsulation strategy combined with the DNA programmable assembly for a bottom-up fabrication of biologically functional protein arrays with 2D and 3D prescribed organizations. We showed that ferritin, an iron storage protein, was integrated with DNA frames, of which each vertex and their internal space were encoded with addressable strands to program the protein position and vertex-to-vertex interconnection. Such designed arrays allow to maintain a biological activity of ferritin in the nanoscale lattices at relevant environments, and meanwhile, small molecules can access the iron core of ferritin within the 3D array and convert it into a core-less form, apoferritin. Our study, through the use of *in situ* small angle X-ray scattering, electron microscopy and tomographic modelling, revealed the complex arrangement of designed protein arrays and their ability to perform functions within 3D arrays, thus confirming a new strategy for creating bio-active protein-containing materials.

F.SM08.09.04
Late News: Polymer-Ceramic Scaffold for Bone Tissue Applications Katia Mendoza-Calderón[1], Nancy Nelly Zurita Méndez[2], Javier Ortiz Ortiz[2], Marco Antonio Espinosa Medina[2] and Georgina Carbajal de la Torre[2]; [1]Tecnológico Nacional de México., Mexico; [2]Universidad Michoacana de San Nicolás de Hidalñgo, Mexico

Defects in bone tissue have been more common in recent years, based on this a section has been dedicated in the area of biomaterials for research. Currently, knowledge about new biomaterials has led to the discovery of sets of precursors that work effectively in the recovery of damaged tissue, which must meet certain requirements to be recognized as biomaterials, that is, they must be biocompatible, biodegradable, non-toxic, have mechanical resistance, as well as the appropriate density, weight, shape and size. Once these characteristics are known, it has been decided to experiment with three basic precursors in bone regeneration. The work that was carried out aims to manufacture three-dimensional matrices using precursors such as hydroxyapatite, polylactic acid and polycaprolactone. The characterizations were carried out to verify the purity of such biomaterials. Differential Scanning Calorimetry for both tests in a nitrogen/air atmosphere (80/20) at a temperature range of 100 °C to 1000 °C with a heating of 10 °C/min; on the other hand, for polylactic acid an analysis was carried out using

Fourier Transform Infrared Spectrometry. Once the results were obtained, the scaffolding was manufactured using leaching and solvent casting techniques. With this, two groups of samples were developed with concentrations of 30% HAp -10% PLA -60% PCL and 10% HAp - 10% PLA - 80% PCL, they were mixed with an organic solvent and sodium chloride. The resulting scaffolds were subjected to mechanical compression and tension tests. Obtaining promising results for application in bone tissue.

F.SM08.09.05

A Study of Silver Nanoparticles Control with Three Biocompatible Reducing Substances Qixing Liu[1], Arthur McClelland[2] and Tingying (Helen) Zeng[3,4]; [1]Zhejiang University, China; [2]Harvard University, United States; [3]Academy for Advanced Research and Development, United States; [4]Massachusetts Institute of Technology, United States

Silver nanoparticles play a significant role in public health. They have been proven to be effective substrates for high-intensity surface-enhanced Raman spectroscopy (SERS) in biomedical applications. The nanoparticles are able to detect organic molecules at nanomolar concentration and has the potential for early disease detection or virus killing. Since SERS technology has gained traction in public health uses recently, the synthesis of AgNPs which is considered as the essential and fundamental key of applications, has attracted numerous researchers. In this study, we propose a green, wet-chemical way to control the synthesis of AgNPs and explore three different reducing agents under similar conditions. Sodium citrate, L-cysteine, and oxalic acid, all used as reducing agents, are respectively added into the $AgNO_3$ aqueous solution where the Ag^+ concentration is 2.5mmol/L in room temperature. L-cysteine, a specially selected amino acid, exists in every group acting as the capping agent to restrict the aggregation and control the size of nanoparticles. According to the surface-enhanced Raman spectrum and SEM images, sodium citrate demonstrates the best reducing ability under the same concentration of the carboxy group and can be used for a quick synthesis. On the other hand, the particle size of oxalic acid carpets is more controlled regardless of concentration. It is suitable for precise synthesis associated with the time when the surface-enhanced Raman spectrum indicates the size growth of silver nanoparticles as time increases. Some mechanisms during the process are revealed as well. After analyzing the spectrum, we deem that Ag^+ ion combines with carboxy groups more easily than sulfur in this system. Consequently, these three reducing agents exhibit their unique advantages which provide us with various selections for the synthesis of silver nanoparticles under different requirements for different applications in public health.

Stress Induced Mesoscale Assembly of Nanoparticles for Active Nanostructures Hongyou Fan; Sandia National Laboratories, United States

Due to the size- and shape-dependent properties, nanoparticles have been successfully used as functional building blocks to fabricate 1-3D ordered assemblies for the development of artificial metamaterials. At ambient pressure, entropy driven self-assembly of monosized or binary nanoparticles generally results in polycrystalline 2- or 3D close-packed arrangements, and extensive efforts have been made to develop structural perfection of nanoparticle arrays or 'single crystal-like' domain structures with precise long range order for their definite advantages for electron transport. To date, fabrications of ordered nanoparticle assemblies have been relied on specific interparticle chemical or physical interactions such as van der Waals interactions, dipole-dipole interaction, chemical reactions, etc. Recently we have discovered a pressure-induced assembly method to engineer nanoparticle assembly at mesoscale and to fabricate new nanoparticle architectures without relying on specific nanoparticle interactions. We show that under a hydrostatic pressure field, the unit cell dimension of a 3D ordered nanoparticle arrays can be manipulated to reversibly shrink, allowing fine-tuning of interparticle separation distance. Under a uniaxial pressure field, nanoparticles are forced to contact and coalesce, forming hierarchical nanostructures. Depending on the orientation of the initial nanoparticle arrays, 1-3D ordered nanostructures including nanorod, nanowire, and nanoporous network can be fabricated through the pressure-induced self-assembly method. Guided by computational simulations, we were able to rationalize the pressure-induced self-assembly of nanoparticle arrays for predictable nanostructures. Moreover, we discovered for the first time a transition from an ordered polycrystalline nanoparticle mesophase to quasi-single crystalline nanoparticle lattices induced by PDA process. Exerting pressure-dependent control over the structure of nanoparticle arrays provides a unique and robust system to understand collective chemical and physical characteristics and to develop novel electronic and photonic behavior for energy transduction related applications.

Supercritical Elasticity and Its Potential Applications in Extreme Conditions Haiyang Chen[1], Yan-Dong Wang[1] and Yang Ren[2]; [1]University of Science and Technology Beijing, China; [2]Argonne National Laboratory, United States

Developing elastic materials for technological applications in extreme conditions has been a challenging task. Normal metals have an elastic strain limit rarely exceeding 1%. A large pseudo-elastic strain up to 10% can be achieved in the so-called shape-memory alloys (SMAs). However, the intrinsic hysteresis and temperature sensitivity of the first-order phase transformation significantly hinder their usage in many critical areas. We recently discovered a new type elasticity: supercritical elasticity (SCE), in NiCoFeGa single crystals, which exhibit a large elasticity up to 15.2% strain, with non-hysteretic mechanical responses, a small temperature dependence and high-energy-storage capability and cyclic stability over a wide temperature and composition range [Chen et al., Nature Materials, (2020). https://doi.org/10.1038/s41563-020-0645-4]. Such a giant SCE is conceived to work even down to absolute zero Kelvin. In situ synchrotron X-ray diffraction measurements show that the SCE is correlated with a stress-induced continuous variation of lattice parameter accompanied by structural fluctuation. Neutron diffraction and electron microscopy observations reveal an unprecedented microstructure consisting of atomic-level entanglement of ordered and disordered crystal structures, which can be manipulated to tune the SCE. The discovery of the giant SCE and associated the entangled structure paves the way for exploiting elastic strain engineering and development of related functional materials for a wide variety of high-performance engineering applications, ranging from deep-space and deep-sea exploration to intelligent robotics.

5:39 PM *F.SF01.01.05
Pressure-Induced Dramatic Changes in Electronically Low-Dimensional Metal Halides Xujie Lu, Songhao Guo, Hui Luo, Yongsheng Zhao and Wenge Yang; Center for High Pressure Science & Technology Advanced Research, China

Metal halide perovskites are promising for advanced photovoltaic and optoelectronic applications. Solar cells and light-emitting diodes based on metal halides have achieved an impressive power conversion efficiency of 25.2% and a high external quantum efficiency of over 20%, respectively. Importantly, exceptional structural turnability enables enhanced and/or emergent properties. By using appropriate organic and inorganic components, many perovskite variants with 2D, 1D, and 0D structures on the molecular level have been obtained. These electronically low-dimensional metal halides have exhibited rich emergent properties and significantly expanded the scope of halide perovskites, while critical challenges remain. Future design of high-performance metal halides calls for a deeper understanding of the structure-property relationships. In this talk, we will present our recent efforts in using external pressure to tune the structures and physical properties of low-dimensional metal halides. Using state-of-the-art high-pressure techniques coupled with *in situ* synchrotron-based and in-laboratory property measurements, we characterized the changes in their structural, electronic, and optical properties. Pressure-enhanced properties such as higher photoluminescence quantum yields, as well as pressure-induced novel phenomena including emergent photocurrent, were observed. Our findings demonstrate that high pressure is able to realize enhanced and/or emergent properties of various metal halides, and further our understanding of the underlying mechanisms.

5:51 PM *F.SF01.01.13
Heterostructured Materials—Strain Gradient Near Interface and Its Dislocation Mechanisms Yuntian T. Zhu[1,2]; [1]Southeast University, China; [2]City University of Hong Kong, China

Recently, heterostructures are found to produce unprecedented combination of strength and ductility that is considered impossible from our textbook knowledge and materials history. Heterostructured (HS) materials consist of domains with dramatic strength differences. The superior mechanical properties have been attributed to back-stress strengthening and back-stress work hardening, which are related to strain gradient near the heterogeneous domain interfaces. Here I'll discuss *in-situ* observations of strain gradient evolution near the domain interface and the dislocation mechanisms for the formation of strain gradient. It is found that contrary to our conventional understanding, negative strain gradient was developed near the interface. It is also observed under in-situ TEM that the Frank-Read dislocation sources are dynamically created and destroyed although postmortem examinations do not observe many Frank Read sources. These observations provide a new piece of scientific foundation for heterostructured materials, which is becoming a hot research field.

Initiation of the CuO/Al Thermite Reaction Through High-Velocity Microparticle Impact Testing Carlos Parra[1,2], Yuchen Sun[3,3], David A. Veysset[3], Digvijay R. Yadav[4], Kelvin Xie[4] and Zachary Cordero[3]; [1]Rice University, United States; [2]Escuela Superior Politecnica del Litoral, ESPOL, Ecuador; [3]Massachusetts Institute of Technology, United States; [4]Texas A&M University, United States

Thermite reactions between a metallic fuel and a solid oxide can be thermally or mechanically activated. The ignition temperature in a thermally activated thermite reaction generally increases with heating rate but is ultimately limited by the onset of melting of the lower melting point constituent. In mechanically activated thermite reactions, there is often a structure-sensitive threshold pressure required to drive the reaction. Historically, thermally activated thermite reactions have been explained using diffusion-based reaction mechanisms while mechanically activated thermite reactions have been described using deformation-based mechanical mixing models. Here we probe mechanically activated thermite reactions at a single well-defined heterophase interface using a combination of hydrocode simulations and laser-induced particle impact testing, where a CuO powder particle strikes an aluminum target at supersonic velocities. No reactions are observed through *in situ* imaging; however, post-mortem characterization of embedded CuO particles reveals a thin nanocrystalline Al_2O_3 reaction layer, with a thickness roughly equal to that of a molten lubricating layer predicted to form during penetration. These results suggest that local melting at hot spots drives the ultrafast reactions observed in mechanically activated thermite

reactions and that thermally and mechanically activated thermite reactions may in fact result from the same underlying mechanisms.

Silica-Titania Nanocomposite Based Fiber Optic Sensor for Aromatic Hydrocarbons Detection Shumaila Islam and Adil Alshoaibi; King Faisal University, Saudi Arabia

Surface stability of deposited sensing material is becoming a crucial issue in the field of opto-chemical sensor technology due to cracks/stresses. Porous silica-titania (ST) nanocomposite coating material is synthesized and doped with CdTe as transducers for sensing cyclic compounds. Ultra-thin coatings are obtained, ~11 nm for ST nanocomposite, and 5 nm for encapsulated and heat-treated samples. BET analysis shows large surface area ~441 m2/g ± 3 m2/g and pore diameter 58 Å of ST nanocomposite. It decreases down to ~410 m2/g ± 2
m2/g, and pore diameter to 24 Å, after encapsulation. However, after heat treatment, it again increases up to 419 m2/g ± 2 m2/g and pore diameter to 38 Å. The sensitivity of 71.37 counts per unit change in the carbon chain with correlation determination coefficient R2 ~0.89 at 468 nm is observed. The prepared sensor device shows excellent stability, signal-to-noise ratio, and good reversibility towards different hydrocarbons and non-hydrocarbons (inorganic materials).

6:34 PM F.SF01.01.08
Modeling and Experimental Studies of Neat and Metal-Doped Stishovite, Coesite and Quartz Under High Pressure Iskander G. Batyrev, Michael C. Golt and Rosario C. Sausa; CCDC Army Research Laboratory, United States

The results of a comparative study of neat and doped silicon dioxide polymorphs (Fe, Ni or Cu) obtained by density functional theory (DFT) at 0 K and at ambient pressure, 10 GPa, and 20 GPa are presented. The metal atoms are introduced at substitutional and octahedral interstitial sites of the crystal, and the relaxed structures are analyzed and ranked according to the enthalpy. Changes in the enthalpy of the neat and doped crystals are estimated at selected temperatures using quantum mechanics molecular dynamics (DFT-MD). We report the modeled enthalpy of the neat and doped crystals, as well as the dependency of the unit-cell parameters, band gaps, and Raman-active modes on pressure, and compare some of these results to those obtained experimentally using a diamond anvil cell. In addition, we present our search results of the high-pressure phases of silicon dioxide using DFT - based evolutionary simulations and report on the stability of the silica phases, as evaluated by convex-hull construction.

Shear Localization in Molecular Crystal Cyclotetramethylene-Tetranitramine (β-HMX) Mohammad Jane Alam Khan and Catalin Picu; Rensselaer Polytechnic Institute, United States

Cyclotetramethylene-Tetranitramine (β-HMX) is an energetic molecular crystal widely used as a constituent for plastic bonded explosives (PBXs). At high pressures encountered under shock conditions, dislocation motion is inhibited and plastic deformation takes place primarily by shear localization. Atomistic simulations of shear localization are performed in β-HMX under isothermal-isobaric conditions. The post localization flow stress for different pressures (0 to 15 GPa) and strain rates (10^7 to 10^{10} s^{-1}) and at different temperatures of the shear band is investigated. The flow stress decreases linearly with temperature and increases quadratically with the pressure and exponentially with the strain rates. Shear thinning is observed, i.e. the viscosity decreases with increasing the strain rate. It is concluded that the flow stress increases exponentially with the density of the amorphous shear band and hence it can be described as a function of this single variable. The pressure, temperature and strain rates control the flow stress through the density.
The critical stress for shear localization (CSSL) was investigated for different strain rates at different pressures. The critical stress depends significantly on pressure and weakly on strain rates.

Friction and Dislocation Motion Using Objective Molecular Dynamics Gunjan Pahlani[1], Ananya Renuka Balakrishna[2,1] and Richard D. James[1]; [1]University of Minnesota, United States; [2]University of Southern California, United States

Atomic features, such as surface roughness and dislocations, affect the mechanical strength and plastic deformation of materials under high shear rates. The precise role of how these atomic features influence the wear and tear of materials under nonequilibrium settings is not well understood. We use Objective Molecular Dynamics (OMD) to investigate the links

between atomic features and high shear rates. This method has two advantages over traditional MD simulations: First, it simplifies solutions by exploiting the group invariance of the equations of molecular dynamics. For example, in OMD only a modest number of atoms are simulated (typically, 50-1000) and the motions of the other, typically infinite, set of atoms (the non-simulated atoms) are given by the group action on the simulated atoms. Second, it provides a framework for modeling continuum loads at an atomic scale. For example, a Lagrangian velocity gradient tensor is introduced to describe affine motion of simulated atoms. In today's talk, we demonstrate these advantages of OMD through two examples: 1) frictional behavior of sliding surfaces, and 2) dislocation movement under shear stress. Both of these computations were done under high shear rates, and demonstrate how atomic features, such as rough surfaces, edge dislocations, and vacancies, affect mechanical deformation. Broadly, we present a theoretical framework to explore the interplay between extreme mechanical loads at the continuum scale and mechanical deformation at the atomic scale.

6:40 PM F.SF01.01.18
Superhard Conductive Rhenium Nitride Thin Films via Magnetic Field-Assisted CVD from Volatile Rhenium Precursors Michael Frank, Lasse Jurgensen, David Graf, Daniel Stadler, Isabel Gessner and Sanjay Mathur; University of Cologne, Germany

Rhenium nitride is a promising candidate as superhard conductor. Different rhenium-to-nitrogen ratios and several phases result in challenging synthetic strategies for phase pure rhenium nitride. Novel heteroleptic rhenium(I) compounds, [*fac*-$Re(I)(CO)_3(L)$] (e.g., L= tfb-dmpda, (*N,N*-(4,4,4-trifluorobut-1-en-3-on)-dimethyl propylene diamine)), containing preformed Re−N bonds act as efficient precursors for selective growth of polycrystalline rhenium nitride (ReN) films by vapor phase deposition. This is the first known access to synthesize phase pure rhenium nitride by single source precursor approach without the need of additional gases. Interdependence of materials strength and thin film orientation is strongly influenced by external magnetic fields. Deposition of ReN films in presence of an external magnetic field showed an orientation effect with preferred growth of crystallites along 〈100〉 direction.

6:42 PM F.SF01.01.19
Synthesis of Molecular Metallic Barium Superhydride—Pseudocubic BaH_{12} Dmitrii Semenok[1], Wuhao Chen[2], Alexander Kvashnin[1], Xiaoli Huang[2], Alexander F. Goncharov[3], Artem Oganov[1,4] and Tian Cui[2,5]; [1]Skolkovo Institute of Science and Technology, Russian Federation; [2]Jilin University, China; [3]Carnegie Institution of Washington, United States; [4]Northwestern Polytechnical University, China; [5]Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, China

Inspired by recent progress in chemistry of compressed polyhydrides [1-2] and the discovery of high-temperature superconductivity above 250 K in the La–H system [3-4], we experimentally studied the high-pressure chemistry of Ba hydrides in four independent DACs. We successfully synthesized novel barium superhydride BaH_{12} with a pseudocubic crystal structure, stabilized in the pressure range of 75–173 GPa. The compound was obtained by laser-heating of metallic barium with an excess of ammonia borane compressed to 173, 160, 146, and 90 GPa. The Ba sublattice structure of BaH_{12} was resolved using the X-ray synchrotron diffraction, evolutionary structure prediction, and several postprocessing Python scripts, including an XRD matching algorithm. The ab initio calculations confirm a small distortion of the ideal *fcc*-barium sublattice to space group $Cmc2_1$ (or even $P2_1$), determined by the presence of additional weak reflections in the diffraction patterns. Discovered BaH_{12} has unique combination of molecular H_2 and H_3 fragments formed due to Peierls-type distortion of one-dimensional H-chains, metallic conductivity, and even superconductivity with T_C = 20 K at 140 GPa, and one of the highest hydrogen content (>92 mol %) among all metal hydrides synthesized so far. Discovered barium dodecahydride is also the first known example of molecular metal amid polyhydrides with one-dimensional conductivity and superconductivity, realized in the H sublattice without its atomization. The results of these experiments confirm that the comparative stability of superhydrides increases with the growth of the period number of a hydride-forming element in the periodic table. [5]

Thermal Stability of XeF_2 at High Pressures Elena Bykova[1], Maxim Bykov[2], S. Chariton[3], V. Prakapenka[3] and Alexander

F. Goncharov[1]; [1]Earth and Planets Laboratory, United States; [2]Howard University, United States; [3]Argonne National Laboratory, United States

Xenon is quite a reactive noble gas, and xenon difluoride (XeF_2) being stable at ambient conditions is used in organic synthesis as fluorinating agent. Formation of XeF_2 is possible because xenon is bonded to highly electronegative fluorine atoms that take electrons from xenon filled outermost electron shell, forming cation Xe^{2+}.
High-pressure behavior of XeF_2 (sp. gr. *I*4/*mmm*) is still under debate. Early powder X-ray diffraction and Raman experiments propose that XeF_2 should transform from a molecular compound to extended graphite-like layer structure at 50 GPa, and then above 70 GPa to a metallic fluorite structure. Contrary, the later experimental studies suggest just slight decrease in XeF_2 lattice symmetry, first to *Immm* and then to *Pnma* structure at 28 GPa and 59 GPa, respectively. Theoretical calculations predict that XeF_2 becomes unstable above 81 GPa, while high pressures should stabilize other xenon–fluorine compounds, such as XeF_4, XeF_6 and Xe_2F.
In order to resolve this issues, we investigated thermal stability of XeF_2 at pressures up to 54 GPa by means of single crystal X-ray diffraction in laser-heated diamond anvil cells. Single-crystal XRD opens the way to determine not only crystal structure of the material at truly extreme conditions, but also allows to refine its chemical composition. We report here the crystal structures of novel fluorides xenon, synthesized at high-pressure and high temperature conditions. In particular, the crystal structures of XeF_4 and Xe_3F_2, that both formed under heating-induced disproportionation of XeF_2 at 54 GPa. Similarly to ambient pressure structure, XeF_4 is a molecular compound composed of XeF_4 units with square planar geometry. Xe_3F_2 is not known at ambient conditions, and its structure is formed by isolated Xe atoms and linear XeF_2 molecules.

Effects of Ultrahigh Strain and Strain Rates on the Heterogeneous Microstructual Evolution of Cold-Sprayed Coatings Yu Zou; University of Toronto, Canada

Cold spray, initially a coating technique, is being touted as a ‘near-net shape’ manufacturing technology that minimizes material waste by virtue of the high rate of deposition. During the cold spray process, metallic bulk components can be produced by spraying metal powders at high velocity, generating bonding through severe plastic deformation at temperatures well below the melting point of the powders. To fully understand the cold spray processing of metal powders, we systematically compare and study the microstructure evolution in Cu, Ni, Al, Ti, Ti-6Al-4V samples prepared by cold spray using electron backscatter diffraction (EBSD), transmission electron microscopy (TEM) and nanoindentation. We show complex microstructure in these powder particles after cold spraying: nanocrystalline, nanotwins, annealing twins, gradient grains, deformation bands, dynamic/static recovery and recrystallization. The effects of gas temperature and powder velocity on the microstructure and mechanical properties in the cold sprayed samples are also discussed. Of particular interest are grain refinement, recrystallization and particle/particle bonding mechanisms of the cold sprayed powders.

Late News: Atomic-Scale Insight into Melting of BCC Tungsten Under Shear Stresses by Extended Finnis-Sinclair Potential—Molecular Dynamics Simulation Dulat Akzhigitov, Tamerlan Srymbetov, Boris Golman, Christos Spitas and Zhandos Utegulov; Nazarbayev University, Kazakhstan

Understanding melting processes in refractory materials under external stresses is important and can be of particular interest in harsh environment applications ranging from aerospace to nuclear and fusion energy where these materials have to simultaneously withstand the effect of high temperatures and complex stress states in such ways, that a melting process might be initiated in extreme conditions. However, most if not all of the prior research was focused on melting phenomena in the presence of hydrostatic compression.
In our work, we investigate the melting phenomenon in BCC tungsten under different shear stress types. We explore these relationships numerically by molecular dynamics simulations employing extended Finnis-Sinclair potential [1-2] and solid-liquid coexistence method and validate our results with theoretical and experimental findings previously reported in the literature for a hydrostatic compression case.
Regarding other stress states, no similar results have been reported yet for bcc tungsten. The melting behaviour was investigated for all studied stress states and compared both quantitatively and qualitatively on the basis of equivalent strain, least-square atomic-scale strain invariants, maximum shear stress, radial distribution function (RDF), thermal expansion and Lindemann melting criterion. For the majority of shear stress states, an abrupt decline of stress-induced melting point values was detected after certain critical stress values, which was explored with regard to the change of an RDF’s amplitude of the first peak. New high-temperature thermo-mechanical results are correlated with intricate structural changes taking place on the atomic scale during metal-melt phase transition.

Late News: *In Situ* Characterization of Dynamic Deformation of AZ31B Magnesium Alloys at High Strain Rate Impact Using 3D-Digital Image Correlation Technique Francis Tetteh; York University, Canada

The deployment of Magnesium (Mg) alloys have increased significantly in the automotive, aerospace, and defense industries due to their lightweight structural integrity. In structural applications, these materials components are exposed to a wide range of strain rates such as explosive forming, high-speed impact, and shock loadings. These alloy components are placed in extreme loading environments where high strain rates are commonly achieved. Therefore, the evolution of failure mechanisms from strain localization and formation of adiabatic Shear Bands (ASBs) and the mechanical behavior at high strain rates is of desirable interest by the aerospace and automotive industries. The deformation behavior of Mg has extensively been studied under low strain rate loadings. However, the high strain rate deformation still requires further investigation. Deformation and damage accumulation in Mg alloys at high strain rate loading conditions such as impact is not fully understood. Thus, the correlation between the accuracy of the reported mechanical data and microstructural features that leads to the credence of failure mechanisms within Mg is not well understood. It is therefore critical to extending the understanding of the mechanism of failure of Mg at high strain rates of loadings by exploiting other techniques. In this work, the dynamic mechanical impact response and ASBs nucleation of heat-treated AZ31B Mg alloys at different strain rates and impact momentums are characterized in-situ during impact at room temperature using the Direct Impact Hopkinson Pressure Bar (DIHPB) coupled with an in-situ 3D Digital Image Correlation (DIC) and high speed and high-resolution thermal imaging techniques. DIC provides an independent measurement of surface strains directly on test specimens during deformation to monitor stain evolution and strain localization. It is found that the flow stress increased gradually to (~50 %) with increasing strain rates and impact momentums and the AZ31B Mg exhibits strain rate sensitivity at dynamic loadings. This is due to an increasingly selective grain refinement under dynamic compression. Evaluation of DIC results indicated that strain occurrence is linear at the onset of deformation but becomes heterogeneous at the later stage of deformation with multiple nucleation sites of strain localization leading to ASB at ~80% of the specimen length after ~340 us of deformation. The region of peak non-linearity of maximum strain concentration leads to ASB formation with characteristic fine grains, voids, and crack initiation. At most, ~22 °C temperature rise is observed. The temperature rise is, however, lower with respect to the homologous temperature of Mg, and a hence higher degree of strain hardening behavior is induced after deformation. These results suggest that ASB forms in AZ31B Mg alloy despite its brittle nature that leads to crack initiation and ultimate failure under high strain rates and large strains of deformation and can be used to extend the understanding of the mechanism of failure in Mg alloys.

High Strength—High Conductivity Materials for High Field Magnets Francois Debray, Olivier Jay and Florence Lecouturier; UGA-INSA-UPS-CNRS, France

Magnetic field is a powerful tool to study new materials and new processes. The highest magnetic field generated with superconducting magnets made of NbTi and Nb_3Sn windings is 23.5 T. During the last years, technological breakthroughs have confirmed the feasibility of superconducting magnets generating more than 30 T thanks to the integration of high temperature superconductors. Still, higher magnetic fields are only available through copper-based magnets. Steady high magnetic field can be generated during several hours and implies a large electrical power (typically 30 MW for 40 T) whereas pulsed magnetic field can reach 100 T for some milliseconds with negligible power consumption. The French High Magnetic Field Facility (LNCMI) is developing both technologies, on its pulsed field site in Toulouse and its steady field site in Grenoble. Optimizing the high field magnets requires to search for the best material and associated shaping process for the realization of these highly constrained machines. The main high field magnet constraints are the mechanical constraints due to Lorentz forces and the thermal constraints coming from Joule losses.
For steady field magnets, copper alloys with high strength and high electrical conductivity are required for an operating temperature that can reached 150°C. To keep the windings of the magnet at a temperature acceptable for a given alloy a high velocity water flow is injected in it to manage heat fluxes as high as 10 $MW.m^{-2}$. Steady high field resistive magnets used two technologies: the Bitter and the polyhelix one. Bitter magnets are made of thin plates (from 0.2 to 1 mm) up to 1000 mm in diameter. In this shape Copper alloys with a high content of Silver (18 wt.%, yield strength up to 1000 MPa and electrical conductivity at room temperature of 50 $MS.m^{-1}$) have been industrialized by one company worldwide up to 250 mm in diameter. For larger diameters, copper plates with a possible addition of a low content of Silver are proposed by different companies with yield strength ranging from 400 to 450 MPa and a conductivity around 58 $MS.m^{-1}$. For the polyhelix technology, the LNCMI has set a R&D program to replace forged tubes (CuCrZr) with limited mechanical properties. Copper alloy tubes prepared by the Cold Spray technology are now in operation on the high field facility in Grenoble.
For pulsed field magnets, the highest priority is set on the mechanical properties of conductors at cryogenic temperature which have to cope with the increasingly severe mechanical constraints at fields beyond 60 T. To avoid excessive heating, the duration of the current that passes through a magnet is reduced to the order of 10-100 milliseconds. The LNCMI Toulouse disposes of several capacitor banks with a total energy of 22 MJ able to produce non-destructive fields over 60 T in 28 mm and close to 100 T in 8 mm bore. Beyond 100 T, it also features a Megagauss installation that makes use of dynamic effects in exploding copper single-turn coils to produce 200 T on a microsecond time scale. “In-house” copper/stainless steel macrocomposite conductors for wire wound pulsed field magnets generating magnetic fields up to 80 T are developed. High strength multiscale Cu/Nb nanocomposite wires produced by severe plastic deformation by ADB (Accumulative Drawing and Bundling) process are dedicated to the production of magnetic field over 90 T. New innovative composite copper based conductors, processed by powder metallurgy, reinforced with carbon nanotube or silver nanowires- are under development to reach non-destructive pulsed fields over 100 T.

Materials Requirements for Ultra-High-Field Magnets at the National High Magnetic Field Laboratory Mark D. Bird; Florida State University, United States

Ultra-High-Field (UHF) electromagnets require high current densities in high magnetic field with resulting intense Lorentz forces. A central part of developing higher field magnets is managing the Lorentz forces to keep stress and strain within the materials’ allowables.
The simplest UHF magnets are dc resistive ones. DC operations results in maximum performance being presently attained by high-strength copper and its alloys. Fatigue performance has started to emerge as a challenge in CuAg nano-composites. Pulsed resistive magnets are able to mix high-strength conductors and reinforcing materials with both high strength and high stiffness by appropriately adjusting the pulse length. High strength copper and a number of its alloys are productively employed, as are metallic and polymer/epoxy composite reinforcements. The highest field superconducting magnets employ the high-temperature superconducting (HTS) materials along with high strength reinforcement.
The present state of the art of material requriements for UHF magnets is briefly presented along with challenges for next-generation systems.

8:24 AM *F.SF01.02.03
Understanding Requirements of Advanced Magnet Materials to go Beyond 100 Tesla Doan Nguyen and Do T. Vo; Los Alamos National Laboratory, United States

High magnetic fields have a long history of uncovering fundamentally important information about materials. They take their place among e.g. X-ray and neutron techniques, as a critically important tool of condensed matter physicists. The National High Magnetic Field Laboratory's Pulsed Field Facility at Los Alamos National Laboratory is one of few research centers in

the world that can create and use ultra-high pulsed magnetic field for scientific research. The facility houses several types of non-destructive pulsed magnets which can provide the peak fields ranging from 60 tesla to 100 tesla for users. However, present frontiers in quantum matter, including topological matter and superconductivity, require magnetic fields beyond 100 tesla and several high field facilities around the world are currently working toward that ambitious goal. The power and stored energy required to generate a magnetic field increase exponentially with the field amplitude. Therefore the better conductors with higher mechanical strength and electrical conductivity are required to nondestructively generate magnetic fields above 100 tesla with acceptable risk and cost. Finite Element Modeling (FEM) simulations and our in-house mid-plane pulsed magnet design codes were employed to understand the requirements of advanced magnet materials to practically achieve magnetic fields beyond 100 tesla.

8:36 AM *F.SF01.02.01
Material Requirements for Pulsed Magnets at the HLD Sergei Zherlitsyn, Thomas Herrmannsdoerfer and Joachim Wosnitza; Helmholtz-Zentrum Dresden-Rossendorf (HZDR), Germany

The Dresden High Magnetic Field Laboratory (HLD) is a pulsed-field user facility, which provides external and in-house researchers with the possibility to perform a broad range of experiments in pulsed magnetic fields [1]. The HLD develops, manufactures, and operates the non-destructive pulsed magnets for the field range up to 90 T and beyond. A design of the magnets requires high-strength, high-conductivity wires with selected cross-sections and high-strength reinforcement materials. Currently some test coils are fabricated at the HLD for a prototype triple-coil magnet for magnetic fields of about 100 T. We will discuss the choice of materials for this pulsed magnet, material-based limitations, long standing experience with available materials, and material challenges for generating even higher magnetic fields by the non-destructive pulsed magnets.

Ultra-High Local Plasticity Induced by Room-Temperature Restoration in High-Strength Nanocomposite Rongmei Niu and Ke Han; Florida State Univ, United States

We subject an aged Cu-24 wt%Ag ingot to heavily cold drawing to develop a nanocomposite. The as-drawn wire is composed of Cu-rich proeuctectic components and Ag-rich eutectic components. A fine lamellar structure are developed in the proeuctectic component embedded a high density of Ag fibers. The average lamellar spacing is 20±6 nm. Ag fiber width is below 5nm. The eutectic component has a relative coarse structure with Ag grain size around 100 nm. This bimodal size distributed Ag fibers yield ultra-high bending plasticity—up to 59% bending strain at the outermost edge-- 15 times the tensile elongation of the wire (3.6%). During our bending tests, dynamic recovery and partial recrystallization occurr primarily in the eutectic component, and are more frequently at the inner edge than the outer edge. The high bending strain causes some of the thick Ag fibers to become discontinuous and lose their original alignment. This structural evolution increases local plasticity, resulting in unexpectedly high achievable bending strain. This is unusual in nano-sized, Ag-fiber-reinforced high-strength composite.

9:04 AM *F.SF01.02.05
Properties of Copper-Silver Alloys Obtained by the Cold Spray Process Christophe Verdy[1], Olivier Jay[2] and Francois Debray[2]; [1]LERMPS, ICB, UMR 6303, CNRS, Univ. Bourgogne Franche-Comté, UTBM, France; [2]Univ. Grenoble Alpes, INSA Toulouse, Univ. Toulouse Paul Sabatier, EMFL, CNRS, LNCMI, France

The cold spray process was developed at the end of the 20th century and his principle is mainly based on the kinetic energy transmitted to micron size particles to allow their deposition. The particles remain solid and the deposits are generated by the particles impacting the substrate at high velocity. Working at low temperature, below the melting point of the deposited material, appears particularly interesting for deposition of oxygen sensitive materials like copper alloys. In comparison with conventional thermal spray processes, cold spray can retain the original properties of powder feedstock (grain size, nanostructured particles), prevent the adverse influence on the underlying substrate materials, and can produce very thick coatings due to compressive stresses.
To spray oxygen sensitive material like copper alloys, it is preferable to select an inert gas as propellant gas for cold spray deposition. Nitrogen is mainly used but, as the gas velocity is strongly linked to the gas mass, gases with low atomic weight like hydrogen or helium are particularly interesting to reach high velocities. Among those gases, helium is much better from

the human safety point of view but its price is very high due to limited amounts on earth. A closed loop avoiding costly helium losses was implemented. Thus, deposition efficiency of cold spray copper alloys higher than 96 %, porosity below 0.1 % and oxygen content below 150 ppm were obtained. High deposition rates up to 7 kg/h were also reached.
Copper silver alloys present attractive mechanical properties combined with high thermal conductivity suitable for many applications like high field magnets. In the present work, CrCrZr and CuAg with various Ag percentage deposits were manufactured by cold spray using helium as propellant gas. The work hardening mechanisms are involved by comparison with classically forged materials. A large tailoring of the material's properties can be obtained through specific heat treating. Residual stresses are very low after heat treating and allow machining helices without deformation. This process now allows to produce tubes for polyhelix magnets at LNCMI with a major performance gain.

9:16 AM *F.SF01.02.07
A Powder Metallurgy Route Involving Spark Plasma Sintering Towards High-Strength Wires for DC or Pulsed Resistive Magnets Christophe Laurent[1], Simon Tardieu[1,2], David Mesguich[1], Antoine Lonjon[1], Nelson Ferreira[2], Geoffroy Chevallier[2], Arnaud Proietti[1], Claude Estournes[2] and Florence Lecouturier[2]; [1]Université Toulouse 3 Paul Sabatier, France; [2]CNRS, France

There is a demand for stronger yet lighter conducting copper wires in high-technology domains of global interest where weight is at a premium, such as power and aerospace engineering as well as in niche applications, such as materials for high-field magnets.
Many proposed solutions involve the preparation of copper-matrix composite wires or copper-rich alloyed wires with ultrafine but complex microstructures. Wires are prepared by wire-drawing billets (cylinders). This is a severe plastic deformation method and may be followed by appropriate thermal treatments. There are many variants but the importance of the characteristics of the cylinder is not to be neglected. The usual routes for cylinder preparation involve melting-solidification at some point, and therefore a relatively high temperature, either for alloying or for the preparation of the pure copper sample to be used in a composite.
We have proposed an alternative method based on powder metallurgy routes, involving the consolidation of a suitable powder into a cylinder by sintering at a relatively low temperature. This is done by spark plasma sintering (SPS), which has several advantages over pressureless sintering and hot-pressing, including rapid heating and cooling rates. Therefore, lower sintering temperatures and shorter holding times make it possible to avoid grain growth and prepare copper cylinders with micrometer-sized grains, typically ten times lower than conventional copper cylinders.
SPS typically differs from hot-pressing by the application of a dc pulsed current to the pressing die and powder compact, while a uniaxial pressure is simultaneously applied. Interestingly, cylinders with only about 90% of their full density were found suitable for the rest of the study, because a too high density hampers the deformability of the cylinder during wire-drawing, resulting in sample breaking.
The basics of SPS will be presented and we will show several examples of the preparation of wires of pure copper, carbon nanotube - copper composites and silver nanowire - copper composites. The microstructure of the powders, cylinders (typically 8 mm in diameter and 33 mm long) and wires will be presented as well as the mechanical properties and electrical resistivity of the wires measured at 293 K and 77 K.

9:28 AM *F.SF01.02.09
Application of the Nanostructured Cu-Nb *In Situ* Microcomposites as Strengthening Elements in High Strength Cu-Matrix Composites V. Pantsyrny[1,2]; [1]Nanoelectro LLC, Russian Federation; [2]Bochvar Institute of Inorganic Materials, Russian Federation

Advanced electrical and electronic devices sometimes require that conductor's material properties should be counteracting, e.g. high electrical conductivity and high mechanical strength. Traditional high strength Cu-matrix composites consists of Cu-based matrix, which contains a uniformly distributed nanoscaled particles of intermetallic compounds or oxides. The required microstructure is usually formed by the doping of the initial Cu matrix alloy by the combination of elements which would form the intermetallic compounds during the aging heat treatment at specific temperature range of 300-500 ° C (Cu-Zr-Nb; Cu-Ni-Si; Cu-Cr-Zr alloys) or to form fine oxides through the process of internal oxidation (Cu-Al alloys). These submicron particles of oxides and intermetallic compounds altogether with increase of ultimate strength lead to substantial decrease of fatigue properties. The paper describes the alternative approach to development of the advanced high strength Cu-matrix composites with the application of the plastic nanostructured Cu-Nb *in situ* microcomposites as a strengthening element. As an example the principally new design of composite Contact Wire for high speed railways has been proposed to attain at least 20% better combination of ultimate tensile strength (610-660 MPa) and high conductivity (more than 80% IACS). Composite conductor contains the bundles of nanostructured anomalously high strength Cu-Nb filamentary cores and outer layer made of low doped high conductivity Cu-Zr-Nb alloy with improved tribological properties. The microcomposite

Contact Wire has very high fatigue properties due to filamentary architecture of microstructure of Cu-Nb strengthening component. This Contact wire was designed for the use in the scope of Overhead Contact Line CS-400 for railways with the speeds of 400 km per hour. The results of laboratory complex tests of contact wire are presented.

SESSION F.SF01.13: Live Lightning/Flash Talks II: Materials for Extreme Conditions (MEC)
Thursday Morning, December 3, 2020
F.SF01

9:40 AM F.SF01.02.11
New High Strength Silver Nanowire-Copper Composite Conductors by Spark Plasma Sintering and Wire-Drawing for High Field Magnets Simon Tardieu[1,2], David Mesguich[2], Antoine Lonjon[2], Florence Lecouturier[1], Nelson Ferreira[1], Geoffroy Chevallier[2,3], Arnaud Proietti[4], Claude Estournès[2,3] and Christophe Laurent[2]; [1]LNCMI, France; [2]CIRIMAT, France; [3]Plateforme Nationale CNRS de Frittage Flash, France; [4]Centre de Microcaractérisation Raimond Castaing, France

LNCMI-Toulouse produces some of the most intense non-destructive pulsed magnetic fields in the world with a European record of 98.8 Tesla and aims at reaching more than 100 Tesla. The generation of pulsed magnetic fields higher than 60 T requires the use of coils wound of wires with exceptional properties. The wires need a high conductivity to limit the heating and they must have a high strength to be able to resist the Lorentz forces. The Lorentz forces are tangential to the coil and proportional to the square of the magnetic field. The resulting von Mises stress is 1 GPa at 60 T and higher than 2.2 GPa at 100 T.

Classical methods for strengthening copper wires involve the preparation of composite wires, such as copper-stainless steel (Cu-SS) and copper-niobium (Cu-Nb) or alloyed wires such as copper/silver (Cu/Ag). Cu-Nb and Cu/Ag wires present a nanostructured microstructure with fine and elongated grains. Cu-Nb microstructure is made up of pure Cu and pure Nb grains, while the Cu/Ag microstructure presents Cu-rich and Ag-rich solid solution. These wires exhibit a UTS value higher than 1 GPa but they are distinguished by their high resistivity. The aim of this work is the preparation of composite wires based on pure Cu and pure Ag.

LNCMI and CIRIMAT explore the design and preparation of novel Cu-based nanocomposite wires with the use of powder metallurgy, spark plasma sintering (SPS) and wire-drawing at room temperature. This preparation method is adapted to the preparation of Ag-Cu composite wires. Ag nanowires (200 nm in diameter and 30 µm in length) were synthetized and mixed with a commercial micrometric (about 1µm) Cu powder. Samples containing 1, 5 and 10 vol. % Ag were prepared. Cu and Ag-Cu cylinders (diameter 8 mm, length 33 mm) are prepared by SPS. Cylinders are sintered at 400, 500 or 600 °C. The so-obtained cylinders serve as precursors to wire-drawing. Their diameter is reduced by wire-drawing at room temperature, in several passes, thus producing progressively finer wires (diameter in the range 1 - 0.2 mm).

The wires show a lamellar microstructure with ultrafine Cu grains (200 - 700 nm for a 0.5 mm diameter wire) elongated over several micrometers. The Ag nanowires are dispersed along the grain boundaries of Cu. Cu and Ag grains exhibit major <111> and minor <100> orientations like most of wire-drawn face centered cubic metals.

The electrical resistivity and tensile strength were measured at 293 K and 77 K. The tensile strength for the composite wires is more than twice the value measured for the corresponding pure Cu wires. Interestingly, the wires containing only 1 vol.% Ag offer the best combination of high strength (1100 MPa at 77 K) and low electrical resistivity (0.50 µΩ.cm at 77 K).

We have obtained wires with excellent mechanical properties while greatly reducing the electrical resistivity compared to Cu/Ag alloy. The present 1 vol. % Ag-Cu composite wires compare favorably with Cu/Ag alloy wires containing about 20 times more Ag.

Enhanced Properties of High-Strength Reinforcement Materials for High-Field Magnets Ke Han, Rongmei Niu, Jun Lu and Vince Toplosky; Florida State University, United States

Nanostructured reinforcement materials, which have been successfully used in high field magnets and at cryogenic

temperatures, reach their most desirable strength level when their scale of microstructure is below 100 nanometers. This refined microstructure can be achieved by plastic deformation and heat treatment, which create obstacles, such as dislocations and precipitates, for dislocation motions. Both deformation and heat treatment also introduce microstructure and property anisotropy. Investigating both anisotropy and microstructure changes helps us to understand the plasticity of these materials, particularly at cryogenic temperatures. The goal of our research is to relate microstructural scale and anisotropy to the mechanical and physical properties of these materials. This presentation describes microstructure in different orientations, with emphasis on the impact of high anisotropy and fine microstructure on properties.
This work was performed at the National High Magnetic Field Laboratory, which is supported by the National Science Foundation Cooperative Agreement No. DMR-1644779 and the State of Florida.

Giant Thermal Hall Conductivity from Phonons in the Pseudogap Phase of Cuprate Superconductors G. Grissonnanche[1], A. Legros[1,2], S. Thériault[1], S. Badoux[1], E. Lefrancois[1], M.-E. Boulanger[1], V. Zatko[1], M. Lizaire[1], F. Laliberté[1], A. Gourgout[1], J.-S. Zhou[3], S. Pyon[4], T. Takayama[4], H. Takagi[4], S. Ono[5], N. Doiron-Leyraud[1] and L. Taillefer[1,6]; [1]Université de Sherbrooke, Canada; [2]CEA Saclay, France; [3]The University of Texas at Austin, United States; [4]The University of Tokyo, Japan; [5]Central Research Institute of Electric Power Industry, Japan; [6]Canadian Institute for Advanced Research, Canada

The nature of the pseudogap phase of cuprates remains a major puzzle. Although there are indications that this phase breaks various symmetries, there is no consensus on its fundamental nature [1].
Fermi-surface, transport and thermodynamic signatures of the pseudogap phase are reminiscent of a transition into a phase with antiferromagnetic order, but evidence for an associated long-range magnetic order is still lacking. Here we report measurements of the thermal Hall conductivity κ_{xy} in the normal state of four different cuprates and show that a large negative κ_{xy} signal is a property of the pseudogap phase, appearing with the onset of that phase at the critical doping p^*[2]. It is also a property of the Mott insulator at $p \approx 0$, where κ_{xy} has the largest reported magnitude of any insulator. Since this negative κ_{xy} signal grows as the system becomes increasingly insulating electrically, it cannot be attributed to conventional mobile charge carriers. Nor is it due to magnons, since it exists in the absence of magnetic order.
In order to identify the heat carriers responsible for this negative κ_{xy}, we turn to transverse heat transport along the c-axis: κ_{zy}. Here we show that the thermal Hall conductivity at $p = 0$ is roughly isotropic, being nearly the same for heat transport parallel and normal to the CuO_2 planes, *i.e.* $\kappa_{zy}(T) \approx \kappa_{xy}(T)$. This shows that the negative thermal Hall response must come from phonons, these being the only heat carriers able to move as easily normal and parallel to the planes. At $p > p^*$, we observe no c-axis Hall signal, *i.e.* $\kappa_{zy}(T) = 0$, showing that phonons have zero Hall response outside the pseudogap phase. The microscopic mechanism by which phonons become chiral in cuprates remains to be identified. This intrinsic phonon Hall effect provides a new window on quantum materials and it may explain the thermal Hall signal observed in other topologically nontrivial insulators [4].

Superconducting Superhydrides—Novel Materials and Possible Applications Maddury S. Somayazulu; Argonne National Laboratory, United States

Since the prediction of metallization and superconductivity of hydrogen and hydrogen-rich materials at high pressures /1,2/, there has been a sustained effort to make advances in high pressure sciences (theory, experiments and techniques) to realize this dream. In comparison to the much larger research landscape spawned by the discovery of high T_c cuprate

superconductors, the high pressure (and high temperature) superconductivity field has been slow to encapsulate the attention of many. Partly, this has to do with the paucity of experimental probes that can be broguth to bear and to a major extent, it is the question of transitioning discovery to application. Nevertheless, the discovery of superconductivity in H_3S, YH_6 and LaH_{10} /3,4,5/ and the phenomenal rise in transition temperatures has begged the question of revisiting these two questions. These discoveries have been aided by theoretical predictions and those can be used to make technological feasibility a likelihood /6-9/. However, there are experimental limitations that need to be surmounted to understand the physics and chemistry of these materials that constitute and important feedback to these simulations /10,11/. This talk will aim at connecting these dots and discus the rapidly evolving picture we have of these fascinating materials.

Plasma Facing Materials by Self Interstitial Solid Solution Strengthening Muhammad Musaddique Ali Rafique; Eastern Engineering Solutions LLC, United States

Bubble – a precursor of undersense nanostructure or fuzz formation is crystal lattice defect and is approached by Frenkel pair formation mechanism. One needs to have crystal lattice that inhibits Frenkel Pair generation by ejection of W self-interstitial atom by He cluster and its bonding with vacancy. However, this mechanism is very commonly observed in nuclear materials. It is applicable in conventional nuclear materials where α and β particles, γ rays and neutron flux strike the material. Plasma does not constitute of aforementioned and thus it is not very applicable mechanism. In the present study, author addresses this problem of development of plasma facing materials by primitive method of self-interstitial solid solution strengthening. Actual mechanism of bubble formation in studied and a suitable lattice is selected and proposed which inhibits possible Frenkel pair generation thus inherently promotes formation of plasma facing material.

Helium Compounds and Their Dynamical Properties Under Extreme Conditions Jian Sun; Nanjing University, China

Helium is the most inert element in the periodic table and generally considered to be unreactive under ambient conditions. On the other hand, helium is one of the main components of giant icy planets' atmosphere. It is unclear whether the helium can diffuse into the depths and react with the mantle materials (water, ammonia and methane). In this talk, I will introduce some of our recent theoretical predictions on helium compounds, including helium-water, helium-ammonia, helium-methane and helium-alkali metal oxides/sulfides, etc [1-4], using our own machine learning accelerated crystal structure search method [5]. In addition, we also found that some of these compounds exhibit exotic dynamical properties at high pressure and high temperature, including the superionic, plastic states and their co-existence.

Thermomechanical Stability of Metallic Interfaces Containing 3D Character Nathan Mara[1], Justin Y. Cheng[1], Shuozhi Xu[2], Youxing Chen[3], Jonathan Poplawsky[4], Nan Li[5], Kevin Baldwin[5] and Irene Beyerlein[2]; [1]University of Minnesota, United States; [2]University of California, Santa Barbara, United States; [3]University of North Carolina at Charlotte, United States; [4]Oak Ridge National Laboratory, United States; [5]Los Alamos National Laboratory, United States

2-dimensional (2-D) sharp interfaces with distinct boundaries demarcating an abrupt discontinuity in material properties in nanolayered composites have been studied for almost twenty years and are responsible for enhanced behaviors such as strength, radiation damage tolerance, and deformability. However, 2-D interfaces have their limitations with respect to deformability and toughness. 3-D interfaces are defined as heterophase interfaces that extend out of plane into the two crystals on either side and are chemically, crystallographically, and/or topologically divergent, in three dimensions, from both crystals they join. Here, we focus on the thermal stability and mechanical behavior of nanolayered Cu/Nb containing interfaces with 3-D character. By co-sputtering the bimaterial interfaces between the constituent pure phases, the resulting compositional gradient gives rise to new interphase boundary structures, which have been analyzed and quantified via S/TEM and Atom Probe Tomography. Micropillar compression results show that the strength of Cu/Nb nanocomposites containing 3-D interfaces is significantly greater than those containing 2-D interfaces. Mechanical anisotropy, as well as shear banding is observed during pillar compression with retention of continuous layers across the shear band. We will present our recent results on deformation of such 3-D interfaces and structures, and describe their structural evolution mechanistically through the use of atomistic simulations.

Self-Regulation of Current Sharing in High-Temperature Superconducting Cables by Temperature-Dependent Resistivity Switching in Vanadium Oxide Coatings Sachin V. Muley[1,2], Aurora Cecilia Araujo Martinez[1,3], Zhenuai Yang[1,4], Xiaorong Wang[1], Qing Ji[1] and Andre Anders[1,5,6]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of Wisconsin–Madison, United States; [3]University of Guanajuato, Mexico; [4]Harbin Institute of Technology, China; [5]Leibniz Institute of Surface Engineering, Germany; [6]Universität Leipzig, Germany

The high-temperature superconductors (HTS), e.g., RE-$Ba_2Cu_3O_x$ (RE = rare earth) can sustain significant transport current at high background magnetic field and elevated temperatures, enabling various applications including fusion energy generation, next generation high-energy physics particle accelerators, and medical accelerators for carbon therapy. However, reliable protection against catastrophic superconducting-to-normal transitions (quenches) remains to be addressed for successful applications of HTS magnet technology. To address this issue, we investigated the potential of vanadium oxide (VO_x) coatings as a temperature-dependent switching medium to self-regulate current sharing. VO_x coatings ($1.70 \leq x \leq$ to 2.07) were deposited by reactive cathodic arc deposition on insulating glass and commercial REBCO tapes to study their electrical properties. The process gas was monitored *in situ* by a residual gas analyzer. Effects of varying process parameters such as argon-to-oxygen ratio and substrate manipulator speed on coating properties were studied. The coatings were X-ray amorphous but Raman spectrometry showed short-range crystalline ordering. Hall effect measurements found a decrease in resistivity of VO_x by at least three orders of magnitude when the temperature increased from 80 to 300 K. The coating

process did not damage the REBCO tapes as evidenced by a negligible change in critical current after versus before coating. The results from current-sharing experiments and circuit analysis suggest that the VO_x coating can effectively self-regulate current sharing in REBCO magnets and enable self-protection during quenches. This work was supported by the Office of Science, Office of Fusion Energy Sciences, U.S. Department of Energy under Contract No. DE-AC02- 05CH11231 and the Laboratory Directed Research and Development (LDRD) funding from the Lawrence Berkeley National Laboratory provided by the Director. Swift Heavy Ion Irradiation Effects in Pre-Damaged Gallium Nitride Kristina Tomić Luketić[1], René Heller[2], Shavkat Akhmadaliev[2], Henning Lebius[3], Abdenacer Benyagoub[3], Isabelle Monnet[3], Corneliu Ghica[4], Ferdinand Scholz[5], Oliver Rettig[5], Branko Šantić[1], Stjepko Fazinić[1] and Marko Karlušić[1]; [1]Ruder Boskovic Institute, Croatia; [2]Helmholtz-Zentrum Dresden-Rossendorf, Germany; [3]Normandie Univ, ENSICAEN, UNICAEN, CEA, CNRS, CIMAP, France; [4]National Institute of Materials Physics, Romania; [5]Institute of Functional Nanosystems, Germany

*Corresponding author: marko.karlusic@irb.hr

When a beam of swift heavy ions (SHI) impinges onto a material, the formation of defects called ion tracks is possible as a result, either in the bulk or on the surface of the material. As a consequence, effects produced by means of SHI irradiation that lead to structural changes of the material can be used to modify the properties of the material via defects engineering. SHI damage introduction to materials can result in complex behavior, especially in radiation harsh environments. To assess the final damage of the material, the effect of the energy deposition from the ions to the atoms within the material must be taken under consideration. Deposition of energy occurs through two main channels: either to the electronic subsystem of the material (electronic stopping power) or to the nuclei (nuclear stopping power). Here we investigate the influence of ion beams with different stopping powers, used in a sequence, on defects formation. It is known that sequential irradiation of ion beams can lead to the SHIBIEC effect (Swift Heavy Ion Beam Induced Epitaxial Crystallization) i.e. the annealing of defects that occurs during the second irradiation step. Alternatively, the anti-SHIBIEC effect is also possible, i.e. the enhanced defect formation during the second step of irradiation.
Sequential ion irradiation of GaN has not been investigated so far. This material is an important semiconductor for high-power electronics. The results presented here are of importance for basic research in this field as well. In our previous work [1], we found no evidence of ion track formation in the bulk after SHI irradiation using 23 MeV I and 90 MeV Xe beams. However, recently we were able to introduce additional disorder into moderately damaged GaN crystals using the same 23 MeV I and 90 MeV Xe beams, in cases where GaN samples have been pre-irradiated with 2 MeV Au or with 900 MeV Xe ion beams. Two different ion beams are expected to introduce damage into GaN either by nuclear or electronic stopping, respectively [2,3]. We observe the difference in total damage in the material depending on the fluence of the beams applied. In this contribution, we report new results of sequential ion irradiation of GaN based on RBS/c (Rutherford Backscattering Spectroscopy in Channeling) and TEM (Transmission Electron Microscopy) measurements.

5:09 PM F.SF01.04.06

Plasma-Assisted Atomic Layer Annealing as a Low-Temperature Technique Enabling Crystalline Growth of β-Ga_2O_3 Films for Wearable/Flexible Electronics Saidjafarzoda Ilhom[1], Adnan Mohammad[1], Deepa R. Shukla[1], John Grasso[1], Brian Willis[1], Ali Okyay[2] and Necmi Biyikli[1]; [1]The University of Connecticut, United States; [2]Stanford University, United States

The rapid evolution in technology and its integration with humans requires the development of novel processes that enable the incorporation of the crucial electronic materials, such as the wide bandgap semiconductors (Ga_2O_3 and GaN) into the wearable electroinc systems. Wide bandgap semiconductors form the building blocks of the current high-power high-frequency electronics and the upcoming mmWave fifth-generation (5G) device technologies. To make such technologies integrable with wearable/flexible systems, it is critical that high quality and in particular as-grown crystalline thin films of these materials can be produced on highly temperature-sensitive substrates at very low temperatures.
In this work, we report on the low-temperature, as-grown crystalline Ga_2O_3 films on various substrates (Si, sapphire, glass,

and Kapton) via a hollow-cathode plasma-ALD system. Triethylgallium (TEG) and Ar/O_2 plasma were employed as metal precursor and oxygen co-reactant, respectively. Growth experiments have been performed at 160 – 240 °C substrate temperature and 30 – 200 W rf-power range. Additionally, each unit AB-type ALD-cycle was followed by an in situ Ar-plasma annealing treatment, which consisted of Ar-plasma exposure for 20 seconds scanned over 50 – 300 W rf-power. Both in situ and ex situ ellipsometry were employed to measure the thickness and optical properties of the films. The thickness of the films without Ar-annealing stage, ranged between 20.74 – 39.30 nm and as-grown refractive indices were between 1.75 - 1.67 within the scanned plasma power range. X-ray diffraction (XRD) showed that Ga_2O_3 films grown without in situ plasma annealing exhibited amorphous structure irrespective of both substrate temperature and rf-power. However, with the in situ Ar-annealing phase incorporated, the thickness of the films ranged between 22.9 – 31.4 nm with refractive indices of 1.75 – 1.79. The increased refractive index (1.79) and reduced thickness gain (31.4 nm) at 250 W Ar-annealing power indicates possible densification and crystallization of the films. Indeed, XRD and XRR confirmed that in situ Ar-plasma treated films grow in a monoclinic β-Ga_2O_3 crystal phase with further improving crystallinity and film density (from 5.07 to 5.80 g/cm^3) with increasing Ar-annealing plasma power. Additionally, we will discuss the impact of varying in situ Ar-annealing plasma chemistries (Ar-only, O_2-only, and Ar/O_2) coupled with x-ray photoelectron spectroscopy (XPS) measurements, which will provide additional insight into the elemental composition of the films that might help to understand the changes in the structural, optical, and electrical properties. A future outlook will be provided to overcome the challenges to achieve device quality layers on temperature-sensitive flexible substrates.

5:11 PM F.SF01.04.05
Late News: Novel Defect-Fluorite Pyrochlore Sodium Niobate Nanoparticles—Solution-Phase Synthesis and Analysis of Neutron Tolerance Rana Faryad Ali and Byron Gates; Simon Fraser University, Canada

Materials possessing a defect-fluorite pyrochlore structure can have a range of useful properties that are sought after, which include radiation tolerance, nuclear waste immobilization, and phase stability at elevated temperatures. In this study, we demonstrate for the first time the synthesis and a detailed analysis of defect-fluorite pyrochlore sodium niobate ($NaNbO_3$) nanoparticles. This analysis included an investigation into the stability of these nanoparticles at elevated temperatures, as well as to neutron irradiation. A surfactant-assisted solvothermal method was used to prepare nanoparticles of $NaNbO_3$. This solution-phase approach results in the formation of crystalline nanoparticles of a defect-fluorite pyrochlore $NaNbO_3$ at relatively low temperatures. The products had an average diameter of ~74 ± 11 nm. The nanoparticles adopted a defect-fluorite pyrochlore phase and matched the cubic space group. This pyrochlore form of $NaNbO_3$ was stable up to at least 500 °C. The nanoparticles transformed into the cubic and rhombohedral perovskite phases of $NaNbO_3$, along with the introduction of a pseudo-hexagonal Nb_2O_5 at higher temperatures. These defect-fluorite pyrochlore nanoparticles of $NaNbO_3$ also exhibited a resistance to radiation induced amorphization. The dimensions, phase, and crystallinity of the defect-fluorite pyrochlore nanoparticles after exposure to a flux of neutrons were comparable to the as-synthesized product. The thermal stability and radiation tolerance of these pyrochlore nanoparticles could be useful in the design of thermally resilient materials, high temperature catalysts, and durable materials for the handling and storage of radioactive waste.

5:13 PM F.SF01.05.03
Molecular Layer Deposition Approach for Synthesis of SiAlCO Polymer Derived Ceramic (PDC) Thin Films Kristina Ashurbekova[1], Karina Ashurbekova[2], Iva Saric[3], Evgenii Modin[2], Mladen Petravić[3], Aziz Abdulagatov[1], Mato Knez[2,4] and Ilmutdin Abdulagatov[1]; [1]Dagestan State University, Russian Federation; [2]CIC nanoGUNE, Spain; [3]University of Rijeka, Croatia; [4]IKERBASQUE, Basque Foundation for Science, Spain

Organosilicon polymer derived ceramic (PDC) materials and its derivatives have gained interest as an emerging class of materials capable of providing mechanical stability and heat dissipation upon operation in extreme environments. PDC's found various applications such as electrode material for Li-ion batteries, ultra-high temperature composites and others [1]. Being X-ray amorphous, PDC's consist of nanodomains of different structures and compositions, demonstrating nanoscale heterogeneity that influence their unique mechanical, chemical and functional properties. Conventionally, PDC coatings are prepared by wet-chemical dipping, spinning thermal-spraying or by plasma-assisted chemical vapor deposition (CVD), followed by high temperature pyrolysis [2].
In this work, molecular layer deposited (MLD) hybrid organic-inorganic films serve as precursors for the synthesis of SiAlCO PDC composite coatings. Alumina-polysiloxane films were grown using sequential surface reactions between 1,3,5,7-tetravinyl-1,3,5,7-tetramethylcyclotetrasiloxane (V_4D_4) and trimethylaluminum (TMA). The deposition was conducted at temperatures between 120 and 220 °C. *In-situ* quartz crystal microbalance (QCM) monitoring showed linear mass increase with the number of MLD cycles with the highest mass gain rate of 24 ng/cm^2/cycle at 180 °C. The QCM study revealed a self-limiting surface chemistry. An infrared analysis (FTIR) of the deposited films showed vibrational features characteristic of organosilicon polymers: Si-CH_3, Si-O-Si, Si-CH=CH_2 and Si-O-Al peaks. High-resolution transmission

electron microscopy (HRTEM) imaging confirmed the conformal nature of the deposited MLD film.
In order to increase mass yield during the polymer-to-ceramic transformation, cross-linking of the growing polymer chains is needed. Cross-linking was achieved at 200°C by introducing a third precursor, di-tert-butyl peroxide (TBPO), into the MLD cycle, following a V_4D_4/TBP/TMA sequence. A positive mass gain after TBPO dosing, observed by QCM, indicates the formation of radicals and cross-linking. The cross-linking occurs through the activation of the vinyl groups. Characteristic signals, related to the generated polyethylene chains, were identified by ATR-FTIR and XPS. The formed Si-C-C-Si units are expected to improve the mechanical and thermal properties of the cross-linked SiAlCO PDCs, since the Si–C and C–C bonds are not affected by thermal depolymerization reactions.
X-ray and optical characterization techniques were employed to analyze the structural changes and composition of the films after pyrolysis. After pyrolysis at 900°C in an Ar atmosphere, the composite thin film remained amorphous. The resulting film contained uniformly distributed Si, Al, O, and C. Raman spectroscopy showed presence of graphitic carbon within the film. This MLD-derived SiAlCO thin film is expected to have exceptional uniformity, high temperature stability, creep, and corrosion resistance.

Late News: Size-Controlled Formation and Functionalization of Superparamagnetic Magnetite Nanoparticles with Enhanced Colloidal Stability at Extreme High Salinity Condition Wei Wang, Hooisweng Ow, Sehoon Chang and Bora Yoon; Aramco Services Company: Aramco Research Center-Boston, United States

Magnetic nanoparticles (MNPs) have attracted significant attention in the oil industry in the past decade due to their potential applications including reservoir sensing and mapping, enhanced oil recovery, drilling and completion improvement, oil-water separation in produced water, oil spill clean-up, and directional transport and local heating. For these specific applications, the dispersity and stability of the MNPs in suspension are of great importance. Surface coating and specific functionalization of the MNPs are typically used to improve their stability and to reduce aggregation for the successful use of the nanoparticles. However, many of the well-established methods and procedures of surface coating chemistry for lab applications are not suitable for harsh environmental conditions such as at extreme high salinity for industrial oil applications. In this research, we synthesized magnetite MNPs with tuned particle sizes to optimize their superparamagnetic properties, and developed a new procedure for surface functionalization to enhance their colloidal stability at high salinity. The functionalized magnetite MNPs have been characterized by XRD, HR-TEM, cryo-TEM, dynamic light scattering and zeta potentials. Colloidal stabilities have been studied in a wide pH range and salinity with 5000-230000 ppm of TDS (Total Dissolved Solids). The results have demonstrated that the covalently bonded zwitterionic functional groups and cross-linked saccharide highly enhance the colloidal stability in high salinity brines.

5:17 PM F.SF01.06.01
Strain-Coupled Electronic Polarization in Semiconducting Oxides Under Extreme Electric Field Yen-Ting Chi[1], Mostafa Youssef[2,1], Bilge Yildiz[1] and Krystyn Van Vliet[1]; [1]Massachusetts Institute of Technology, United States; [2]The American University in Cairo, Egypt

The polarization response of ionic and electronic defects in complex oxides under high electric field is critical for applications such as memristors and ferroelectrics, but historically challenging to model or measure. Here we developed a localized Hubbard U approach that resolves the dilemma of maintaining in-gap localized defect states for an oxygen vacancy while simultaneously retaining non-linear dielectric behavior of perovskite oxides. With this approach, we obtained accurate dielectric constant and electronic configuration for $SrTiO_3$ under electric field, using density functional theory and Berry phase calculations. We identified a direct relationship between oxygen vacancy polarizability and lattice strain, which can be generalized to other materials with similar crystal structure. For example, a neutral oxygen vacancy in $BaTiO_3$ and in $SrTiO_3$ strained to exhibit the same lattice constants showed identical polarization behavior under the same electric field. To trace the site polarizability difference between defected crystals and their defect-free counterparts, we utilized maximally localized Wannier functions to obtain the site-decomposed polarization. These simulations illustrated that not only the vacant site, but also the neighboring ions around the vacancy have significant influence on the system polarization with field applied either parallel or perpendicular to the $Ti - V_O^x - Ti$ chain. Together, this model and identification of driving factors in defect displacement under electric field contribute generalizable approaches to study and optimize materials in memristors, ferroelectrics, electrocaloric refrigeration and flash sintering.

5:19 PM F.SF01.07.01

High-Temperature and Abrasion Resistant Selective Solar Absorber Yanpei Tian, Xiaojie Liu and Yi Zheng; Northeastern University, United States

Selective solar absorbers with high performance are the key to concentrated solar power systems. Optical metamaterials are emerging as a promising strategy to enhance selective photon absorption, however, the high-temperature resistance (500 C) remains as one of the main challenges for practical applications. Here, a multilayered metamaterial system (Al_2O_3/W/SiO_2/W) based on metal-insulator-metal resonance effect has been demonstrated with high solar absorptance over 92%, low thermal emittance loss below 6%, and significant high-temperature resistance: it has been proved that the optical performance remains 94% after 1-hour thermal annealing under ambient environment up to 500 C, and 94% after 96-hour thermal cycle test at 400 C. Outdoor tests demonstrate that a peak temperature rise (193.5 C) can be achieved with unconcentrated solar irradiance and surface abrasion resistance test yields that SSAs have a robust resistance to abrasion attack for engineering applications.

Deformation Mechanisms of Alumina-Forming Austenitic Stainless Steels for High Temperature Applications Andrew Peterson; Dartmouth College, United States

Alumina-forming austenitic stainless steels (AFAs) are a class of alloys that are showing promise for use in high temperature applications, particularly for use in power generation. AFAs have been shown to demonstrate good high temperature strength, great oxidation resistance due to a protective alumina scale, and are cheaper than nickel-base alloys. While showing great promise, these alloys need to continue to be studied and improved to be practical for use. In particular, the deformation behavior of these alloys is not well understood. The austenitic matrix can contain various precipitates, including: $L1_2$ structured precipitates, B2 precipitates, Laves precipitates, carbides, and others. The grain boundary (GB) also can become covered by Laves and/or B2 precipitates. In a complex alloy with different types and sizes of precipitates, it can be difficult to determine what effect each of these precipitates are having on the high temperature strength.
In this work, we studied the deformation mechanisms in the model AFA alloy Fe-20Cr-30Ni-2Nb-5Al (at%). This alloy displays many characteristics of AFA alloys, and thus is a good alloy for scientific studies. This alloy contains $L1_2$, Laves, and B2 precipitates in the matrix as well as Laves and B2 precipitates on the GBs. Creep tests, high temperature tensile tests, and high temperature strain-rate jump tests were performed on this alloy after various heat treatments to determine the deformation mechanisms – including strain-rate jump tests with and without $L1_2$ precipitates (but otherwise similar microstructures) to determine the effect of these precipitates on the high temperature strength. In addition, tests were performed on alloys with different grain size, but otherwise similar microstructure, to determine the effect of GB precipitation. Analysis of the stress – strain rate relationships was used to predict deformation mechanisms and to fit the experimental data to models. In addition, transmission electron microscopy (TEM) and scanning electron microscopy (SEM) were performed on samples after mechanical testing to determine deformation behavior. In-situ straining experiments in the TEM and SEM were also performed. This study found that nano-sized $L1_2$ precipitates provided the majority of the strengthening in this alloy. At low stresses dislocations by-passed these particles by climb, and at high stresses dislocations started to form Orowan loops around the particles. While dislocations piled up at larger Laves and B2 precipitates, these precipitates were not as effective at strengthening the alloy. In addition, work was performed to determine if there was a GB strengthening effect due to coverage of the GB by precipitates.

$Zn_xFe_{3-x}O_4$ Nanoparticles—Structural and Magnetic Behaviour Evolution After Thermal Treatment up to 1400 ºC Angelika Kmita[1], Jan Zukrowski[1], Juliusz Kuciakowski[1,2], Marianna Marciszko-Wiackowska[1], Antoni Zywczak[1], Dorota Lachowicz[1], Marta Gajewska[1] and Marcin Sikora[1]; [1]AGH University of Science and Technology, Academic Centre for Materials and Nanotechnology, Poland; [2]AGH University of Science and Technology,Faculty of Physics and Applied Computer Science, Poland

Zinc ferrite nanoparticles are currently of much interest for their potential applications in extreme conditions like high temperature: e.g. in metal casting, in water splitting reaction for H_2 production (solar fuels) or as high - temperature desulfurizing sorbents [1-3]. Bulk $ZnFe_2O_4$ (ZF) should have paramagnetic nature around room temperature, when it is the normal spinel with Zn^{2+} incorporated mostly in the tetrahedral lattice sites. In the case of nanoparticles, the situation is more complex due to high probability of inversion in the cation distribution between octahedral and tetrahedral sites, which may lead to ferrimagnetism or superparamagnetism [4-6]. It was suggested that during heating Zn^{2+} ions can move from

tetrahedral site to octahedral site whereas Fe^{3+} ions redistribute within the octahedral and tetrahedral sites in order to reduce the strain [7]. It was also speculated the possibility of reduction of Fe^{3+} to Fe^{2+} during high temperature treatment. In order to verify these hypotheses we have performed a comprehensive study of structural and magnetic properties of stoichiometric and non-stoichiometric zinc ferrite $Zn_xFe_{3-x}O_4$ (NZF) nanoparticles synthesized using co-precipitation and thermal decomposition method [2, 8] as well as their evolution after thermal treatment. Nanoparticles with different zinc to iron ratio were obtained and systematically probed with volume (XRD, VSM, TG/DSC), microscopic (TEM) and element sensitive probes (ICP-OES, Mossbauer spectroscopy, XPS, XAFS). Magnetic studies proved paramagnetic response of stoichiometric ZF nanoparticles, while a superparamagnetic behaviour is observed in strongly non-stoichiometric (as synthesized) nanoparticles. After thermal treatment at 1400 ^oC in inert atmosphere, significant changes in the saturation magnetization were observed in the case of NZF. This is related with an increase of the amount of formally Fe^{2+} ions. The estimated saturation magnetization of as synthesized NZF nanoparticles, of approx. 50 emu/g, is increased upon thermal treatment (at 1400 ^oC in inert atmosphere) up to approx. 130 emu/g. As such we have confirmed that zinc concentration and method of synthesis plays important role in magnetic properties of non-stoichiometric zinc ferrite nanoparticles. Moreover, the reduction of Fe^{3+} to Fe^{2+} during high temperature treatment has been observed in NZF nanoparticles annealed in inert atmosphere.

The Influence of Lattice Defects and Recombination on Thermal Transport in Single Crystal Actinide Oxides Cody A. Dennett and David H. Hurley; Idaho National Laboratory, United States

Actinide and lanthanide fluorite oxides, UO_2, CeO_2, ThO_2, form an important class of ceramic energy materials with applications ranging from nuclear fuels to solid oxide fuel cells. Of these systems, ThO_2 (thoria), has been the least explored and offers unique features including an extremely high melting temperature and a fixed tetravalent oxidation state. Many potential application environments for thoria include high radiation fields or temperatures which either promote or directly generate lattice defects. Such defects drastically influence thermal transport, a controlling safety and performance property in many applications. To date, little experimentally-validated understanding has been generated on the role of defect formation and clustering on thermal transport in thoria due to the lack of high-quality starting material in which these effects may be explored. In this work, high-quality oriented single crystals of thoria are grown using hydrothermal synthesis and then exposed to proton irradiation at both room temperature and 600C. The thermal conductivity of the defected surface layer in these crystals is measured using an all-optical spatial domain thermoreflectance (SDTR) technique and sub-electron-microscopy-resolution defects are characterized using Raman spectroscopy. Together, these methods provide important initial insight into the types of defects formed under ionizing radiation, defect clustering, and how these defects impact thermal transport in high-quality thoria.

Tailoring Nanopomposites with Enhanced Failure Tolerance by Interface Engineering Daniel Kiener[1], Michael Wurmshuber[1], Inas Issa[1], Michael Burtscher[1], Mingyue Zhao[1] and Christoph Gammer[2]; [1]Montanuniversity Leoben, Austria; [2]Erich Schmid Institute of Materials Science, Austrian Academy of Sciences, Austria

Designing ever stronger nanostructured materials that can even withstand harsh environments has become a major goal in the last decades. However, the increase in strength commonly comes hand in hand with a severe reduction in ductility, which at the same time also limits the toughness of these materials. Due to the high fraction of interfaces in such nanostructured materials, it is safe to assume that the processes limiting ductility and toughness as well as their response to harsh environments are controlled by the respective interface structures. However, a detailed understanding is at this point still lacking.

Bulk nanostructured materials were synthesized by severe plastic deformation and subject to tailored interface modifications. To investigate the structural properties of these nanomaterials at high stress and strain, we utilize quantitative miniaturized

deformation and fracture experiments performed in situ in scanning or transmission electron microscopes. These highly resoled techniques not only allow to measure material performance, but also to directly identify the underlying deformation and failure mechanisms at the same time.
Using this experimental approach, we will first address the nanoscale processes taking place during deformation and fracture of bcc nanocrystalline metals with modified interfaces. Building on this, the discussion will be extended to the behavior of nanocomposite structures and the influence of an irradiative environment.

Crystal Chemical Design of Novel High Energy Density Polynitrides Maxim Bykov[1,2], Elena Bykova[2], Mohammad Mahmood[1], Leonid Dubrovinsky[3] and Alexander F. Goncharov[2]; [1]Howard University, United States; [2]Carnegie Institution for Science, United States; [3]University of Bayreuth, Germany

The high-pressure chemistry of nitrogen and nitrogen-rich compounds have been in a focus of many studies in the recent years due to both fundamental and practical interest and due to the improvement of high-pressure synthetic and characterization techniques. Poly-nitrogen compounds are usually considered as potential high energy density materials (HEDM) due to the remarkable difference in the average bond energy between the single N–N bond, the double N=N bond , and the triple N≡N bond. Numerous polynitrogen compounds with various nitrogen polymeric networks were theoretically predicted, but there are only a very few experimental attempts to obtain such compounds.

In the present work we have systematically studied reactions between transition metals and nitrogen at pressures up to 130 GPa in laser-heated diamond anvil cells. Despite very high synthesis pressure Hf, W, Re and Os react with nitrogen forming porous metal-inorganic frameworks Hf_4N_{22}, WN_{10}, ReN_{10} and Os_5N_{34} of various topologies. The frameworks are built of metals interconnected via polymeric nitrogen linkers, while the pores are filled with dinitrogen molecules N_2. Lighter transition metals (Fe) form non-porous polynitrides featuring polymeric nitrogen chains, while alkali metals react with nitrogen at extreme conditions with the formation of pentazolate salts. In this contribution we will discuss novel synthetic routes to energetic polynitrogen compounds and crystal-chemical rules governing their formation.

Late News: Multi-Scale Structural Response of Pyrochlore Oxides to Far-from-Equilibrium Processing Eric O'Quinn[1], Devon L. Drey[1], Antonio Fuentes[2] and Maik Lang[1]; [1]University of Tennessee, United States; [2]Cinvestav-Unidad Saltillo, Mexico

Swift heavy ion irradiation and high-energy ball milling are far-from-equilibrium processing techniques which provide access to a unique phase space not achievable by means of traditional synthesis approaches. High-resolution neutron total scattering experiments were utilized to gain fundamental insight into the multi-scale structural details of $A_2B_2O_7$ pyrochlore oxides prepared by these extreme conditions and their subsequent evolution under high-temperature treatment. Pair distribution function analysis revealed unconventional atomic arrangements characterized by an unexpectedly high degree of local order. For instance, the atomic arrangement of ball-milled titanate pyrochlore oxides is nearly identical to the same pyrochlore composition synthesized by solid-state reaction and subsequently amorphized by intense ion irradiation (*1*). Interestingly, the same atomic arrangement is found in pyrochlore oxides that exhibit distinct long-range radiation responses (order-disorder *versus* crystalline-amorphous) (*2*). These phenomena are proposed to be the result of fundamental chemical rules which stringently dictate the atomic configuration in disordered materials (*3*, *4*). This description provides insight into far-from-equilibrium processing of oxides and helps to better elucidate the structural properties and heterogeneity of disordered complex oxides from the local atomic arrangement to the macroscale.

Improved Dielectric Properties of Na1/2Y1/2Cu3Ti4O12 Ceramics Synthesized by Ball-Milling and Reactive Sintering Hicham Kotb and Adil Alshoaibi; King Faisal University, Saudi Arabia

Na1/2Y1/2Cu3Ti4O12 (NYCTO) ceramics with giant dielectric constant (ε′) were synthesized by simple reactive sintering. NYCTOnanopowder was first synthesized using high energy ball-mill. Then the pelletized powder was sintered in air at temperatures in the range 975 °C to 1050 °C for 10–20 h. The obtained ceramics showed pure CaCu3Ti4O12 (CCTO)-like cubic phase as revealed by x-ray diffraction measurements. Field effect-SEM observations showed that the grain size increases from 2 μmto5 μmwith increasing sintering temperature. NYCTO samples sintered at temperatures higher than 975 °C showed giant dielectric constant (103–104) over most of the frequency range. The minimum dielectric loss (tanδ) of∼0.055 at 300 K has been approved for the ceramic sample sintered at 1050 °C. Impedance and modulus spectra of the current samples showed two relaxations related to semiconductor (grain) and high resistance (grain-boundaries) elements. The activation energy for conduction located in the range 0.1–0.5 eV highlighted the role of single ionized oxygen vacancies in the dielectric properties of the investigated NYCTO ceramics.

Simulations of Hydrogen Retention in Polycrystalline Tungsten Brandon Laufer and Karl D. Hammond; University of Missouri, United States

Tungsten will be the plasma-facing material in the ITER divertor. Hydrogen blistering has been observed in plasma-facing materials, but to date, all electronic structure and molecular mechanics simulations have indicated that hydrogen atoms repel one another in perfect crystals. The influence of grain boundaries on hydrogen retention is also not well-understood. We conducted simulations intended to elucidate the mechanisms of blister formation. These studies were accelerated using direct implantation, as we have used in the past for helium, so that computational time ordinarily required to simulate hydrogen atoms that reflect is instead used to simulate diffusion. Consistent with prior observations, we observe that hydrogen is generally repelled by other hydrogen atoms in single-crystal tungsten and we observe neither self-clustering nor cluster growth of any kind. Near grain boundaries, however, the excess volume present allows hydrogen to cluster. Eventually, sufficient hydrogen concentration can build up and weaken the grain boundary, possibly resulting in delamination of the grains and forming a blister.

Electric Current and Field Effects on the Microstructural Development of Al Doped ZnO Claudia Gorynski and Markus Winterer; University Duisburg-Essen, Germany

The present work focuses on understanding the microstructural development during sintering of nanopowders under pressure and electric fields/currents. For this purpose, a method has been developed which combines flash sintering (FS) and spark plasma sintering (SPS) [1]. This FS-SPS combination enables us to combine the advantages of both techniques: to force the electric current through the sample (FS) and to sinter pellet-shaped samples under mechanical loads (SPS). We explored the novel device on the model material Al doped ZnO and discovered a different microstructure, compared to conventional SPS. Grain growth and second phase formation were emphasized by FS-SPS. It remains controversial if the observed microstructure is a result of an intrinsic electric current/field effect or of a temperature-distribution. However, this method helps to understand mechanisms involved in electric current or field assisted sintering techniques and possibly produces new microstructures and, hence, materials.

Stress Induced Mesoscale Assembly of Nanoparticles for Active Nanostructures Hongyou Fan; Sandia National

Laboratories, United States

Due to the size- and shape-dependent properties, nanoparticles have been successfully used as functional building blocks to fabricate 1-3D ordered assemblies for the development of artificial metamaterials. At ambient pressure, entropy driven self-assembly of monosized or binary nanoparticles generally results in polycrystalline 2- or 3D close-packed arrangements, and extensive efforts have been made to develop structural perfection of nanoparticle arrays or 'single crystal-like' domain structures with precise long range order for their definite advantages for electron transport. To date, fabrications of ordered nanoparticle assemblies have been relied on specific interparticle chemical or physical interactions such as van der Waals interactions, dipole-dipole interaction, chemical reactions, etc. Recently we have discovered a pressure-induced assembly method to engineer nanoparticle assembly at mesoscale and to fabricate new nanoparticle architectures without relying on specific nanoparticle interactions. We show that under a hydrostatic pressure field, the unit cell dimension of a 3D ordered nanoparticle arrays can be manipulated to reversibly shrink, allowing fine-tuning of interparticle separation distance. Under a uniaxial pressure field, nanoparticles are forced to contact and coalesce, forming hierarchical nanostructures. Depending on the orientation of the initial nanoparticle arrays, 1-3D ordered nanostructures including nanorod, nanowire, and nanoporous network can be fabricated through the pressure-induced self-assembly method. Guided by computational simulations, we were able to rationalize the pressure-induced self-assembly of nanoparticle arrays for predictable nanostructures. Moreover, we discovered for the first time a transition from an ordered polycrystalline nanoparticle mesophase to quasi-single crystalline nanoparticle lattices induced by PDA process. Exerting pressure-dependent control over the structure of nanoparticle arrays provides a unique and robust system to understand collective chemical and physical characteristics and to develop novel electronic and photonic behavior for energy transduction related applications.

Supercritical Elasticity and Its Potential Applications in Extreme Conditions Haiyang Chen[1], Yan-Dong Wang[1] and Yang Ren[2]; [1]University of Science and Technology Beijing, China; [2]Argonne National Laboratory, United States

Developing elastic materials for technological applications in extreme conditions has been a challenging task. Normal metals have an elastic strain limit rarely exceeding 1%. A large pseudo-elastic strain up to 10% can be achieved in the so-called shape-memory alloys (SMAs). However, the intrinsic hysteresis and temperature sensitivity of the first-order phase transformation significantly hinder their usage in many critical areas. We recently discovered a new type elasticity: supercritical elasticity (SCE), in NiCoFeGa single crystals, which exhibit a large elasticity up to 15.2% strain, with non-hysteretic mechanical responses, a small temperature dependence and high-energy-storage capability and cyclic stability over a wide temperature and composition range [Chen et al., Nature Materials, (2020). https://doi.org/10.1038/s41563-020-0645-4]. Such a giant SCE is conceived to work even down to absolute zero Kelvin. In situ synchrotron X-ray diffraction measurements show that the SCE is correlated with a stress-induced continuous variation of lattice parameter accompanied by structural fluctuation. Neutron diffraction and electron microscopy observations reveal an unprecedented microstructure consisting of atomic-level entanglement of ordered and disordered crystal structures, which can be manipulated to tune the SCE. The discovery of the giant SCE and associated the entangled structure paves the way for exploiting elastic strain engineering and development of related functional materials for a wide variety of high-performance engineering applications, ranging from deep-space and deep-sea exploration to intelligent robotics.

Initiation of the CuO/Al Thermite Reaction Through High-Velocity Microparticle Impact Testing Carlos Parra[1,2], Yuchen Sun[3,3], David A. Veysset[3], Digvijay R. Yadav[4], Kelvin Xie[4] and Zachary Cordero[3]; [1]Rice University, United States; [2]Escuela Superior Politecnica del Litoral, ESPOL, Ecuador; [3]Massachusetts Institute of Technology, United States; [4]Texas A&M University, United States

Thermite reactions between a metallic fuel and a solid oxide can be thermally or mechanically activated. The ignition temperature in a thermally activated thermite reaction generally increases with heating rate but is ultimately limited by the onset of melting of the lower melting point constituent. In mechanically activated thermite reactions, there is often a structure-sensitive threshold pressure required to drive the reaction. Historically, thermally activated thermite reactions have been explained using diffusion-based reaction mechanisms while mechanically activated thermite reactions have been

described using deformation-based mechanical mixing models. Here we probe mechanically activated thermite reactions at a single well-defined heterophase interface using a combination of hydrocode simulations and laser-induced particle impact testing, where a CuO powder particle strikes an aluminum target at supersonic velocities. No reactions are observed through *in situ* imaging; however, post-mortem characterization of embedded CuO particles reveals a thin nanocrystalline Al_2O_3 reaction layer, with a thickness roughly equal to that of a molten lubricating layer predicted to form during penetration. These results suggest that local melting at hot spots drives the ultrafast reactions observed in mechanically activated thermite reactions and that thermally and mechanically activated thermite reactions may in fact result from the same underlying mechanisms.

5:40 AM F.SF01.01.04
Silica-Titania Nanocomposite Based Fiber Optic Sensor for Aromatic Hydrocarbons Detection Shumaila Islam and Adil Alshoaibi; King Faisal University, Saudi Arabia

Surface stability of deposited sensing material is becoming a crucial issue in the field of opto-chemical sensor technology due to cracks/stresses. Porous silica-titania (ST) nanocomposite coating material is synthesized and doped with CdTe as transducers for sensing cyclic compounds. Ultra-thin coatings are obtained, ~11 nm for ST nanocomposite, and 5 nm for encapsulated and heat-treated samples. BET analysis shows large surface area ~441 m2/g ± 3 m2/g and pore diameter 58 Å of ST nanocomposite. It decreases down to ~410 m2/g ± 2
m2/g, and pore diameter to 24 Å, after encapsulation. However, after heat treatment, it again increases up to 419 m2/g ± 2 m2/g and pore diameter to 38 Å. The sensitivity of 71.37 counts per unit change in the carbon chain with correlation determination coefficient R2 ~0.89 at 468 nm is observed. The prepared sensor device shows excellent stability, signal-to-noise ratio, and good reversibility towards different hydrocarbons and non-hydrocarbons (inorganic materials).

5:50 AM *F.SF01.01.05
Pressure-Induced Dramatic Changes in Electronically Low-Dimensional Metal Halides Xujie Lu, Songhao Guo, Hui Luo, Yongsheng Zhao and Wenge Yang; Center for High Pressure Science & Technology Advanced Research, China

Metal halide perovskites are promising for advanced photovoltaic and optoelectronic applications. Solar cells and light-emitting diodes based on metal halides have achieved an impressive power conversion efficiency of 25.2% and a high external quantum efficiency of over 20%, respectively. Importantly, exceptional structural turnability enables enhanced and/or emergent properties. By using appropriate organic and inorganic components, many perovskite variants with 2D, 1D, and 0D structures on the molecular level have been obtained. These electronically low-dimensional metal halides have exhibited rich emergent properties and significantly expanded the scope of halide perovskites, while critical challenges remain. Future design of high-performance metal halides calls for a deeper understanding of the structure-property relationships. In this talk, we will present our recent efforts in using external pressure to tune the structures and physical properties of low-dimensional metal halides. Using state-of-the-art high-pressure techniques coupled with *in situ* synchrotron-based and in-laboratory property measurements, we characterized the changes in their structural, electronic, and optical properties. Pressure-enhanced properties such as higher photoluminescence quantum yields, as well as pressure-induced novel phenomena including emergent photocurrent, were observed. Our findings demonstrate that high pressure is able to realize enhanced and/or emergent properties of various metal halides, and further our understanding of the underlying mechanisms.

Shear Localization in Molecular Crystal Cyclotetramethylene-Tetranitramine (β-HMX) Mohammad Jane Alam Khan and Catalin Picu; Rensselaer Polytechnic Institute, United States

Cyclotetramethylene-Tetranitramine (β-HMX) is an energetic molecular crystal widely used as a constituent for plastic bonded explosives (PBXs). At high pressures encountered under shock conditions, dislocation motion is inhibited and plastic deformation takes place primarily by shear localization. Atomistic simulations of shear localization are performed in β-HMX under isothermal-isobaric conditions. The post localization flow stress for different pressures (0 to 15 GPa) and strain rates (10^7 to 10^{10} s^{-1}) and at different temperatures of the shear band is investigated. The flow stress decreases linearly with temperature and increases quadratically with the pressure and exponentially with the strain rates. Shear thinning is observed, i.e. the viscosity decreases with increasing the strain rate. It is concluded that the flow stress increases exponentially with the density of the amorphous shear band and hence it can be described as a function of this single variable. The pressure, temperature and strain rates control the flow stress through the density.
The critical stress for shear localization (CSSL) was investigated for different strain rates at different pressures. The critical stress depends significantly on pressure and weakly on strain rates.

Modeling and Experimental Studies of Neat and Metal-Doped Stishovite, Coesite and Quartz Under High Pressure Iskander G. Batyrev, Michael C. Golt and Rosario C. Sausa; CCDC Army Research Laboratory, United States

The results of a comparative study of neat and doped silicon dioxide polymorphs (Fe, Ni or Cu) obtained by density functional theory (DFT) at 0 K and at ambient pressure, 10 GPa, and 20 GPa are presented. The metal atoms are introduced at substitutional and octahedral interstitial sites of the crystal, and the relaxed structures are analyzed and ranked according to the enthalpy. Changes in the enthalpy of the neat and doped crystals are estimated at selected temperatures using quantum mechanics molecular dynamics (DFT-MD). We report the modeled enthalpy of the neat and doped crystals, as well as the dependency of the unit-cell parameters, band gaps, and Raman-active modes on pressure, and compare some of these results to those obtained experimentally using a diamond anvil cell. In addition, we present our search results of the high-pressure phases of silicon dioxide using DFT - based evolutionary simulations and report on the stability of the silica phases, as evaluated by convex-hull construction.

Thermal Stability of XeF_2 at High Pressures Elena Bykova[1], Maxim Bykov[2], S. Chariton[3], V. Prakapenka[3] and Alexander F. Goncharov[1]; [1]Earth and Planets Laboratory, United States; [2]Howard University, United States; [3]Argonne National Laboratory, United States

Xenon is quite a reactive noble gas, and xenon difluoride (XeF_2) being stable at ambient conditions is used in organic synthesis as fluorinating agent. Formation of XeF_2 is possible because xenon is bonded to highly electronegative fluorine atoms that take electrons from xenon filled outermost electron shell, forming cation Xe^{2+}.
High-pressure behavior of XeF_2 (sp. gr. *I*4/*mmm*) is still under debate. Early powder X-ray diffraction and Raman experiments propose that XeF_2 should transform from a molecular compound to extended graphite-like layer structure at 50 GPa, and then above 70 GPa to a metallic fluorite structure. Contrary, the later experimental studies suggest just slight decrease in XeF_2 lattice symmetry, first to *Immm* and then to *Pnma* structure at 28 GPa and 59 GPa, respectively. Theoretical calculations predict that XeF_2 becomes unstable above 81 GPa, while high pressures should stabilize other xenon–fluorine compounds, such as XeF_4, XeF_6 and Xe_2F.
In order to resolve this issues, we investigated thermal stability of XeF_2 at pressures up to 54 GPa by means of single crystal X-ray diffraction in laser-heated diamond anvil cells. Single-crystal XRD opens the way to determine not only crystal structure of the material at truly extreme conditions, but also allows to refine its chemical composition. We report here the crystal structures of novel fluorides xenon, synthesized at high-pressure and high temperature conditions. In particular, the crystal structures of XeF_4 and Xe_3F_2, that both formed under heating-induced disproportionation of XeF_2 at 54 GPa. Similarly to ambient pressure structure, XeF_4 is a molecular compound composed of XeF_4 units with square planar geometry. Xe_3F_2 is not known at ambient conditions, and its structure is formed by isolated Xe atoms and linear XeF_2 molecules.

Heterostructured Materials—Strain Gradient Near Interface and Its Dislocation Mechanisms Yuntian T. Zhu[1,2]; [1]Southeast University, China; [2]City University of Hong Kong, China

Recently, heterostructures are found to produce unprecedented combination of strength and ductility that is considered impossible from our textbook knowledge and materials history. Heterostructured (HS) materials consist of domains with dramatic strength differences. The superior mechanical properties have been attributed to back-stress strengthening and back-stress work hardening, which are related to strain gradient near the heterogeneous domain interfaces. Here I'll discuss *in-situ* observations of strain gradient evolution near the domain interface and the dislocation mechanisms for the formation of strain gradient. It is found that contrary to our conventional understanding, negative strain gradient was developed near the interface. It is also observed under in-situ TEM that the Frank-Read dislocation sources are dynamically created and destroyed although postmortem examinations do not observe many Frank Read sources. These observations provide a new piece of scientific foundation for heterostructured materials, which is becoming a hot research field.

Effects of Ultrahigh Strain and Strain Rates on the Heterogeneous Microstructual Evolution of Cold-Sprayed Coatings Yu Zou; University of Toronto, Canada

Cold spray, initially a coating technique, is being touted as a 'near-net shape' manufacturing technology that minimizes material waste by virtue of the high rate of deposition. During the cold spray process, metallic bulk components can be produced by spraying metal powders at high velocity, generating bonding through severe plastic deformation at temperatures well below the melting point of the powders. To fully understand the cold spray processing of metal powders, we systematically compare and study the microstructure evolution in Cu, Ni, Al, Ti, Ti-6Al-4V samples prepared by cold spray using electron backscatter diffraction (EBSD), transmission electron microscopy (TEM) and nanoindentation. We show complex microstructure in these powder particles after cold spraying: nanocrystalline, nanotwins, annealing twins, gradient grains, deformation bands, dynamic/static recovery and recrystallization. The effects of gas temperature and powder velocity on the microstructure and mechanical properties in the cold sprayed samples are also discussed. Of particular interest are grain refinement, recrystallization and particle/particle bonding mechanisms of the cold sprayed powders.

Friction and Dislocation Motion Using Objective Molecular Dynamics Gunjan Pahlani[1], Ananya Renuka Balakrishna[2,1] and Richard D. James[1]; [1]University of Minnesota, United States; [2]University of Southern California, United States

Atomic features, such as surface roughness and dislocations, affect the mechanical strength and plastic deformation of materials under high shear rates. The precise role of how these atomic features influence the wear and tear of materials under nonequilibrium settings is not well understood. We use Objective Molecular Dynamics (OMD) to investigate the links between atomic features and high shear rates. This method has two advantages over traditional MD simulations: First, it simplifies solutions by exploiting the group invariance of the equations of molecular dynamics. For example, in OMD only a modest number of atoms are simulated (typically, 50-1000) and the motions of the other, typically infinite, set of atoms (the non-simulated atoms) are given by the group action on the simulated atoms. Second, it provides a framework for modeling continuum loads at an atomic scale. For example, a Lagrangian velocity gradient tensor is introduced to describe affine motion of simulated atoms. In today's talk, we demonstrate these advantages of OMD through two examples: 1) frictional behavior of sliding surfaces, and 2) dislocation movement under shear stress. Both of these computations were done under high shear rates, and demonstrate how atomic features, such as rough surfaces, edge dislocations, and vacancies, affect mechanical deformation. Broadly, we present a theoretical framework to explore the interplay between extreme mechanical loads at the continuum scale and mechanical deformation at the atomic scale.

Superhard Conductive Rhenium Nitride Thin Films via Magnetic Field-Assisted CVD from Volatile Rhenium Precursors Michael Frank, Lasse Jurgensen, David Graf, Daniel Stadler, Isabel Gessner and Sanjay Mathur; University of Cologne, Germany

Rhenium nitride is a promising candidate as superhard conductor. Different rhenium-to-nitrogen ratios and several phases result in challenging synthetic strategies for phase pure rhenium nitride. Novel heteroleptic rhenium(I) compounds, [*fac*-$Re(I)(CO)_3(L)$] (e.g., L= tfb-dmpda, (*N,N*-(4,4,4-trifluorobut-1-en-3-on)-dimethyl propylene diamine)), containing preformed Re−N bonds act as efficient precursors for selective growth of polycrystalline rhenium nitride (ReN) films by vapor phase deposition. This is the first known access to synthesize phase pure rhenium nitride by single source precursor approach without the need of additional gases. Interdependence of materials strength and thin film orientation is strongly influenced by external magnetic fields. Deposition of ReN films in presence of an external magnetic field showed an orientation effect with preferred growth of crystallites along〈100〉direction.

7:30 AM F.SF01.01.19
Synthesis of Molecular Metallic Barium Superhydride—Pseudocubic BaH_{12} Dmitrii Semenok[1], Wuhao Chen[2], Alexander Kvashnin[1], Xiaoli Huang[2], Alexander F. Goncharov[3], Artem Oganov[1,4] and Tian Cui[2,5]; [1]Skolkovo Institute of Science and Technology, Russian Federation; [2]Jilin University, China; [3]Carnegie Institution of Washington, United States; [4]Northwestern Polytechnical University, China; [5]Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, China

Inspired by recent progress in chemistry of compressed polyhydrides [1-2] and the discovery of high-temperature superconductivity above 250 K in the La–H system [3-4], we experimentally studied the high-pressure chemistry of Ba hydrides in four independent DACs. We successfully synthesized novel barium superhydride BaH_{12} with a pseudocubic crystal structure, stabilized in the pressure range of 75–173 GPa. The compound was obtained by laser-heating of metallic barium with an excess of ammonia borane compressed to 173, 160, 146, and 90 GPa. The Ba sublattice structure of

BaH_{12} was resolved using the X-ray synchrotron diffraction, evolutionary structure prediction, and several postprocessing Python scripts, including an XRD matching algorithm. The ab initio calculations confirm a small distortion of the ideal *fcc*-barium sublattice to space group $Cmc2_1$ (or even $P2_1$), determined by the presence of additional weak reflections in the diffraction patterns. Discovered BaH_{12} has unique combination of molecular H_2 and H_3 fragments formed due to Peierls-type distortion of one-dimensional H-chains, metallic conductivity, and even superconductivity with T_C = 20 K at 140 GPa, and one of the highest hydrogen content (>92 mol %) among all metal hydrides synthesized so far. Discovered barium dodecahydride is also the first known example of molecular metal amid polyhydrides with one-dimensional conductivity and superconductivity, realized in the H sublattice without its atomization. The results of these experiments confirm that the comparative stability of superhydrides increases with the growth of the period number of a hydride-forming element in the periodic table. [5]

Late News: Atomic-Scale Insight into Melting of BCC Tungsten Under Shear Stresses by Extended Finnis-Sinclair Potential—Molecular Dynamics Simulation Dulat Akzhigitov, Tamerlan Srymbetov, Boris Golman, Christos Spitas and Zhandos Utegulov; Nazarbayev University, Kazakhstan

Understanding melting processes in refractory materials under external stresses is important and can be of particular interest in harsh environment applications ranging from aerospace to nuclear and fusion energy where these materials have to simultaneously withstand the effect of high temperatures and complex stress states in such ways, that a melting process might be initiated in extreme conditions. However, most if not all of the prior research was focused on melting phenomena in the presence of hydrostatic compression.
In our work, we investigate the melting phenomenon in BCC tungsten under different shear stress types. We explore these relationships numerically by molecular dynamics simulations employing extended Finnis-Sinclair potential [1-2] and solid-liquid coexistence method and validate our results with theoretical and experimental findings previously reported in the literature for a hydrostatic compression case.
Regarding other stress states, no similar results have been reported yet for bcc tungsten. The melting behaviour was investigated for all studied stress states and compared both quantitatively and qualitatively on the basis of equivalent strain, least-square atomic-scale strain invariants, maximum shear stress, radial distribution function (RDF), thermal expansion and Lindemann melting criterion. For the majority of shear stress states, an abrupt decline of stress-induced melting point values was detected after certain critical stress values, which was explored with regard to the change of an RDF's amplitude of the first peak. New high-temperature thermo-mechanical results are correlated with intricate structural changes taking place on the atomic scale during metal-melt phase transition.

Late News: *In Situ* Characterization of Dynamic Deformation of AZ31B Magnesium Alloys at High Strain Rate Impact Using 3D-Digital Image Correlation Technique Francis Tetteh; York University, Canada

The deployment of Magnesium (Mg) alloys have increased significantly in the automotive, aerospace, and defense industries due to their lightweight structural integrity. In structural applications, these materials components are exposed to a wide

range of strain rates such as explosive forming, high-speed impact, and shock loadings. These alloy components are placed in extreme loading environments where high strain rates are commonly achieved. Therefore, the evolution of failure mechanisms from strain localization and formation of adiabatic Shear Bands (ASBs) and the mechanical behavior at high strain rates is of desirable interest by the aerospace and automotive industries. The deformation behavior of Mg has extensively been studied under low strain rate loadings. However, the high strain rate deformation still requires further investigation. Deformation and damage accumulation in Mg alloys at high strain rate loading conditions such as impact is not fully understood. Thus, the correlation between the accuracy of the reported mechanical data and microstructural features that leads to the credence of failure mechanisms within Mg is not well understood. It is therefore critical to extending the understanding of the mechanism of failure of Mg at high strain rates of loadings by exploiting other techniques. In this work, the dynamic mechanical impact response and ASBs nucleation of heat-treated AZ31B Mg alloys at different strain rates and impact momentums are characterized in-situ during impact at room temperature using the Direct Impact Hopkinson Pressure Bar (DIHPB) coupled with an in-situ 3D Digital Image Correlation (DIC) and high speed and high-resolution thermal imaging techniques. DIC provides an independent measurement of surface strains directly on test specimens during deformation to monitor stain evolution and strain localization. It is found that the flow stress increased gradually to (~50 %) with increasing strain rates and impact momentums and the AZ31B Mg exhibits strain rate sensitivity at dynamic loadings. This is due to an increasingly selective grain refinement under dynamic compression. Evaluation of DIC results indicated that strain occurrence is linear at the onset of deformation but becomes heterogeneous at the later stage of deformation with multiple nucleation sites of strain localization leading to ASB at ~80% of the specimen length after ~340 us of deformation. The region of peak non-linearity of maximum strain concentration leads to ASB formation with characteristic fine grains, voids, and crack initiation. At most, ~22 °C temperature rise is observed. The temperature rise is, however, lower with respect to the homologous temperature of Mg, and a hence higher degree of strain hardening behavior is induced after deformation. These results suggest that ASB forms in AZ31B Mg alloy despite its brittle nature that leads to crack initiation and ultimate failure under high strain rates and large strains of deformation and can be used to extend the understanding of the mechanism of failure in Mg alloys.

Material Requirements for Pulsed Magnets at the HLD Sergei Zherlitsyn, Thomas Herrmannsdoerfer and Joachim Wosnitza; Helmholtz-Zentrum Dresden-Rossendorf (HZDR), Germany

The Dresden High Magnetic Field Laboratory (HLD) is a pulsed-field user facility, which provides external and in-house researchers with the possibility to perform a broad range of experiments in pulsed magnetic fields [1]. The HLD develops, manufactures, and operates the non-destructive pulsed magnets for the field range up to 90 T and beyond. A design of the magnets requires high-strength, high-conductivity wires with selected cross-sections and high-strength reinforcement materials. Currently some test coils are fabricated at the HLD for a prototype triple-coil magnet for magnetic fields of about 100 T. We will discuss the choice of materials for this pulsed magnet, material-based limitations, long standing experience with available materials, and material challenges for generating even higher magnetic fields by the non-destructive pulsed magnets.

Materials Requirements for Ultra-High-Field Magnets at the National High Magnetic Field Laboratory Mark D. Bird; Florida State University, United States

Ultra-High-Field (UHF) electromagnets require high current densities in high magnetic field with resulting intense Lorentz forces. A central part of developing higher field magnets is managing the Lorentz forces to keep stress and strain within the materials' allowables.
The simplest UHF magnets are dc resistive ones. DC operations results in maximum performance being presently attained by high-strength copper and its alloys. Fatigue performance has started to emerge as a challenge in CuAg nano-composites.

Pulsed resistive magnets are able to mix high-strength conductors and reinforcing materials with both high strength and high stiffness by appropriately adjusting the pulse length. High strength copper and a number of its alloys are productively employed, as are metallic and polymer/epoxy composite reinforcements. The highest field superconducting magnets employ the high-temperature superconducting (HTS) materials along with high strength reinforcement.
The present state of the art of material requriements for UHF magnets is briefly presented along with challenges for next-generation systems.

Understanding Requirements of Advanced Magnet Materials to go Beyond 100 Tesla Doan Nguyen and Do T. Vo; Los Alamos National Laboratory, United States

High magnetic fields have a long history of uncovering fundamentally important information about materials. They take their place among e.g. X-ray and neutron techniques, as a critically important tool of condensed matter physicists. The National High Magnetic Field Laboratory's Pulsed Field Facility at Los Alamos National Laboratory is one of few research centers in the world that can create and use ultra-high pulsed magnetic field for scientific research. The facility houses several types of non-destructive pulsed magnets which can provide the peak fields ranging from 60 tesla to 100 tesla for users. However, present frontiers in quantum matter, including topological matter and superconductivity, require magnetic fields beyond 100 tesla and several high field facilities around the world are currently working toward that ambitious goal. The power and stored energy required to generate a magnetic field increase exponentially with the field amplitude. Therefore the better conductors with higher mechanical strength and electrical conductivity are required to nondestructively generate magnetic fields above 100 tesla with acceptable risk and cost. Finite Element Modeling (FEM) simulations and our in-house mid-plane pulsed magnet design codes were employed to understand the requirements of advanced magnet materials to practically achieve magnetic fields beyond 100 tesla.

High Strength—High Conductivity Materials for High Field Magnets Francois Debray, Olivier Jay and Florence Lecouturier; UGA-INSA-UPS-CNRS, France

Magnetic field is a powerful tool to study new materials and new processes. The highest magnetic field generated with superconducting magnets made of NbTi and Nb_3Sn windings is 23.5 T. During the last years, technological breakthroughs have confirmed the feasibility of superconducting magnets generating more than 30 T thanks to the integration of high temperature superconductors. Still, higher magnetic fields are only available through copper-based magnets. Steady high magnetic field can be generated during several hours and implies a large electrical power (typically 30 MW for 40 T) whereas pulsed magnetic field can reach 100 T for some milliseconds with negligible power consumption. The French High Magnetic Field Facility (LNCMI) is developing both technologies, on its pulsed field site in Toulouse and its steady field site in Grenoble. Optimizing the high field magnets requires to search for the best material and associated shaping process for the realization of these highly constrained machines. The main high field magnet constraints are the mechanical constraints due to Lorentz forces and the thermal constraints coming from Joule losses.
For steady field magnets, copper alloys with high strength and high electrical conductivity are required for an operating temperature that can reached 150°C. To keep the windings of the magnet at a temperature acceptable for a given alloy a high velocity water flow is injected in it to manage heat fluxes as high as 10 $MW.m^{-2}$. Steady high field resistive magnets used two technologies: the Bitter and the polyhelix one. Bitter magnets are made of thin plates (from 0.2 to 1 mm) up to 1000 mm in diameter. In this shape Copper alloys with a high content of Silver (18 wt.%, yield strength up to 1000 MPa and electrical conductivity at room temperature of 50 $MS.m^{-1}$) have been industrialized by one company worldwide up to 250 mm in diameter. For larger diameters, copper plates with a possible addition of a low content of Silver are proposed by different companies with yield strength ranging from 400 to 450 MPa and a conductivity around 58 $MS.m^{-1}$. For the polyhelix technology, the LNCMI has set a R&D program to replace forged tubes (CuCrZr) with limited mechanical properties. Copper alloy tubes prepared by the Cold Spray technology are now in operation on the high field facility in Grenoble.
For pulsed field magnets, the highest priority is set on the mechanical properties of conductors at cryogenic temperature which have to cope with the increasingly severe mechanical constraints at fields beyond 60 T. To avoid excessive heating, the duration of the current that passes through a magnet is reduced to the order of 10-100 milliseconds. The LNCMI Toulouse disposes of several capacitor banks with a total energy of 22 MJ able to produce non-destructive fields over 60 T in 28 mm and close to 100 T in 8 mm bore. Beyond 100 T, it also features a Megagauss installation that makes use of dynamic effects in exploding copper single-turn coils to produce 200 T on a microsecond time scale. “In-house” copper/stainless steel macrocomposite conductors for wire wound pulsed field magnets generating magnetic fields up to 80 T are developed. High strength multiscale Cu/Nb nanocomposite wires produced by severe plastic deformation by ADB (Accumulative Drawing

and Bundling) process are dedicated to the production of magnetic field over 90 T. New innovative composite copper based conductors, processed by powder metallurgy, reinforced with carbon nanotube or silver nanowires- are under development to reach non-destructive pulsed fields over 100 T.

6:00 AM *F.SF01.02.05
Properties of Copper-Silver Alloys Obtained by the Cold Spray Process Christophe Verdy[1], Olivier Jay[2] and Francois Debray[2]; [1]LERMPS, ICB, UMR 6303, CNRS, Univ. Bourgogne Franche-Comté, UTBM, France; [2]Univ. Grenoble Alpes, INSA Toulouse, Univ. Toulouse Paul Sabatier, EMFL, CNRS, LNCMI, France

The cold spray process was developed at the end of the 20th century and his principle is mainly based on the kinetic energy transmitted to micron size particles to allow their deposition. The particles remain solid and the deposits are generated by the particles impacting the substrate at high velocity. Working at low temperature, below the melting point of the deposited material, appears particularly interesting for deposition of oxygen sensitive materials like copper alloys. In comparison with conventional thermal spray processes, cold spray can retain the original properties of powder feedstock (grain size, nanostructured particles), prevent the adverse influence on the underlying substrate materials, and can produce very thick coatings due to compressive stresses.
To spray oxygen sensitive material like copper alloys, it is preferable to select an inert gas as propellant gas for cold spray deposition. Nitrogen is mainly used but, as the gas velocity is strongly linked to the gas mass, gases with low atomic weight like hydrogen or helium are particularly interesting to reach high velocities. Among those gases, helium is much better from the human safety point of view but its price is very high due to limited amounts on earth. A closed loop avoiding costly helium losses was implemented. Thus, deposition efficiency of cold spray copper alloys higher than 96 %, porosity below 0.1 % and oxygen content below 150 ppm were obtained. High deposition rates up to 7 kg/h were also reached.
Copper silver alloys present attractive mechanical properties combined with high thermal conductivity suitable for many applications like high field magnets. In the present work, CrCrZr and CuAg with various Ag percentage deposits were manufactured by cold spray using helium as propellant gas. The work hardening mechanisms are involved by comparison with classically forged materials. A large tailoring of the material's properties can be obtained through specific heat treating. Residual stresses are very low after heat treating and allow machining helices without deformation. This process now allows to produce tubes for polyhelix magnets at LNCMI with a major performance gain.

6:15 AM *F.SF01.02.06
Ultra-High Local Plasticity Induced by Room-Temperature Restoration in High-Strength Nanocomposite Rongmei Niu and Ke Han; Florida State Univ, United States

We subject an aged Cu-24 wt%Ag ingot to heavily cold drawing to develop a nanocomposite. The as-drawn wire is composed of Cu-rich proeuctectic components and Ag-rich eutectic components. A fine lamellar structure are developed in the proeuctectic component embedded a high density of Ag fibers. The average lamellar spacing is 20±6 nm. Ag fiber width is below 5nm. The eutectic component has a relative coarse structure with Ag grain size around 100 nm. This bimodal size distributed Ag fibers yield ultra-high bending plasticity—up to 59% bending strain at the outermost edge-- 15 times the tensile elongation of the wire (3.6%). During our bending tests, dynamic recovery and partial recrystallization occurr primarily in the eutectic component, and are more frequently at the inner edge than the outer edge. The high bending strain causes some of the thick Ag fibers to become discontinuous and lose their original alignment. This structural evolution increases local plasticity, resulting in unexpectedly high achievable bending strain. This is unusual in nano-sized, Ag-fiber-reinforced high-strength composite.

6:30 AM *F.SF01.02.07
A Powder Metallurgy Route Involving Spark Plasma Sintering Towards High-Strength Wires for DC or Pulsed Resistive Magnets Christophe Laurent[1], Simon Tardieu[1,2], David Mesguich[1], Antoine Lonjon[1], Nelson Ferreira[2], Geoffroy Chevallier[2], Arnaud Proietti[1], Claude Estournes[2] and Florence Lecouturier[2]; [1]Université Toulouse 3 Paul Sabatier, France; [2]CNRS, France

There is a demand for stronger yet lighter conducting copper wires in high-technology domains of global interest where weight is at a premium, such as power and aerospace engineering as well as in niche applications, such as materials for high-field magnets.
Many proposed solutions involve the preparation of copper-matrix composite wires or copper-rich alloyed wires with ultrafine but complex microstructures. Wires are prepared by wire-drawing billets (cylinders). This is a severe plastic deformation method and may be followed by appropriate thermal treatments. There are many variants but the importance of the characteristics of the cylinder is not to be neglected. The usual routes for cylinder preparation involve melting-

solidification at some point, and therefore a relatively high temperature, either for alloying or for the preparation of the pure copper sample to be used in a composite.
We have proposed an alternative method based on powder metallurgy routes, involving the consolidation of a suitable powder into a cylinder by sintering at a relatively low temperature. This is done by spark plasma sintering (SPS), which has several advantages over pressureless sintering and hot-pressing, including rapid heating and cooling rates. Therefore, lower sintering temperatures and shorter holding times make it possible to avoid grain growth and prepare copper cylinders with micrometer-sized grains, typically ten times lower than conventional copper cylinders.
SPS typically differs from hot-pressing by the application of a dc pulsed current to the pressing die and powder compact, while a uniaxial pressure is simultaneously applied. Interestingly, cylinders with only about 90% of their full density were found suitable for the rest of the study, because a too high density hampers the deformability of the cylinder during wire-drawing, resulting in sample breaking.
The basics of SPS will be presented and we will show several examples of the preparation of wires of pure copper, carbon nanotube - copper composites and silver nanowire - copper composites. The microstructure of the powders, cylinders (typically 8 mm in diameter and 33 mm long) and wires will be presented as well as the mechanical properties and electrical resistivity of the wires measured at 293 K and 77 K.

7:00 AM *F.SF01.02.09
Application of the Nanostructured Cu-Nb *In Situ* Microcomposites as Strengthening Elements in High Strength Cu-Matrix Composites V. Pantsyrny[1,2]; [1]Nanoelectro LLC, Russian Federation; [2]Bochvar Institute of Inorganic Materials, Russian Federation

Advanced electrical and electronic devices sometimes require that conductor's material properties should be counteracting, e.g. high electrical conductivity and high mechanical strength. Traditional high strength Cu-matrix composites consists of Cu-based matrix, which contains a uniformly distributed nanoscaled particles of intermetallic compounds or oxides. The required microstructure is usually formed by the doping of the initial Cu matrix alloy by the combination of elements which would form the intermetallic compounds during the aging heat treatment at specific temperature range of 300-500 ° C (Cu-Zr-Nb; Cu-Ni-Si; Cu-Cr-Zr alloys) or to form fine oxides through the process of internal oxidation (Cu-Al alloys). These submicron particles of oxides and intermetallic compounds altogether with increase of ultimate strength lead to substantial decrease of fatigue properties. The paper describes the alternative approach to development of the advanced high strength Cu-matrix composites with the application of the plastic nanostructured Cu-Nb *in situ* microcomposites as a strengthening element. As an example the principally new design of composite Contact Wire for high speed railways has been proposed to attain at least 20% better combination of ultimate tensile strength (610-660 MPa) and high conductivity (more than 80% IACS). Composite conductor contains the bundles of nanostructured anomalously high strength Cu-Nb filamentary cores and outer layer made of low doped high conductivity Cu-Zr-Nb alloy with improved tribological properties. The microcomposite Contact Wire has very high fatigue properties due to filamentary architecture of microstructure of Cu-Nb strengthening component. This Contact wire was designed for the use in the scope of Overhead Contact Line CS-400 for railways with the speeds of 400 km per hour. The results of laboratory complex tests of contact wire are presented.

7:15 AM *F.SF01.02.10
Thermomechanical Stability of Metallic Interfaces Containing 3D Character Nathan Mara[1], Justin Y. Cheng[1], Shuozhi Xu[2], Youxing Chen[3], Jonathan Poplawsky[4], Nan Li[5], Kevin Baldwin[5] and Irene Beyerlein[2]; [1]University of Minnesota, United States; [2]University of California, Santa Barbara, United States; [3]University of North Carolina at Charlotte, United States; [4]Oak Ridge National Laboratory, United States; [5]Los Alamos National Laboratory, United States

2-dimensional (2-D) sharp interfaces with distinct boundaries demarcating an abrupt discontinuity in material properties in nanolayered composites have been studied for almost twenty years and are responsible for enhanced behaviors such as strength, radiation damage tolerance, and deformability. However, 2-D interfaces have their limitations with respect to deformability and toughness. 3-D interfaces are defined as heterophase interfaces that extend out of plane into the two crystals on either side and are chemically, crystallographically, and/or topologically divergent, in three dimensions, from both crystals they join. Here, we focus on the thermal stability and mechanical behavior of nanolayered Cu/Nb containing interfaces with 3-D character. By co-sputtering the bimaterial interfaces between the constituent pure phases, the resulting compositional gradient gives rise to new interphase boundary structures, which have been analyzed and quantified via S/TEM and Atom Probe Tomography. Micropillar compression results show that the strength of Cu/Nb nanocomposites containing 3-D interfaces is significantly greater than those containing 2-D interfaces. Mechanical anisotropy, as well as shear banding is observed during pillar compression with retention of continuous layers across the shear band. We will

present our recent results on deformation of such 3-D interfaces and structures, and describe their structural evolution mechanistically through the use of atomistic simulations.

7:30 AM F.SF01.02.11
New High Strength Silver Nanowire-Copper Composite Conductors by Spark Plasma Sintering and Wire-Drawing for High Field Magnets Simon Tardieu[1,2], David Mesguich[2], Antoine Lonjon[2], Florence Lecouturier[1], Nelson Ferreira[1], Geoffroy Chevallier[2,3], Arnaud Proietti[4], Claude Estournès[2,3] and Christophe Laurent[2]; [1]LNCMI, France; [2]CIRIMAT, France; [3]Plateforme Nationale CNRS de Frittage Flash, France; [4]Centre de Microcaractérisation Raimond Castaing, France

LNCMI-Toulouse produces some of the most intense non-destructive pulsed magnetic fields in the world with a European record of 98.8 Tesla and aims at reaching more than 100 Tesla. The generation of pulsed magnetic fields higher than 60 T requires the use of coils wound of wires with exceptional properties. The wires need a high conductivity to limit the heating and they must have a high strength to be able to resist the Lorentz forces. The Lorentz forces are tangential to the coil and proportional to the square of the magnetic field. The resulting von Mises stress is 1 GPa at 60 T and higher than 2.2 GPa at 100 T.

Classical methods for strengthening copper wires involve the preparation of composite wires, such as copper-stainless steel (Cu-SS) and copper-niobium (Cu-Nb) or alloyed wires such as copper/silver (Cu/Ag). Cu-Nb and Cu/Ag wires present a nanostructured microstructure with fine and elongated grains. Cu-Nb microstructure is made up of pure Cu and pure Nb grains, while the Cu/Ag microstructure presents Cu-rich and Ag-rich solid solution. These wires exhibit a UTS value higher than 1 GPa but they are distinguished by their high resistivity. The aim of this work is the preparation of composite wires based on pure Cu and pure Ag.

LNCMI and CIRIMAT explore the design and preparation of novel Cu-based nanocomposite wires with the use of powder metallurgy, spark plasma sintering (SPS) and wire-drawing at room temperature. This preparation method is adapted to the preparation of Ag-Cu composite wires. Ag nanowires (200 nm in diameter and 30 µm in length) were synthetized and mixed with a commercial micrometric (about 1µm) Cu powder. Samples containing 1, 5 and 10 vol. % Ag were prepared. Cu and Ag-Cu cylinders (diameter 8 mm, length 33 mm) are prepared by SPS. Cylinders are sintered at 400, 500 or 600 °C. The so-obtained cylinders serve as precursors to wire-drawing. Their diameter is reduced by wire-drawing at room temperature, in several passes, thus producing progressively finer wires (diameter in the range 1 - 0.2 mm).

The wires show a lamellar microstructure with ultrafine Cu grains (200 - 700 nm for a 0.5 mm diameter wire) elongated over several micrometers. The Ag nanowires are dispersed along the grain boundaries of Cu. Cu and Ag grains exhibit major <111> and minor <100> orientations like most of wire-drawn face centered cubic metals.

The electrical resistivity and tensile strength were measured at 293 K and 77 K. The tensile strength for the composite wires is more than twice the value measured for the corresponding pure Cu wires. Interestingly, the wires containing only 1 vol.% Ag offer the best combination of high strength (1100 MPa at 77 K) and low electrical resistivity (0.50 µΩ.cm at 77 K).

We have obtained wires with excellent mechanical properties while greatly reducing the electrical resistivity compared to Cu/Ag alloy. The present 1 vol. % Ag-Cu composite wires compare favorably with Cu/Ag alloy wires containing about 20 times more Ag.

7:40 AM F.SF01.02.12
Enhanced Properties of High-Strength Reinforcement Materials for High-Field Magnets Ke Han, Rongmei Niu, Jun Lu and Vince Toplosky; Florida State University, United States

Nanostructured reinforcement materials, which have been successfully used in high field magnets and at cryogenic temperatures, reach their most desirable strength level when their scale of microstructure is below 100 nanometers. This refined microstructure can be achieved by plastic deformation and heat treatment, which create obstacles, such as dislocations and precipitates, for dislocation motions. Both deformation and heat treatment also introduce microstructure and property anisotropy. Investigating both anisotropy and microstructure changes helps us to understand the plasticity of these materials, particularly at cryogenic temperatures. The goal of our research is to relate microstructural scale and anisotropy to the mechanical and physical properties of these materials. This presentation describes microstructure in different orientations, with emphasis on the impact of high anisotropy and fine microstructure on properties.

Superconducting Superhydrides—Novel Materials and Possible Applications Maddury S. Somayazulu; Argonne National Laboratory, United States

Since the prediction of metallization and superconductivity of hydrogen and hydrogen-rich materials at high pressures /1,2/, there has been a sustained effort to make advances in high pressure sciences (theory, experiments and techniques) to realize this dream. In comparison to the much larger research landscape spawned by the discovery of high T_c cuprate superconductors, the high pressure (and high temperature) superconductivity field has been slow to encapsulate the attention of many. Partly, this has to do with the paucity of experimental probes that can be broguth to bear and to a major extent, it is the question of transitioning discovery to application. Nevertheless, the discovery of superconductivity in H_3S, YH_6 and LaH_{10} /3,4,5/ and the phenomenal rise in transition temperatures has begged the question of revisiting these two questions. These discoveries have been aided by theoretical predictions and those can be used to make technological feasibility a likelihood /6-9/. However, there are experimental limitations that need to be surmounted to understand the physics and chemistry of these materials that constitute and important feedback to these simulations /10,11/. This talk will aim at connecting these dots and discus the rapidly evolving picture we have of these fascinating materials.

Giant Thermal Hall Conductivity from Phonons in the Pseudogap Phase of Cuprate Superconductors G. Grissonnanche[1], A. Legros[1,2], S. Thériault[1], S. Badoux[1], E. Lefrancois[1], M.-E. Boulanger[1], V. Zatko[1], M. Lizaire[1], F. Laliberté[1], A. Gourgout[1], J.-S. Zhou[3], S. Pyon[4], T. Takayama[4], H. Takagi[4], S. Ono[5], N. Doiron-Leyraud[1] and L. Taillefer[1,6]; [1]Université de Sherbrooke, Canada; [2]CEA Saclay, France; [3]The University of Texas at Austin, United States; [4]The University of Tokyo, Japan; [5]Central Research Institute of Electric Power Industry, Japan; [6]Canadian Institute for Advanced Research, Canada

The nature of the pseudogap phase of cuprates remains a major puzzle. Although there are indications that this phase breaks various symmetries, there is no consensus on its fundamental nature [1].
Fermi-surface, transport and thermodynamic signatures of the pseudogap phase are reminiscent of a transition into a phase with antiferromagnetic order, but evidence for an associated long-range magnetic order is still lacking. Here we report measurements of the thermal Hall conductivity κ_{xy} in the normal state of four different cuprates and show that a large

negative κ_{xy} signal is a property of the pseudogap phase, appearing with the onset of that phase at the critical doping p^*[2]. It is also a property of the Mott insulator at $p \approx 0$, where κ_{xy} has the largest reported magnitude of any insulator. Since this negative κ_{xy} signal grows as the system becomes increasingly insulating electrically, it cannot be attributed to conventional mobile charge carriers. Nor is it due to magnons, since it exists in the absence of magnetic order.
In order to identify the heat carriers responsible for this negative κ_{xy}, we turn to transverse heat transport along the c-axis: κ_{zy}. Here we show that the thermal Hall conductivity at $p = 0$ is roughly isotropic, being nearly the same for heat transport parallel and normal to the CuO_2 planes, *i.e.* $\kappa_{zy}(T) \approx \kappa_{xy}(T)$. This shows that the negative thermal Hall response must come from phonons, these being the only heat carriers able to move as easily normal and parallel to the planes. At $p > p^*$, we observe no c-axis Hall signal, *i.e.* $\kappa_{zy}(T) = 0$, showing that phonons have zero Hall response outside the pseudogap phase. The microscopic mechanism by which phonons become chiral in cuprates remains to be identified. This intrinsic phonon Hall effect provides a new window on quantum materials and it may explain the thermal Hall signal observed in other topologically nontrivial insulators [4].

Self-Regulation of Current Sharing in High-Temperature Superconducting Cables by Temperature-Dependent Resistivity Switching in Vanadium Oxide Coatings Sachin V. Muley[1,2], Aurora Cecilia Araujo Martinez[1,3], Zhenuai Yang[1,4], Xiaorong Wang[1], Qing Ji[1] and Andre Anders[1,5,6]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of Wisconsin–Madison, United States; [3]University of Guanajuato, Mexico; [4]Harbin Institute of Technology, China; [5]Leibniz Institute of Surface Engineering, Germany; [6]Universität Leipzig, Germany

The high-temperature superconductors (HTS), e.g., RE-$Ba_2Cu_3O_x$ (RE = rare earth) can sustain significant transport current at high background magnetic field and elevated temperatures, enabling various applications including fusion energy generation, next generation high-energy physics particle accelerators, and medical accelerators for carbon therapy. However, reliable protection against catastrophic superconducting-to-normal transitions (quenches) remains to be addressed for successful applications of HTS magnet technology. To address this issue, we investigated the potential of vanadium oxide (VO_x) coatings as a temperature-dependent switching medium to self-regulate current sharing. VO_x coatings ($1.70 \leq x \leq$ to 2.07) were deposited by reactive cathodic arc deposition on insulating glass and commercial REBCO tapes to study their electrical properties. The process gas was monitored *in situ* by a residual gas analyzer. Effects of varying process parameters such as argon-to-oxygen ratio and substrate manipulator speed on coating properties were studied. The coatings were X-ray amorphous but Raman spectrometry showed short-range crystalline ordering. Hall effect measurements found a decrease in resistivity of VO_x by at least three orders of magnitude when the temperature increased from 80 to 300 K. The coating process did not damage the REBCO tapes as evidenced by a negligible change in critical current after versus before coating. The results from current-sharing experiments and circuit analysis suggest that the VO_x coating can effectively self-regulate current sharing in REBCO magnets and enable self-protection during quenches. Plasma Facing Materials by Self Interstitial Solid Solution Strengthening Muhammad Musaddique Ali Rafique; Eastern Engineering Solutions LLC, United States

Bubble – a precursor of undersense nanostructure or fuzz formation is crystal lattice defect and is approached by Frenkel pair formation mechanism. One needs to have crystal lattice that inhibits Frenkel Pair generation by ejection of W self-interstitial

atom by He cluster and its bonding with vacancy. However, this mechanism is very commonly observed in nuclear materials. It is applicable in conventional nuclear materials where α and β particles, γ rays and neutron flux strike the material. Plasma does not constitute of aforementioned and thus it is not very applicable mechanism. In the present study, author addresses this problem of development of plasma facing materials by primitive method of self-interstitial solid solution strengthening. Actual mechanism of bubble formation in studied and a suitable lattice is selected and proposed which inhibits possible Frenkel pair generation thus inherently promotes formation of plasma facing material.

Swift Heavy Ion Irradiation Effects in Pre-Damaged Gallium Nitride Kristina Tomić Luketić[1], René Heller[2], Shavkat Akhmadaliev[2], Henning Lebius[3], Abdenacer Benyagoub[3], Isabelle Monnet[3], Corneliu Ghica[4], Ferdinand Scholz[5], Oliver Rettig[5], Branko Šantić[1], Stjepko Fazinić[1] and Marko Karlušić[1]; [1]Ruder Boskovic Institute, Croatia; [2]Helmholtz-Zentrum Dresden-Rossendorf, Germany; [3]Normandie Univ, ENSICAEN, UNICAEN, CEA, CNRS, CIMAP, France; [4]National Institute of Materials Physics, Romania; [5]Institute of Functional Nanosystems, Germany

*Corresponding author: marko.karlusic@irb.hr

When a beam of swift heavy ions (SHI) impinges onto a material, the formation of defects called ion tracks is possible as a result, either in the bulk or on the surface of the material. As a consequence, effects produced by means of SHI irradiation that lead to structural changes of the material can be used to modify the properties of the material via defects engineering. SHI damage introduction to materials can result in complex behavior, especially in radiation harsh environments. To assess the final damage of the material, the effect of the energy deposition from the ions to the atoms within the material must be taken under consideration. Deposition of energy occurs through two main channels: either to the electronic subsystem of the material (electronic stopping power) or to the nuclei (nuclear stopping power). Here we investigate the influence of ion beams with different stopping powers, used in a sequence, on defects formation. It is known that sequential irradiation of ion beams can lead to the SHIBIEC effect (Swift Heavy Ion Beam Induced Epitaxial Crystallization) i.e. the annealing of defects that occurs during the second irradiation step. Alternatively, the anti-SHIBIEC effect is also possible, i.e. the enhanced defect formation during the second step of irradiation.
Sequential ion irradiation of GaN has not been investigated so far. This material is an important semiconductor for high-power electronics. The results presented here are of importance for basic research in this field as well. In our previous work [1], we found no evidence of ion track formation in the bulk after SHI irradiation using 23 MeV I and 90 MeV Xe beams. However, recently we were able to introduce additional disorder into moderately damaged GaN crystals using the same 23 MeV I and 90 MeV Xe beams, in cases where GaN samples have been pre-irradiated with 2 MeV Au or with 900 MeV Xe ion beams. Two different ion beams are expected to introduce damage into GaN either by nuclear or electronic stopping, respectively [2,3]. We observe the difference in total damage in the material depending on the fluence of the beams applied. In this contribution, we report new results of sequential ion irradiation of GaN based on RBS/c (Rutherford Backscattering Spectroscopy in Channeling) and TEM (Transmission Electron Microscopy) measurements.

Late News: Novel Defect-Fluorite Pyrochlore Sodium Niobate Nanoparticles—Solution-Phase Synthesis and Analysis of Neutron Tolerance Rana Faryad Ali and Byron Gates; Simon Fraser University, Canada

Materials possessing a defect-fluorite pyrochlore structure can have a range of useful properties that are sought after, which include radiation tolerance, nuclear waste immobilization, and phase stability at elevated temperatures. In this study, we demonstrate for the first time the synthesis and a detailed analysis of defect-fluorite pyrochlore sodium niobate ($NaNbO_3$) nanoparticles. This analysis included an investigation into the stability of these nanoparticles at elevated temperatures, as well as to neutron irradiation. A surfactant-assisted solvothermal method was used to prepare nanoparticles of $NaNbO_3$. This solution-phase approach results in the formation of crystalline nanoparticles of a defect-fluorite pyrochlore $NaNbO_3$ at relatively low temperatures. The products had an average diameter of ~74 ± 11 nm. The nanoparticles adopted a defect-fluorite pyrochlore phase and matched the cubic space group. This pyrochlore form of $NaNbO_3$ was stable up to at least 500 °C. The nanoparticles transformed into the cubic and rhombohedral perovskite phases of $NaNbO_3$, along with the introduction of a pseudo-hexagonal Nb_2O_5 at higher temperatures. These defect-fluorite pyrochlore nanoparticles of

$NaNbO_3$ also exhibited a resistance to radiation induced amorphization. The dimensions, phase, and crystallinity of the defect-fluorite pyrochlore nanoparticles after exposure to a flux of neutrons were comparable to the as-synthesized product. The thermal stability and radiation tolerance of these pyrochlore nanoparticles could be useful in the design of thermally resilient materials, high temperature catalysts, and durable materials for the handling and storage of radioactive waste.

Plasma-Assisted Atomic Layer Annealing as a Low-Temperature Technique Enabling Crystalline Growth of β-Ga_2O_3 Films for Wearable/Flexible Electronics Saidjafarzoda Ilhom[1], Adnan Mohammad[1], Deepa R. Shukla[1], John Grasso[1], Brian Willis[1], Ali Okyay[2] and Necmi Biyikli[1]; [1]The University of Connecticut, United States; [2]Stanford University, United States

The rapid evolution in technology and its integration with humans requires the development of novel processes that enable the incorporation of the crucial electronic materials, such as the wide bandgap semiconductors (Ga_2O_3 and GaN) into the wearable electroinc systems. Wide bandgap semiconductors form the building blocks of the current high-power high-frequency electronics and the upcoming mmWave fifth-generation (5G) device technologies. To make such technologies integrable with wearable/flexible systems, it is critical that high quality and in particular as-grown crystalline thin films of these materials can be produced on highly temperature-sensitive substrates at very low temperatures.
In this work, we report on the low-temperature, as-grown crystalline Ga_2O_3 films on various substrates (Si, sapphire, glass, and Kapton) via a hollow-cathode plasma-ALD system. Triethylgallium (TEG) and Ar/O_2 plasma were employed as metal precursor and oxygen co-reactant, respectively. Growth experiments have been performed at 160 – 240 °C substrate temperature and 30 – 200 W rf-power range. Additionally, each unit AB-type ALD-cycle was followed by an in situ Ar-plasma annealing treatment, which consisted of Ar-plasma exposure for 20 seconds scanned over 50 – 300 W rf-power. Both in situ and ex situ ellipsometry were employed to measure the thickness and optical properties of the films. The thickness of the films without Ar-annealing stage, ranged between 20.74 – 39.30 nm and as-grown refractive indices were between 1.75 - 1.67 within the scanned plasma power range. X-ray diffraction (XRD) showed that Ga_2O_3 films grown without in situ plasma annealing exhibited amorphous structure irrespective of both substrate temperature and rf-power. However, with the in situ Ar-annealing phase incorporated, the thickness of the films ranged between 22.9 – 31.4 nm with refractive indices of 1.75 – 1.79. The increased refractive index (1.79) and reduced thickness gain (31.4 nm) at 250 W Ar-annealing power indicates possible densification and crystallization of the films. Indeed, XRD and XRR confirmed that in situ Ar-plasma treated films grow in a monoclinic β-Ga_2O_3 crystal phase with further improving crystallinity and film density (from 5.07 to 5.80 g/cm^3) with increasing Ar-annealing plasma power. Additionally, we will discuss the impact of varying in situ Ar-annealing plasma chemistries (Ar-only, O_2-only, and Ar/O_2) coupled with x-ray photoelectron spectroscopy (XPS) measurements, which will provide additional insight into the elemental composition of the films that might help to understand the changes in the structural, optical, and electrical properties. A future outlook will be provided to overcome the challenges to achieve device quality layers on temperature-sensitive flexible substrates.

SESSION F.SF01.05: Corrosion

5:00 AM F.SF01.05.03
Molecular Layer Deposition Approach for Synthesis of SiAlCO Polymer Derived Ceramic (PDC) Thin Films Kristina Ashurbekova[1], Karina Ashurbekova[2], Iva Saric[3], Evgenii Modin[2], Mladen Petravić[3], Aziz Abdulagatov[1], Mato Knez[2,4] and Ilmutdin Abdulagatov[1]; [1]Dagestan State University, Russian Federation; [2]CIC nanoGUNE, Spain; [3]University of Rijeka, Croatia; [4]IKERBASQUE, Basque Foundation for Science, Spain

Organosilicon polymer derived ceramic (PDC) materials and its derivatives have gained interest as an emerging class of materials capable of providing mechanical stability and heat dissipation upon operation in extreme environments. PDC's found various applications such as electrode material for Li-ion batteries, ultra-high temperature composites and others [1]. Being X-ray amorphous, PDC's consist of nanodomains of different structures and compositions, demonstrating nanoscale heterogeneity that influence their unique mechanical, chemical and functional properties. Conventionally, PDC coatings are prepared by wet-chemical dipping, spinning thermal-spraying or by plasma-assisted chemical vapor deposition (CVD), followed by high temperature pyrolysis [2].
In this work, molecular layer deposited (MLD) hybrid organic-inorganic films serve as precursors for the synthesis of

SiAlCO PDC composite coatings. Alumina-polysiloxane films were grown using sequential surface reactions between 1,3,5,7-tetravinyl-1,3,5,7-tetramethylcyclotetrasiloxane (V_4D_4) and trimethylaluminum (TMA). The deposition was conducted at temperatures between 120 and 220 ºC. *In-situ* quartz crystal microbalance (QCM) monitoring showed linear mass increase with the number of MLD cycles with the highest mass gain rate of 24 ng/cm^2/cycle at 180 ºC. The QCM study revealed a self-limiting surface chemistry. An infrared analysis (FTIR) of the deposited films showed vibrational features characteristic of organosilicon polymers: Si-CH_3, Si-O-Si, Si-CH=CH_2 and Si-O-Al peaks. High-resolution transmission electron microscopy (HRTEM) imaging confirmed the conformal nature of the deposited MLD film.
In order to increase mass yield during the polymer-to-ceramic transformation, cross-linking of the growing polymer chains is needed. Cross-linking was achieved at 200ºC by introducing a third precursor, di-tert-butyl peroxide (TBPO), into the MLD cycle, following a V_4D_4/TBP/TMA sequence. A positive mass gain after TBPO dosing, observed by QCM, indicates the formation of radicals and cross-linking. The cross-linking occurs through the activation of the vinyl groups. Characteristic signals, related to the generated polyethylene chains, were identified by ATR-FTIR and XPS. The formed Si-C-C-Si units are expected to improve the mechanical and thermal properties of the cross-linked SiAlCO PDCs, since the Si–C and C–C bonds are not affected by thermal depolymerization reactions.
X-ray and optical characterization techniques were employed to analyze the structural changes and composition of the films after pyrolysis. After pyrolysis at 900ºC in an Ar atmosphere, the composite thin film remained amorphous. The resulting film contained uniformly distributed Si, Al, O, and C. Raman spectroscopy showed presence of graphitic carbon within the film. This MLD-derived SiAlCO thin film is expected to have exceptional uniformity, high temperature stability, creep, and corrosion resistance.

5:10 AM F.SF01.05.04
Late News: Size-Controlled Formation and Functionalization of Superparamagnetic Magnetite Nanoparticles with Enhanced Colloidal Stability at Extreme High Salinity Condition Wei Wang, Hooisweng Ow, Sehoon Chang and Bora Yoon; Aramco Services Company: Aramco Research Center-Boston, United States

Magnetic nanoparticles (MNPs) have attracted significant attention in the oil industry in the past decade due to their potential applications including reservoir sensing and mapping, enhanced oil recovery, drilling and completion improvement, oil-water separation in produced water, oil spill clean-up, and directional transport and local heating. For these specific applications, the dispersity and stability of the MNPs in suspension are of great importance. Surface coating and specific functionalization of the MNPs are typically used to improve their stability and to reduce aggregation for the successful use of the nanoparticles. However, many of the well-established methods and procedures of surface coating chemistry for lab applications are not suitable for harsh environmental conditions such as at extreme high salinity for industrial oil applications. In this research, we synthesized magnetite MNPs with tuned particle sizes to optimize their superparamagnetic properties, and developed a new procedure for surface functionalization to enhance their colloidal stability at high salinity. The functionalized magnetite MNPs have been characterized by XRD, HR-TEM, cryo-TEM, dynamic light scattering and zeta potentials. Colloidal stabilities have been studied in a wide pH range and salinity with 5000-230000 ppm of TDS (Total Dissolved Solids). The results have demonstrated that the covalently bonded zwitterionic functional groups and cross-linked saccharide highly enhance the colloidal stability in high salinity brines.

SESSION F.SF01.06: Electrical Field

F-SF01

5:00 AM F.SF01.06.01
Strain-Coupled Electronic Polarization in Semiconducting Oxides Under Extreme Electric Field Yen-Ting Chi[1], Mostafa Youssef[2,1], Bilge Yildiz[1] and Krystyn Van Vliet[1]; [1]Massachusetts Institute of Technology, United States; [2]The American University in Cairo, Egypt

The polarization response of ionic and electronic defects in complex oxides under high electric field is critical for applications such as memristors and ferroelectrics, but historically challenging to model or measure. Here we developed a localized Hubbard U approach that resolves the dilemma of maintaining in-gap localized defect states for an oxygen vacancy

while simultaneously retaining non-linear dielectric behavior of perovskite oxides. With this approach, we obtained accurate dielectric constant and electronic configuration for $SrTiO_3$ under electric field, using density functional theory and Berry phase calculations. We identified a direct relationship between oxygen vacancy polarizability and lattice strain, which can be generalized to other materials with similar crystal structure. For example, a neutral oxygen vacancy in $BaTiO_3$ and in $SrTiO_3$ strained to exhibit the same lattice constants showed identical polarization behavior under the same electric field. To trace the site polarizability difference between defected crystals and their defect-free counterparts, we utilized maximally localized Wannier functions to obtain the site-decomposed polarization. These simulations illustrated that not only the vacant site, but also the neighboring ions around the vacancy have significant influence on the system polarization with field applied either parallel or perpendicular to the $Ti - V_O^x - Ti$ chain. Together, this model and identification of driving factors in defect displacement under electric field contribute generalizable approaches to study and optimize materials in memristors, ferroelectrics, electrocaloric refrigeration and flash sintering.

High-Temperature and Abrasion Resistant Selective Solar Absorber Yanpei Tian, Xiaojie Liu and Yi Zheng; Northeastern University, United States

Selective solar absorbers with high performance are the key to concentrated solar power systems. Optical metamaterials are emerging as a promising strategy to enhance selective photon absorption, however, the high-temperature resistance (500 C) remains as one of the main challenges for practical applications. Here, a multilayered metamaterial system (Al_2O_3/W/SiO_2/W) based on metal-insulator-metal resonance effect has been demonstrated with high solar absorptance over 92%, low thermal emittance loss below 6%, and significant high-temperature resistance: it has been proved that the optical performance remains 94% after 1-hour thermal annealing under ambient environment up to 500 C, and 94% after 96-hour thermal cycle test at 400 C. Outdoor tests demonstrate that a peak temperature rise (193.5 C) can be achieved with unconcentrated solar irradiance and surface abrasion resistance test yields that SSAs have a robust resistance to abrasion attack for engineering applications.

5:10 AM F.SF01.07.02
Deformation Mechanisms of Alumina-Forming Austenitic Stainless Steels for High Temperature Applications Andrew Peterson; Dartmouth College, United States

Alumina-forming austenitic stainless steels (AFAs) are a class of alloys that are showing promise for use in high temperature applications, particularly for use in power generation. AFAs have been shown to demonstrate good high temperature strength, great oxidation resistance due to a protective alumina scale, and are cheaper than nickel-base alloys. While showing great promise, these alloys need to continue to be studied and improved to be practical for use. In particular, the deformation behavior of these alloys is not well understood. The austenitic matrix can contain various precipitates, including: $L1_2$ structured precipitates, B2 precipitates, Laves precipitates, carbides, and others. The grain boundary (GB) also can become covered by Laves and/or B2 precipitates. In a complex alloy with different types and sizes of precipitates, it can be difficult to determine what effect each of these precipitates are having on the high temperature strength.
In this work, we studied the deformation mechanisms in the model AFA alloy Fe-20Cr-30Ni-2Nb-5Al (at%). This alloy displays many characteristics of AFA alloys, and thus is a good alloy for scientific studies. This alloy contains $L1_2$, Laves, and B2 precipitates in the matrix as well as Laves and B2 precipitates on the GBs. Creep tests, high temperature tensile tests, and high temperature strain-rate jump tests were performed on this alloy after various heat treatments to determine the deformation mechanisms – including strain-rate jump tests with and without $L1_2$ precipitates (but otherwise similar microstructures) to determine the effect of these precipitates on the high temperature strength. In addition, tests were performed on alloys with different grain size, but otherwise similar microstructure, to determine the effect of GB precipitation. Analysis of the stress – strain rate relationships was used to predict deformation mechanisms and to fit the experimental data to models. In addition, transmission electron microscopy (TEM) and scanning electron microscopy (SEM) were performed on samples after mechanical testing to determine deformation behavior. In-situ straining experiments in the TEM and SEM were also performed. This study found that nano-sized $L1_2$ precipitates provided the majority of the strengthening in this alloy. At low stresses dislocations by-passed these particles by climb, and at high stresses dislocations

started to form Orowan loops around the particles. While dislocations piled up at larger Laves and B2 precipitates, these precipitates were not as effective at strengthening the alloy. In addition, work was performed to determine if there was a GB strengthening effect due to coverage of the GB by precipitates.

$Zn_xFe_{3-x}O_4$ Nanoparticles—Structural and Magnetic Behaviour Evolution After Thermal Treatment up to 1400 ºC Angelika Kmita[1], Jan Zukrowski[1], Juliusz Kuciakowski[1,2], Marianna Marciszko-Wiackowska[1], Antoni Zywczak[1], Dorota Lachowicz[1], Marta Gajewska[1] and Marcin Sikora[1]; [1]AGH University of Science and Technology, Academic Centre for Materials and Nanotechnology, Poland; [2]AGH University of Science and Technology,Faculty of Physics and Applied Computer Science, Poland

Zinc ferrite nanoparticles are currently of much interest for their potential applications in extreme conditions like high temperature: e.g. in metal casting, in water splitting reaction for H_2 production (solar fuels) or as high - temperature desulfurizing sorbents [1-3]. Bulk $ZnFe_2O_4$ (ZF) should have paramagnetic nature around room temperature, when it is the normal spinel with Zn^{2+} incorporated mostly in the tetrahedral lattice sites. In the case of nanoparticles, the situation is more complex due to high probability of inversion in the cation distribution between octahedral and tetrahedral sites, which may lead to ferrimagnetism or superparamagnetism [4-6]. It was suggested that during heating Zn^{2+} ions can move from tetrahedral site to octahedral site whereas Fe^{3+} ions redistribute within the octahedral and tetrahedral sites in order to reduce the strain [7]. It was also speculated the possibility of reduction of Fe^{3+} to Fe^{2+} during high temperature treatment. In order to verify these hypotheses we have performed a comprehensive study of structural and magnetic properties of stoichiometric and non-stoichiometric zinc ferrite $Zn_xFe_{3-x}O_4$ (NZF) nanoparticles synthesized using co-precipitation and thermal decomposition method [2, 8] as well as their evolution after thermal treatment. Nanoparticles with different zinc to iron ratio were obtained and systematically probed with volume (XRD, VSM, TG/DSC), microscopic (TEM) and element sensitive probes (ICP-OES, Mossbauer spectroscopy, XPS, XAFS). Magnetic studies proved paramagnetic response of stoichiometric ZF nanoparticles, while a superparamagnetic behaviour is observed in strongly non-stoichiometric (as synthesized) nanoparticles. After thermal treatment at 1400 ºC in inert atmosphere, significant changes in the saturation magnetization were observed in the case of NZF. This is related with an increase of the amount of formally Fe^{2+} ions. The estimated saturation magnetization of as synthesized NZF nanoparticles, of approx. 50 emu/g, is increased upon thermal treatment (at 1400 ºC in inert atmosphere) up to approx. 130 emu/g. As such we have confirmed that zinc concentration and method of synthesis plays important role in magnetic properties of non-stoichiometric zinc ferrite nanoparticles. Moreover, the reduction of Fe^{3+} to Fe^{2+} during high temperature treatment has been observed in NZF nanoparticles annealed in inert atmosphere.

The Influence of Lattice Defects and Recombination on Thermal Transport in Single Crystal Actinide Oxides Cody A. Dennett and David H. Hurley; Idaho National Laboratory, United States

Actinide and lanthanide fluorite oxides, UO_2, CeO_2, ThO_2, form an important class of ceramic energy materials with applications ranging from nuclear fuels to solid oxide fuel cells. Of these systems, ThO_2 (thoria), has been the least explored and offers unique features including an extremely high melting temperature and a fixed tetravalent oxidation state. Many potential application environments for thoria include high radiation fields or temperatures which either promote or directly generate lattice defects. Such defects drastically influence thermal transport, a controlling safety and performance property in many applications. To date, little experimentally-validated understanding has been generated on the role of defect formation and clustering on thermal transport in thoria due to the lack of high-quality starting material in which these effects may be

explored. In this work, high-quality oriented single crystals of thoria are grown using hydrothermal synthesis and then exposed to proton irradiation at both room temperature and 600C. The thermal conductivity of the defected surface layer in these crystals is measured using an all-optical spatial domain thermoreflectance (SDTR) technique and sub-electron-microscopy-resolution defects are characterized using Raman spectroscopy. Together, these methods provide important initial insight into the types of defects formed under ionizing radiation, defect clustering, and how these defects impact thermal transport in high-quality thoria.

Helium Compounds and Their Dynamical Properties Under Extreme Conditions Jian Sun; Nanjing University, China

Helium is the most inert element in the periodic table and generally considered to be unreactive under ambient conditions. On the other hand, helium is one of the main components of giant icy planets' atmosphere. It is unclear whether the helium can diffuse into the depths and react with the mantle materials (water, ammonia and methane). In this talk, I will introduce some of our recent theoretical predictions on helium compounds, including helium-water, helium-ammonia, helium-methane and helium-alkali metal oxides/sulfides, etc [1-4], using our own machine learning accelerated crystal structure search method [5]. In addition, we also found that some of these compounds exhibit exotic dynamical properties at high pressure and high temperature, including the superionic, plastic states and their co-existence.

Crystal Chemical Design of Novel High Energy Density Polynitrides Maxim Bykov[1,2], Elena Bykova[2], Mohammad Mahmood[1], Leonid Dubrovinsky[3] and Alexander F. Goncharov[2]; [1]Howard University, United States; [2]Carnegie Institution for Science, United States; [3]University of Bayreuth, Germany

The high-pressure chemistry of nitrogen and nitrogen-rich compounds have been in a focus of many studies in the recent years due to both fundamental and practical interest and due to the improvement of high-pressure synthetic and characterization techniques. Poly-nitrogen compounds are usually considered as potential high energy density materials (HEDM) due to the remarkable difference in the average bond energy between the single N–N bond, the double N=N bond , and the triple N≡N bond. Numerous polynitrogen compounds with various nitrogen polymeric networks were theoretically predicted, but there are only a very few experimental attempts to obtain such compounds.

In the present work we have systematically studied reactions between transition metals and nitrogen at pressures up to 130 GPa in laser-heated diamond anvil cells. Despite very high synthesis pressure Hf, W, Re and Os react with nitrogen forming porous metal-inorganic frameworks Hf_4N_{22}, WN_{10}, ReN_{10} and Os_5N_{34} of various topologies. The frameworks are built of metals interconnected via polymeric nitrogen linkers, while the pores are filled with dinitrogen molecules N_2. Lighter transition metals (Fe) form non-porous polynitrides featuring polymeric nitrogen chains, while alkali metals react with nitrogen at extreme conditions with the formation of pentazolate salts. In this contribution we will discuss novel synthetic

routes to energetic polynitrogen compounds and crystal-chemical rules governing their formation.

Improved Dielectric Properties of Na1/2Y1/2Cu3Ti4O12 Ceramics Synthesized by Ball-Milling and Reactive Sintering Hicham Kotb and Adil Alshoaibi; King Faisal University, Saudi Arabia

Na1/2Y1/2Cu3Ti4O12 (NYCTO) ceramics with giant dielectric constant (ε′) were synthesized by simple reactive sintering. NYCTOnanopowder was first synthesized using high energy ball-mill. Then the pelletized powder was sintered in air at temperatures in the range 975 °C to 1050 °C for 10–20 h. The obtained ceramics showed pure CaCu3Ti4O12 (CCTO)-like cubic phase as revealed by x-ray diffraction measurements. Field effect-SEM observations showed that the grain size increases from 2 μmto5 μmwith increasing sintering temperature. NYCTO samples sintered at temperatures higher than 975 °C showed giant dielectric constant (103–104) over most of the frequency range. The minimum dielectric loss (tanδ) of∼0.055 at 300 K has been approved for the ceramic sample sintered at 1050 °C. Impedance and modulus spectra of the current samples showed two relaxations related to semiconductor (grain) and high resistance (grain-boundaries) elements. The activation energy for conduction located in the range 0.1–0.5 eV highlighted the role of single ionized oxygen vacancies in the dielectric properties of the investigated NYCTO ceramics.

Simulations of Hydrogen Retention in Polycrystalline Tungsten Brandon Laufer and Karl D. Hammond; University of Missouri, United States

Tungsten will be the plasma-facing material in the ITER divertor. Hydrogen blistering has been observed in plasma-facing materials, but to date, all electronic structure and molecular mechanics simulations have indicated that hydrogen atoms repel one another in perfect crystals. The influence of grain boundaries on hydrogen retention is also not well-understood. We conducted simulations intended to elucidate the mechanisms of blister formation. These studies were accelerated using direct implantation, as we have used in the past for helium, so that computational time ordinarily required to simulate hydrogen atoms that reflect is instead used to simulate diffusion. Consistent with prior observations, we observe that hydrogen is generally repelled by other hydrogen atoms in single-crystal tungsten and we observe neither self-clustering nor cluster growth of any kind. Near grain boundaries, however, the excess volume present allows hydrogen to cluster. Eventually, sufficient hydrogen concentration can build up and weaken the grain boundary, possibly resulting in delamination of the grains and forming a blister.

Electric Current and Field Effects on the Microstructural Development of Al Doped ZnO Claudia Gorynski and Markus Winterer; University Duisburg-Essen, Germany

The present work focuses on understanding the microstructural development during sintering of nanopowders under pressure and electric fields/currents. For this purpose, a method has been developed which combines flash sintering (FS) and spark plasma sintering (SPS) [1]. This FS-SPS combination enables us to combine the advantages of both techniques: to force the electric current through the sample (FS) and to sinter pellet-shaped samples under mechanical loads (SPS). We explored the novel device on the model material Al doped ZnO and discovered a different microstructure, compared to conventional SPS. Grain growth and second phase formation were emphasized by FS-SPS. It remains controversial if the observed microstructure is a result of an intrinsic electric current/field effect or of a temperature-distribution. However, this method helps to understand mechanisms involved in electric current or field assisted sintering techniques and possibly produces new microstructures and, hence, materials.

Tailoring Nanopomposites with Enhanced Failure Tolerance by Interface Engineering Daniel Kiener[1], Michael Wurmshuber[1], Inas Issa[1], Michael Burtscher[1], Mingyue Zhao[1] and Christoph Gammer[2]; [1]Montanuniversity Leoben,

Austria; [2]Erich Schmid Institute of Materials Science, Austrian Academy of Sciences, Austria

Designing ever stronger nanostructured materials that can even withstand harsh environments has become a major goal in the last decades. However, the increase in strength commonly comes hand in hand with a severe reduction in ductility, which at the same time also limits the toughness of these materials. Due to the high fraction of interfaces in such nanostructured materials, it is safe to assume that the processes limiting ductility and toughness as well as their response to harsh environments are controlled by the respective interface structures. However, a detailed understanding is at this point still lacking.
Bulk nanostructured materials were synthesized by severe plastic deformation and subject to tailored interface modifications. To investigate the structural properties of these nanomaterials at high stress and strain, we utilize quantitative miniaturized deformation and fracture experiments performed in situ in scanning or transmission electron microscopes. These highly resoled techniques not only allow to measure material performance, but also to directly identify the underlying deformation and failure mechanisms at the same time.
Using this experimental approach, we will first address the nanoscale processes taking place during deformation and fracture of bcc nanocrystalline metals with modified interfaces. Building on this, the discussion will be extended to the behavior of nanocomposite structures and the influence of an irradiative environment.

Late News: Multi-Scale Structural Response of Pyrochlore Oxides to Far-from-Equilibrium Processing Eric O'Quinn[1], Devon L. Drey[1], Antonio Fuentes[2] and Maik Lang[1]; [1]University of Tennessee, United States; [2]Cinvestav-Unidad Saltillo, Mexico

Swift heavy ion irradiation and high-energy ball milling are far-from-equilibrium processing techniques which provide access to a unique phase space not achievable by means of traditional synthesis approaches. High-resolution neutron total scattering experiments were utilized to gain fundamental insight into the multi-scale structural details of $A_2B_2O_7$ pyrochlore oxides prepared by these extreme conditions and their subsequent evolution under high-temperature treatment. Pair distribution function analysis revealed unconventional atomic arrangements characterized by an unexpectedly high degree of local order. For instance, the atomic arrangement of ball-milled titanate pyrochlore oxides is nearly identical to the same pyrochlore composition synthesized by solid-state reaction and subsequently amorphized by intense ion irradiation (*1*). Interestingly, the same atomic arrangement is found in pyrochlore oxides that exhibit distinct long-range radiation responses (order-disorder *versus* crystalline-amorphous) (*2*). These phenomena are proposed to be the result of fundamental chemical rules which stringently dictate the atomic configuration in disordered materials (*3*, *4*). This description provides insight into far-from-equilibrium processing of oxides and helps to better elucidate the structural properties and heterogeneity of disordered complex oxides from the local atomic arrangement to the macroscale.

Gallium Nitride Nanowire Field Effect Transistor for High Temperature Applications Kasif Teker and Mustafa A. Yildirim; Istanbul Sehir University, Turkey

Wide bandgap (WBG) semiconductor-based electronics are becoming the center of interest due to their ability to operate at high temperatures and high voltages. Gallium Nitride (GaN), as one of the WBG semiconductors, is a strong candidate that

can meet expectations in high-temperature electronic applications such as military systems, automotive and aerospace control units, gas and oil exploration drilling systems. The superior physical properties of GaN nanowires such as high direct bandgap, high breakdown voltage, and high thermal conductivity, as well as high surface area to volume ratio, make it even more significant material for harsh environments. In this work, we investigate the electrical transport properties of a back-gated single GaN nanowire field-effect transistor (GaNNW-FET) at elevated temperatures.
In order to analyze transport properties (I_{DS}-V_{DS} and I_{DS}-V_{GS}), electrical measurements were performed at temperatures ranging from room temperature to as high as 350°C. The device performs very well until 250°C, whereas it shows some reduction in current values beyond 300°C. In fact, the drain current increases by 2.1, 13.6 and 19.7 times at the temperatures of 100°C and 200°C, 250°C, respectively, with respect to room temperature current at the same bias voltage of 1 V. The enhancement of current is likely due to the reduction of contact resistance between the nanowire and electrodes as well as an increase in thermally excited carrier concentration. On the other hand, degradation of current is likely due to the increase in lattice scattering, lowering the carrier mobility, of the GaN nanowire. Moreover, the influence of high temperature on important transport properties such as transconductance, carrier concentration and carrier mobility will be presented in details. The device offers the following unique advantages: (i) stable operation at high temperatures (at 350°C), (ii) exhibiting an on/off current ratio of 5.5 x 10^2 and a high transconductance value of 3.09 μS at 350°C indicating a good gating effect even at high temperatures, and iii) offering solutions not only for high-power but also for low-power circuit and photonic applications at high temperature ambients (> 300°C). In summary, GaNNW-FET proves to be an excellent device capable of operating at high temperatures enabling the development of high-performance nanoelectronic/photonic devices especially for harsh conditions.

F.SF01.09.06
Mechanical Response of Engineered Segmented Copolymer Coatings to the Growing Tin Whiskers Under Harsh Environments Preeth Sivakumar[1], Surbhi Du[2], John Daye[2], Matt Selter[2] and Junghyun Cho[1,1]; [1]Binghamton University, The State University of New York, United States; [2]Honeywell Federal Manufacturing & Technologies, National Security Campus, United States

Electrical short circuits caused by the growing tin whiskers can be mitigated by applying a polymeric conformal coating over the whisker-prone tin (Sn) surface which is now common in Pb-free electronics. These conformal coatings should be mechanically adaptable to resist the metallic whisker nucleation and growth while providing enough toughness to avoid cracking ahead of the growing tin whiskers. Importantly, the delamination of conformal coating would provide a space for tin whisker activities that will ultimately result in the vertical growth of tin whisker and its penetration through the coating; hence, the adhesion strength of the conformal coating to tin surface plays an important role. The selection of a conformal coating should consider all these mechanical characteristics because these coatings will be exposed to extreme environmental conditions over a long period. In this study, silicone rubbers were added to the polyurethane-based conformal coatings to form phase-separated nanosized domains for enhanced toughness, which were tested under high temperature and high humidity (HTHH) exposure (85°C/85% relative humidity). Furthermore, in an effort to increase the adhesion of these coatings to the tin surface, silane coupling agents were also applied to the tin surface. The effect of long-term exposure with temperature and moisture (up to 5000 hours) on the chemical degradation of the polymeric coating and its adhesion to the tin surface was examined using Fourier transform infrared spectroscopy (FTIR), Raman spectroscopy, and thermogravimetric analysis (TGA). Mechanical degradation of the nanocomposite coatings under HTHH conditions was evaluated at various length scales by universal testing machine and indentation techniques. In particular, interplays between the degradation of aged conformal coating and the growing tin whiskers under highly compressive stress in the tin layer are highlighted to understand the effectiveness of the conformal coating for tin whisker mitigation. For this, cross-sectional SEM images were obtained from the microtome-sliced coated tin coupons to monitor the growth of tin whiskers under various time stages under HTHH. This study, therefore, provides a potential source of developing an effective polymer coating strategy under harsh environments with optimal mechanical and adhesion properties that can well prevent or entrap the growth of tin whiskers and nodules beneath its coating.

Seebeck Coefficient of Boride at Ultra-High Temperatures Over 2000 Celsius Yucheng Lan, Kit Sze, Mikel Tucker and Saroj Pramanik; Morgan State University, United States

Thermoelectric materials have been widely employed to convert heat into electricity and thermocouples. The state-of-art

materials are usually working below 1000 celsius. Here, a boride with a thermally stable structure up to 3000°C is synthesized. The Seebeck coefficient (thermopower) of the boride is characterized over 2000 Celsius. The phonon/electron transports are investigated under extreme conditions. The investigation would explore applications of thermoelectric materials at ultra-high temperatures.

F.SF01.09.08
Late News: Precipitates Distribution on Susceptibility to Shear Band Formation of Heat Treated 7050 Aluminium Alloy Francis Tetteh and Solomon Boakye-Yiadom; York University, Canada

The goal of this work was to investigate the influence of grain boundary (GB) precipitates on the susceptibility of 7050 Aluminium alloy to Adiabatic shear band (ASB) during high strain rates using a Direct Impact Hopkinson Pressure Bar (DIHPB). It is demonstrated continuous distributed GB precipitates increase the propensity of ASB formation whereas discontinuously distributed GB precipitates coupled with large precipitation free zones decreases susceptibility to ASB formation of 7050 Aluminium. It is apparent that precipitates within the initial microstructure of 7050 Aluminium before deformation undergo fragmentation and/or dissolution during the occurrence of ASBs at high strain rate deformation.

F.SF01.09.09
Late News: DFT Study of "Unlayered-Graphene Solid" Formation in Liquid Carbon Droplets at Low Pressures Chathuri Silva[1], Philip Chrostoski[1] and P. Fraundorf[1,2]; [1]University of Missouri St. Louis, United States; [2]Washington University in St. Louis, United States

At ambient and lower pressures elemental carbon sublimates to vapor near 4000K, even though quenched carbon droplets have been reported in laboratory laser ablation studies [1,2]. However, a subset of meteoritic carbon particles from red giant atmospheres show an “unlayered-graphene solid” core/graphite-rim structure [3,4], likely following condensation of super-cooled carbon droplets from the vapor phase, which nucleated ~40-Å graphene sheets (about 10^19/cc) on randomly-oriented 5-member rings before solidification and subsequent coating with a graphite rim. Similar core-rim particles (with ~15-Å sheets) can be formed by slow cooling of carbon vapor in the lab [5,6].
The difficulty of experimentation under extreme conditions in a lab remains as a challenge to study the properties of liquid carbon. Therefore, we investigated nucleation and growth of carbon rings and graphene sheets using density functional theory (DFT). Our computations target growth of carbon rings & graphene sheets at the experimental 1.8g/cc density estimate, by relaxing randomized positions of liquid-like 13/20/30/40/60/100-carbon atom clusters in a cubic supercell. Inter-atom distances characteristic of covalent vs. metallic interactions (with a gap in 1.7Å -2.0Å range) allow us to identify covalent “bonds” with small separation. Local energy minima at T = 0K show a mix of sp^2 and sp coordination numbers, plus few sp^3 as in the literature which reports that liquid carbon favors sp coordination at lower densities, sp^3 coordination at higher densities, and a mix of sp and sp^2 coordination at intermediate densities [7-11].
The formation of rings continues to be the same trend in all different sizes of atom clusters, where the ring sizes vary from triangle to heptagon but pentagons are more abundant than hexagons as possible nucleation seeds, also consistent with previous reports [10,11]. The properties of unlayered graphene sheets in a frozen liquid matrix, e.g. as a diffusion barrier, should be interesting to explore further both experimentally and computationally. Further work remains to see if such ab initio studies can confirm that abundant pentagonal rings at this density, during slow cooling of the liquid, can nucleate the growth of faceted pentacones as suggested by electron phase-contrast imaging of the presolar cores [12].

Late News: Pressure-Induced Phase Transformations in Iron Carbon Under Hydrostatic Compression Hoang Thien Luu and Nina Gunkelmann; Clausthal University of Applied Technology, Germany

Pressure-induced phase transformations from body-centered cubic to hexagonal close-packed iron occur at pressuresabove 13 GPa. The contribution of allyoing elements may change the transition pressure. Several studies have documented the role of different alloying elements on diffusionless phase transitions. However, iron-carbon under high pressure conditions has not been analyzed in detail, although carbon forms the basis of modern steels. This study aims to determine the influence of interstitial carbon on the transformation mechanism. We performed molecular dynamics simulations using the Embedded Atom Method (EAM) to explore the potential relationship between carbon and the phase transition in iron. Our results show that octahedral sites are energetically favorable for interstitial carbon atoms. We findthat carbon atoms tend to be trapped in tetrahedral sites during the transformation, which results in an increasing threshold pressure.

F.SF01.09.11
Late News: Molecular Dynamics Study of Shock Waves in Iron—On the Role of Plasticity Hoang Thien Luu[1], Ramon J. Ravelo[2], Martin Rudolph[3], Eduardo M. Bringa[4], Timothy C. Germann[5], David Rafaja[3] and Nina Gunkelmann[1]; [1]Clausthal University of Applied Technology, Germany; [2]The University of Texas at El Paso, United States; [3]TU Bergakademie Freiberg, Germany; [4]University of Mendoza, Argentina; [5]Los Alamos National Laboratory, United States

Shock compression is widely used to investigate the mechanical responses of iron under dynamic loading. With shock waves, it is possible to investigate new, previously undiscovered regimes of material dynamics for the discovery of materials inaccessible at ambient conditions. It has been long known that α-iron transforms to ε-iron under high pressure. Recently, molecular dynamics simulations have shown that plasticity occurs just before the parent phase transforms into ε-iron. To provide insights into the interplay of elastic and plastic activities during shocks in iron, we performed atomistic simulations of shock compression of nanocrystalline iron with a mean grain size of 20 nm comprising a total number of 267.5 million atoms. We observed elastic and plastic deformations before the phase transformation takes place. The plastic state is metastable and highly depends on the deformation rate. After a relaxation process of a few picoseconds, the structure transforms into a quasi-3D compressed state in which the new phase is stable. We found that with increasing ramp time of the piston, plastic relaxation is stronger.
Analysis of the X-ray diffraction patterns calculated from the atomistic structure using the Debye equation revealed pronounced anisotropy of the line broadening in hcp Fe that is due to stacking faults and dislocations.

Gallium Nitride Nanowire Field Effect Transistor for High Temperature Applications Kasif Teker and Mustafa A. Yildirim; Istanbul Sehir University, Turkey

Wide bandgap (WBG) semiconductor-based electronics are becoming the center of interest due to their ability to operate at high temperatures and high voltages. Gallium Nitride (GaN), as one of the WBG semiconductors, is a strong candidate that can meet expectations in high-temperature electronic applications such as military systems, automotive and aerospace control units, gas and oil exploration drilling systems. The superior physical properties of GaN nanowires such as high direct bandgap, high breakdown voltage, and high thermal conductivity, as well as high surface area to volume ratio, make it even more significant material for harsh environments. In this work, we investigate the electrical transport properties of a back-gated single GaN nanowire field-effect transistor (GaNNW-FET) at elevated temperatures.
In order to analyze transport properties (I_{DS}-V_{DS} and I_{DS}-V_{GS}), electrical measurements were performed at temperatures ranging from room temperature to as high as 350°C. The device performs very well until 250°C, whereas it shows some reduction in current values beyond 300°C. In fact, the drain current increases by 2.1, 13.6 and 19.7 times at the temperatures of 100°C and 200°C, 250°C, respectively, with respect to room temperature current at the same bias voltage of 1 V. The

enhancement of current is likely due to the reduction of contact resistance between the nanowire and electrodes as well as an increase in thermally excited carrier concentration. On the other hand, degradation of current is likely due to the increase in lattice scattering, lowering the carrier mobility, of the GaN nanowire. Moreover, the influence of high temperature on important transport properties such as transconductance, carrier concentration and carrier mobility will be presented in details. The device offers the following unique advantages: (i) stable operation at high temperatures (at 350°C), (ii) exhibiting an on/off current ratio of 5.5 x 10^2 and a high transconductance value of 3.09 μS at 350°C indicating a good gating effect even at high temperatures, and iii) offering solutions not only for high-power but also for low-power circuit and photonic applications at high temperature ambients (> 300°C). In summary, GaNNW-FET proves to be an excellent device capable of operating at high temperatures enabling the development of high-performance nanoelectronic/photonic devices especially for harsh conditions.

Mechanical Response of Engineered Segmented Copolymer Coatings to the Growing Tin Whiskers Under Harsh Environments Preeth Sivakumar[1], Surbhi Du[2], John Daye[2], Matt Selter[2] and Junghyun Cho[1,1]; [1]Binghamton University, The State University of New York, United States; [2]Honeywell Federal Manufacturing & Technologies, National Security Campus, United States

Electrical short circuits caused by the growing tin whiskers can be mitigated by applying a polymeric conformal coating over the whisker-prone tin (Sn) surface which is now common in Pb-free electronics. These conformal coatings should be mechanically adaptable to resist the metallic whisker nucleation and growth while providing enough toughness to avoid cracking ahead of the growing tin whiskers. Importantly, the delamination of conformal coating would provide a space for tin whisker activities that will ultimately result in the vertical growth of tin whisker and its penetration through the coating; hence, the adhesion strength of the conformal coating to tin surface plays an important role. The selection of a conformal coating should consider all these mechanical characteristics because these coatings will be exposed to extreme environmental conditions over a long period. In this study, silicone rubbers were added to the polyurethane-based conformal coatings to form phase-separated nanosized domains for enhanced toughness, which were tested under high temperature and high humidity (HTHH) exposure (85°C/85% relative humidity). Furthermore, in an effort to increase the adhesion of these coatings to the tin surface, silane coupling agents were also applied to the tin surface. The effect of long-term exposure with temperature and moisture (up to 5000 hours) on the chemical degradation of the polymeric coating and its adhesion to the tin surface was examined using Fourier transform infrared spectroscopy (FTIR), Raman spectroscopy, and thermogravimetric analysis (TGA). Mechanical degradation of the nanocomposite coatings under HTHH conditions was evaluated at various length scales by universal testing machine and indentation techniques. In particular, interplays between the degradation of aged conformal coating and the growing tin whiskers under highly compressive stress in the tin layer are highlighted to understand the effectiveness of the conformal coating for tin whisker mitigation. For this, cross-sectional SEM images were obtained from the microtome-sliced coated tin coupons to monitor the growth of tin whiskers under various time stages under HTHH. This study, therefore, provides a potential source of developing an effective polymer coating strategy under harsh environments with optimal mechanical and adhesion properties that can well prevent or entrap the growth of tin whiskers and nodules beneath its coating.

Seebeck Coefficient of Boride at Ultra-High Temperatures Over 2000 Celsius Yucheng Lan, Kit Sze, Mikel Tucker and Saroj Pramanik; Morgan State University, United States

Thermoelectric materials have been widely employed to convert heat into electricity and thermocouples. The state-of-art materials are usually working below 1000 celsius. Here, a boride with a thermally stable structure up to 3000°C is synthesized. The Seebeck coefficient (thermopower) of the boride is characterized over 2000 Celsius. The phonon/electron transports are investigated under extreme conditions. The investigation would explore applications of thermoelectric materials at ultra-high temperatures.

Late News: Precipitates Distribution on Susceptibility to Shear Band Formation of Heat Treated 7050 Aluminium Alloy Francis Tetteh and Solomon Boakye-Yiadom; York University, Canada

The goal of this work was to investigate the influence of grain boundary (GB) precipitates on the susceptibility of 7050 Aluminium alloy to Adiabatic shear band (ASB) during high strain rates using a Direct Impact Hopkinson Pressure Bar (DIHPB). It is demonstrated continuous distributed GB precipitates increase the propensity of ASB formation whereas discontinuously distributed GB precipitates coupled with large precipitation free zones decreases susceptibility to ASB formation of 7050 Aluminium. It is apparent that precipitates within the initial microstructure of 7050 Aluminium before deformation undergo fragmentation and/or dissolution during the occurrence of ASBs at high strain rate deformation.

Late News: DFT Study of "Unlayered-Graphene Solid" Formation in Liquid Carbon Droplets at Low Pressures Chathuri Silva[1], Philip Chrostoski[1] and P. Fraundorf[1,2]; [1]University of Missouri St. Louis, United States; [2]Washington University in St. Louis, United States

At ambient and lower pressures elemental carbon sublimates to vapor near 4000K, even though quenched carbon droplets have been reported in laboratory laser ablation studies [1,2]. However, a subset of meteoritic carbon particles from red giant atmospheres show an “unlayered-graphene solid” core/graphite-rim structure [3,4], likely following condensation of super-cooled carbon droplets from the vapor phase, which nucleated ~40-Å graphene sheets (about 10^19/cc) on randomly-oriented 5-member rings before solidification and subsequent coating with a graphite rim. Similar core-rim particles (with ~15-Å sheets) can be formed by slow cooling of carbon vapor in the lab [5,6].
The difficulty of experimentation under extreme conditions in a lab remains as a challenge to study the properties of liquid carbon. Therefore, we investigated nucleation and growth of carbon rings and graphene sheets using density functional theory (DFT). Our computations target growth of carbon rings & graphene sheets at the experimental 1.8g/cc density estimate, by relaxing randomized positions of liquid-like 13/20/30/40/60/100-carbon atom clusters in a cubic supercell. Inter-atom distances characteristic of covalent vs. metallic interactions (with a gap in 1.7Å -2.0Å range) allow us to identify covalent “bonds” with small separation. Local energy minima at T = 0K show a mix of sp^2 and sp coordination numbers, plus few sp^3 as in the literature which reports that liquid carbon favors sp coordination at lower densities, sp^3 coordination at higher densities, and a mix of sp and sp^2 coordination at intermediate densities [7-11].
The formation of rings continues to be the same trend in all different sizes of atom clusters, where the ring sizes vary from triangle to heptagon but pentagons are more abundant than hexagons as possible nucleation seeds, also consistent with previous reports [10,11]. The properties of unlayered graphene sheets in a frozen liquid matrix, e.g. as a diffusion barrier, should be interesting to explore further both experimentally and computationally. Further work remains to see if such ab initio studies can confirm that abundant pentagonal rings at this density, during slow cooling of the liquid, can nucleate the growth of faceted pentacones as suggested by electron phase-contrast imaging of the presolar cores [12].

Late News: Pressure-Induced Phase Transformations in Iron Carbon Under Hydrostatic Compression Hoang Thien Luu and Nina Gunkelmann; Clausthal University of Applied Technology, Germany

Pressure-induced phase transformations from body-centered cubic to hexagonal close-packed iron occur at pressuresabove 13 GPa. The contribution of allyoing elements may change the transition pressure. Several studies have documented the role of different alloying elements on diffusionless phase transitions. However, iron-carbon under high pressure conditions has not been analyzed in detail, although carbon forms the basis of modern steels. This study aims to determine the influence of interstitial carbon on the transformation mechanism. We performed molecular dynamics simulations using the Embedded

Atom Method (EAM) to explore the potential relationship between carbon and the phase transition in iron. Our results show that octahedral sites are energetically favorable for interstitial carbon atoms. We findthat carbon atoms tend to be trapped in tetrahedral sites during the transformation, which results in an increasing threshold pressure.

Late News: Molecular Dynamics Study of Shock Waves in Iron—On the Role of Plasticity Hoang Thien Luu[1], Ramon J. Ravelo[2], Martin Rudolph[3], Eduardo M. Bringa[4], Timothy C. Germann[5], David Rafaja[3] and Nina Gunkelmann[1]; [1]Clausthal University of Applied Technology, Germany; [2]The University of Texas at El Paso, United States; [3]TU Bergakademie Freiberg, Germany; [4]University of Mendoza, Argentina; [5]Los Alamos National Laboratory, United States

Shock compression is widely used to investigate the mechanical responses of iron under dynamic loading. With shock waves, it is possible to investigate new, previously undiscovered regimes of material dynamics for the discovery of materials inaccessible at ambient conditions. It has been long known that α-iron transforms to ε-iron under high pressure. Recently, molecular dynamics simulations have shown that plasticity occurs just before the parent phase transforms into ε-iron. To provide insights into the interplay of elastic and plastic activities during shocks in iron, we performed atomistic simulations of shock compression of nanocrystalline iron with a mean grain size of 20 nm comprising a total number of 267.5 million atoms. We observed elastic and plastic deformations before the phase transformation takes place. The plastic state is metastable and highly depends on the deformation rate. After a relaxation process of a few picoseconds, the structure transforms into a quasi-3D compressed state in which the new phase is stable. We found that with increasing ramp time of the piston, plastic relaxation is stronger.
Analysis of the X-ray diffraction patterns calculated from the atomistic structure using the Debye equation revealed pronounced anisotropy of the line broadening in hcp Fe that is due to stacking faults and dislocations.

Molecular Dynamics Features for Predicting Metallic Glass Critical Casting Thickness Lane E. Schultz, Benjamin T. Afflerbach, Izabela Szlufarska and Dane Morgan; University of Wisconsin-Madison, United States

Determining metal compositions that have good Glass Forming Ability (GFA), and in particular that yield bulk metallic glasses through cooling, has been an outstanding grand challenge in metallic glass research. Previous attempts to predict GFA for metals often include some functional form of T_g, T_x, and T_l, known as the glass transition, the onset of crystallization, and the liquidus temperatures, respectively. For example, the reduced glass transition temperature, $T_{rg}=T_g/T_l$, is a well-known GFA indicator. Another well-known GFA indicator is the liquid fragility, m, which is measured by finding the slope of viscosity as a function of temperature near T_g for an alloy. Multiple researchers have shown that direct measures of GFA, in particular the critical cooling rate (R_c) and critical casting diameter (d_{max}), can be written as relatively simple functions of T_g, T_x, T_l, and m [1, 2]. However, these relationships have limited applicability for new materials discovery because a material must be synthesized and measured in order to obtain these features, and they cannot be readily predicted accurately from molecular simulations. However, there are other characteristic temperatures and kinetic properties that have similar physics to that represented in the above features and which are accessible to molecular simulations.

Our study explores to what extent characteristic temperatures of metallic alloys readily accessible to molecular dynamics (MD) can be correlated with d_{max}. We use MD to predict a set of characteristic temperatures $\{T_i\}$ for 73 metal alloys and fit d_{max} as a function of $\{T_i\}$ using experimental d_{max} values for 19 of the alloys. We find a 3-fold cross-validation root mean squared error (RMSE) score of 0.512 for the model, well below the standard deviation of 0.848 for the 19 dmax values. The remaining 54 alloys are used as a test set and the d_{max} predictions are used to determine if the alloy should form a glass under melt spinning, and this categorization was then compared to experimental results. We find a maximum F1 score of 0.75 for the categorization model. These cross-validation and F1 scores suggest that the model has significant predictive ability, providing a potential pathway to predicting d_{max} directly from MD.

Direct Measurement of Critical Cooling Rates in Metallic Glass Forming Alloys Through a Combinatorial Strategy Naijia Liu[1], Tianxing Ma[2], Chaoqun Liao[3], Shaofan Zhao[3], Jonathan P. Singer[2] and Jan Schroers[1]; [1]Yale University, United States; [2]Rutgers, The State University of New Jersey, United States; [3]Qian Xuesen Laboratory of Space Technology, China

Critical Cooling Rate (R_c) is the lowest rate a liquid can be cooled to avoid crystallization and vitrify into a glass. While it is a key factor to quantify the glass forming ability (GFA), direct measurement of Critical Cooling Rate (R_c) of metallic glass has been cumbersome and challenging and only determined for a few alloys.
The development of science and technologies raise demand for new materials including new Bulk Metallic Glasses. However, it has been estimated that only about 10% of the composition space of potential BMG formation has been considered thus far. To address the large potential compositional space more effectively, combinatorial approaches have been used for the fabrication of large number of alloys in thin film alloy libraries. But attempts to directly quantify critical cooling rates of alloys in such libraries have been limited to the as-sputtered state which forms under a cooling rate exceeding 10^8 K/s. Although scientifically important, this high cooling rate is not able to probe practical BMGs, of which the R_c is always below 10^3 K/s. Some progress was made recently by reheating the thin films and reducing the cooling rate to ~10^5 K/s. However, this is with a still high cooling rate rage.
We will report a fast screening method which is based on Single Pulse Laser Annealing to directly measure R_c in thin film alloy libraries. Cooling rates ranging from 10^2 to 10^6 K/s can be realized during solidification of the alloys. To demonstrate this method, we determined R_c for a large number of alloys in the Al-Ge-Ni system, and identified the best glass forming composition as $Al_{51}Ge_{35}Ni_{14}$ with a critical cooling rate of 10^4 K/s.

Accelerated Discovery and Mechanical Property Characterization of Bioresorbable Amorphous Alloys Using High-Throughput Methods Amit Datye, Sebastian A. Kube, Jan Schroers and Udo Schwarz; Yale University, United States

Bioresorbable materials have been of increased interest in the last two decades due to their potentially transforming impact on human body implants. However, even with a large number of groups working on it, there is data available only for a very small number of alloy compositions (<20) in the ternary amorphous alloy systems of magnesium (Mg)–zinc (Zn)–calcium (Ca) and iron (Fe)–Mg–Zn. The optimal alloy compositions for biomedical applications should be chosen from a large variety of available alloys with best combination of mechanical properties (modulus, strength, hardness) and biological response (in-situ degradation rates, cell adhesion and proliferation). This research presents high-throughput screening of more than 150 different compositions each in two different bioresorbable alloy systems. We demonstrate that this new approach will allow future researchers to develop patient- and implant-specific bioresorbable alloys based on specific application requirements. As a first step towards establishing a database designed to enable such targeted material selection, amorphous alloy composition libraries were fabricated employing a combinatorial magnetron sputtering approach where Mg, Zn, and Ca/Fe are co-deposited from separate sources onto a silicon wafer substrate, followed by composition analysis using energy dispersive X-ray spectroscopy and X-ray diffraction measurements and mechanical properties characterization using nanoindentation.

Coupling Among Shear Band Initiation, Propagation and Sliding During Plastic Deformation of Metallic Glass Under Constrained Deformation Zenon H. Melgarejo[1], Joseph E. Jakes[2] and Donald S. Stone[1]; [1]University of Wisconsin-Madison, United States; [2]Forest Biopolymer Science and Engineering, USDA Forest Products Lab, United States

When, in the regime of inhomogenous flow, a metallic glass is constrained during plastic deformation, all aspects of the kinetics of shear banding, including initiation, advance of the tip, and "shear," or displacement across its thickness, become coupled. An example is the indentation experiment, in which surrounding material, loaded elastically, constrains deformation within the plastic zone and leads to a self-similar, hemispherical pattern of shear bands falling along multiple orientations surrounding the indent. Likewise, in metallic glass composites the reinforcement phases introduce constraints because they disrupt shear band propagation and
shear. In each case, the effect of the constraint is to introduce a back stress, which leads to an increase in deformation resistance similar to kinematic hardening in crystalline composites. From indentation experiments, we can measure the

strength of this coupling in terms of a "hardening modulus," the magnitude of which can be determining from the fluctuations in slope of the load-depth curve during serrated loading. It is expected that the hardening modulus will depend on both material properties and the geometry of the constraint.
Using nanoindentation experiments with a Berkovich indenter, we measure
the hardening modulus in ZrCuAl metallic glass ribbons and ingots across 2 decades of strain rate during loading and 6 decades of strain rate during constant load creep. Hardening modulus is nearly independent of load despite a size effect in the serrations. Relaxing the glass near T influences the hardening modulus. The magnitude of the constraint is the same during constant load creep and during loading. Work arguments allow us to arrive at a model for coupled deformation, from which we estimate the magnitude of the constraint modulus in terms of the shear modulus of the glass, G. We compare this estimate with experimentally measured values.

Bicontinuous Nanoporous Design Induced Homogenization of Strain Localization in Metallic Glasses Chang Liu and Paulo Branicio; University of Southern California, United States

Bicontinuous nanoporous metallic glasses (MG) synergize the outstanding properties of MGs and open cell nanoporous materials. The low-density and high-specific-surface-area of bicontinuous nanoporous structures have the potential to enhance the applicability of MGs in catalysis, sensors, and lightweight structural designs. In this work we generated stochastic bicontinuous structure using an efficient direct method based on Cahn's idea and Fibonacci grids. We then perform molecular-dynamics simulations of tensile loading on a bicontinuous nanoporous $Cu_{64}Zr_{36}$ and characterize the deformation mechanisms dictating its elastic and plastic response preceding failure. Results indicate an anomalous MG mechanical behavior featuring extensive plastic deformation preceding a typically ductile failure. Results show progressive necking of ligaments aligned with the loading direction and progressive alignment of randomly oriented ligaments during the loading. Failure occurs by fracture following successive necking and rupture of ligaments. This work indicates that a bicontinuous nanoporous design is able to effectively delocalize strain localization in a bulk MG by utilizing the size effect of MG nanopillars and nanowires that induces a brittle to ductile transition in their mechanical behavior as ligament sizes are reduced to less than 100 nm.

F.SF02.09.06
Tuning the Mechanical Properties of Shape Memory Metallic Glass Composites with Brick and Mortar Designs Suyue Yuan and Paulo Branicio; University of Southern California, United States

The intricate deformation and failure of a shape memory alloy-bulk metallic glass composites (BMGC) under tensile loading is investigated with large-scale molecular dynamics simulations. By carefully choosing the volume fraction and the arrangement of the crystalline phase the failure of the BMGC is shifted from the propagation of a critical shear band in the amorphous matrix to yield and failure of the crystalline second phase. Results show that a brick and mortar design with staggered crystalline bricks (stg-BMGC) is able to further synergize the mechanical properties of the amorphous and crystalline phases. By effectively distributing the local stress and preventing the generation of a critical shear band the stg-BMGC design displays enhanced ductility while preserving the strength of the metallic glass matrix.

Thermal Behaviors of Hydrocarbon-Coated Aluminum Nanoparticles as Energetic Metamaterials in Combustion Applications—A ReaxFF Molecular Dynamics Study Sungwook Hong, Roxanne Esparza and Ryan Parlier; California State University, Bakersfield, United States

Aluminum nanoparticles (ANPs) have been considered attractive additives for combustible applications because the ANPs possess a high energy density with an increased burning rate, owing to an increased surface area-to-volume ratio.[1] Unfortunately, use of the ANPs is limited by two factors: (1) ANPs can be readily sintered; and (2) ANPs can be easily oxidized, prior to the combustion process due to their high reactivity, degrading the combustion performance. To resolve this issue, synthesis of metamaterials, using ANPs and hydrocarbon has been suggested. For example, ANPs could be effectively coated by hydrocarbon precursors to improve its combustion performance.[2,3] The previous studies reported that the hydrocarbon-coated ANPs are less reactive at low temperatures and they became susceptible to the oxidation at higher temperatures, suggesting that the hydrocarbon coating is essential for the ANPs to be used as combustible materials.[4,5] However, a molecular-level understanding of thermal behaviors of the hydrocarbon-coated ANPs has yet to be achieved. Here we perform reactive molecular dynamics (RMD) simulations based on ReaxFF[6] to investigate effects of hydrocarbon coating on the combustion process of the ANPs including sintering and oxidation processes. Our RMD

simulations reveal molecular-level reaction steps for the combustion process of the bare/hydrocarbon coated ANPs. As such, our RMD simulations will help guide an experimental design of a novel energetic metamaterial using ANPs and hydrocarbon, providing a valuable input for the community of solid-fuel propellants.

Computational Design of Energetic Metamaterials Using Graphene-Supported Aluminum Nanoparticles—A ReaxFF Molecular Dynamics Study Ryan Parlier, Andrew Martinez and Sungwook Hong; California State University, Bakersfield, United States

Aluminum nanoparticles (ANPs) have attracted a great amount of interest owing to their high energy density, high reaction rate, earth abundance, and low toxicity.[1] ANPs have been considered effective energetic materials. Unfortunately, ANPs are easily oxidized at room temperature, leading to oxide layers on their surfaces. Those oxide layers work as a dead weight. Therefore, it is vitally important to design a novel metamaterial that improves the combustion performance of ANPs. Recent studies show that adding graphene oxide and graphene fluoride improves the combustion performance of ANPs.[2,3] This is mainly due to a synergistic effect between graphene sheets and ANPs. For example, oxygen molecules could be easily dissociated when they get closer to both graphene sheets and ANPs. As such, we hypothesize that graphene-supported ANPs, which could be considered novel energetic metamaterials, provide a remarkable combustion performance. Here we simulate the oxidation of graphene-supported ANPs using reactive molecular dynamics (RMD) simulations based on ReaxFF.[4] Our RMD simulations reveal atomic-level reaction mechanism for the improved oxidation process of graphene-supported ANPs. As such, the RMD results will help guide an experimental design of a novel energetic metamaterial using graphene sheets and ANPs, providing a valuable input for the community of energetic metamaterials.

Spin-Valley Locked Edge States in Staggered Chiral Photonic Crystal Yeseul Kim, Minkyung Kim and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Topological phases of matters, firstly investigated in condensed matter physics, have been extended to other wave physics such as photonics. In this poster presentation, we present spin-valley locking of edge states in a chiral photonic crystal in the two-dimensional honeycomb lattice. Using a coupled dipole method, we demonstrate bulk band structure with a band gap, which is spanned by the spin-valley locked edge states. The staggered chirality breaks the inversion symmetry and the chirality provides the spin-valley locking characteristics.

F.SF03.12.06
Late News: Computational Synthesis of Novel Energetic Metamaterials Using Metal Nanoparticles and Hydrocarbon Precursors for Combustion Applications Roxanne Esparza and Sungwook Hong; California State University, Bakersfield, United States

The use of aluminum nanoparticles (ANPs) in combustion applications has attracted a great amount of attention owing to their high energy density with an increased burning rate.[1] Unfortunately, due to the nature of ANPs' high reactivity, the ANPs are easily sintered, leading to an increase in their particle size, and thus lowering the combustion efficiently. In order to tackle this issue, recent efforts have been made to synthesize novel metamaterials, using ANPs and hydrocarbon precursors. For example, ANPs could be effectively coated by hydrocarbon precursors to lower their reactivity, thus preventing sintering effects of ANPs. However, an effect of precursor types of hydrocarbon on sintering behaviors of ANPs has yet to be understood at the atomic level. Here we perform reactive molecular dynamics (RMD) simulations based on ReaxFF[2] to investigate computational synthesis of energetic metamaterials using ANPs and carbon precursors. In particular, we employed different types of carbon precursors to evaluate the sintering behaviors of ANPs. Our RMD simulations suggest detailed reaction steps for the sintering process of the bare/hydrocarbon coated ANPs. As such, our RMD simulations will help provide a valuable input for experimental synthesis of a novel metamaterial using ANPs and hydrocarbon for combustion application.

Late News: Humidity-Dependent Flaw Sensitivity in the Crack Propagation Resistance of 3D-Printed Nano-Ceramics Edoardo M. Rossi[1], Jens Bauer[2] and Marco Sebastiani[1]; [1]Università degli Studi Roma Tre, Italy; [2]University of California, United States

Pyrolitic 3D-printed carbon nano-ceramics currently emerge as a class of lightweight materials with exceptional mechanical strength and stiffness, being characterized by feature-sizes well below the capabilities of the highest-resolution 3D additive manufacturing techniques alone. Despite the increasing applications, their use is hampered by the lack of knowledge on their mechanical reliability. Few studies have investigated their intrinsic mechanical properties: important characteristics, like hardness and fracture toughness, and their dependency on environmental conditions, which can be relevant for a thorough understanding of the complex mechanical behaviour of additively manufactured pyrolitic carbon structures, are unknown. In this work, we present nanoindentation splitting of TPP-DLW-derived pyrolitic carbon micro-pillar specimens, characterized by a diameter of 5.3 μm and a hight-to-diameter ratio of two, as a straight-forward method to measure the fracture toughness and nanoindentation continuous stiffness measurements for the assessment of the elastic modulus and hardness. Micro-pillars with and without SEM detectable surface flaws, absent of STEM-detectable internal defects, were

tested at two extremal intervals of the environmental relative humidity, humid air was used to adjust RH at values greater than 60% and dry nitrogen at room pressure ensured RH levels below 5%, to investigate the impact of pyrolysis-induced surface flaws and the interplayed effects with the testing environment on the mechanical reliability of the 3D printed nanoceramics. We show that TPP-derived pyrolytic carbon can achieve 500% increased fracture toughness over macroscopic forms of vitreous carbon, which typically lies in the range of 0.5-1.4 $MPam^{0.5}$, with values up to 3.1 $MPam^{0.5}$. However, experiments at RH > 60% revealed a detrimental effect of high relative humidity environments on the fracture toughness of the pyrolitic carbon nano-ceramic structures, causing embrittlement due to liquid diffusion ascribed to the presence of only a few, nanometer-sized, which probably promotes crack propagation under external loading due to chemically induced structural weakening of the glassy carbon structure. While comparable effects are less relevant in macro-size ceramics, this study demonstrates that reliability and durability of micro- and nano-architected ceramic metamaterials and devices require toughening design approaches which focus on size-dependent surface effects. The observed humidity effect can have a remarkable impact on the scale-up of such nano-architected metamaterial in a wide range of applications, especially biomedical and micro-fluidics fields.

Late News: Infrared Reflecting/Transmitting Smart Glass For Energy Efficient Windows Mark Altwerger, Yashashvini Andugula, Harry Efstathiadis and Iulian Gherasoiu; SUNY Polytechnic Institute CNSE, United States

Low-e glass panes are not well adapted for use in regions where the predominant heat that passes through windows has its origin indirect solar radiation. Almost 49% of solar energy is distributed in the spectrum from 0.7-2.5μm for which low-e glass-pane reflectivity is below 10%. This is the case with 14% of the contiguous U.S. according to NREL. The metamaterial that we propose is a robust, thin-film structure that has the ability to reflect near-infrared heat radiation (NIR) with λ 0.7-10μm while transmitting more than 90% of the visible light intensity. The ability to reflect NIR and transmit selected wavelength range is obtained through the field-enhanced electron concentration of moderately doped metal oxide thin films. Approximately 48% of the total energy produced in the U.S. or 18.6 billion kWh is spent on heating and cooling. Therefore, the ability to retrofit this technology onto existing buildings is of considerable interest. Electrical and optical characterization demonstrate the synthesis of state-of-the-art materials with properties suitable for the fabrication of smart glass devices.

Low-Voltage IGZO Thin-Film Transistors Using SAM Surface Modification on Ta_2O_5 as the Gate Dielectric Navid Mohammadian and Leszek A. Majewski; The University of Manchester, United Kingdom

Low-voltage, high-performance thin-film transistors (TFTs) have been getting tremendous attention over recent years due to the increasing demand for low-power, portable electronic devices and sensor arrays. However, reducing the power consumption of TFTs is an extremely challenging task [1]. High-κ dielectric materials are thought to play an essential role in applications where a low-power device operation is needed.
In particular, tantalum pentoxide (Ta_2O_5) is a very promising candidate due to the high dielectric constant in the bulk (κ_{bulk} ~27) and as a thin-film ($\kappa_{thin\text{-}film}$ ~20). These values are at least two times larger than that of Al_2O_3 (κ_{bulk} ~9) and five times larger than that of SiO_2 (κ_{bulk} ~3.9) [2]. As a result, Ta_2O_5 has been abundantly used in electrolytic capacitors, DRAM devices, and recently in solution-processed inorganic semiconductor thin-film transistors as a promising gate dielectric for low-power electronics [3].
whereas high-k insulators introduce undesirable effects at the semiconductor-insulator interface which generally leads to increased trapping which causes a rise of V_{TH} and SS, as well as lowers the field-effect mobility of charge carriers in TFTs [4]. To overcome both issues in low voltage organic thin-film transistors (OTFTs) passivating of the high-k metal oxides surfaces with self-assembled monolayer (SAM) compounds is routinely used [5]. Although modification of ultra-thin ($d \leq 20$ nm) metal oxide gate dielectrics with SAMs is currently a common process in organic TFTs [6], this approach has not yet been explored in metal oxide semiconductor transistors.
In this talk, low-voltage a-IGZO TFTs using solution-deposited, OTS-modified Ta_2O_5 operating at 1 V are presented. The optimised devices display threshold voltages V_{TH} around 0.4 V, subthreshold swings (SS) below 90 mV/dec, current on/off ratios larger than 10^5, and field-effect mobility in excess of 2.3 cm^2/Vs. The morphology and dielectric properties of both pristine and OTS-treated thin Ta_2O_5 films have been studied. It is shown that the proposed approach has a high potential to enable the design of stable, low-voltage organic semiconductor circuitry in a highly reproducible manner.

Direct Langmuir-Blodgett Deposition of Few-Layered 2H WSe_2 Flakes for Electrical Characterization Madina Telkhozhayeva[1], Rajashree Konar[1], Eti Teblum[1], Hagit Aviv[1], Maria Tkachev[2], Olga Girshevitz[2], Yaakov Tischler[1] and Gilbert D. Nessim[1]; [1]Bar-Ilan University, Israel; [2]Institute of Nanotechnology and Advanced Materials, Bar-Ilan University, Israel

Two-dimensional (2D) semiconductors have attracted extensive research interest due to their unique size, atomic thickness and band structure. In this respect, transition metal di-chalcogenides (TMDCs) are leading candidates because of strong in-plane chemical bonds and out-of-plane weak interactions. This allows them to be exfoliated into so-called 2D flakes, which can be micrometers wide but less than a nanometer thick. Among them, 2H-WSe_2 as a layered 2D material demonstrates remarkable properties such as low thermal conductivity, high carrier mobility, and direct band-gap, thus offering a suitable platform for next generation nanoscale devices [1-2].
Liquid-phase exfoliation (LPE) of bulk TMDCs can yield high-quality semiconducting flakes dispersed in commonly used solvents. Although a considerable number of research with LPE methods towards 2H-WSe_2 has been conducted, there are lack of reports on controlled organization of these exfoliated flakes on substrates. This step is crucial since produced 2H-WSe_2 flakes tend to restack into a bulk structure via van der Waals interactions, which significantly limit device applications. Langmuir-Blodgett (LB) assembly is an effective and easily integrated approach for arranging 2D flakes into highly ordered single-layer and multilayered films with controllable thickness, well-defined structure, and homogeneity.
Here, we present a cost-effective and facile technique for the controlled processing of 2D 2H-WSe_2 dispersions into uniform close-packed flakes via the LB method. Bulk 2H-WSe_2, synthesized using an atmospheric-pressure chemical vapor deposition (AP-CVD) technique, was exfoliated into mono- to few-layered 2H-WSe_2 flakes using low-boiling solvent (ethanol) at high-frequency bath sonication system. The compression of the liquid-exfoliated WSe_2 flakes on the water sub-phase was used to form a continuous layer, which was subsequently transferred onto a pretreated substrate. UV-Vis, Raman, AFM, HRSEM and HRTEM prove that the as-deposited material is successfully exfoliated from bulk 2H-WSe_2 into mono- to few-layered flakes. Furthermore, we studied the electrical properties of the FIB-fabricated 2H-WSe_2 flake device using a two-probe current versus voltage (I-V) measurements. The proposed technique provides a simple path to assemble structures of solution-processed 2D semiconductors avoiding the challenges related to high cost and high temperature processing for further applications in electronics and optoelectronics.

Effect of DUV Curing on Low-Temperature Synthesis of IZO Semiconductor-Based TFTs Alessio Mancinelli[1], Sami Bolat[2], Jaemin Kim[1], Yaroslav E. Romanyuk[2] and Danick Briand[1]; [1]EPFL, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Solution processing is an attractive alternative to standard vacuum fabrication techniques for the large-area manufacturing of metal-oxide (MO_x) based electron devices. In this frame, thin-film transistors (TFTs), which serve as the essential electronics building blocks, have to be primarily addressed. Furthermore, when these TFTs are realized on flexible substrates, many

potential applications such as displays, chemical sensors, and conformable wearable devices, could be envisioned. However, the need for high-temperature sintering processes (T > 350 °C) has restrained thus far their commercial diffusion. The necessity for temperature-resistant polyimide as a substrate has restrained their field of application mainly to displays (e.g. indium gallium zinc oxide (IGZO) on polyimide). More economic and environmental-friendly substrates such as PET, cellulose, and biopolymers will become essential in future daily life applications requiring cheap and perhaps disposable devices. Among others, smart label sensors for temperature and chemical monitoring of food, realized directly in the packaging could be enabled. Accordingly, the development of a production process compatible with such thermosensitive substrates has to be addressed.

One of the key challenges for the full exploitation of these devices is the reduction of the thermal budget required for the MO_x synthesis. Our approach is based on the use of deep ultraviolet light (DUV) to promote the sol-gel synthesis reaction and therefore reduce the thermal budget of the process. The energetic photons generated by the DUV lamp are used to photo-activated the chemical reactions and initiating the M–O–M bond formation inside the deposited thin film. The quality of the MO_x layer is further enhanced by the heat treatment which eliminates the undesired reaction residuals and densifies the film. Similar photonic processes for solution-processed metal-oxide transistors have been mainly based on indium oxide (InO_x) as semiconductor material. The more convenient chemistry of InO_x facilitates its solution processing at low-temperature. However, the films obtained from these compounds can suffer from unstable behaviour and operation at negative voltages. We report on TFTs based on a solution-processed indium zinc oxide (IZO) semiconductor utilizing a DUV enhanced curing, which enables a reduction of the processing temperature. A parametric analysis of the curing parameters has been carried out in to investigate the minimal conditions required to achieve performing devices. In this frame, we compared the efficiency of a post-annealing step in with in-situ combined DUV exposure and heating). Furthermore, the curing processes have been investigated using two different DUV light sources evaluating the different outcomes: a single-wavelength (172 nm) emitting excimer lamp and a broader emitting DUV lamp (184 nm/253 nm). The electrical characteristics of the TFT have been extracted and used to establish optimal curing conditions. Notably using DUV, short curing times as low as 10 minutes at 200 °C (e.g. 5 min DUV + 5 min post-annealing @ 200 °C) achieved mobility of 3 cm^2/Vs. Higher mobility values (>15 cm^2/Vs) have been achieved with prolonged processes (>80 min). While a temperature reduction to 180 °C yielded ~1 cm^2/Vs. The effects of the different curing protocols on the chemical composition of the IZO films have been studied using Fourier-transform infrared spectroscopy and X-ray photoelectron spectroscopy. The IZO semiconductor has been eventually paired with a printed high-k MO_x dielectric film, cured using the same methodology, to realize fully solution-processed MO_x TFTs, with as ultimate goal producing full printed TFTs. The identification of the most effective tool, combined with a fine-tuning of the parameters, allows to the DUV enhanced curing to diminish the thermal budget required to process IZO TFTs, paving the way for its further implementation on temperature-sensitive substrates.

Uniform and Stable Aerosol-Jet Printing of Carbon Nanotube Thin-Film Transistors Shiheng Lu, Joanne Zheng, Jorge Cardenas, Nicholas Williams, Yuh-Chen Lin and Aaron D. Franklin; Duke University, United States

Carbon nanotube thin-film transistors (CNT-TFTs) have attracted intensive attention due to their potential use in various applications, including display backplanes and sensing systems. Device uniformity, which is largely determined by the homogeneity and reproducibility of CNT thin films, is essential for large-scale manufacturing and practical applications. Here, we demonstrate an aerosol-jet printing approach to realizing CNT-TFTs with device characteristics that are among the most uniform of CNT-based transistors to date. The key enabling factors include proper ink formulation, polymer surfactant removal via rapid thermal anneal (RTA), and careful ink temperature control. Terpineol was added as a secondary solvent, and both optical and atomic force microscopy (AFM) reveal that the addition of this nonvolatile and viscous component efficiently suppresses the unwanted coffee-ring effect. The effectiveness of RTA-based polymer removal was supported by AFM results. It was discovered that a lower CNT ink temperature during printing offers higher ink output, increased CNT density, larger field-effect mobility, as well as enhanced device uniformity. This ink temperature-device uniformity relationship was further examined by fabricating batches of CNT-TFTs at a range of different ink temperatures, which revealed that low ink temperature (e.g., 8 °C) not only benefits uniformity of devices printed within a short period of time (~ 70 s), but also improves long-term (~1 h) printing stability. A set of several dozen CNT-TFTs printed from a CNT ink at 8 °C exhibited a mobility of 12.5 ± 0.5 $cm^2\ V^{-1}\ s^{-1}$, with a relative standard deviation $\sigma(\mu_h) / \mu_h$ as small as 4%. These results unveil the role that ink temperature and other critical processing factors play in aerosol jet printed films and have the potential to address device uniformity issues that have previously plagued the utility of printed CNT thin films.

F.SF04.07.05
Fine-Tuning of Molecular Conformations for High-Speed Organic Photodetectors with Enhanced Charge Transport Jisoo Shin, Sungyoung Yun, Hye Sung Choi, Taejin Choi, Younhee Lim, Seon-Jeong Lim, Kyung-Bae Park and

Sunghan Kim; Samsung Advanced Institute of Technology, Korea (the Republic of)

Organic semiconductors have the advantages of high absorption coefficients and wavelength selectivity compared with those of inorganic materials. As such, organic photodetectors (OPDs) are emerging as the next candidates for commercialized organic electronic devices, organic CMOS image sensors (OCISs). Wavelength-selective OPDs are applicable to the three-dimensional (3D) stacked structure that can replace the existing CMOS image sensors for the expansion of the light-input surface area by maximizing the photons absorbed effectively by each pixel, leading to high sensitivity and resolution since they can absorb selective wavelength from incident light without color filters.
To realize these advantages, systematic approach for molecular design of OPDs and optimized device architecture has been reported by our group recently. Noteworthy, through recent years of research on OPDs, the improvement of charge transport properties is also indispensable for commercialization of high-speed image sensors. Compared to silicon CMOS image sensors, some charges are slowly transported and remain in organic layer, then slow decays of photocurrent induced image lags closely related to remaining charges (RCs) in OCISs.
Here, combined with simulation and experiment, we designed and synthesized novel push-pull type molecules with different moieties by tuning the molecular conformations, which showed improved optical properties as well as charge carrier mobility. According to the improved device performance, we experimentally find out that charge transport properties including RCs are closely related to molecular structure with introduction of carbon-bridge and various types of side group. The effect of molecular conformations on the optoelectronic properties of high-speed OPDs will be discussed in detail.

F.SF04.07.06
Unsubstituted and Fluorinated CoPc Nanowires, Ultrathin Films and Composites for Room Temperature ppb Environmental Gas Monitoring in Highly Humid Terrains Soraya Flores[1], Jean Gonzalez[1], Juan Cintron[1], Dalice M. Piñero Cruz[1], Jose Hernandez[1], Nerida deJesus[2], Ruben E. Diaz-Rivera[2] and Luis F. Fonseca[1]; [1]University of Puerto Rico at Río Piedras, United States; [2]University of Puerto Rico at Mayagüez, United States

Metallo Phthalocyanines (MPc) have been widely studied as promising material to develop sensitive gas sensor devices. In particular, its electrical response when exposed to gas analytes encourages its use in chemiresistors. This is so because they show some characteristics that can be exploited for the development of very sensitive gas sensors. When compared with other semiconductors, such as metal oxides, their baseline resistivity is relatively high and can change orders of magnitude when exposed to the sensing gas, which can be easily tuned through the incorporation of substituents in the periphery of the Pc platform. Moreover, there is little difference between their room temperature and higher temperature response. Recent publications report reproducible single digit parts-per-million sensitivities at room temperature, usually when preparing the material at the nanoscale.
This work summarizes advances in the synthesis, solution preparation, and gas sensing applications of CoPc and fluorinated CoPc nanowires and films with thicknesses below 20nm. In this case, room temperature parts-per-billion response is reported. Novel sensors prototypes based on F_{16}CoPc composites activated with Pt nanoclusters show significant reduction in their sensor response time. The report includes a systematic comparison with unsubstituted CoPc, and the response to different reducing and oxidizing gases. These new prototypes will be optimized for the detection of environmental contaminants in areas with high atmospheric relative humidity.

F.SF04.07.07
Metal Oxide Nanostructure Patterns via Modified Immersion Transfer Printing for Internal Light Extraction of Quantum Dot Light-Emitting Diodes Moohyun Kim, Eugene Cho, Jeong Min Shin, Min Seok Jang and Yeon Sik Jung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Quantum dot light-emitting diodes (QLEDs) are considered as next-generation displays due to the outstanding advantages of quantum dots (QDs) such as large color gamut by narrow emission, high brightness, solution-processability and potential long term stability. The performance of QLED is characterized by external quantum efficiency (EQE), which is the multiplication of internal quantum efficiency (IQE) and light out-coupling efficiency (EQE = IQE×light out-coupling efficiency). Recent progress has improved EQE of QLEDs for red, green and blue color to about 20%, which is on the level of commercial phosphorescent organic light-emitting diodes (OLEDs). Considering that the light out-coupling efficiency of a typical multilayer structure device is 20%, it can be seen that the IQE of QLEDs reached 100%. Therefore, research on light out-coupling efficiency or light extraction of QLEDs has been gaining attention to further improve the EQE.
In OLEDs, light is commonly extracted through corrugated structure or photonic crystal like internal light extraction nanostructure. Generally, these nanostructures are located between the multilayer structure and transparent electrode to interact with the target wavelength. However, applying this strategy for enhancement of QLEDs has difficulty even though the structural similarity of the multilayer structure. This is because multilayer structure of QLEDs is fabricated based on

solution process while OLEDs are fabricated through vacuum deposition. Therefore, in QLED, the light extraction nanostructure strongly effects the morphology of the multilayer device causing degradation of the operation characteristic. Furthermore, very narrow QDs emission with 30nm of full-width at half maximum (FWHM) suggests the need for more advanced technique with finer and more precise nanostructures.
In this study, we demonstrate a metal oxide (MoO_3) nanostructure fabricated by modifying immersion transfer printing (iTP) method for internal light extraction of QLEDs. MoO_3 was applied as the internal light extraction material on the basis of high refractive index value (n) of 2.1 at 520 nm and semiconducting properties as a hole transport layer in optoelectronic devices. iTP is introduced as the fabrication method for its compatibility with the solution processed QLEDs and capability for forming high resolution MoO_3 nanostructure. Previous reported iTP, which uses hydrophobic particles, was modified to compensate for the incompatibility between hydrophilic MoO_3 particles and PDMS brushed substrates. PDMS-PS co-brush system was applied to control the surface affinity as a way to achieve MoO_3 incorporation onto the Si template. In addition, PDMS/PS bilayer was used as the picking carrier polymer to increase the transfer yield of the MoO_3 nanostructure. As a result, nanoscale line patterns with widths of 1000, 350, and 50 nm in large areas are well demonstrated. Finite-difference time-domain (FDTD) simulations are conducted to help design the precise size and shape of the pattern for light extraction to optimize the QLED internal light extraction. QLED was fabricated based on this design and showed improvement in the performance of the QLED device.

F.SF04.07.10
Examining the Impact of Air Exposure and Temperature Variation on N- and P-Type Polymer Charge Transport for Transistor and Photovoltaic Applications Samantha Brixi and Benoit Lessard; University of Ottawa, Canada

Enhancing device stability is essential to the widespread commercial adoption of organic electronic devices. Interactions of organic semiconductors with their environment often lead to degradation of device performance; therefore, it is important to understand how such devices as organic thin-film transistors and organic photovoltaics are affected by these interactions. This allows scientists and engineers to both choose appropriate applications for these materials and guide the development of new materials with enhanced stability. Polymers are of particular interest due to their capacity to be processed in solution for a new generation highly scalable and inexpensive electronic devices from sensors to solar cells. We have studied the stability of p- and n-type materials of interest for transistor and photovoltaic applications in environments relevant to commercial applications of these materials, including exposure to air, vacuum, and varied temperatures. In all cases, significant degradation could be observed. After 18 days of air exposure for p-type materials P3HT and PBDB-T, a 95% loss in hole mobility (μ_h) was observed for P3HT, while PBDB-T only experienced a μ_h loss of 42%.[1] For n-type polymers studied, a loss in electron mobility (μ_e) of 99% was observed for N2200 exposed to air for two weeks, while an 84% μ_e loss was observed for PIBDFBT-37.[2] Preliminary studies on polymers in organic photovoltaics indicate similar trends, but the degradation of charge transport properties does not give the full picture. We plan to further explore the impact of polymer degradation and charge transport on the stability of organic photovoltaics and transistors.

Dielectrophoretic Assembly of Single Nanowires for Advanced Characterisation Nanoscale Standards Maxim Shkunov[1], Sebastian Wood[2], Ruth Rawcliffe[1], Filipe Richheimer[2], Tomas Peach[1] and Fernando Castro[2]; [1]University of Surrey, United Kingdom; [2]National Physical Laboratory, United Kingdom

Nano-characterisation techniques, including confocal microscopy, atomic force microscopy (AFM) and tip enhanced Raman scattering (TERS), rely on the ability of each instrument to resolve nano-scale features without distortions and artefacts, however, reference samples allowing to perform fully quantitative characterisation of their responses are not available. Calibration of lateral and depth resolution of advanced scanning-probe microscopy methods is currently very challenging and calls for the development of nanoscale standards with features in 10-200 nm range with various morphological and optoelectronic characteristics.
We demonstrate the development of solution-based, single-nanowire-based reference samples, where easily identifiable device positions each contain a semiconducting nanowire with a particular set of properties. Key parameters that are considered include: diameter and length, Raman response, photoluminescence and conductivity. The devices are self-assembled from a wide range of solution-processed semiconducting nanowires, including Si, Ge, InAs, InP, GaN, Ge/Si. Individual nanowires are positioned in pre-defined locations using electric-field assisted process, dielectrophoresis (DEP), by applying controllable DEP signal voltage and frequency. Nanowires are characterised, and various response metrics are analysed using conducting-AFM, confocal Raman, TERS and other techniques to establish which nanowire materials provide

highly distinguishable responses, necessary for reference standards. Challenges in identifying most suitable nanowire materials, including their spectroscopic characteristics (e.g. Raman) and morphological features (e.g. diameters) are discussed and several reference samples for the characterisation of lateral and vertical resolution of nanoscale scanning probe techniques are suggested.

F.SF04.07.13
Effect of Oxygen Pressure on Optical and Electrical Properties of Single-Crystalline Cu_2O Fabricated by Pulsed Laser Deposition Jan Lancok, Lenka Volfova, Premysl Fitl and Michal Novotny; Czech Academy of Sciences, Czechia

Copper oxide Cu_2O is an important and well known p-type transition metal oxide semiconductor material, which has already been employed in the fabrication of electronic devices. For example Cu_2O has been used in thin photovoltaic devices, resistive switching, transistors, gas sensors or catalysts. The films were fabricated by Pulsed Laser Deposition from CuO ceramic target by means of Nd:YAG laser operated at 266 nm wavelength. MgO(100) substrates were mounted on substrate holder 5 cm away from the target and maintained at temperature in the range 500-700 °C. Our attention was mainly focused on the influence of the oxygen pressure, which was varied between 10^{-5} Pa and 1 Pa, on the structural and following on optical and electrical properties. The investigation of the plasma was carried out by Optical emission spectroscopy. The surface morphology and composition were characterised by AFM and XPS, respectively. The crystalline quality of the films were characterised by means of XRD and following by TEM and HRTEM, which confirmed the epitaxial grown of the films in low oxygen pressure up to 0.1 Pa. When the oxygen pressure exceeded 0.1 Pa the growing films started to be polycrystalline and the CuO phase also appeared. Because we focused on utilization of the Cu2O films as gas sensors, the near ambient pressure photoelectron spectroscopy was carried out to investigation of surfaces composition in the presence of gasses and vapours such as ethanol, hydrogen and NO2.

F.SF04.07.14
Thermal Dedoping of Doped Poly (3-hexylthiophene) for Multimodal Temperature Sensing Hemanth Maddali[1] and Deirdre O'Carroll[1,2]; [1]Rutgers, The State University of New Jersey, United States; [2]Rutgers University, United States

Conjugated polymers have a wide range of applications in optoelectronic devices and in numerous sensing technologies. Conjugated polymers that have thermally activated optical or electrical responses have garnished interest due to their potential as thermal sensors. These thermochromic properties are often introduced via doping. In this study, we investigate the use of electrochemically doped poly(3-hexylthiophene) (P3HT) thin films as multimodal temperature sensors. P3HT thin films spin coated on indium-tin oxide coated glass substrates are electrochemically doped using tetrabutylammonium perchlorate (TBAP) dissolved in acetonitrile. The pristine P3HT thin films, which are purple in color, exhibit a color change to blue, upon doping. The doped P3HT thin films are then heated under vacuum at 140^0 C and the color of the thin films reverts from blue to purple indicating thermally activated dedoping. UV-visible absorbance spectra of pristine, doped and dedoped P3HT thin films show that the change in optical absorption properties upon doping is reversed due to thermally activated dedoping. Energy dispersive X-ray spectroscopy (EDS) reveal the presence of dopant molecules (TBAP) distributed throughout the doped P3HT film. Upon dedoping, the EDS maps show almost negligible levels of the dopant molecules. This further proves that heating of doped P3HT thin films triggers dedoping and causes the distinctive thermochromic response, i.e., a color change from blue to purple. The electrical properties of doped and dedoped films are also expected to result in a significantly different current upon application of voltage. This warrants fabrication of a current-based temperature sensor that would perform colorimetrically and electrically.

F.SF04.07.15
A 13.56 MHz Rectifier Based on Fully Inkjet Printed Organic Diodes Fabrizio A. Viola and Mario Caironi; Istituto Italiano di Tecnologia - IIT, Italy

The increasing diffusion of portable and wearable technologies results in a growing interest in electronic devices having features such as flexibility, lightness-in-weight, transparency and wireless operation. Organic electronics was proposed as a potential candidate to fulfill such needs, in particular targeting pervasive Radio-Frequency (RF) applications. Still, limitations in terms of device performances at RF, particularly severe when large-area and scalable fabrication techniques are employed, have largely precluded the achievement of such an appealing scenario. In this work, we demonstrate a high-frequency rectifier based on fully inkjet printed organic Schottky diodes fabricated through scalable large-area methods on plastic. The inkjet printing of the organic semiconductor, the core of the diode structure, has been carefully optimized in order to obtain a low series resistance, which is mandatory to improve the diode cut off frequency. Moreover, the employed materials in the presented device have been chosen to finely tune the barriers formed at metal-semiconductor interface, in order to increase the rectification ratio of the diode: the obtained value is higher than 10^6 which is, to the best of our knowledge, the highest

value ever reported with a fully printed structure. Furthermore, we show, as a proof-of-concept, how a rectifier circuit integrating the fully printed diode, can successfully supply power to a polymer micro-electronic circuit printed on a plastic foil with a similar process. In particular, by rectifying a 13.56 MHz AC voltage the rectifier enables the correct operation of a D-Flip Flop, which is a fundamental logic building block for serialization elements. The possibility of harvesting electrical power from RF waves and delivering it to a cheap flexible substrate through a simple printed circuitry paves the way to a plethora of appealing distributed electronic applications.

F.SF04.07.16
Thermally Stable Au Decorated Silica-Titania Mesoporous Nanocomposite for pH Sensing Evaluation Shumaila Islam and Adil Alshoaibi; King Faisal University, Pakistan

Herein, doping/decoration of gold nanoparticles (AuNPs) within mesoporous silica-titania nanocomposite is achieved via a facile and co-assembly sol-gel method. Polyethylene glycol is used as a co-structure-directingagent. For sensing analysis, a mixture of organic dyes i.e., bromophenol blue, phenol red, and cresol red is encapsulated in the AuST nanocomposite matrix. FESEM/EDX analysis shows a crack-free surface, porous network and uniform distribution of Au, Ti, Si, along with dye species. FTIR and XRD suggested the heterogeneous chemical bonding and crystallite size 24 nm after encapsulation. AuST nanocomposite shows thermally stable behavior after 450 °C even after co-dyes encapsulation. High surface area 322 ± 2.5 m2/g, pore diameter 30.2 Å, and pore volume 0.24 cm3/g, average surface roughness 10 nm, and refractive index 1.29 is advantageous for good sensing response at pH 1–12. The sensitivity is measured as 10 counts/pH at 441 nm. Moreover, good reversible response, fast response time 2.1 sec in acidic media, and 0.9 sec in basic media is observed.

Late News: Hybrid Surface Treatment of Elastomer Substrates for Robust and Reliable Integration of Rigid Components with Inkjet-Printed Stretchable Circuits Hyungsoo Yoon, Byeongmoon Lee, Sujin Jeong and Yongtaek Hong; Seoul National University, Korea (the Republic of)

Stretchable electronics has emerged as a next-generation technology that goes beyond rigid and flexible electronics to enable novel form-free devices and provide advanced user-experiences. Integration of rigid integrated circuit (IC) chips and inkjet-printed circuits on pre-strained elastomers has been regarded as one of the most powerful methods for fabricating stretchable multifunctional systems due to their unique advantages such as a facile and low-cost process, and a high degree of customizability. However, direct inkjet-printing on elastomers is challenging due to their low surface energy that causes dewetting. Furthermore, the super-hydrophobic surface shows poor adhesion with inkjet-printed metal films as well as conductive adhesives for chip bonding, significantly limiting system stability under deformation. Therefore, appropriate surface modification is indispensable for the robust implementation of inkjet-printing-based stretchable hybrid electronic system. Surface modification of elastomers has been realized by oxygen-plasma or ultraviolet/ozone (UVO) treatments. Both methods render the surface of the elastomers wettable by creating a large number of hydrophilic groups on it, where well-defined patterns can be formed by inkjet-printing. However, the methods have several limitations when applied to inkjet-printing on pre-strained elastomers. Plasma-treated elastomers undergo fast hydrophobic recovery due to the molar migration from the bulk to the surface, resulting in unstable wettability, uneven patterns, and poor adhesion. Alternatively, the UVO treatment provides improved stability and uniformity. However, a thick layer of the elastomer from the surface is stiffened by UV energy, which causes a large strain mismatch between the thick stiff surface and soft bulk. Consequently, the pre-stretched elastomer cannot completely return to its original dimension, restricting the maximum stretchability of the system far behind compared to the applied pre-strain. Therefore, a new surface modification strategy that simultaneously offers stable wetting and a high level of adhesion without compromising their stretchability is highly required.
In this work, we demonstrate robust stretchable hybrid electronic system based-on inkjet-printing and hybrid surface modification of polydimethylsiloxane (PDMS). The surface treatment offers stable wettability and great adhesion and preserves the substrate stretchability. Specifically, the pre-strained PDMS (mixed at 10:1) is exposed with oxygen-plasma to form hydroxyl groups and poly-L-lysine (PLL) solution (aqueous solution, 0.1% (w/v) in H_2O) is sequentially drop-casted on the plasma-treated PDMS. After that, the PDMS is rinsed with deionized (DI) water. Abundant amine groups functionalized on the surface of the PDMS enable stable wetting and good adhesion for inkjet-printing process. Furthermore, the modified surface shows remarkable adhesion with conductive epoxy, allowing robust IC chip bonding on the printed stretchable circuits. To investigate the effect of the hybrid surface treatment, we compare three biaxially pre-stretched PDMS substrates that undergo UVO, oxygen-plasma, and oxygen-plasma with PLL treatments, respectively. The plasma-treated PDMS results in uneven patterns and poor adhesion due to its instability and fast hydrophobic recovery. While the UVO-treated PDMS only shows stretchability of 19% when it is pre-stretched ~70%, the PDMS with hybrid surface treatment restores its original dimension, *i.e.*, it shows the same stretchability as the pre-strain value. Finally, a series of stretchable hybrid electronic

systems are demonstrated with their mechanical robustness, including stretchable LED displays, which proves the superiority of our hybrid surface treatment. The detailed methods and results will be discussed at the conference.

Late News: Implementing ITO-Free Transparent Conductive Electrodes in Flexible Organic and Hybrid Light-Emitting Diodes Felix Hermerschmidt[1], Lukas Kinner[1,2], Theodoros Dimopoulos[2] and Emil List-Kratochvil[1,3]; [1]Humboldt-Universität zu Berlin, Germany; [2]Austrian Institute of Technology, Austria; [3]Helmholtz-Zentrum Berlin, Germany

We utilize 25% of our total electricity consumption for lighting and display applications. To address this consumption, several efficient lighting technologies have been targeted. Inorganic solid-state lighting together with organic light-emitting diodes (OLEDs) are the candidates spearheading the lighting revolution of the 21st century. However, while OLEDs have shown commercial success in rigid display applications, a number of challenges remain to be overcome in order to fulfil their full potential.
Among these are the continued quest for stable emitter materials and to improve strategies for the outcoupling of light from the device. Additionally, energy, temperature and cost efficient processing methods need to be targeted in order to fabricate the transparent conductive electrodes (TCEs) needed for device operation.
Today, transparent conductive oxides, and in particular indium tin oxide (ITO), represent the dominant class of TCEs. ITO combines high transparency (>85% in the visible wavelength range) with low sheet resistance (ca. 10 Ω sq^{-1}) when deposited on glass. As a result, most optoelectronic devices utilize ITO as the transparent electrode. However, ITO has some inherent limits in its range of applications. It is mechanically unstable upon bending, while its scarcity translates to a volatile and high price. It is therefore desirable to replace ITO with other transparent conductive electrodes [1].
Of particular interest are low temperature processes (<130 °C), since these are compatible with the use of temperature-sensitive and low cost flexible substrates, such as polyethylene terephthalate (PET). In this contribution we highlight our recent work on the design, fabrication and characterization of a number of different low temperature processes using, among others, inkjet printing and spray coating to produce TCEs [2,3]. These approaches are based on Ag and Cu nanoparticle, particle-free and nanowire inks. We will show that the developed ITO-free electrodes on PET show superior optical, electrical and mechanical performance compared to PET/ITO reference samples.

Late News: Organic Radiation Dosimeter for X-Ray, Gamma and Neutron Detection Zachary Lamport[1], Marco R. Cavallari[2], Michael Bardash[3] and Ioannis Kymissis[1]; [1]Columbia University, United States; [2]Federal University for Latin American Integration, Brazil; [3]QEL System Services, Inc., United States

In many professions, ionizing radiation is either a by-product of some process or is itself utilized, posing a significant hazard to those in the surrounding area. Workers will usually be required to wear a personal radiation dosimeter which measures and integrates the cumulative radiation dose experienced such that either prolonged or flash exposures are recorded and analyzed for the safety of the wearer. For personal dosimeter badges, the sensing element is usually made of relatively high-Z elements which absorb radiation differently than the lighter elements found in the human body.[1,2] An all-organic radiation dosimeter could more closely approximate the effect of radiation on biological tissues. Another added benefit of such organic-based devices is that they can be made quite cheaply and on a lightweight, flexible substrate. These factors together with the burgeoning IoT systems could allow for a more robust detector network in areas relevant to homeland security. Here, we report on an all-organic radiation dosimeter using the conducting polymer poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS)[3] as both the detector region and conductive traces patterned on a polyethylene napthalate (PEN) substrate. Ionizing radiation incident on a central PEDOT:PSS pad induces a static charge in the air, the PEDOT:PSS itself, and the underlying PEN substrate that is measured as a voltage by the connected op-amp voltage follower.[4–6] Two organic field-effect transistors (OFETs) with the PEDOT:PSS source and drain, respectively, connected to the central PEDOT:PSS region allow for an initial biasing of the central pad, as the semiconductor 6,13-bis(triisopropylsilylethynyl) pentacene (TIPS-pentacene) functions as two very large resistors. The OFETs allow for a very small amount of current to flow through the ungated semiconductor in order to place the central pad at a desired voltage, from which any deviations are measured. To clear the charge from the central pad, one or both of the OFETs can be turned on through the respective PEDOT:PSS gate electrode underneath a parylene dielectric. We show reproducible and reliable

measurements of the radiation dosimeters subjected to a wide range of exposure energies of both X-ray and gamma rays using wide and focused beams resulting in an approximate detection limit of 5 mRad/hour. In addition, there is very strong evidence that the PEDOT:PSS-based devices can detect neutrons from a shielded and unshielded beryllium-encased plutonium source at a dose of 620 mRad/hour. This represents a significant step forward in the production of cheap, reusable radiation dosimeters made with materials of similar radiation cross-section to the human body.

Late News: Highly Conformable Pressure-Sensitive Thin-Film Transistors Using Capacitance Modulation via Nanostructured Surface Morphology of AgNWs Hayun Kim, Byeongmoon Lee, Hyunuk Oh, Hyunjun Yoo and Yongtaek Hong; Seoul National University, Korea (the Republic of)

Electronic skin that can map pressure distribution on arbitrary surfaces has gained tremendous significance for its wide range of use in various fields such as skin prosthesis, artificial nerve systems for soft robotics, and advanced human-machine interfaces. To keep pace with these trends, many studies have focused on reporting high-performance pressure sensors and their passive-matrix array using novel materials and structures. Among various types of pressure sensors, capacitive pressure sensors with engineered microstructures offer significant potential owing to their high sensitivity, fast response time, and great mechanical flexibility. However, previous works on capacitive pressure sensors mainly focused on the performance of a single sensor, and their application to a high-resolution array was challenging because of their complex structure and fabrication process. Therefore, reported sensor arrays using capacitive pressure sensors generally showed low spatial fidelity due to the crosstalk among pixels and low pixel density. Furthermore, to exploit the capacitance change in practical applications, the circuit requires a capacitance-to-current converter that can limit the design freedom and make the system unstable on complex 3-dimensional surfaces. Therefore, device-scale integration between capacitive pressure sensors and thin-film transistors(TFTs) is highly desirable for capacitance-to-current conversion and further active-matrix applications. Although a few studies have reported pressure-sensitive thin-film transistors, they usually suffer from complex fabrication processes and limited flexibility due to their sophisticated structures such as sidewall spacers to make air gaps in dielectric layers.
In this work, we propose a facile and large-area compatible method for pressure-sensitive TFTs (PSTFTs) and their application to flexible sensor arrays. Our PSTFT is based on all-inkjet-printed single-wall carbon nanotube(SWCNT) TFTs, where a silver nanowire (AgNW) gate electrode with nanostructured surface morphology softly touch the top surface of the dielectric layer. The fabrication process of the PSTFT is fairly simple, highly customizable, and cost-effective. The SWCNT active channel, silver (Ag) source and drain electrodes, and poly(4-vinylphenol) (PVP) dielectric layer were sequentially inkjet-printed on a surface-engineered polyethylene naphthalate (PEN) substrate. The AgNW gate electrode was then formed on another flexible substrate by spray-coating. The 3D nanostructures in the AgNW random network form nano-scale air gaps between the gate electrode and dielectric. These nanoscale air gaps are key to the capacitance modulation in the PSTFTs. When the vertical pressure is applied to the top gate electrode, as the air gaps disappear and the contact area between the gate electrode and dielectric increased, the capacitance between the gate electrode and active layer drastically increases without any supporting spacer. Our PSTFT showed well-split transfer curves with on-off ratios of from 1 to $1.3*10^4$ according to the applied pressure. When the pressure reached 700 kPa, the TFT showed $1.3*10^4$ on/off ratio. We further demonstrate the feasibility of our approach by mounting the highly conformable sensor array on human skin to read out the change of the pressure such as finger touch and joint flexure. This study provides a new pathway to map pressure distribution using capacitive pressure sensors without any crosstalk among adjacent pixels, which can be further applied to any type of deformable substrates with potential applications such as skin-mounted device, deforming soft robotics, and

display. The detailed methods and results will be discussed later.

Vitrification Kinetics versus Alpha-Process in Metallic Glass-Formers Isabella Gallino[1], Daniele Cangialosi[2,3], Beatrice Ruta[4], Xavier Monnier[2] and Ralf Busch[1]; [1]Saarland University, Germany; [2]Donostia International Physics Center, Spain; [3]Centro de Fisica de Materiales (CSIC-UPV/EHU), Spain; [4]Universite Claude Bernard Lyon 1, France

Understanding how glasses form remains a challenge in material science. Vitrification is the thermal transition from a supercooled liquid in metastable equilibrium into a non-equilibrium glass. One of the major questions is whether vitrification in viscous liquids is related to sluggish atomic mobility exclusively *via* the primary structural α-relaxation process or rather other atomic motions play a role. Here, we present experimental evidences that multicomponent bulk metallic glasses can display heterogeneity of vitrification kinetics and that the cooling rate dependency of the vitrification kinetics is decoupled from the temperature dependence of the α-relaxation [1-3]. The evidences are based on exhaustive studies of the atomic mobility of an Au-based metallic glass former by dynamic mechanical analysis (DMA), x-ray photon correlation spectroscopy (XPCS), and fast scanning calorimetry (FSC); the latest by means of a step response analysis *via* the temperature and frequency dependence of the complex specific heat. The vitrification kinetics is characterized in FSC in terms of the limiting fictive temperature, i.e., the temperature at which a glass formed after cooling at a given rate would be at equilibrium. The separation of these two aspects of the glassy dynamics (vitrification kinetics and α-process) becomes more pronounced at larger undercooling, suggesting a larger contribution of additional dynamical processes to the vitrification process, which are not connected to the α-process. The observed heterogeneity of vitrification kinetics hints toward the existence of multiple relaxation mechanisms, which are observed during aging experiments [3].

Tracing Structural Dynamics in Metallic Glasses During Cryogenic Cycling Robert Maass[1,2]; [1]University of Illinois at Urbana-Champaign, United States; [2]Federal Institute for Materials Research and Testing (BAM), Germany

Highly unrelaxed structural states of metallic glasses have often advantageous mechanical properties. Since metallic glasses continuously relax with time (age) or inherently are well relaxed after processing, methods to uniformly rejuvenate the material are needed. One approach that has received attention is the so-called cryogenic-cycling method, during which a metallic glass is repeatedly immersed into liquid nitrogen. In some cases, cryogenic cycling is truly efficient in increasing the stored excess enthalpy of metallic glasses, but it does not seem to be universally applicable to all alloys and structural states. The origins for these differences remain unclear due to our limited understanding of the underlying structural evolution. In order to shed more light onto the fundamental structural processes of cryogenic cycling, we pursue in-situ x-ray photon correlation spectroscopy (XPCS) to trace the atomic-scale structural dynamics of a Zr-based metallic glass in two different structural states (ribbon and bulk metallic glass). This method allows calculating the relaxation times as a function of time throughout the thermal cycling. It is found that the investigated glasses exhibit heterogeneous structural dynamics at 300 K, which changes to monotonic aging at 78 K. Cryogenic cycling homogenizes the relaxation time distribution for both structural states. This effect is much more pronounced in the ribbon, which is the only structural state that rejuvenates upon cycling. We furthermore reveal how fast atomic-scale dynamics is correlated with long-time average structural relaxation times irrespective of the state, and that the ribbon exhibits unexpected additional fast atomic-scale relaxation in comparison to the plate material. Overall, a picture emerges that points towards heterogeneities in fictive temperature as a requirement for cryogenic energy storage.

12:30 PM *F.SF02.01.05
The Non-Equilibrium Origin of a Brittle-to-Ductile Transition in Metallic Glasses Eran Bouchbinder[1], Manish Vasoya[2,1], Christopher Rycroft[3], Jittisa Ketkaew[4] and Jan Schroers[4]; [1]Weizmann Institute of Science, Israel; [2]Texas A&M University, United States; [3]Harvard University, United States; [4]Yale University, United States

Understanding the fracture toughness of glasses is a fundamental problem of prime theoretical and practical importance. We develop a theory of the notch fracture toughness of glasses using a non-equilibrium thermodynamic approach to the elastoplastic deformation of glassy materials. We show that the notch fracture toughness results from a competition between the initial plastic relaxation timescale, which depends on initial non-equilibrium structural state of the glass (e.g. its age and its preparation protocol), and an effective loading timescale, which depends on the notch radius, the system's geometry and the external loading rate. The initial glass structure, which controls the initial plastic relaxation timescale, is characterized by a non-equilibrium (effective/fictive) temperature. The theory predicts a rather abrupt increase in the toughness – a brittle-to-ductile transition – as a function of the ratio between these two timescales. Novel experiments on various Bulk Metallic Glasses (BMGs), which allow to carefully controlling the initial structural state of the glass and accurately measure the toughness, verify the theoretical predictions. In particular, they show that BMGs can be significantly toughened by carefully controlling their initial non-equilibrium state. These results highlight the importance of timescales competition and far from steady-state plastic deformation dynamics for understanding the toughness of glasses, and open up the way for a broader usage of BMGs as tough, highly-reproducible structural materials.

Effects of Testing Temperature and Sample-Size on Tensile Deformation of Metallic Glass Golden Kumar and Chandra Sekhar Meduri; University of Texas at Dallas, United States

Deformation of nanoscale metallic glasses has attracted increasing attention but remains controversial due to difficulty in fabrication and testing of small samples. Here, we report the effects of systematic variation in sample-size and testing temperature. Pt-based metallic glass samples with varying diameters (100 nm -500 mm) were prepared by thermoplastic drawing. Multiple samples were deformed at different temperatures and the fracture morphologies were characterized using SEM. The results show that the fraction of vein-like morphology decreases with decreasing sample size and mirror-like fracture surface was observed in samples smaller than about 2 mm in diameter. With further decreasing diameter, transition from shear-localized to necking was observed and the extent of neck increased with decreasing sample diameter. The lowering in temperature had similar effect as decrease in sample diameter. This temperature-size equivalence is discussed in terms of temperature rise and formation of liquid-like layer in shear bands.

Concept of Defects in Glasses and Liquids Takeshi Egami[1,2]; [1]University of Tennessee, United States; [2]Oak Ridge National

Laboratory, United States

In crystals atomic mobility in transport and deformation is governed by structural defects, such as vacancies and dislocations. This was carried over to the study of glasses and liquids, and various defect-like concepts have been proposed, including free-volume, cooperatively rearranging region and shear-transformation-zone (STZ). However, whereas in crystals defects are topologically protected by the lattice and preserve their identity after motion, the same does not apply for liquid and glass. For this reason, today these defects in glass are considered to be transient; they do not pre-exist and disappear after the action. In this talk this view is advanced even further to suggest that the dynamics in liquid and glass is governed not by defects but by the structural medium-range order (MRO) of the bulk. The MRO is defined by the coherence length which characterizes the decay of the oscillation in the pair-distribution function (PDF) beyond the first peak. Because the higher-order peaks of the PDF are broad, ~ 1 Å in width, the MRO does not describe the order at the atomic level. It represents the strength of the coarse-grained density wave, represented by the first peak in the structure function, S(Q). We show that the coherence volume is proportional to the fragility coefficient, *m*, at the glass transition temperature, Tg, and also to the activation energy of viscosity above Tg. In crystal atoms are mobile only at defects of which density is low. But in liquid all atoms are mobile and participate in transport. Whereas the defect-like sites have a higher propensity to start deformation or atomic transport, as soon as deformation starts extensive atomic rearrangement ensues, and the structure of the final state is very different from the initial one. Furthermore, at the saddle point of transition the effective temperature becomes so high that the system locally melts for a short time, and the system locally loses its thermal history. Therefore, the mobility is not determined by the initial structure but by the resistance to local collective motion which is determined by the MRO. For this reason, the structural coherence, which is a bulk property in equilibrium, controls the dynamics in liquid and glass. Defects are relevant only as outliers in the equilibrium statistical distribution where action could start.

Multiscale Modeling of Plastic Flow and Failure in Amorphous Solids—The Role of Effective (Fictive) Temperature as a Measure of Disorder Michael L. Falk; Johns Hopkins University, United States

We have undertaken to develop multiscale models of plastic flow and failure processes in amorphous solids, materials that exhibit a complete lack of crystalline order. In this we have taken metallic glass as an exemplar material and applied molecular dynamics simulation to examine the physics at the atomic scale. This has allowed us to uncover the statistics of the shear transformation zone (STZ) defects that control plastic deformation. We have then sought to relate this defect structure to statistical mechanics models of "effective temperature" that characterize the degree of glass disorder in an effort to build a constitutive model of plastic deformation. The constitutive model has been incorporated into a high-fidelity viscoplastic finite differencing scheme that adapts techniques originally developed for solving the Navier-Stokes equation. A novel machine learning algorithm then utilizes the atomistic data to guide the parameterization of the constitutive model so as to inform the continuum method. In doing so we have begun to ask some fundamental questions about the concept of "effective temperature."
The concept of fictive-temperature has long been utilized to characterize the processing dependence of glass structure, and has recently been shown to be predictive of metallic glass ductility. Some theories have hypothesized that it is actually a real temperature related to the configurational degrees of freedom of the glass, i.e. an "effective-temperature," notably the shear-transformation-zone (STZ) and soft-glassy-rheology (SGR) theories. We derive a thermodynamic integration scheme for calculating effective-temperature based on a 2-temperature hypothesis. To test this scheme we simulate a binary Cu-Zr metallic glass modeled with an EAM potential. Measures of the energy fluctuations associated with both the fast and slow degrees of freedom are measured during the glass quench. The resulting effective-temperature is consistent with estimates of fictive-temperature obtained from simulation in more heuristic ways. The results indicate that effective-temperature can be understood as a purely structural quantity. The method provides a means to measure the effective-temperature in the absence of fluctuations induced by shear and without resorting computationally expensive and impractical methods for explicitly measuring the configurational entropy.

6:55 PM *F.SF02.02.04
Metallic Glass Stability and Surface Dynamics Sachin V. Muley[1], Debaditya Chatterjee[1], Carter Francis[1], Ajay Annamareddy[1], Chengrong Cao[1], Jittisa Ketkaew[2], Jan Schroers[2], John Perepezko[1], Dane Morgan[1] and Paul M. Voyles[1]; [1]University of Wisconsin, United States; [2]Yale University, United States

Metallic glasses can have widely varying thermodynamic and kinetic stability at constant composition depending on their processing history. For bulk glasses, fast quenching or post-synthesis deformation result in a high free energy, less stable states and slow quenching or post-synthesis sub-T_g annealing result in low free energy, more stable states.

For thin films and nanostructures, surfaces play a larger role. We have used electron correlation microscopy experiments and molecular dynamics simulations to show that metallic glass surfaces have approximately ten times faster dynamics than the bulk at the same temperature for temperatures near T_g. The fast surface layer has a glass transition temperature that is suppressed with respect to the bulk by ~20 K. We have extended the understanding of diffusion in supercooled liquids based on caging and hopping of atoms to surfaces to explain this behavior.

Enhanced surface dynamics enable deposition of highly stable thin films, since every atom at some point has been a surface atom and the surface layer maintains sufficient mobility for the atoms to find low-energy configurations even at temperatures well below the bulk T_g. We have deposited $Zr_{65}Cu_{27.5}Al_{7.5}$ metallic glass thin films with varying stability by varying the deposition rate at a substrate temperature of $0.7T_g$. The stability of the films is demonstrated by calorimetry and creates changes in films' modulus and hardness. We show using electron nanodiffraction that more stable films have greater nanometer-scale structural order, demonstrated by an increase in Friedel speckle pairs associated with Bragg diffraction from ordered structures. Analysis of rotational symmetries in nanodiffraction patterns show that the order is dominated by icosahedra, but that crystal-like rotational symmetries are also present. The ability to create glasses with widely varying stability at constant composition enables disentangling the influence of atomic rearrangements created by processing and changes in chemistry.

Additive Manufacturing and Deposition of Bulk Glass Forming Alloys and Composites—Progress and Outlook Douglas C. Hofmann[1], Punnathat Bordeenithikasem[1], Samad Firdosy[1], Andre Pate[1] and Daniel East[2]; [1]NASA JPL/Caltech, United States; [2]Commonwealth Scientific and Industrial Research Organisation, Australia

Additive manufacturing (AM) has emerged as a unique method for producing highly specialized metal alloys and composites. The high cooling rates and customizable cooling rates afforded by AM are particularly useful in the creation of bulk metallic glasses (BMGs) and BMG metal matrix composites. While AM allows for net-shaped fabrication of even the weakest glass-forming alloys, macroscale parts still suffer from embrittlement due to annealing, porosity, partial crystallization and oxygen. In contrast, thin coatings and overlays made from BMGs and BMG composites may be ideal for some wear-resistant applications. This talk will provide an overview of how BMG printing and deposition technologies might be matured and infused into applications. It will cover Fe-based, Zr-based, Cu-based, and Ti-based BMG alloys.

7:35 PM BREAK

7:50 PM *F.SF02.05.01
Syntheses and Features of Pseudo-High Entropy Bulk Metallic Glasses Akihisa Inoue[1,2,3], Fanli Kong[2], Baolong Shen[1], Shengli Zhu[3] and Alan Lindsay Greer[4]; [1]China University of Mining and Technology, China; [2]Josai International University, Japan; [3]Tianjin University, China; [4]University of Cambridge, United Kingdom

Since the first synthesis of a bulk metallic glass (BMG) by copper mold casting in 1989, a large number of BMGs with centimeter-size diameter were synthesized in a variety of multicomponent alloy systems such as La, Mg, Zr, Ti, Hf, Fe, Co, Ni, Cu, Pd, Pt and Au metal bases. These BMGs are composed of multicomponent with negative and nearly zero heats of mixing and significant atomic size mismatches, while there has been little information on the influence of additional metallic elements with positive heat of mixing on the formation, thermal stability, crystallization behavior and fundamental properties for BMGs. Very recently, the pseudo-high entropy (PHE) BMGs containing solute atomic pairs with positive heats of mixing, which are different from the component rule for ordinary BMGs, have attracted an increasing interest because of their unique properties[1)]. In particular, the PHE BMGs exhibit two exothermic peaks on the continuously heating DSC curve

and the temperature interval between the two peaks is as large as 200-400 K. Besides, no crystalline phase is observed even after annealing for 1-5 h at the temperatures well above the first exothermic peak. The unusual high stability to the progress in crystallization has been reported for various PHE BMGs such as Zr-Al-(Ni,Cu)-Nb, Zr-Al-(Ni,Cu)-Ag, Zr-Al-(Co,Cu)-Ag, Zr-(Fe,Co,Ni,Cu), Ti-Zr-(Cu,Pd)-Nb and Fe-Cr-Mo-C-B-Y systems. These results indicate the possibility of developing a heat resistant BMG by utilizing this novel phenomenon. Here we present the formation, thermal stability, crystallization behavior and mechanical properties of PHE BMGs and to investigate the criterion for the synthesis of BMGs with ultrahigh thermal stability.

8:10 PM *F.SF02.04.01
The Controlled Large-Area Synthesis of Freestanding Two-Dimensional Metallic-Glass Nanosheets/Nanostructures Yong Yang; City University of Hong Kong, China

The rise of nanotechnology has been propelled by low dimensional metals. Albeit the long-perceived importance, synthesis of freestanding metallic nanomembranes (or the so-called 2D metals), however, has been mainly restricted to elemental metals with a very limited in-plane size (< 10 μm). In this talk, I would like to talk about the development of a low-cost method to synthesize 2D metals through polymer surface buckling enabled exfoliation (PSBEE). The 2D metals so obtained could be as chemically complex as conventional metallic glasses while possessing in-plane dimensions at the scale of bulk metals (> 1 cm). With our approach, we successfully synthesized a variety of 2D metallic glasses with controllable geometries and morphologies. Interestingly, our results clearly show that, as the thickness of the 2D metallic glasses reduces to a few nanometers, its modulus is significantly reduced to only a fraction of the modulus of their bulk counterparts. Aside from rather low elastic modulus, these 2D metallic glasses also exhibit unusual properties, such as good stretchability and tunable optical properties. Finally, we demonstrate that 2D ceramic glasses and 2D metallic composites can be also fabricated through PSBEE aside from 2D metallic glasses.

Multiscale Modeling of Plastic Flow and Failure in Amorphous Solids—The Role of Effective (Fictive) Temperature as a Measure of Disorder Michael L. Falk; Johns Hopkins University, United States

We have undertaken to develop multiscale models of plastic flow and failure processes in amorphous solids, materials that exhibit a complete lack of crystalline order. In this we have taken metallic glass as an exemplar material and applied molecular dynamics simulation to examine the physics at the atomic scale. This has allowed us to uncover the statistics of the shear transformation zone (STZ) defects that control plastic deformation. We have then sought to relate this defect structure to statistical mechanics models of “effective temperature” that characterize the degree of glass disorder in an effort to build a constitutive model of plastic deformation. The constitutive model has been incorporated into a high-fidelity viscoplastic finite differencing scheme that adapts techniques originally developed for solving the Navier-Stokes equation. A novel machine learning algorithm then utilizes the atomistic data to guide the parameterization of the constitutive model so as to inform the continuum method. In doing so we have begun to ask some fundamental questions about the concept of “effective temperature.”
The concept of fictive-temperature has long been utilized to characterize the processing dependence of glass structure, and has recently been shown to be predictive of metallic glass ductility. Some theories have hypothesized that it is actually a real temperature related to the configurational degrees of freedom of the glass, i.e. an “effective-temperature,” notably the shear-transformation-zone (STZ) and soft-glassy-rheology (SGR) theories. We derive a thermodynamic integration scheme for calculating effective-temperature based on a 2-temperature hypothesis. To test this scheme we simulate a binary Cu-Zr metallic glass modeled with an EAM potential. Measures of the energy fluctuations associated with both the fast and slow degrees of freedom are measured during the glass quench. The resulting effective-temperature is consistent with estimates of fictive-temperature obtained from simulation in more heuristic ways. The results indicate that effective-temperature can be understood as a purely structural quantity. The method provides a means to measure the effective-temperature in the absence

of fluctuations induced by shear and without resorting computationally expensive and impractical methods for explicitly measuring the configurational entropy.

Concept of Defects in Glasses and Liquids Takeshi Egami[1,2]; [1]University of Tennessee, United States; [2]Oak Ridge National Laboratory, United States

In crystals atomic mobility in transport and deformation is governed by structural defects, such as vacancies and dislocations. This was carried over to the study of glasses and liquids, and various defect-like concepts have been proposed, including free-volume, cooperatively rearranging region and shear-transformation-zone (STZ). However, whereas in crystals defects are topologically protected by the lattice and preserve their identity after motion, the same does not apply for liquid and glass. For this reason, today these defects in glass are considered to be transient; they do not pre-exist and disappear after the action. In this talk this view is advanced even further to suggest that the dynamics in liquid and glass is governed not by defects but by the structural medium-range order (MRO) of the bulk. The MRO is defined by the coherence length which characterizes the decay of the oscillation in the pair-distribution function (PDF) beyond the first peak. Because the higher-order peaks of the PDF are broad, ~ 1 Å in width, the MRO does not describe the order at the atomic level. It represents the strength of the coarse-grained density wave, represented by the first peak in the structure function, S(Q). We show that the coherence volume is proportional to the fragility coefficient, *m*, at the glass transition temperature, Tg, and also to the activation energy of viscosity above Tg. In crystal atoms are mobile only at defects of which density is low. But in liquid all atoms are mobile and participate in transport. Whereas the defect-like sites have a higher propensity to start deformation or atomic transport, as soon as deformation starts extensive atomic rearrangement ensues, and the structure of the final state is very different from the initial one. Furthermore, at the saddle point of transition the effective temperature becomes so high that the system locally melts for a short time, and the system locally loses its thermal history. Therefore, the mobility is not determined by the initial structure but by the resistance to local collective motion which is determined by the MRO. For this reason, the structural coherence, which is a bulk property in equilibrium, controls the dynamics in liquid and glass. Defects are relevant only as outliers in the equilibrium statistical distribution where action could start.

The Energy Landscape Governs Ductility in Bulk Metallic Glasses Longwen Tang and Mathieu Bauchy; University of California, Los Angeles, United States

Depending on their thermal history, bulk metallic glasses can fail in a brittle or ductile fashion. However, the nature of the link between structure and propensity for ductility has remained elusive. Here, based on molecular dynamics simulations, we investigate how the degree of structural disorder affects the fracture of bulk metallic glasses. As expected, we observe that structural disorder results in an increase in ductility. By applying the activation-relaxation technique (an open-ended saddle point search algorithm), we demonstrate that the propensity for ductility is controlled by the topography of the energy landscape. Interestingly, we observe a power-law relationship between the particle non-affine displacement upon fracture and the average local energy barrier. This reveals that the dynamics of the atoms upon fracture is encoded in the static energy landscape, i.e., before any load is applied. Besides bulk metallic glasses, this relationship is shown to apply to several classes of non-crystalline materials (oxide glasses, amorphous solids, and colloidal gels), which suggests that it may be a generic feature of disordered materials.

Structural Relaxation and Mechanical Properties of Model Glass Systems at the Micro-Second Timescale Peter M. Derlet[1] and Robert Maass[2]; [1]Paul Scherrer Institute, Switzerland; [2]University of Illinois at Urbana-Champaign, United States

It is now possible to routinely perform atomistic simulations at the microsecond timescale. In the present work, we exploit this for a model binary Lennard-Jones glass to study structural relaxation at a timescale spanning several tens of microseconds, and the collective plastic shear activity under simple shear spanning six orders of magnitude strain rate. It is found that at these longer time-scales, significant mobility and relaxation occurs. Under load, such structural activity during collective and system-spanning plasticity plays an important role, producing a rich spectrum of atomic-scale activity in terms of spatial and temporal correlation, both in the elastic and plastic regimes of deformation.

6:30 AM *F.SF02.01.05
The Non-Equilibrium Origin of a Brittle-to-Ductile Transition in Metallic Glasses Eran Bouchbinder[1], Manish Vasoya[2,1], Christopher Rycroft[3], Jittisa Ketkaew[4] and Jan Schroers[4]; [1]Weizmann Institute of Science, Israel; [2]Texas A&M University, United States; [3]Harvard University, United States; [4]Yale University, United States

Understanding the fracture toughness of glasses is a fundamental problem of prime theoretical and practical importance. We develop a theory of the notch fracture toughness of glasses using a non-equilibrium thermodynamic approach to the elastoplastic deformation of glassy materials. We show that the notch fracture toughness results from a competition between the initial plastic relaxation timescale, which depends on initial non-equilibrium structural state of the glass (e.g. its age and its preparation protocol), and an effective loading timescale, which depends on the notch radius, the system's geometry and the external loading rate. The initial glass structure, which controls the initial plastic relaxation timescale, is characterized by a non-equilibrium (effective/fictive) temperature. The theory predicts a rather abrupt increase in the toughness – a brittle-to-ductile transition – as a function of the ratio between these two timescales. Novel experiments on various Bulk Metallic Glasses (BMGs), which allow to carefully controlling the initial structural state of the glass and accurately measure the toughness, verify the theoretical predictions. In particular, they show that BMGs can be significantly toughened by carefully controlling their initial non-equilibrium state. These results highlight the importance of timescales competition and far from steady-state plastic deformation dynamics for understanding the toughness of glasses, and open up the way for a broader usage of BMGs as tough, highly-reproducible structural materials.

Towards a Better Atomistic Understanding of Deformation and Relaxation Mechanisms in Metallic Glasses Daniel Sopu[1,2] and Jurgen H. Eckert[1,3]; [1]Erich Schmid Institute, Austria; [2]Technical University of Darmstadt, Germany; [3]Montanuniversität Leoben, Austria

Over time, a variety of environmental descriptors have been proposed to indentify and characterize the atomic scale heterogeneities and to guide us towards an inherent structure-property relationship for metallic glasses. By using the STZ-vortex coupling the atomic-level mechanisms underlying elastic and plastic deformation in metallic glasses are disclosed. Removing the thermal noise by simulating athermal quasistatic shearing processes even small elastic/structural fluctuations can be identified and analysed. Given to complex morphology and a long range signature of STZs the activation of low number of events could strongly perturb the initial configuration and explain the observed weak correlations between structure and dynamics. The rotation field calculation reveals that elastic and plastic STZs have similar signature but different dynamics. Additionally, the observed deformation mechanisms have significant implications for understanding relaxation phenomena in amorphous metals and allow distinguishing between the different relaxation mechanisms. These results highlight that the classical definition of STZ should be reconsidered and a full understanding of this elementary event must be assured as they play a decisive role in controlling plasticity in metallic glasses

Machine Learning for the Analysis of Deformation Experiments on Colloidal Glasses Agnese Curatolo[1], Seong Ho Pahng[1], Katharine E. Jensen[2], Michael P. Brenner[1], David Weitz[1] and Frans Spaepen[1]; [1]Harvard University, United States; [2]Williams College, United States

Plastic deformation of glasses is governed by local shear transformation zones (STZs). We need to know their concentration, their size, their transformation rate, how they nucleate, whether they are reversible or not, and if there are correlations between them. STZs can be studied by deforming colloidal glasses and tracking the particles in space and time. As modeling systems, colloidal glasses have the advantage of being dynamic, three-dimensional and large (>50,000 particles). The data in this study were obtained during cyclic deformation in pure shear up at 10^{-5} s^{-1} between 0 and 10%. To study how the dynamics and properties of the STZs are related to the evolution of the glassy structure, we have employed three machine learning techniques: Support Vector Machines (SVM), Convolutional Neural Networks (CNN) and Graph Neural Networks (GNN). We will discuss how these methods can be applied to experimental data with physical boundary conditions. We use them to predict the evolution of local strain, which particles are most likely to move, and which particles undergo irreversible rearrangements. The results of the three methods for each of these tasks will be compared.

7:30 AM F.SF02.01.09
Effective Quantification of Liquid Structure in Metallic Alloys and Its Relation to Glass-Forming Ability Porter Weeks and Katharine Flores; Washington University in St. Louis, United States

Recent research[1-3] has proposed that structural order present in the liquid is related to glass-forming ability in metallic alloys suggesting that high order in the metallic liquid makes crystallization easier due to the lack of atomic motion needed for this process to occur in comparison to a liquid with little order in the liquid. However, the effective quantification of this liquid structure is extremely challenging due to the inherent long-range disorder present. While Voronoi tessellation is a common method for describing the short-range order of disordered systems, there are many drawbacks to this technique. Namely,

Voronoi indices describe the topology of the polyhedral volume associated with a particular atom, but provide little insight into the relative similarity of the various polyhedra that make up the material. That is, a minor distortion in atomic positions may result in vastly different Voronoi indices without dramatically impacting the local environment of an atom or the overall degree of ordering in the system. A more rigorous approach would ask if local environments are *similar enough* to be considered the same. Here, we show that a density-based machine learning approach (HDBSCAN) provides such characterization of structure in the liquid. Out of this method emerge groups of atoms with similar atomic arrangements. The relative degree of order is described by the variance in the group sizes; a low variance indicates that most atoms belong to a small number of groups, implying a high degree of order. To demonstrate the effectiveness of this approach, we analyze the structures of simulated Cu-Zr and Al-Sm alloys to show that this variance is inversely correlated to experimentally observed glass-forming ability. This work has the potential to fundamentally change our understanding of glass formation. While the historical approach to glass formation is to consider the competition between the thermodynamic driver and the kinetic mobility of atoms within the super-cooled liquid, this data suggests that the ease of glass formation in a given material is predetermined in the liquid state, before ever reaching the melting point or the glass transition temperature.

Late News: Predicting Plastic Events via the Local Yield Stress Method in 3D Model Glasses Dihui Ruan[1], Sylvain Patinet[2] and Michael L. Falk[1]; [1]Johns Hopkins University, United States; [2]ESPCI, France

Within the context of the 'shear transformation zone' model, the local yield stress (LYS) method provides a straightforward assessment of the local elastoplastic response for the sake of identifying shear transformation zone defects in amorphous materials. Here, for the first time in 3D, we study as-quenched binary Lennard-Jones glasses using the LYS method. We first systematically vary the size of the LYS probing region. At an optimal LYS probing region size ~5 atomic diameters in radius, high correlations are confirmed between the incremental stress required to trigger the local plasticity (i.e., the local yield stress) and the locations of the plastic events. When local probing is limited to align with the loading applied at the boundary, the averaged correlations remain positive until 1/3 of the yielding strain (200 plastic events). At the location of the first plastic event, the anisotropy of the local yield surface is systematically investigated by varying a unit strain tensor which determines the orientation and triaxiality of the local probing. The results indicate that the lowest local yield stress is not necessary to align with the loading on the boundary, but can be inferred by projecting the stress applied on the boundary onto the local yield surface. Thus, the predictivity of the local yield stress method for locating the plastic events may be enhanced by more completely sampling the local yield surface at each local probing region.

Atomic-Resolution Observation of Crystal Growth in Metallic Glass Nanorods Yujun Xie[1,2,3], Sungwoo Sohn[1], Jan Schroers[1] and Judy Cha[1]; [1]Yale University, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]University of California, Berkeley, United States

Crystallization induced microstructure plays a central role in tailoring materials properties, yet our understanding of its formation process is limited due to its complexity. Classical crystallization theories assume that nucleation and growth are separate processes in which thermodynamically unstable clusters fluctuate in the nucleation stage, but do not participate in the later growth. Here, we apply in situ aberration-corrected transmission electron microscopy (TEM) technique to directly observe the crystal growth of metallic glass nanorods at the atomic resolution and test the classical theories. Surprisingly, we

show that, at the atomic scale, the isothermal growth rate for a single crystalline phase is asymmetric upon thermal history. This observation is in direct contrast to what would be expected based on classical theories. We further observe that the asymmetric growth rate depends on the diameter of the nanorod. Thus, our in situ TEM observations mark departure from classical theories in metallic glass system[1,2,3].

***In Situ* Heating TEM Study on Structural Evolution of Metallic Glasses** Yuan Tian and Mingwei Chen; Johns Hopkins University, United States

Metastable metallic glasses experience significant structural evolution and phase transition in supercooled liquid regions at high temperatures. In this research, we employed a MEMS based ultra-stable heating stage to *in situ* investigate the coalescence and crystallization of metallic glasses in a Cs-corrected high-resolution transmission electron microscope. The atomic-scale *in situ* observations reveal the significant kinetic difference between crystals and glasses in particle coalescence, demonstrating that the fast surface dynamics of metallic glasses is associated with the isotropic atomic structure and supercooling state. On the other hand, the kinetics-controlled crystallization process at temperatures close to T_g is found to be manipulated by both liquid diffusivity and chemical defects at liquid/crystal interfaces. These results provide new insights into the relation between structural stability and surface/interface dynamics of metallic glasses.

5:20 AM *F.SF02.02.04
Metallic Glass Stability and Surface Dynamics Sachin V. Muley[1], Debaditya Chatterjee[1], Carter Francis[1], Ajay Annamareddy[1], Chengrong Cao[1], Jittisa Ketkaew[2], Jan Schroers[2], John Perepezko[1], Dane Morgan[1] and Paul M. Voyles[1]; [1]University of Wisconsin, United States; [2]Yale University, United States

Metallic glasses can have widely varying thermodynamic and kinetic stability at constant composition depending on their processing history. For bulk glasses, fast quenching or post-synthesis deformation result in a high free energy, less stable states and slow quenching or post-synthesis sub-T_g annealing result in low free energy, more stable states.

For thin films and nanostructures, surfaces play a larger role. We have used electron correlation microscopy experiments and molecular dynamics simulations to show that metallic glass surfaces have approximately ten times faster dynamics than the bulk at the same temperature for temperatures near T_g. The fast surface layer has a glass transition temperature that is suppressed with respect to the bulk by ~20 K. We have extended the understanding of diffusion in supercooled liquids based on caging and hopping of atoms to surfaces to explain this behavior.

Enhanced surface dynamics enable deposition of highly stable thin films, since every atom at some point has been a surface atom and the surface layer maintains sufficient mobility for the atoms to find low-energy configurations even at temperatures well below the bulk T_g. We have deposited $Zr_{65}Cu_{27.5}Al_{7.5}$ metallic glass thin films with varying stability by varying the deposition rate at a substrate temperature of $0.7T_g$. The stability of the films is demonstrated by calorimetry and creates changes in films' modulus and hardness. We show using electron nanodiffraction that more stable films have greater nanometer-scale structural order, demonstrated by an increase in Friedel speckle pairs associated with Bragg diffraction from ordered structures. Analysis of rotational symmetries in nanodiffraction patterns show that the order is dominated by icosahedra, but that crystal-like rotational symmetries are also present. The ability to create glasses with widely varying stability at constant composition enables disentangling the influence of atomic rearrangements created by processing and changes in chemistry.

5:35 AM F.SF02.02.05

Electron Correlation Microscopy Measurements of Metallic Glass Surface Dynamics Debaditya Chatterjee[1], Ajay Annamareddy[1], Jittisa Ketkaew[2,3], Jan Schroers[3], Dane Morgan[1] and Paul M. Voyles[1]; [1]University of Wisconsin–Madison, United States; [2]Supercool Metals, United States; [3]Yale University, United States

We have applied electron correlation microscopy (ECM) to study near-surface layer dynamics in metallic glass forming liquids as a function of temperature using *in situ* heating. Previous ECM studies showed that the near-surface layer relaxation dynamics in $Pt_{57.5}Cu_{14.7}Ni_{5.3}P_{22.5}$ metallic glass nanowires are an order of magnitude faster than bulk dynamics at the same temperature [1]. We have performed ECM experiments with higher spatial resolution and at temperatures lower than the bulk glass transition temperature, where the surface layer dynamics are still active but the bulk is vitrified. Our investigations reveal a ~1 nm layer with faster dynamics near the surface of the nanowire, which has a glass transition temperature 20 K lower than the bulk. Coating the nanowire with a thin layer of amorphous carbon suppresses the fast near-surface layer, which indicates that access to free volume available at the surface is responsible for the enhanced mobility.

Parallel investigations were performed via molecular dynamics simulations on a $Ni_{80}P_{20}$ system. Simulated $Ni_{80}P_{20}$ has a ~1 nm thick surface layer with faster dynamics and a glass transition temperature suppressed by 40 K compared to the bulk. With the surface layer held immobile in the simulation, the near-surface layer dynamics become slower than the bulk, but speed up with distance away from the surface, converging to the bulk dynamics. Based on these observations, we will briefly present a mechanism of diffusion in supercooled liquids based on caging and hopping of atoms, and how caging barriers control atomic diffusion and relaxation phenomena even in the near-surface region.

Effects of Minor Alloying on Stability and Mechanical Properties of Al-Based Metallic Glasses Izabela Szlufarska, Vrishank Jambur, Jianqi Xi, Chaiyapat Tangpatjaroen, George Bokas, Dane Morgan and John Perepezko; University of Wisconsin, United States

While minor alloying is used extensively to manipulate stability and mechanical properties of metallic glasses (MGs), a mechanistic understanding of these effects is still lacking, limiting rational design of new MGs. In crystalline metals, alloying elements can, for instance, pin dislocations and thereby have a large effect on the overall mechanical response, but MGs do not have a long-range order and they do not exhibit dislocation plasticity. It is therefore puzzling how a small amount of impurities can lead to significant changes in mechanical properties of an amorphous material. To understand the role of minor alloying on stability and mechanical properties of MGs, we have investigated Al-Sm glasses microalloyed with transition metal (TM) elements. Al-based glasses were chosen because of the many excellent properties of these materials, such as light weight, high specific strength, good corrosion resistance, and thermoplastic forming ability.

We have found experimentally that TMs increase both the glass forming ability (GFA) and the strength of Al-Sm-TM glasses, and we have used atomistic simulations to discover the underlying mechanisms for these effects. First, we have found that in the binary Al-Sm glasses, the experimentally determined GFA (quantified based on the critical cooling rate) is correlated with a local topology determined from classical molecular dynamics (MD) simulations. Specifically, the GFA was found to be higher for glasses that have a higher fraction of icosahedral clusters. We have then used this topological descriptor combined with *ab initio* MD simulations to predict ternary Al-Sm-TM glasses with high GFA. The predictions were then verified experimentally. This result shows that, similarly to what has been reported in commonly studied Cu-Zr MGs, the topology plays a dominant role in determining stability of Al-Sm MGs. The results also demonstrate that *ab initio* simulations can be used directly to design new glass compositions with high GFA.

Interestingly, we have found the topology to be correlated with mechanical strength of binary Al-Sm glasses, but not with the strength of Al-Sm-TM glasses. A commonly accepted explanation for the strengthening of MGs with minor alloying is based on the impurity-induced increase in the topological order and a more efficient packing of atoms. It has been confirmed to be

the case for instance in Cu-Zr glasses and by us in Al-Sm binary glasses. However, in the case of Al-Sm-TM, we discovered that a small amount of impurities can increase the strength of MGs by changing the chemical bond strength alone. In fact, we find that the favorable changes in the chemical bond strength overcome the effect of impurity-induced unfavorable changes in the topological order.

Our results are important for design of new MGs, as they demonstrate that the effect of bond chemistry and the effect of topology should be separated from each other and they could potentially compete with each other in controlling mechanical response of MGs. These results also highlight the importance of investigating structure-property relations in a number of different MGs, beyond the Cu-Zr model system, in order to extract generally applicable trends.

5:15 AM *F.SF02.03.02
Coupling Between MRO Structure and Local Plasticity of Metallic Glasses Gerhard H. Wilde; University of Muenster, Germany

Plastic deformation of metallic glasses is usually carried by local plastic instabilities, eventually leading to shear banding that is coupled to work softening. As a result, metallic glasses often show macroscopically brittle behaviour, thus limiting practical applications. This short description already signifies that plastic deformation of metallic glasses inherently involves vastly different length scales from the scale of locally ordered regions (so-called medium range order, MRO) to the macroscopic and system-spanning dimensions of shear bands. In this contribution, emphasis is laid on the local MRO structure of metallic glasses and specifically its modifications upon applying an external shear stress.
For this reason, the MRO structure of both as-cast and deformed states of different metallic glasses were analysed using variable resolution fluctuation electron microscopy. After deformation, significant changes of the MRO structure were observed inside the shear bands and also inside the adjacent matrix; the MRO structure was altered in terms of types, sizes and volume fractions. The changes in the matrix upon deformation confirm the existence of a shear affected zone around shear bands.
To understand the coupling between medium range order structure and local deformation behaviour further, sputtered nanolaminates of a binary metallic glass, $Cu_{40}Zr_{60}$, and nanocrystalline Cu were synthesized and subsequently co-deformed. The nanolaminates deform in shear zones, including nanocrystalline Cu layers, amorphous layers and the surrounding matrix. Due to the confinement of the glass, large plastic strains can be realized without premature macroscopic failure, allowing to assess deformation states in one sample that have carried between several ten percent and up to several hundred percent of strain. Analyses of nanobeam-diffraction patterns reveal an extraordinary modification of the MRO structure of amorphous $Cu_{40}Zr_{60}$ after deformation. This transformation shows similarities to a reverse martensitic transformation in the corresponding crystal from the B19 to the B2 structure, as shown by fluctuation electron microscopy and a symmetry analysis of nanobeam-diffraction patterns. Since the local ordered domain size surprisingly stays similar, this phenomenon is attributed to transformation-induced plasticity of the local units in the glass that carry the shear.
The current work illustrates the significance of the MRO structure for the deformation of metallic glasses and further suggests that the plasticity of monolithic BMGs might be improved by tailoring the topological order based on MRO types, sizes and volume fractions.

Structure of Shear Bands in a Zr-Based Bulk Metallic Glass Chaoyang Liu[1] and Robert Maass[1,2]; [1]University of Illinois at Urbana-Champaign, United States; [2]Federal Institute for Materials Research and Testing (BAM), Germany

Damage accumulation as a function of plastic strain is well understood in crystalline metals but not in metallic glasses, where strain localizes into nano-scale shear bands. Here we aim at revealing how the nanoscale and mesocopic signature of strain localization evolves during deformation. Using high-energy x-ray tomography, we first address how the gradual emergence of shear-band cavities leads to a large reduction in the load bearing area as a function of strain (Scripta Materialia 170 (2019) 29). Determining the true flow stress on the basis of the tomography data indicates significantly larger stresses than the yield stress of the material. This apparent strain hardening can be rationalized by taking into account the shear-plane roughness and its contribution to the friction condition between the two shearing sample parts. As a second step, we pay attention to the shear band itself with the interest in tracing any structural or chemical changes as a function of shear strain. To this end, we use a combination of high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM,), synchrotron-based nano-beam x-ray fluorescence, atom probe tomography (APT), scanning electron nano-beam diffraction (SEND) and energy-dispersive x-ray spectroscopy (EDS). Apparent chemical changes in the shear band are found that can be shown to be due to the density change of the shear band relative to the matrix (Scripta Materialia 169 (2019) 23). We further discuss if the shear-band width and density change are related and how the depend on position (Acta Materialia 140 (2017) 206). Finally, we provide first evidence for that the locally admitted shear strain determines the locally determined density

change of the shear-band material. This body of work highlights the locallay varying complexity of shear-band structure in bulk metallic glasses.

5:40 AM F.SF02.03.04
Revealing the Role of Cluster Connectivity in Plastic Deformation of Pd-Si Metallic Glasses Sinan Liu[1], Jiacheng Ge[1], Xun-Li Wang[2], Yang Ren[3] and Si Lan[1]; [1]Nanjing University of Science and Technology, China; [2]City University of Hong Kong, China; [3]Argonne National Laboratory, United States

It would be interesting to study the atomic-scale structure response to deformation for better understanding the structure-property relationship for metallic glasses. The atomic-scale structure evolution during plastic deformation of $Pd_{82}Si_{18}$ metallic glasses was studied using the high-energy X-ray pair-distribution function. Our experimental results revealed that the change of the cluster connectivity on the medium-range length scale plays an essential role during plastic deformation. It was found that the transformation between 2-atom and 3-atom connection modes would be responsible for the densification process during tension. Our findings would be helpful in deepening the understanding of the plastic deformation mechanism of metallic glasses.

5:50 AM *F.SF02.03.05
Atomic-Scale Details of Structural Relaxation, Rejuvenation and Plasticity of Metallic Glasses from Anelastic Deformation Michael Atzmon[1], Tianjiao Lei[1], Luis Rangel DaCosta[1], Jie Shen[2], Ming Liu[2], Alan Lindsay Greer[3], Yonghao Sun[2] and Wei Hua Wang[2]; [1]University of Michigan, United States; [2]Institute of Physics, Chinese Academy of Sciences, China; [3]University of Cambridge, United Kingdom

Current understanding of plastic deformation of crystalline solids has benefitted greatly from electron-microscopic imaging of lattice defects. In the absence of periodicity, atomic-scale imaging of glasses is far more limited. However, similar to crystalline materials, physical analogs have provided important initial insights. Bubble-raft experiments by Argon et al. indicated that time-dependent deformation of a glass, permanent or reversible, is accommodated by localized rearrangements, termed shear transformations. Using Eshelby's theory of deformation of inclusions embedded in an elastic medium, Argon developed a theory of thermally activated, stress-biased, shear transformation kinetics. It is based on a single size of a shear transformation zone (STZ). Since the activation free energy for a shear transformation is proportional to the STZ volume, the spread in time constants associated with different STZ sizes can be significant. Dynamic-mechanical analysis results have, indeed, demonstrated a range of time constants. However, with the loss modulus peak associated with a single time constant being a Cauchy function, details cannot be readily resolved.
We have used quasi-static anelastic relaxation measurements spanning more than ten orders of magnitude of time, 10^{-3} – $6x10^{7}$ s. Non-instrumented curvature measurements at stable room temperature, with automated curvature determination from images, provide relaxation curves with small error bars. The inverse problem of obtaining relaxation-time spectra from the seemingly featureless experimental curves was solved computationally. The spectra exhibited distinct peaks, which we showed to correspond to an atomically-quantized hierarchy of STZs. The resolution level achieved is assisted by the relatively low temperature of the experiment. Using Argon's theory, the spectra yield the volume of each STZ type as well as the volume fraction occupied by the corresponding potential STZs.
We have used the methodology detailed above to obtain the following results:
1) At small radii of curvature, for which the strain is large and the anelastic strain rate is not linear in the stress, we obtained the transformation shear strain and volume of the largest STZs independently. The value of the former is 0.18, in agreement with physical analogs. This result indicates that reports of STZ volume values of hundreds of atoms are unrealistically high, as they were based on a transformation strain value equal to the much-smaller macroscopic yield strain.
2) Structural relaxation increases each of the time constants and reduces the volume fraction occupied by the largest active potential STZs. The former effect is a result of an increase in shear modulus. Rejuvenation by cryogenic cycling reverses the increase in time constants, suggesting a reversal of densification. However, the volume fraction occupied by the largest active potential STZs is not restored.
3) Some metallic glasses exhibit a distinct high-frequency β relaxation. While it has been suggested to correspond to a mechanism distinct from that of the α relaxation, we find that both α and β are consistent with the STZ model. However, they exhibit different properties – either the STZ volume increment in the hierarchy or the corresponding shear modulus is different for the two mechanical relaxation modes. Both possibilities are consistent with composition fluctuations.
4) While it has been suggested that an intense β relaxation correlates with alloy plasticity, a comparison between $La_{70}Cu_{15}Al_{15}$ and $La_{70}Ni_{15}Al_{15}$ shows the opposite – the former exhibits far greater plasticity and its β relaxation intensity is smaller. We find that the overall anelastic response, which is equal to the integrated area of the relaxation-time spectrum, can be used as a predictor of plasticity.

Tailoring Shear Banding in Bulk Metallic Glasses and Composites Jurgen H. Eckert[1,2]; [1]Erich Schmid Institute of Materials Science, Austrian Academy of Sciences, Austria; [2]Montanuniversitaet Leoben, Austria

Shear banding is the main mechanism dominating plastic deformation of bulk metallic glasses (BMGs). Under constrained loading conditions, such as bending or compression, BMGs generally deform through serrated flow at room temperature. A serration event is accomplished by fast nucleation and propagation, together with the arrest of a shear band. A shear band forms by cooperative shear of nanometer-size shear transformation zones (STZ), developing into a highly localized deformation band with a thickness of ~10 nm. The dynamics of serrated flow in BMGs have been intensively studied, and the cumulative distribution of shear-avalanche sizes follows a universal power-law relation multiplied by an exponentially decaying scaling function as depicted by the mean-field theory. In contrast, under uniaxial tension, BMGs exhibit almost zero plasticity due to the fast runaway of a detrimental shear band.
In order to improve the tensile plasticity of BMGs, bulk metallic glass composites (BMGCs) containing *in-situ* formed crystals during solidification have been developed. Zr/Ti-based BMGCs containing beta-Zr/Ti phases and CuZr-based BMGCs containing B2 CuZr phases are the two most intensively investigated kinds of BMGCs. Generally, macroscopic serrated flow of BMGCs under tension disappears, because the shear bands are well restricted in the inter-crystalline glassy regions. BMGCs often exhibit strain-softening, because hardening caused by dislocation entanglement in the crystals cannot sufficiently compensate shear-softening in the glassy matrix. Recent research has shown that this drawback can be overcome and strain-hardening can be obtained *via* incorporating deformation-induced phase transformations or twinning of metastable crystals.
This talk explores the possibilities for tuning shear band initiation and propagation in metallic glasses and composites considering structural heterogeneity, phase transformation and size effects for glasses and composites with different composition and inherent stability. The findings will be discussed with respect to short- and medium-range order modulation, local stress and strain states, and their impact on shear band nucleation, bifurcation, blunting and modulation of cooperative shear events in the presence of crystals or triggered by the precipitation of secondary phases. The structure changes will be correlated with plastic deformability and strain-hardening capacity, and the effectiveness of composition tuning and structure modulation for ductility improvement will be discussed to derive guidelines for property optimization.

Effects of Testing Temperature and Sample-Size on Tensile Deformation of Metallic Glass Golden Kumar and Chandra Sekhar Meduri; University of Texas at Dallas, United States

Deformation of nanoscale metallic glasses has attracted increasing attention but remains controversial due to difficulty in fabrication and testing of small samples. Here, we report the effects of systematic variation in sample-size and testing temperature. Pt-based metallic glass samples with varying diameters (100 nm -500 mm) were prepared by thermoplastic drawing. Multiple samples were deformed at different temperatures and the fracture morphologies were characterized using SEM. The results show that the fraction of vein-like morphology decreases with decreasing sample size and mirror-like fracture surface was observed in samples smaller than about 2 mm in diameter. With further decreasing diameter, transition from shear-localized to necking was observed and the extent of neck increased with decreasing sample diameter. The lowering in temperature had similar effect as decrease in sample diameter. This temperature-size equivalence is discussed in terms of temperature rise and formation of liquid-like layer in shear bands.

Plastic Deformation of Metallic Glasses Under Triaxial Stress State at Room Temperature Yi Li[1] and Alan Lindsay Greer[2]; [1]Institute of Metal Research, China; [2]University of Cambridge, United Kingdom

Usually, plastic deformation of large-sized metallic glasses (MGs) is highly localized into shear bands under uniaxial stress state. Because of this, the plastic deformation is heterogeneous and strain softening would occur. Over the past few years, we have studied the plastic behaviour of metallic glasses under triaxial stress state. Under this condition, shear banding is suppressed, and metallic glasses are capable homogeneous plastic flow at room temperature under either tension or compression. Our talk will present a summary on the mechanical behaviour of BMGs in a deep notched cylindrical bar. We will show that the plasticity and strength of Zr-based BMG can be significantly enhanced by suppressing shear banding under tension condition due to strain hardening and densification (e.g. free volume annihilation) due to mechanical relaxation. Meanwhile, the samples also exhibit different fracture behaviour with new fracture features. Under the compression

condition, however, metallic glasses can be rejuvenated and extreme softening is seen in the sample. Such softened glass enables subsequent strain hardening. The mechanism for these observations will be discussed in terms of annihilation and generation of free volume under triaxial stress state.

Strain-Hardening in Metallic Glasses Alan Lindsay Greer[1] and Yi Li[2]; [1]University of Cambridge, United Kingdom; [2]Chinese Academy of Sciences, China

Conventional polycrystalline alloys show strain-hardening. This is a key factor underpinning their usefulness in structural applications, delocalizing plastic deformation, enabling ductility, and preventing catastrophic failure. In contrast, metallic glasses (MGs) generally show strain-softening, leading to extreme localization of plastic flow in thin (10–20 nm) shear bands. This shear banding leads to early catastrophic failure in tension, and to unsightly surface steps when significant plastic strains can be achieved in other deformation modes, notably bending.

There have been many attempts at 'shear-band engineering', mainly to stimulate as many shear bands as possible to promote more uniform plastic flow, and by such means uniquely high damage tolerance has been achieved [1]. Nevertheless, shear-banding is the key obstacle to the wider use of MGs in mechanical applications [2]. Elimination of shear bands would be highly desirable. Yet there is the concern that shear-banding might be inevitable, given that the yield stress of MGs is a high fraction of the theoretical strength, so that any capacity for hardening must be limited.

In recent years, there has been a focus on the range of MG states that can be obtained at a given composition. As annealing and relaxation often lead to embrittlement, there is particular interest in the reverse process ('rejuvenation'), by which the MG is taken to higher-energy, less dense states. It is speculated that a sufficiently rejuvenated MG could show strain-hardening [3], but it has been unclear whether the required rejuvenation could be achieved without destabilizing the MG against, for example, crystallization.

Thermomechanical processing, particularly in compression, can induce extreme rejuvenation in significant (mm-scale) volumes of MG [4]. When these rejuvenated volumes are subjected to uniaxial stress, in tension or compression, they do show strain-hardening, and correspondingly shear-banding is suppressed [5]. With this finding, it is possible that the aim of MG research should shift from shear-band engineering to the elimination of shear bands.

The first well accepted explanation of strain-hardening in polycrystalline metals was that proposed by G.I. Taylor in 1934 [6]: plastic strain involves the generation of dislocations, and as the imposed macroscopic strain increases, internal local strain gradients increasingly impede the motion of those dislocations. In general terms, this has remained the only explanation for strain-hardening until that now offered for MGs. In Taylor's model, it is intrinsic that strain-hardening involves increased defect density and a higher energy for the system. In contrast, the strain-hardening of MGs involves a lower energy and, effectively a decreased density of defects. We survey the strain-hardening rate of metallic materials, and find that this is particularly high for MGs.

Engineering Structure Defects for Controlled Mechanical Behaviors in 3D-Printed Bulk Metallic Glasses Shuai Wei; Aarhus University, Denmark

In the last decades, researchers have been developing amorphous metals with bulk size, so-called bulk metallic glasses (BMGs) through carefully designing the alloy compositions and the quenching processes. Although the critical cooling rates required to bypass crystallization have been much reduced, BMGs still suffer from the constraints in dimensions and geometries when they are produced by casting. Here, we use the selective laser melting (SLM) technique to 3D-print the near-net-shape bulk metallic glasses. Their microstructures and mechanical properties are characterized. The defects such as porosity, pore size and morphology are analyzed in the relation with their tensile fracture behaviors of large-scale fully

amorphous 3D-printed BMGs. The results show that the characteristics of porosity in 3D-printed BMGs play a crucial role in the ultimate tensile strength (UTS). The UTS decreases drastically from ~ 1.5 GPa for pore-free samples to ~ 1.25 GPa for samples with a porosity of 0.26%. Yet, the Young's modulus is found to be insensitive in the low-porosity regime. Finite element simulations show different deformation behaviors of pore-free and pore-containing models, where the former fractures with multi shear bands initiated at the material weak point, while the latter experiences plastic deformation around pores with the shear transformation zone (STZs) perpendicular to the normal stress. The understanding of microstructure defects enables us to engineer the defects for controlled tensile fracture behaviors in 3D-printed BMGs.

Micro- and Macroplasticity Mechanisms in Polymer-Supported Thin-Film Metallic Glasses Oleksandr Glushko[1], Christoph Gammer[2], Christian Mitterer[1] and Jurgen H. Eckert[1]; [1]Montanuniversität Leoben, Austria; [2]Erich Schmid Institute of Materials Science, Austrian Academy of Sciences, Austria

The in-depth understanding of the mechanisms of plastic deformation in metallic glasses is still missing despite years of dedicated experimental and theoretical effort. Here we demonstrate how polymer-supported films can be utilized to capture different stages of shear band formation and propagation opening new perspectives to uncover plasticity mechanisms in metallic glasses.
By means of in-situ resistance measurements, in-situ optical microscopy as well as quasi-in-situ SEM and FIB characterization, different stages of evolution of shear bands and cracks with increasing strain are detected and described. Two distinct types of shear bands appear in polymer-supported sputter deposited $Pd_{80}Si_{20}$ and $Au_{60}Ag_{20}Si_{20}$ metallic glasses with increasing strain: (i) the "out-of-plane" shear bands (the direction of shear is not in the film plane) which are formed at about 2% strain and develop quickly into through-thickness cracks and (ii) in-plane shear bands (the direction of shear is within the film plane) which appear after crack density saturation (at about 10% strain) and do not lead to crack formation. If the film thickness is above 500-700 nm the propagation of single out-of-plane shear bands which do not develop into cracks is observed. If the film thickness is reduced below 15 nm, the formation of shear bands is generally suppressed and the film can deform up to strains of about 6% elasto-plastically (i.e. without cracking) showing formation of homogeneously distributed short nanocracks at higher strains. It is demonstrated, that with increasing applied strain, new in-plane shear bands can easily intersect the existing ones, whereupon the intersected shear bands become inactive and cannot carry further plastic deformation. This mechanism can lead to effective strain hardening of metallic glasses. Furthermore, the existence of droplet-like extrusion directly on top of the traces of in-plane shear bands provides a direct evidence of specific material state characterized by high free volume and low viscosity during the shear banding event.
Reported results demonstrate that polymer-supported films offer an alternative way to investigate plasticity of metallic glasses through higher control over generation, propagation and topology of shear bands. It is believed that new insights into such controversial topics as the propagation mode, propagation speed as well as temperature of operating shear bands can be gained.

Traction Rheoscopy of Colloidal Glass J. Z. Terdik, David Weitz and Frans Spaepen; Harvard University, United States

Micron sized colloidal particles, which interact with nearly hard-sphere potentials, can be used to form dense amorphous packings using a variety of well established techniques. Due to the large size and slow dynamics of colloidal particles, confocal microscopy can be used to measure the 3D structure and dynamics of these densely packed colloidal glasses. For example, previous work has directly visualized, as a function of applied strain, both the inhomogeneous particle level rearrangements that occur within a colloidal glass, and the emergence of continuum elastic strain fields that surround these rearrangements. While microscopic visualization of colloidal glasses provides real-space information not readily obtainable in atomic systems, measuring the stress response of colloidal glasses, in addition to visualization, is a significant challenge. The large, micron-size of the colloidal particles and their thermal interactions produce solids with exceptionally small elastic moduli on the order to 10-100 mPa. We introduce a new technique, traction rheoscopy, to directly measure the mechanical response of these hghly compliant colloidal glasses under simple shear strain while simultaneously visualizing their microstructure. The method consists of placing a bilayer of colloidal glass atop a well calibrated soft polymer gel of similar shear modulus. The composite bilayer undergoes strain-controlled shear; shear stresses are inferred from the displacement of embedded tracer particles in the calibrated polymer gel. Using these stress measurements, we show that under applied shear the colloidal glass goes through as sequence of reversible and irreversible microscopic rearrangements as the stress develops correlated spatial heterogeneities. The stress measurements with simultaneous real space visualization of the particle dynamics corroborate previously reported microscopic flow mechanisms and present new insight into the shear response of the colloidal glass.

7:30 AM F.SF02.03.13
Microstructural Dependence of Shear Localization in Metallic Glass Composites Jonathan M. Gentile[1], Douglas Stauffer[2], Douglas C. Hofmann[3] and Jason R. Trelewicz[1,1]; [1]Stony Brook University, The State University of New York, United States; [2]Hysitron Products, United States; [3]California Institute of Technology, United States

Metallic glass composites employ extrinsic approaches to improving the ductility and toughness of classically brittle amorphous alloys through the introduction of a distributed crystalline phase upon solidification. The crystalline heterogeneities have been shown to distribute the process of shear localization in the amorphous matrix while simultaneously promoting dislocation plasticity, manifesting as a more homogeneous plastic response. Although studies have demonstrated such mechanisms, there exists a disparity in the effective mechanical length scales of delocalization as well as a lack of a definitive approach for quantifying the crossover from incipient to homogeneous flow as a function of the underlying composite microstructural length scales. Here, we use nanoindentation combined with a bonded interface indentation technique to quantify individual shear banding events and map the role of composite microstructure on the shift in the governing yield criterion. Our results reveal a reduction in the stress required to nucleate a shear band when mechanical length scales were coincident with the composite microstructural length scales, i.e., the nucleating shear band interacts with the amorphous-crystalline interfaces. At larger indentation depths producing a fully developed plastic zone, a reduction in the propensity for shear localization was observed and attributed to strain accommodation by the crystalline dendrites suppressing shear band propagation. A crossover from the shear plane to maximum shear stress yield criterion is uncovered at a crystalline fraction of approximately 60%, thus signaling an effective transition from incipient to homogeneous flow as the dominant deformation mode of the composite.

The Controlled Large-Area Synthesis of Freestanding Two-Dimensional Metallic-Glass Nanosheets/Nanostructures Yong Yang; City University of Hong Kong, China

The rise of nanotechnology has been propelled by low dimensional metals. Albeit the long-perceived importance, synthesis of freestanding metallic nanomembranes (or the so-called 2D metals), however, has been mainly restricted to elemental metals with a very limited in-plane size (< 10 μm). In this talk, I would like to talk about the development of a low-cost method to synthesize 2D metals through polymer surface buckling enabled exfoliation (PSBEE). The 2D metals so obtained could be as chemically complex as conventional metallic glasses while possessing in-plane dimensions at the scale of bulk metals (> 1 cm). With our approach, we successfully synthesized a variety of 2D metallic glasses with controllable geometries and morphologies. Interestingly, our results clearly show that, as the thickness of the 2D metallic glasses reduces to a few nanometers, its modulus is significantly reduced to only a fraction of the modulus of their bulk counterparts. Aside from rather low elastic modulus, these 2D metallic glasses also exhibit unusual properties, such as good stretchability and tunable optical properties. Finally, we demonstrate that 2D ceramic glasses and 2D metallic composites can be also fabricated through PSBEE aside from 2D metallic glasses.

Thermal Drawing of Structured Nanoscale Metallic Glass Fibers Inès Richard[1], Wei Yan[2,1], Güven Kurtuldu[3], Nicholas D. James[1], Giuseppe Schiavone[1], Stephanie P. Lacour[1], Vasiliki Tileli[1], Grégoire Courtine[1], Jörg F. Löffler[3] and Fabien Sorin[1]; [1]Ecole Polytechnique Federale de Lausanne, Switzerland; [2]Massachusetts Institute of Technology, United States; [3]ETH Zürich, Switzerland

Micro- and nanoscale metallic glass systems offer exciting opportunities for both fundamental research and applications in healthcare, micro-engineering, optics and electronics. In addition to their functional attributes, exceptional mechanical properties and corrosion resistance, a singular feature of bulk metallic glasses (BMGs) is their ability to be processed in the supercooled liquid state thanks to their sluggish crystallization kinetics and relatively low viscosity. However, thus far the scientific challenges and technological opportunities associated with exploiting viscous deformation to realize advanced micro- and nanoscale MG architectures remain to a large extent unexplored. Moreover, integrating nano-scale MG structures

into well-functioning devices still poses great challenges.
Here, we present a scalable method to produce fibers containing continuous and well-ordered micro- and nanoscale Pt-based MG conductors via their thermal co-drawing in the supercooled liquid state within a polymer matrix [1]. Designing the parts in a macroscopic scaled-up preform enables the fabrication of structured MGs with arbitrary transverse geometries and controllable feature size down to a few tens of nanometers, previously unachievable. This approach allows us to deepen our fundamental understanding of deformation and size effects on crystallization kinetics, and engineer innovative MG-based devices within advanced fibers and smart textiles.
First, we discuss how we selected the right combination of MG and polymer for a successful co-drawing. *In situ* heating transmission electron microscopy (TEM) on drawn MG ribbons is then presented to reveal the influence of the thermal drawing process on the crystallization kinetics, which ultimately determines the achievable feature size. After establishing this fundamental understanding, we show a variety of complex MG nanostructures in flexible polymer matrices. Finally, we demonstrate the potential of BMGs in comparison to more traditional drawable materials by presenting applications in optoelectronic and neuroscience. We show that the MG ribbons can serve as electrodes to enhance the performance of optoelectronics fibers and fabrics. We then present two implantable MG-based fiber probes integrating multiple MG conductors, and in one case a microfluidic channel for local chemical delivery. Chronic experiments in rats show the ability to elicit robust behavioral responses when delivering electrical neurostimulation in deep structures, to record neuronal activity during unconstrained locomotion, and to deliver pharmacological agents to manipulate local circuits.

Nanomolding Far and Close to Equilibrium and Its Mechanism Naijia Liu, Guannan Liu, Arindam Raj, Sungwoo Sohn and Jan Schroers; Yale Univeristy, United States

Tremendous effort has been taken during the last two decades in the development of nano fabrication techniques for materials exhibiting desirable functional properties. However, both bottom-up and top-down fabrication approaches are limited in some critical aspects such as material choice, geometry, and scalability.
A highly versatile and widely used fabrication method is molding, which is generally associated with a soft state of a material. Nanomolding has been realized, based on creep flow, for polymers, gels, and some glasses that soften at elevated temperatures, but not for crystalline materials that remain hard in their crystalline state.
Recently, we discovered that nanomolding is possible with crystalline materials. Processing usually around ~0.5 T_m, such thermomechanical nanomolding (TMNM) results in very high aspect ratio up to 1000 and nanowires as small as 5 nm in diameter. It offers itself as a versatile nanomolding technique for metals, alloys and even ordered phases.
By tracking the atomic moving in TMNM with multilayer samples and analyzing scaling experiments, we studied the underlying mechanism to be based on interface atomic diffusion and dislocation. They dominate TMNM in different temperature ranges as an interface diffusion mechanism works most effectively with a temperature above ~0.4 Tm and a dislocation mechanism works at lower temperature. A diffusion dominated mechanism is also found effective to form nanowires through amorphous phases (BMGs), with a processing temperature below T_g.
We will discuss the underlying mechanisms in TMNM, and their effect on structure and composition of formed nanowires in solid solutions, ordered phases and amorphous phases (BMGs).

SESSION F.SF02.05: Glass Formation

5:00 AM *F.SF02.05.01
Syntheses and Features of Pseudo-High Entropy Bulk Metallic Glasses Akihisa Inoue[1,2,3], Fanli Kong[2], Baolong Shen[1], Shengli Zhu[3] and Alan Lindsay Greer[4]; [1]China University of Mining and Technology, China; [2]Josai International University, Japan; [3]Tianjin University, China; [4]University of Cambridge, United Kingdom

Since the first synthesis of a bulk metallic glass (BMG) by copper mold casting in 1989, a large number of BMGs with centimeter-size diameter were synthesized in a variety of multicomponent alloy systems such as La, Mg, Zr, Ti, Hf, Fe, Co,

Ni, Cu, Pd, Pt and Au metal bases. These BMGs are composed of multicomponent with negative and nearly zero heats of mixing and significant atomic size mismatches, while there has been little information on the influence of additional metallic elements with positive heat of mixing on the formation, thermal stability, crystallization behavior and fundamental properties for BMGs. Very recently, the pseudo-high entropy (PHE) BMGs containing solute atomic pairs with positive heats of mixing, which are different from the component rule for ordinary BMGs, have attracted an increasing interest because of their unique properties[1)]. In particular, the PHE BMGs exhibit two exothermic peaks on the continuously heating DSC curve and the temperature interval between the two peaks is as large as 200-400 K. Besides, no crystalline phase is observed even after annealing for 1-5 h at the temperatures well above the first exothermic peak. The unusual high stability to the progress in crystallization has been reported for various PHE BMGs such as Zr-Al-(Ni,Cu)-Nb, Zr-Al-(Ni,Cu)-Ag, Zr-Al-(Co,Cu)-Ag, Zr-(Fe,Co,Ni,Cu), Ti-Zr-(Cu,Pd)-Nb and Fe-Cr-Mo-C-B-Y systems. These results indicate the possibility of developing a heat resistant BMG by utilizing this novel phenomenon. Here we present the formation, thermal stability, crystallization behavior and mechanical properties of PHE BMGs and to investigate the criterion for the synthesis of BMGs with ultrahigh thermal stability.

Core-Shell Energy State of Icosahedral Clusters Inside Undercooled Metallic Liquids and Its Relationship with Glass-Forming Ability Donghua Xu; Oregon State University, United States

This presentation will start by introducing the new Cu-based bulk metallic glasses (CBMGs) in the Cu-Zr-Hf-Al system that my group has developed recently. These new CBMGs are free of rare earths, precious metals or toxic elements, and yet possess the highest glass-forming ability known to any copper-based alloys. The presentation will then shift to focus on a computation study of the energy state of icosahedral clusters inside undercooled metallic liquids in some simpler metallic systems, in order to gain fundamental insights into glass formation and glass-forming ability.

Icosahedral clusters have been experimentally confirmed to exist in undercooled metallic liquids. Their existence is generally understood using the argument about an isolated icosahedron Frank made almost 70 years ago. This argument establishes an icosahedron as the most energy-efficient packing for an isolated 13-atom cluster, but fails to consider the effects of surrounding atoms in a liquid and temperature on the energy state of the cluster. The argument suggests core stabilization as the main mechanism for the origin of icosahedral clusters - since the core of an isolated cluster has lower potential energy than the shell.

Using large scale atomistic simulations and statistical analysis of several BCC (body-centered-cubic) and FCC (face-centered-cubic) metals, we have found that the shells of icosahedrons spontaneously formed inside deeply undercooled metallic liquids or glasses in fact have lower (averaged) potential energy than the cores. The shell potential energy deficiency occurs only to the icosahedral clusters but not to the equilibrium-crystal clusters, and, for icosahedral clusters, this deficiency grows with decreasing temperature. Compared with FCC metals, BCC metals exhibit greater potential energy deficiency on the icosahedral shells and produce significantly more icosahedral clusters upon liquid quenching, which explains the higher tendency of BCC metals to be vitrified observed in ultrafast cooling experiments. Inspecting the potential energy deficiency on the icosahedral shells through computation could provide a new avenue to the search for amorphous metals (i.e. metallic glasses) with high glass forming ability and processability.

5:30 AM *F.SF02.05.03
Glass Formation in Binary Alloys with Different Atomic Symmetries Corey O'Hern; Yale University, United States

Prediction of the glass forming ability (GFA) of alloys remains a major challenge. We are not able to predict the composition dependence of the GFA of even binary alloys. To investigate the effect of each element's propensity to form particular crystal structures on glass formation, we focus on binary alloys composed of elements with the same size, but different atomic symmetries using the patchy-particle model. For mixtures with atomic symmetries that promote different crystal structures, the minimum critical cooling rate R_c is only a factor of 5 lower than that for the pure substances. For mixtures with different atomic symmetries that promote local crystalline and icosahedral order, the minimum R_c is more than 3 orders of magnitude lower than that for pure substances. Results for R_c for the patchy-particle model are in agreement with those from embedded atom method simulations and sputtering experiments of NiCu, TiAl, and high entropy alloys.

5:45 AM F.SF02.05.04

Machine Learning Predictions of Glass Forming Ability from Compositional Information Benjamin T. Afflerbach, Lane E. Schultz, Carter Francis, Paul M. Voyles, Izabela Szlufarska and Dane Morgan; University of Wisconsin–Madison, United States

Bulk metallic glasses (BMGs) are generally defined as a subset of metallic glasses which can be synthesized with dimensions exceeding 1 mm while maintaining their amorphous structure. Metallic glasses possess a wide range of mechanical, magnetic, and chemical properties making them exciting for many commercial applications, particularly if they can be made in larger sizes as is possible for BMGs. Unfortunately, today there is no robust method for determining which new alloy compositions will yield BMGs without synthesizing and cooling the alloy, greatly inhibiting materials design in this area. Perhaps the most direct measure of glass forming ability (GFA) is critical cooling rate (Rc), which is the slowest rate at which a glass can be cooled and stay fully amorphous. In this work we focus on predicting Rc from easily obtained compositional information using machine learning. There are on the order of 100 measured values of Rc in the literature, which is too little data to machine learn Rc as a function of composition. In this work we dramatically extent this database by using other sources of approximate Rc values derived from robust correlations, including correlation of Rc with (i) characteristics temperatures (about 480 new values), (ii) critical casting diameters (about 550 new values), and (iii) results of melt spinning experiments (about 2000 new values). We obtain a database of 2884 approximate Rc values which we used to build a Random Forest model for Rc as a function of elemental properties, which in turn can be derived from composition. This model is validated and then used to predict GFA on several new glassy alloys. 5-fold cross validation performance of the model gives RMSE errors of around 0.66 log(K/s) in Rc (30% of the Rc database standard deviation of 2.4 log units). This value is low enough to design BMGs if it can be maintained across new systems, but we will also show that the model has significant challenges in treating new compositions.

5:55 AM F.SF02.05.05
Metastability in Multicomponent Alloys—Solid Solution and Glass Formation Sebastian A. Kube and Jan Schroers; Yale University, United States

While metastability is undoubtedly a key-characteristic of metallic glasses, its role is often underappreciated for multicomponent alloys in general, and High Entropy Alloys (HEAs) in particular. The HEA field has long focused on equilibrium conditions, aiming to stabilize single-phase solid solutions (SPSS). However, the high entropy effect is often insufficient to fully stabilize SPSS, yielding only few, mostly metastable SPSS. While the prospective space of favorable SPSS formation is smaller than commonly assumed, only larger degrees of metastability can open up the vast High Entropy Alloy space. We argue that HEAs form metastable SPSS through polymorphic solidification upon rapid cooling. To quantify a HEA's metastability, we propose the critical cooling rate of SPSS formation R_C^{SPSS}, which is analogous to the critical cooling rate of glass formation R_C^{Glass}. On this unified basis, we can compare multicomponent alloys by their metastability and tendency to form SPSS or glasses, which is determined by their underlying atomic dispersity.

6:05 AM *F.SF02.05.06
Sulfur Bearing Bulk Metallic Glass Ralf Busch, Alexander Kuball, Oliver Gross and Benedikt Bochtler; Univ of Saarland, Germany

Metallic glasses constitute a class of engineering materials having an enormous
potential for many fields of application due to their superior properties. Here, we report on a new family of sulfur-bearing bulk metallic glasses. So far, sulfur was not considered as alloying element for the synthesis of bulk metallic glasses. We observe bulk glass formation in a variety of sulfur-containing systems, including titanium-based bulk glass-forming systems with an extremely high titanium content of 70 at.%. These findings allow the development of a whole new class of amorphous metals, having good processability and consisting of alloying elements suitable for industrial applications.

SESSION F.SF02.06: BMGs for the Energy Transition

Electrochemical Hydrogen Storage and Evolution in Metallic Glasses Baran Sarac[1], Yurii P. Ivanov[2], Tolga Karazehir[3], A. Sezai Sarac[4], Alan Lindsay Greer[2] and Jurgen H. Eckert[5]; [1]Erich Schmid Institute of Materials Science (ÖAW),

Austria; [2]Cambridge University, United Kingdom; [3]Adana Alparslan Turkes Science and Technology University, Turkey; [4]Istanbul Technical University, Turkey; [5]Montanuniversität Leoben, Austria

Among the novel advanced metallic alloy systems, metallic glass (MG) is a potential candidate for long-term use hydrogen interactions owing to its loosely packed structure promoting the number of interaction sites. The hydrogen storage and electrocatalytic activity of Pd-Si-based MG nanofilms and Si/SiO_2 hybrid structures were evaluated by combining electrochemical (chronoamperometry, cyclic voltammetry, electrochemical impedance spectroscopy), structural (aberration-corrected high-resolution transmission electron microscopy, X-ray diffraction), composition (X-ray photoelectron spectroscopy, energy dispersive X-ray) and morphologic (scanning electron microscopy, atomic force microscopy) techniques. Recently we have shown that maximum total hydrogen charge stored in Pd-Si-Au MG nanofilm is equal to that in polycrystalline Pd films with 1 μm thickness [1]. Hydrogen to Palladium ratio of Pd-Si-Cu MG was found to be 1.56 (c.f. 0.61 in polycrystalline Pd + Si/SiO_2 of the same film thickness) [2, 3]. The volume expansion of a palladium hydride unit cell obtained from HRTEM images due to hydrogenation of the Pd-MG nanofilms is around 6 times larger than that of the Pd-polycrystalline counterpart hydrogenated under the same conditions. The same Pd-Cu-Si MG based hybrid structure has a Tafel slope of 109 mV/dec, which is less than the half of the crystalline PdNF electrode of the same thickness. Besides, it shows the highest overpotential at 10 mA/cm^2, indicating a better electrocatalytic activity [4]. We have also established a general evaluation criterion with practicality in assessment and high accuracy for electrocatalytic reactions applicable to different metallic alloy systems.

Additive Manufacturing and Deposition of Bulk Glass Forming Alloys and Composites—Progress and Outlook Douglas C. Hofmann[1], Punnathat Bordeenithikasem[1], Samad Firdosy[1], Andre Pate[1] and Daniel East[2]; [1]NASA JPL/Caltech, United States; [2]Commonwealth Scientific and Industrial Research Organisation, Australia

Additive manufacturing (AM) has emerged as a unique method for producing highly specialized metal alloys and composites. The high cooling rates and customizable cooling rates afforded by AM are particularly useful in the creation of bulk metallic glasses (BMGs) and BMG metal matrix composites. While AM allows for net-shaped fabrication of even the weakest glass-forming alloys, macroscale parts still suffer from embrittlement due to annealing, porosity, partial crystallization and oxygen. In contrast, thin coatings and overlays made from BMGs and BMG composites may be ideal for some wear-resistant applications. This talk will provide an overview of how BMG printing and deposition technologies might be matured and infused into applications. It will cover Fe-based, Zr-based, Cu-based, and Ti-based BMG alloys.

Vitrification Kinetics versus Alpha-Process in Metallic Glass-Formers Isabella Gallino[1], Daniele Cangialosi[2,3], Beatrice Ruta[4], Xavier Monnier[2] and Ralf Busch[1]; [1]Saarland University, Germany; [2]Donostia International Physics Center, Spain; [3]Centro de Fisica de Materiales (CSIC-UPV/EHU), Spain; [4]Universite Claude Bernard Lyon 1, France

Understanding how glasses form remains a challenge in material science. Vitrification is the thermal transition from a supercooled liquid in metastable equilibrium into a non-equilibrium glass. One of the major questions is whether vitrification in viscous liquids is related to sluggish atomic mobility exclusively *via* the primary structural α-relaxation process or rather other atomic motions play a role. Here, we present experimental evidences that multicomponent bulk metallic glasses can display heterogeneity of vitrification kinetics and that the cooling rate dependency of the vitrification kinetics is decoupled from the temperature dependence of the α-relaxation [1-3]. The evidences are based on exhaustive studies of the atomic mobility of an Au-based metallic glass former by dynamic mechanical analysis (DMA), x-ray photon correlation spectroscopy (XPCS), and fast scanning calorimetry (FSC); the latest by means of a step response analysis *via* the temperature and frequency dependence of the complex specific heat. The vitrification kinetics is characterized in FSC in terms of the limiting fictive temperature, i.e., the temperature at which a glass formed after cooling at a given rate would be at equilibrium. The separation of these two aspects of the glassy dynamics (vitrification kinetics and α-process) becomes more pronounced at larger undercooling, suggesting a larger contribution of additional dynamical processes to the vitrification process, which are not connected to the α-process. The observed heterogeneity of vitrification kinetics hints toward the existence of multiple relaxation mechanisms, which are observed during aging experiments [3].

Tracing Structural Dynamics in Metallic Glasses During Cryogenic Cycling Robert Maass[1,2]; [1]University of Illinois at Urbana-Champaign, United States; [2]Federal Institute for Materials Research and Testing (BAM), Germany

Highly unrelaxed structural states of metallic glasses have often advantageous mechanical properties. Since metallic glasses continuously relax with time (age) or inherently are well relaxed after processing, methods to uniformly rejuvenate the material are needed. One approach that has received attention is the so-called cryogenic-cycling method, during which a metallic glass is repeatedly immersed into liquid nitrogen. In some cases, cryogenic cycling is truly efficient in increasing the stored excess enthalpy of metallic glasses, but it does not seem to be universally applicable to all alloys and structural states. The origins for these differences remain unclear due to our limited understanding of the underlying structural evolution. In order to shed more light onto the fundamental structural processes of cryogenic cycling, we pursue in-situ x-ray photon correlation spectroscopy (XPCS) to trace the atomic-scale structural dynamics of a Zr-based metallic glass in two different structural states (ribbon and bulk metallic glass). This method allows calculating the relaxation times as a function of time throughout the thermal cycling. It is found that the investigated glasses exhibit heterogeneous structural dynamics at 300 K, which changes to monotonic aging at 78 K. Cryogenic cycling homogenizes the relaxation time distribution for both structural states. This effect is much more pronounced in the ribbon, which is the only structural state that rejuvenates upon cycling. We furthermore reveal how fast atomic-scale dynamics is correlated with long-time average structural relaxation times irrespective of the state, and that the ribbon exhibits unexpected additional fast atomic-scale relaxation in comparison to the plate material. Overall, a picture emerges that points towards heterogeneities in fictive temperature as a requirement for cryogenic energy storage.

5:30 AM F.SF02.08.03
Surface Dynamics Measurement on a Gold Based Metallic Glass Chengrong Cao, Lian Yu and John Perepezko; University of Wisconsin-Madison, United States

The surface diffusion kinetics has been measured on an $Au_{60}Cu_{15.5}Ag_{7.5}Si_{17}$ metallic glass using the method of surface grating decay from room temperature up to 20 K below the glass transition temperature (T_g). In the early stage of gratings decay the surface diffusion coefficients were evaluated as varying in the range from 10^{-20} to 10^{-18} m^2/s over the temperature range of measurement and the corresponding average activation energy is about 0.67 eV. During longer time annealing the surface gratings decay rate slowed down significantly. The slowing of the initial decay was a result of the surface dynamics and influenced by the surface segregation of silicon at long time which induced a surface crystallization of a silicon-rich phase.

5:40 AM *F.SF02.08.04
Ultrafast Calorimetry Experiments on Bulk Metallic Glasses—Studying Phase Transitions in Slow Motion Jörg F. Löffler; ETH Zurich, Switzerland

Metallic materials generally show rapid nucleation and growth kinetics, which makes studies of their phase transitions and metastable phase formation generally more difficult. Bulk metallic glasses (BMGs), on the other hand, reveal very sluggish crystallization kinetics. By applying ultrafast differential scanning calorimetry to slowly transforming BMG-forming systems

at heating and cooling rates of several 10,000 K/s, we are able to determine phase transitions of metallic systems more or less in slow motion. In this way we find that many metallic systems reveal solid-to-solid phase transitions that proceed via melting of a metastable phase [1]. Ultrafast calorimetry also allows us to interrupt rapid cooling after (metastable) phase formation and then to "up-quench" the frozen structure via rapid heating. Via surpassing the metastable-to-stable solid phase transition, the formed metastable phase can then be fully melted and its thermophysical properties, such as temperature and enthalpy of melting, be investigated in detail [2]. In this way, we are able to discover hidden transient phases, determine the stochastics of nucleation [3], and study multistep crystallization and melting pathways in metals. In fact, we show that even simple binary alloys can reveal multiple melting points [4]. Applying ultrafast calorimetry, we are thus able to construct energy-temperature diagrams including metastable phases, with the final aim of generating complete metastable phase diagrams.

5:55 AM F.SF02.08.06
Sputtering of Zr-Based Metallic Glasses to Vary Kinetic Stability, Icosahedral Ordering and Mechanical Properties Sachin V. Muley[1], Chengrong Cao[1], Debaditya Chatterjee[1], Carter Francis[1], Felix P. Lu[2], Mark Ediger[3], John Perepezko[1] and Paul M. Voyles[1]; [1]University of Wisconsin-Madison, United States; [2]The University of Chicago, United States; [3]University of Wisconsin–Madison, United States

Thermodynamic and kinetic stabilities in glasses can be varied by physical vapor deposition. We investigated the structure and properties in Zr-Cu-Ni-Al and Zr-Cu-Al thin films sputtered from single alloy targets as a function of substrate temperature and deposition rate. For both compositions, we discovered a pseudo-phase boundary between amorphous and crystalline films as a function of rate and temperature. A semi-quantitative model based on surface-diffusion limited crystallization predicts the amorphous / crystalline growth boundary. Kinetic stability in $Zr_{65}Cu_{27.5}Al_{7.5}$ metallic glass thin films, as indicated by their glass transition onset temperature, was significantly increased by lowering deposition rate at constant temperature. The most kinetically stable film's reduced modulus was 20% higher than a glass of the same composition quenched from the liquid by melt spinning, consistent with increased density and improved thermodynamic stability. Fluctuation electron microscopy and angular correlations in coherent electron nanodiffraction reveal that the more stable glasses show enhanced icosahedral medium range structural order. Our results suggest that enhanced nanoscale icosahedral order contributes to resistance of glass to both glass transition and mechanical deformation.

Molecular Dynamics Features for Predicting Metallic Glass Critical Casting Thickness Lane E. Schultz, Benjamin T. Afflerbach, Izabela Szlufarska and Dane Morgan; University of Wisconsin-Madison, United States

Determining metal compositions that have good Glass Forming Ability (GFA), and in particular that yield bulk metallic glasses through cooling, has been an outstanding grand challenge in metallic glass research. Previous attempts to predict GFA for metals often include some functional form of T_g, T_x, and T_l, known as the glass transition, the onset of crystallization, and the liquidus temperatures, respectively. For example, the reduced glass transition temperature, $T_{rg}=T_g/T_l$, is a well-known GFA indicator. Another well-known GFA indicator is the liquid fragility, m, which is measured by finding the slope of viscosity as a function of temperature near T_g for an alloy. Multiple researchers have shown that direct measures of GFA, in particular the critical cooling rate (R_c) and critical casting diameter (d_{max}), can be written as relatively simple functions of T_g, T_x, T_l, and m [1, 2]. However, these relationships have limited applicability for new materials discovery

because a material must be synthesized and measured in order to obtain these features, and they cannot be readily predicted accurately from molecular simulations. However, there are other characteristic temperatures and kinetic properties that have similar physics to that represented in the above features and which are accessible to molecular simulations.

Our study explores to what extent characteristic temperatures of metallic alloys readily accessible to molecular dynamics (MD) can be correlated with d_{max}. We use MD to predict a set of characteristic temperatures $\{T_i\}$ for 73 metal alloys and fit d_{max} as a function of $\{T_i\}$ using experimental d_{max} values for 19 of the alloys. We find a 3-fold cross-validation root mean squared error (RMSE) score of 0.512 for the model, well below the standard deviation of 0.848 for the 19 dmax values. The remaining 54 alloys are used as a test set and the d_{max} predictions are used to determine if the alloy should form a glass under melt spinning, and this categorization was then compared to experimental results. We find a maximum F1 score of 0.75 for the categorization model. These cross-validation and F1 scores suggest that the model has significant predictive ability, providing a potential pathway to predicting d_{max} directly from MD.

Direct Measurement of Critical Cooling Rates in Metallic Glass Forming Alloys Through a Combinatorial Strategy Naijia Liu[1], Tianxing Ma[2], Chaoqun Liao[3], Shaofan Zhao[3], Jonathan P. Singer[2] and Jan Schroers[1]; [1]Yale University, United States; [2]Rutgers, The State University of New Jersey, United States; [3]Qian Xuesen Laboratory of Space Technology, China

Critical Cooling Rate (R_c) is the lowest rate a liquid can be cooled to avoid crystallization and vitrify into a glass. While it is a key factor to quantify the glass forming ability (GFA), direct measurement of Critical Cooling Rate (R_c) of metallic glass has been cumbersome and challenging and only determined for a few alloys.
The development of science and technologies raise demand for new materials including new Bulk Metallic Glasses. However, it has been estimated that only about 10% of the composition space of potential BMG formation has been considered thus far. To address the large potential compositional space more effectively, combinatorial approaches have been used for the fabrication of large number of alloys in thin film alloy libraries. But attempts to directly quantify critical cooling rates of alloys in such libraries have been limited to the as-sputtered state which forms under a cooling rate exceeding 10^8 K/s. Although scientifically important, this high cooling rate is not able to probe practical BMGs, of which the R_c is always below 10^3 K/s. Some progress was made recently by reheating the thin films and reducing the cooling rate to ~10^5 K/s. However, this is with a still high cooling rate rage.
We will report a fast screening method which is based on Single Pulse Laser Annealing to directly measure R_c in thin film alloy libraries. Cooling rates ranging from 10^2 to 10^6 K/s can be realized during solidification of the alloys. To demonstrate this method, we determined R_c for a large number of alloys in the Al-Ge-Ni system, and identified the best glass forming composition as $Al_{51}Ge_{35}Ni_{14}$ with a critical cooling rate of 10^4 K/s.

F.SF02.09.03
Accelerated Discovery and Mechanical Property Characterization of Bioresorbable Amorphous Alloys Using High-Throughput Methods Amit Datye, Sebastian A. Kube, Jan Schroers and Udo Schwarz; Yale University, United States

Bioresorbable materials have been of increased interest in the last two decades due to their potentially transforming impact on human body implants. However, even with a large number of groups working on it, there is data available only for a very small number of alloy compositions (<20) in the ternary amorphous alloy systems of magnesium (Mg)–zinc (Zn)–calcium (Ca) and iron (Fe)–Mg–Zn. The optimal alloy compositions for biomedical applications should be chosen from a large variety of available alloys with best combination of mechanical properties (modulus, strength, hardness) and biological response (in-situ degradation rates, cell adhesion and proliferation). This research presents high-throughput screening of more than 150 different compositions each in two different bioresorbable alloy systems. We demonstrate that this new approach

will allow future researchers to develop patient- and implant-specific bioresorbable alloys based on specific application requirements. As a first step towards establishing a database designed to enable such targeted material selection, amorphous alloy composition libraries were fabricated employing a combinatorial magnetron sputtering approach where Mg, Zn, and Ca/Fe are co-deposited from separate sources onto a silicon wafer substrate, followed by composition analysis using energy dispersive X-ray spectroscopy and X-ray diffraction measurements and mechanical properties characterization using nanoindentation.

F.SF02.09.04
Coupling Among Shear Band Initiation, Propagation and Sliding During Plastic Deformation of Metallic Glass Under Constrained Deformation Zenon H. Melgarejo[1], Joseph E. Jakes[2] and Donald S. Stone[1]; [1]University of Wisconsin-Madison, United States; [2]Forest Biopolymer Science and Engineering, USDA Forest Products Lab, United States

When, in the regime of inhomogenous flow, a metallic glass is constrained during plastic deformation, all aspects of the kinetics of shear banding, including initiation, advance of the tip, and "shear," or displacement across its thickness, become coupled. An example is the indentation experiment, in which surrounding material, loaded elastically, constrains deformation within the plastic zone and leads to a self-similar, hemispherical pattern of shear bands falling along multiple orientations surrounding the indent. Likewise, in metallic glass composites the reinforcement phases introduce constraints because they disrupt shear band propagation and
shear. In each case, the effect of the constraint is to introduce a back stress, which leads to an increase in deformation resistance similar to kinematic hardening in crystalline composites. From indentation experiments, we can measure the strength of this coupling in terms of a "hardening modulus," the magnitude of which can be determining from the fluctuations in slope of the load-depth curve during serrated loading. It is expected that the hardening modulus will depend on both material properties and the geometry of the constraint.
Using nanoindentation experiments with a Berkovich indenter, we measure
the hardening modulus in ZrCuAl metallic glass ribbons and ingots across 2 decades of strain rate during loading and 6 decades of strain rate during constant load creep. Hardening modulus is nearly independent of load despite a size effect in the serrations. Relaxing the glass near T influences the hardening modulus. The magnitude of the constraint is the same during constant load creep and during loading. Work arguments allow us to arrive at a model for coupled deformation, from which we estimate the magnitude of the constraint modulus in terms of the shear modulus of the glass, G. We compare this estimate with experimentally measured values.

F.SF02.09.05
Bicontinuous Nanoporous Design Induced Homogenization of Strain Localization in Metallic Glasses Chang Liu and Paulo Branicio; University of Southern California, United States

Bicontinuous nanoporous metallic glasses (MG) synergize the outstanding properties of MGs and open cell nanoporous materials. The low-density and high-specific-surface-area of bicontinuous nanoporous structures have the potential to enhance the applicability of MGs in catalysis, sensors, and lightweight structural designs. In this work we generated stochastic bicontinuous structure using an efficient direct method based on Cahn's idea and Fibonacci grids. We then perform molecular-dynamics simulations of tensile loading on a bicontinuous nanoporous $Cu_{64}Zr_{36}$ and characterize the deformation mechanisms dictating its elastic and plastic response preceding failure. Results indicate an anomalous MG mechanical behavior featuring extensive plastic deformation preceding a typically ductile failure. Results show progressive necking of ligaments aligned with the loading direction and progressive alignment of randomly oriented ligaments during the loading. Failure occurs by fracture following successive necking and rupture of ligaments. This work indicates that a bicontinuous nanoporous design is able to effectively delocalize strain localization in a bulk MG by utilizing the size effect of MG nanopillars and nanowires that induces a brittle to ductile transition in their mechanical behavior as ligament sizes are reduced to less than 100 nm.

F.SF02.09.06
Tuning the Mechanical Properties of Shape Memory Metallic Glass Composites with Brick and Mortar Designs Suyue Yuan and Paulo Branicio; University of Southern California, United States

The intricate deformation and failure of a shape memory alloy-bulk metallic glass composites (BMGC) under tensile loading is investigated with large-scale molecular dynamics simulations. By carefully choosing the volume fraction and the arrangement of the crystalline phase the failure of the BMGC is shifted from the propagation of a critical shear band in the amorphous matrix to yield and failure of the crystalline second phase. Results show that a brick and mortar design with

staggered crystalline bricks (stg-BMGC) is able to further synergize the mechanical properties of the amorphous and crystalline phases. By effectively distributing the local stress and preventing the generation of a critical shear band the stg-BMGC design displays enhanced ductility while preserving the strength of the metallic glass matrix.

3:02 PM *F.SF03.04.01
Multifunctional Structured Light with Flat Optics Federico Capasso and Ahmed Dorrah; Harvard University, United States

Flat optics based on metasurfaces holds promise for the design of a new class of diffractive optical component that circumvents the limits of refractive as well as Fresnel optics, in terms of control of aberrations, compactness and multifunctionality. Here we highlight the enhanced functions enabled by metasurface flat optics in structuring light. Optical elements coupling the spin and orbital angular momentum (SAM/OAM) of light have found a range of applications in classical and quantum optics. Q-plate type devices based on dielectric metasurfaces have shown superior performance in terms of singularity definition and ability to generate fractional and high OAM beams. A far more general spin to orbital angular momentum scheme has been recently demonstrated based on novel metasurface optical elements (J-plates) not limited to conjugate converted states, which are used to generate new complex structured light. The J-plate, with J referring to the photon's total angular momentum (TAM), is a metasurface device that imparts two arbitrary OAM states on an arbitrary orthogonal basis of spin states. When these J-plates are cascaded in series, they can generate several single quantum number beams and versatile superpositions thereof. Moreover, in contrast to previous spin-orbit-converters, the output polarization states of cascaded J-plates are not constrained to be the conjugate of the input states. Cascaded J-plates are also demonstrated to produce vector vortex beams and complex structured light, providing new ways to control TAM states of light
Metasurfaces hold major potential for multi-functionality, which may play a pivotal role in the next-generation compact nanodevices. OAM from lasers holds the promise for compact, at-the-source solutions to fuel applications from imaging to communications . However, conjugate symmetry between circular spin and opposite helicity OAM states from conventional

spin-orbit (SO) approaches, as well as low purity modes, has meant that complete control of light's angular momentum from lasers has remained elusive. Recent work on metasurface-enhanced lasers that overcomes this limitation will be discussed, including the demonstration of new high-purity OAM states with quantum numbers reaching l= 100, and non-symmetric vector vortex beams that lase simultaneously on independent OAM states as much as $\Delta l = 90$ apart. This laser conveniently emits in the visible, producing new OAM states of light as well as all previously reported OAM modes from lasers, offering a compact and power-scalable source that harnesses intra-cavity structured metasurfaces for the creation of arbitrary chiral states of structured light.
Finally, recent work on beams with light structured along the propagation direction will be presented, where the polarization or the OAM of the beam changes along the propagation direction.

3:18 PM *F.SF03.04.02
Multifunctional Nonlocal Metasurfaces Nanfang Yu, Stephanie Malek and Adam C. Overig; Columbia University, United States

Diffractive photonic devices manipulate light via local and nonlocal optical modes. Local devices, such as metasurfaces, can shape a wavefront at multiple selected wavelengths, but inevitably modify light across the spectrum; nonlocal devices, such as grating filters, offer great frequency selectivity but limited spatial control. In this talk, I will introduce a rational design paradigm using quasi-bound states in the continuum to realize multifunctional nonlocal devices: metasurfaces that produce narrowband spatially tailored wavefronts at multiple selected wavelengths and yet are otherwise transparent.
I will show an experimental demonstration of dielectric metalenses that focus light only for narrowband resonances and leave the rest of the spectrum unaffected. Our resonant metasurfaces can be cascaded to achieve multifunctional behavior with each metasurface independently shaping the wavefront for a distinct resonance resonant wavelength.
These devices may expand the capabilities of multifunctional meta-optics to include active or nonlinear wavefront shaping. Scaled to visible wavelengths, our resonant metalenses may prove useful for augmented reality applications as compact and highly transparent multi-color see-through lenses.

Aqueous Synthesis of 3D Nano-architected Ceramics and Metals—Nano-Architected TiO_2 PhCs Julia R. Greer; California Institute of Technology, United States

Additive manufacturing (AM), or 3D printing, represents a set of processes that enable layer-by-layer fabrication of complex structures using a wide range of materials that include ceramics, polymers, and metals. AM has allowed exploiting novel material properties, especially those that arise at the nano-scale, that do not occur in conventional materials, revolutionizing the production of complex parts for aerospace, military, automotive, optial, and medical applications. Facilitating these technologies requires a fabrication process to create a variety of functional materials in 3D, however the material choice for AM at the nano- and micro-scale is limited. A conspicuous example is a lack of AM processes for high refractive index (n), low absorption materials with nano-sized dimensions, which are typically required for microoptics and device applications. To harness the beneficial properties of 3D nano-architected meta-materials, it is critical to assess their properties at each relevant scale while capturing overall structural complexity. We present the fabrication and synthesis of nano- and micro-architected materials using 3D (two-photon and interference) lithography, as well as characterization of their properties as a function of architecture, constituent materials, and microstructural detail. We focus on additive manufacturing of complex, multi-component and multi-material architectures comprised of metal oxides, metals, and hydrogels that are derived from (metal) salt-based, aqueous photoresin synthesis. The discussion will focus on each representative materials system (metals, oxides, and hydrogels), with a detailed overview of titanium dioxide, with critical feature dimensions between 150 and 600 nm and <1% porosity. Using the described methodology, we created 3D dielectric photonic crystals (PhCs) out of rutile TiO2 patterned into woodpile face-centered tetragonal (FCT) architectures with beam dimensions of 300-600nm and lateral periods of 0.8-1.5 μm. We use Plane Wave Expansion (PWE) simulations and Fourier Transform Infrared Spectroscopy (FTIR) to demonstrate the full photonic bandgaps centered at 1.8-2.9 μm. This fundamental research provides insights into the range of possible, often *transient* attainable chemical compositions, microstructures and architectures of chemically-derived, 3D-archtiected ceramics and metals, enabling advances in multiple technologies, i.e. 3D MEMS, micro-optics, and prototyping of 3D PhCs.

3:50 PM *F.SF03.05.01
Design and Additive Manufacturing of Intelligent Metamaterials Xiaoyu Zheng; University of California, Los Angeles, United States

Metamaterials represent the concept of utilizing artificial material building blocks to create desirable properties derived from three-dimensional layout and compositions. While novel topologies can now be realized via additive manufacturing, the lack of processable materials, multi-material gradients, speed and scalabilities have stymied its further adoption. In this talk, I will outline a suite of new material design and manufacturing routes, enabled by additive manufacturing of topologies, multi-scale features and multi-material cues. Attention is focused on how additive manufacturing techniques will enable processing the unprocessable, from structural composites to functional and stimuli-responsive multi-materials. This unleashes new design freedoms for rapid material property discovery and product realizations; where electrical, thermo, mechanical behaviors and their couplings can be inversely designed and tailored by an end-user at will. I will present a few examples, where structural, electronic and energy transduction materials are 3D architected into a compact form factor, without requiring multiple processing stages such as printing, embedding or wiring. Next, we will present their new applications, such as ultralight and strong materials, self-sensing materials, microsystems for robotics, air and maritime sensing, transducers, wave guiding and telecommunications.

Engineering Light-Matter Interactions in Semiconductor Nanowire Photodetectors and in Optical Nanotweezers Kenneth Crozier; The University of Melbourne, Australia

We present recent studies in which engineering the interaction between light and nanoscale materials has been pursued for applications in photodetectors and in optical tweezers.

We review our recent work that demonstrates that the absorption spectrum of a photodetector can be controlled via waveguide resonances in semiconductor nanowires [1-6]. We discuss the physical interpretation for this phenomenon [1]. We review work in which p-i-n photodiodes were incorporated into vertically oriented silicon nanowires, and then used for colour imaging [2-5]. We also review recent work on extending this concept to the short-wave infrared via Ge nanowires [6]. We describe recent work in which we demonstrated chip-scale microspectrometers based on arrays of nanowire photodetector pixels [7] and an interleaved design with a “fishnet” pattern [8].

We also describe our work on optical trapping with plasmonic nanoapertures [9] and with all-dielectric (silicon) nanoantennas [10,11]. Fluorescence microscopy is used to track the position of, and emission from, individual trapped nanoparticles. The nanoparticles consist of fluorescent polystyrene nanospheres with diameters of 20 nm and 100 nm and streptavidin-coated CdSe/ZnS quantum dots. We observe the Brownian motion of the trapped nanoparticles using fluorescence imaging. Other experiments reported include the two-photon excitation of fluorescence from trapped nanoparticles, and the trapping of multiple nanoparticles simultaneously. We also discuss our recent work on an algorithmic approach to the design of plasmonic nanoapertures for optical tweezers [12].

Parametric Oscillation of Electromagnetic Waves in Momentum Band Gaps of a Spatiotemporal Crystal Seojoo Lee[1], Jagang Park[1], Hyukjoon Cho[1], Yifan Wang[2], Brian Kim[2], Chiara Daraio[2] and Bumki Min[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]California Institute of Technology, United States

Photonic crystals have revolutionized the field of photonics with their unique capabilities of dispersion and energy band gap

engineering, such as the demonstration of extreme group and phase velocities, topologically-protected photonic edge states, and the control of spontaneous emission of photons. On the other hand, time-variant media have shown their distinct functionalities including nonreciprocal propagation, frequency conversion, and amplification of light. However, these phenomena in time-variant media have mostly been investigated for the cases where spatiotemporal modulation is in the form of a simple harmonic wave. Here, we extend the type of spatiotemporal modulation so that time-variant and spatially-discrete photonic crystal structures, or spatiotemporal crystals, can be analyzed. The design of spatiotemporal crystals allows the engineering of momentum band gap, within which the parametric amplification occurs. As a potential platform for the construction of a parametric oscillator, a finite-sized spatiotemporal crystal is proposed and analyzed. The parametric oscillation is initiated by the energy and momentum conversion of an incident wave and the subsequent amplification by parametric gain within the momentum band gap. The oscillation process dominates over frequency mixing interactions above a transition threshold determined by the balance between gain and loss. Furthermore, the asymmetric formation of momentum band gaps can be realized by spatial phase control of temporal modulation, which leads to the directional radiation of oscillations at distinct frequencies. The proposed structure would enable simultaneous engineering of energy and momentum band gaps and provide a guideline to the implementation of advanced dispersion-engineered parametric oscillators.

Metadevices Based on Integration of Microsystems and Metamaterials Xin Zhang; Boston University, United States

Metamaterials, a major type of artificially engineered materials, exhibits unprecedented and controllable effective properties, including electric permittivity and magnetic permeability, and have boosted the development of optical and photonic devices. Metamaterials are composed of arrays of subwavelength unit cells. The effective properties of metamaterials are mainly determined by the structural design of the constituting subwavelength unit cells rather than their chemical composition. The design-driven properties enable versatile designs of their electromagnetic properties. Recent research has shifted to construct reconfigurable, tunable, and nonlinear metamaterials towards the development of metamaterial devices via integrating actuation mechanisms and quantum materials with meta-atoms. Microelectromechanical systems (MEMS) provide a powerful platform for manipulating the effective properties of metamaterials and the integration of multiple functions with metamaterials. In this talk, I will introduce the fundamentals of metamaterials, approaches to integrate MEMS with metamaterials, functional metamaterial devices from the synergy, and outlooks for metamaterial-enabled devices. Specifically, I will talk about terahertz devices based on the tunable metamaterials for dynamic control of the magnitude, phase, wave front, and polarization by MEMS-driven metamaterial unit cells. Terahertz detectors based on nonlinear terahertz metamaterials will be introduced. In addition, I will discuss the recent advances in the metamaterials for magnetic resonance imaging (MRI) based on the controllable nonlinearity in metamaterials. The implementation of intelligent metamaterials to boost the signal to noise ratio of clinical MRI, which will be translated to improvement in image quality and efficiency. The implementation of nonreciprocal devices based on nonlinearity will also be presented. Besides electromagnetic metamaterials, I will also present the construction of acoustic metamaterials for sound wave manipulation. The acoustic lens to focus sound waves based on the horn-like space coiling structures will be discussed. The ultra-open metamaterial for noise mitigation will also be presented. The future of metamaterials will be outlooked. Based on the MEMS and advanced manufacture technology, multifunctional metamaterial in electromagnetic and acoustic domains will be developed to yield functional devices to achieve functions that are not achievable by nature materials.

11:30 AM OPENING REMARKS

11:32 AM *F.SF03.07.02
Non-Hermitian Symmetry and Topology in Photonics Liang Feng; University of Pennsylvania, United States

Symmetry and topology are fundamental notions existing in all kinds of natural systems, from spiral galaxies and hurricanes to amino acids in molecules and non-trivial topologically protected electronic states in condensed matter. A stream of linearly polarized photons is typically topologically trivial, nevertheless, its full-vector nature intrinsically endows light with full capability of creating and carrying unique symmetry and topology. Most notably, the intrinsic capability of photonics of superposing non-Hermitian eigenstates through optical gain and loss provides a powerful toolbox for exploring the symmetry paradigms that were deemed challenging in condensed matter systems. Such investigations of symmetry and topology in photonics are revolutionizing the design principles in optical sciences. We have discovered new synthetic photonic materials, geometries, and field profiles that systematically enable the exploration of symmetry and topology in photonics. As such, the elusive symmetries can simplify the design of photonic meta-atoms and unit cells to reshape the density of states of photons in a topological and ultraflexible manner, which leads to on-demand meta-control of light emission, transmission, scattering and detection [1], thereby sustaining the ever-expanding information explosion for information processing, communication and computing.
For example, we have demonstrated one of the most striking benefits: the creation of eigenstate degeneracies such as exceptional points intrinsically associated with non-Hermitian Hamiltonians. This breaks the natural symmetry between reciprocal counterpropagating resonant modes in a micro-cavity to conduct unidirectional light-matter interaction carrying the large orbital angular momentum for structured light emission. Such a symmetry-driven approach allowed us to create the first microlaser source carrying the desired spin and orbital chirality as unique information carriers [2-4], giving rise to a new dimension of storing and processing information in photon's chiral degree of freedom. In addition to expanding the information dimensions to address the upcoming information explosion, flexible reconfiguration of topological pathways can offer a completely new paradigm for high-density photonics routing. However, the desired topological robustness unfortunately diminishes the hope of topological tunability. To overcome this fundamental limitation, we perform non-Hermitian symmetry to enable a new kind of topological states into the bulk of the topological insulator with a uniform topology, for the first time [5]. Without "battling" against topological protection, the new non-Hermitian topological states facilitate robust transmission links in the entire footprint to route optical signal to any desired output port. The ports-to-footprint ratio is at least 2 orders of magnitude higher than the state-of-the-art.
Hence, our research addresses grand challenges in fundamental quantum physics and also enables entirely new optical sciences and photonic technologies, which advances and benefits both fields simultaneously.

Twisted Polaritonics Andrea Alù; City University of New York, United States

In this talk, we discuss our recent progress in the area of twistronics with light based on twisted metasurfaces or twisted van-der-Waals bilayers, which support topological transitions at photonic magic angles. The unusual interplay between coupled hyperbolic polaritons and the rotation angle between them enables unusual transitions from hyperbolic to elliptical propagation, which can be predicted by counting the number of intersections between the polariton bands of the two individual surfaces when isolated. During the talk, we discuss the unusual phenomena supported by these structures, and their opportunities for nano-imaging and information transport.

Topological Anomalies Made Visible Henning Schomerus; Lancaster University, United Kingdom

Topological photonics and mechanics aim to replicate fermionic symmetries as feats of precision engineering. Here I show how to enhance these systems via effects such as gain, loss and nonlinearities that do not have a direct electronic counterpart. This leads to a topological mechanism of mode selection [1,2,3], formation of compactons in flat band condensates [4] and sonic metamaterials [5], topological response of lasers [6] and robotic metamaterials [7], and practical applications such as for receiver protectors [8]. Common to them all are structured intensity distributions of the topological modes which are associated with topological anomalies and supersymmetry [9,10,11], normally abstract concepts that become directly visible in experiments.

Active Topological Photonics on the Nanoscale Gennady Shvets, Minwoo Jung and Ran Gladstein Gladstone; Cornell University, United States

Topological photonics enables unusual and robust properties of electromagnetic waves, including reflections-free photon propagation along strongly curved interfaces and localization at the corners and other discontinuities of photonic structures. One of the key remaining challenges include bringing topological photonics to the nanoscale and making it active/reconfigurable. In this talk, I will describe our group's progress on using two-dimensional materials such as electrostatically-gated graphene to accomplish these goals. The concept of a metagate – a structured metallic gate used to imprint topologically-complex chemical potential landscape onto graphene – will be introduced. Examples of lower- and higher-order topological structures that, respectively, confine graphene surface plasmon polaritons to edges and corners, will be presented, and the prospects for their experimental realization will be discussed. A novel regime of quantum landscaping, where periodic patterns of chemical potential simultaneously modify electronic and photonic propagation bands, will be introduced and exemplified using meta-gated graphene.

12:40 PM *F.SF03.09.02
Photonics Inverse Design Jelena Vuckovic; Stanford University, United States

Combining state of the art optimization and machine learning techniques with high speed electromagnetic solvers offers a new approach to "inverse" design and implement classical and quantum photonic circuits with superior properties, including robustness to errors in fabrication and environment, compact footprints, novel functionalities, and high efficiencies. We illustrate this with a number of demonstrated devices in silicon, diamond, and silicon carbide, including wavelength and polarization splitters and converters, power splitters, couplers, nonreciprocal switches and routers, on chip laser driven particle accelerators, and efficient quantum emitter-photon interfaces.

12:56 PM *F.SF03.08.01
Revealing the Energy Spectrum of Plasmonic Hot-Carriers via Single Molecule Transport Measurements Vladimir Shalaev[1], Harsha Reddy[1], Kun Wang[2], Zhaxylyk Kudyshev[1], Linxiao Zhu[2], Shen Yan[2], Andrea Vezzoli[3], Simon Higgins[3], Vikram Gavini[2], Alexandra Boltasseva[1], Pramod Reddy[2] and Edgar Meyhofer[2]; [1]Purdue University, United States; [2]University of Michigan–Ann Arbor, United States; [3]University of Liverpool, United Kingdom

The generation of hot-carriers in plasmonic nanostructures, via plasmon decay, is of great current interest as hot-carriers play key roles in applications like photocatalysis, energy harvesting and in novel photodetection schemes that circumvent band-gap limitations. However, experimental quantification of steady-state energy distributions of hot-carriers in plasmonic nanostructures, which is critical for systematic progress, has not been possible. In this talk, we will describe our recent experimental advances that have enabled the direct measurement of hot-carrier energy distributions under steady-state conditions [1]. Specifically, we will explain how a scanning probe-based technique that records charge transport through

single molecular junctions, when combined with nanoplasmonic experimental methods, can be leveraged to directly quantify hot-carrier energy distributions in a key model system—a thin gold film that supports propagating surface plasmon polaritons. Furthermore, key physical insights from our measurements on the role of Landau damping in producing hot-carriers and the contributions of different plasmonic modes towards hot-carrier generation will be discussed. Finally, we will outline how these experimental advances could potentially be leveraged to quantify hot-carrier distributions in plasmonic nanoparticles and other nanophotonic devices.

1:12 PM *F.SF03.11.02
Tunable Chiral Optical Properties in Semiconductor Nanocrystals and Metamaterials Vivian Ferry; University of Minnesota Twin Cities, United States

Optical nanomaterials offer the ability to bend, twist, guide, and confine light in nanoscale dimensions. Among these materials, chiral nanostructures particularly show promise for applications ranging from polarization manipulation to 3D displays, sensing, and spin-selective transport. Compared to their molecular counterparts, chiral nanomaterials exhibit orders of magnitude stronger dissymmetry factors, but have only been realized in a limited set of materials systems. We have recently demonstrated different strategies to tune and manipulate the polarization response of chiral metamaterials that combine metallic nanostructures, dielectric materials, and semiconductor nanocrystals. By controlling the refractive index of the dielectric components in different architectures, we show that the sign of the circular dichroism can be reversed, and the polarization and directionality of the outcoupled luminescence from nearby nanocrystals can be controlled. To create light-emitting metamaterials, it is additionally useful to create nanostructured elements comprised entirely of photoluminescent materials. We have recently developed patterning methods to transform semiconductor nanocrystals into patterned nanocrystal solids, realizing lateral feature sizes as small as 30 nm and heights in excess of 100 nm without degradation of the photoluminescence. We show that by designing the shape of the nanocrystal solid at this length scale and controlling connectivity between the nanocrystals, the refractive index and nanostructure absorptivity can be tailored. This work points to new strategies to design dynamically tunable metamaterials and control nanoscale light-matter interactions.

Aqueous Synthesis of 3D Nano-architected Ceramics and Metals—Nano-Architected TiO_2 PhCs Julia R. Greer; California Institute of Technology, United States

Additive manufacturing (AM), or 3D printing, represents a set of processes that enable layer-by-layer fabrication of complex structures using a wide range of materials that include ceramics, polymers, and metals. AM has allowed exploiting novel material properties, especially those that arise at the nano-scale, that do not occur in conventional materials, revolutionizing the production of complex parts for aerospace, military, automotive, optial, and medical applications. Facilitating these technologies requires a fabrication process to create a variety of functional materials in 3D, however the material choice for AM at the nano- and micro-scale is limited. A conspicuous example is a lack of AM processes for high refractive index (n), low absorption materials with nano-sized dimensions, which are typically required for microoptics and device applications. To harness the beneficial properties of 3D nano-architected meta-materials, it is critical to assess their properties at each relevant scale while capturing overall structural complexity. We present the fabrication and synthesis of nano- and micro-architected materials using 3D (two-photon and interference) lithography, as well as characterization of their properties as a function of architecture, constituent materials, and microstructural detail. We focus on additive manufacturing of complex, multi-component and multi-material architectures comprised of metal oxides, metals, and hydrogels that are derived from

(metal) salt-based, aqueous photoresin synthesis. The discussion will focus on each representative materials system (metals, oxides, and hydrogels), with a detailed overview of titanium dioxide, with critical feature dimensions between 150 and 600 nm and <1% porosity. Using the described methodology, we created 3D dielectric photonic crystals (PhCs) out of rutile TiO2 patterned into woodpile face-centered tetragonal (FCT) architectures with beam dimensions of 300-600nm and lateral periods of 0.8-1.5 μm. We use Plane Wave Expansion (PWE) simulations and Fourier Transform Infrared Spectroscopy (FTIR) to demonstrate the full photonic bandgaps centered at 1.8-2.9 μm. This fundamental research provides insights into the range of possible, often *transient* attainable chemical compositions, microstructures and architectures of chemically-derived, 3D-archtiected ceramics and metals, enabling advances in multiple technologies, i.e. 3D MEMS, micro-optics, and prototyping of 3D PhCs.

SESSION F.SF03.02: New Photonic Structures
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-SF03

5:00 AM *F.SF03.02.01
Some New Physics We Can Learn from Quasi-1D Structures C.T. Chan; The Hong Kong University of Science and Technology, Hong Kong

We will use some examples to illustrate that quasi-1D systems which have very simple structures can give rise to interesting phenomena that are similar to those observed in topological materials.
A unique and very useful property of topological materials is the existence of topological edge modes which are guaranteed to exist by the topological invariants of the bulk through a bulk-edge correspondence. These topological edge modes or surface states support one-way transport that cannot be interrupted by disorder, and such robustness is probably the most sought after property of topological materials. The topological materials usually require a careful design and many have complex structures. Here, we give one example in which many topological properties of one-way edge modes can be realized in very simple quasi-1D photonic waveguides subjected to simple boundary conditions. These properties include the robustness of transport against imperfections and the ability to go around sharp corners. It appears that under some specific conditions, a certain boundary condition can emulate the existence of a material which carries a gap with some specific non-trivial topological characteristics. The same principle work for acoustic waves. The design principle also allows us to realize waveguides which have desirable characteristics such as being single-mode and have linear dispersion, in addition to being robust against disorder.
In the quest for topological materials, momentum space nodal points such as Weyl and Dirac points have attracted much attention. Realizing such nodal points require 3D/2D structures. However, some interesting nodal points can also be obtained using simple quasi-1D systems. For example, we will see that nexus points of nodal lines can be realized in 1D stacks of ordinary dielectric material layers with misaligned optical axes. Hidden symmetries give rise to interesting band crossings and new type of multifold nodal points. We will see that a fractional periodicity of different components of the permittivity tensor can manifest hidden symmetries of the Maxwell's equations. The hidden symmetries cannot be described using the standard space group theory. Such systems carry a new kind of protected band crossings (Kramers-like nodal lines) which are topological features unique to photonic systems. Such systems carry triply degenerate nodal points as the nexuses of several nodal lines enforced by the hidden symmetry, which can be viewed as a new kind of magnetic monopoles terminating Berry flux strings in the momentum space. In the vicinity of the triple nexus points, the iso-frequency surfaces has spin-1 Dirac-like conical dispersion. This implies that the nexus point can serve as a new platform for probing spin-1 physics. Breaking the hidden symmetry give rise to Type-II and Type-III nodal rings in photonic systems.

B_1^+ Homogenization in 7T Brain MRI with Inversely-Designed Metasurfaces Namkyoo Park and Hansol Noh; Seoul National University, Korea (the Republic of)

Abstract
Offering enhanced SNR, contrast, and spatial resolution, ultra-high field (UHF, $B_0 \geq 7T$) MRI has shown its potential for clinical diagnostics, such as evaluation of strokes, Alzheimer's, and Parkinson's disease [1-4]. However, at the Larmor frequency corresponding to B_0 above 7 Tesla, the effective wavelength of the B_1^+ field becomes smaller than the dimension of the head, leading to the spatial phase variation and inhomogeneity of B_1^+ fields inside. For the mitigation of this

detrimental B_1^+ inhomogeneity creating uneven contrast and the variation of SNR in the UHF MRI image, various approaches have been investigated, such as parallel transmission techniques (PTx), high permittivity material (HPM) structures, and metasurfaces. While PTx improves B_1^+ homogeneity in the whole brain, hardware complexity, and the need for real-time SAR assessment prevents its clinical 7T practice [5,6]. Structures with metallic inclusions, such as metasurfaces and hybridized meta-atoms (HMAs) have also been reported to manipulate field profiles at subwavelength scales [7,8], but often resulted in deterioration of the global B1+ homogeneity over the ROI.
In this talk, we propose and present an inverse-design of metasurfaces addressing the *global* B_1^+ homogeneity over the region of interest (ROI) in the whole axial planes. Approximating MRI environments as a 2D system governed by the Helmholtz equation, we inversely obtain permittivity distributions of cylindrical metasurfaces enclosing the head at proximity. With the metasurface constructed of cylindrical HPMs of different permittivity, stacked along the superior direction, it is numerically confirmed that the proposed metasurface excite the target fields near the surfaces and ROI in both approximated and real MRI environments. When tested with an actual anatomical head model (MIDA), it is found that the CV (coefficient of variation) and Max-to-min ratios of B_1^+ in the ROI are reduced on average by 40% and 33% respectively, along with SAR reduction in the head by 34% (average) and 44% (peak). Since the B_1^+ distribution itself is globally homogenized, the proposed structure is expected to be most useful in spin-echo based imaging in UHF MRI, such as T2-weighted imaging and diffusion-weighted imaging in the whole brain.

5:30 AM F.SF03.02.03
Nanoparticle Supercrystals Formed by Covalent Bonding Interaction in Conjunction with Slow Solvent Evaporation Jiwhan Kim[1], Jahar Dey[1], Aminah Umar[1,2], Sang-Jo Lee[1], Jae-Min Ha[1] and Sung-Min Choi[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]University of Indonesia, Indonesia

Nanoparticle supercrystals (NPSCs) are of great interest as materials with new emergent properties. The emergent properties of NPSCs through collective interaction between nanoparticles provide new opportunities for a wide range of applications such as plasmonics, photonics, electronics, magnetics, and catalysis. Different types of intermolecular interactions such as hydrogen bonding, van der Waal's interaction, and electrostatic interaction have been used for fabricating NPSCs of various crystal symmetries and lattice parameters. However, the limited structural stability of NPSCs fabricated by the intermolecular forces still remains a major hurdle for realizing their potential applications.
The covalent bonding, which shares electrons to form stable organic molecules of various structures, is the most representative intramolecular force much stronger than the intermolecular forces such as van der Waals and hydrogen bonding interactions. Recently, the precision and versatility of covalent chemistry has been successfully established through covalent bonding of various large crystal structures such as metal-organic frameworks and covalent organic frameworks. Considering all these successes, covalent bonding interaction can be an excellent choice for fabricating more stable NPSCs. However, the covalent bonding interaction has not been successfully explored as a main driving force for the formation of highly ordered NPSCs yet.
Here, we report a new method to fabricate highly stable and highly ordered three-dimensional NPSCs by using covalent bonding interaction in conjunction with the slow solvent evaporation process, and demonstrated using isotropic and anisotropic building blocks. In this method, the NPSCs stabilized by covalent bonding are highly stable in solvents of different polarity ranging from water to toluene as well as dried states and at temperature up to 160 °C. Considering the diverse combined choices of covalent bonding reactions, ligand molecules with different chain lengths and physicochemical properties, and nanoparticles may allow the designed synthesis of NPSCs for potential applications. In addition to high strength and the large library of covalent chemistry, the low cost of organic ligands molecules used in this method makes the NPSCs induced by covalent bonding interaction highly versatile and economic, providing new opportunities for the fabrication and applications of NPSCs.

5:40 AM F.SF03.02.04
Atomic Network Adjustment in Amorphous Silicon for Optimizing Metasurface in the Visible Spectrum Younghwan

Yang, Gwanho Yoon and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

This work suggests an adjustable index of hydrogenated-amorphous silicon for obtaining high-efficiency metasurface in the visible by modulating chemical equilibrium of deposition. Hydrogenated-amorphous silicon has been widely used for metasurface since it has cost-effective, CMOS-compatible fabrication methods. Also, hydrogenated-amorphous silicon exhibit a high index ~3.0 at the visible frequency, which induces optical property modulation with geometrical structures on thin film. Based on these advantages, many practical metasurface have been reported such as metalenses, meta-hologram, and structural color filters. However, hydrogenated-amorphous silicon suffers from low-efficiency in high-frequency range because it has a bandgap tail in the visible. The bandgap tail is known to be the main obstacle to be transparent materials, so high-efficient metasurface is limited by inherent material properties of silicons. Here, this work explores atomic structure networks of hydrogenated amorphous silicon to modulate complex refractive index, which enables high-efficiency metasurface in the visible spectrum. The adjustability of the refractive index achieved with varying deposition conditions of plasma-enhanced chemical vapor deposition, which affect bonding states and their hydrogenation. It is revealed that substrate temperature and atmospheric pressure are the main factor to change bonding states and hydrogenation. By changing the deposition conditions, atomic structures were verified, and it is confirmed by X-ray diffraction and transmission electron microscopy. Substrate temperature and atmospheric pressure are the main factor to change bonding states and hydrogenation. Optimized pressure creates micro/nano crystallinity in hydrogenated silicon, which reduces the extinction coefficient. Another parameter affects hydrogen contents, which reduce dangling bonds of silicon. These phenomena change the bandgap tail of silicon, it induce high refractive index coverage when chemical equilibrium is manipulated. As a result, the refractive index can modify between 2.6 and 4.2; the extinction coefficient can be lower than 0.1 at the wavelength of 450 nm. Also, the adjusted hydrogenated-amorphous silicon has near-zero absorption at the wavelength of 532 nm and 635 nm, which is comparable to normal transparent materials (TiO2, GaN, etc). Furthermore, conversion efficiency for visible range metasurface was calculated with an optimized complex refractive index, resulting in 96.6%, 90.9%, and 64.7% at the wavelength of 635 nm, 532 nm, and 450 nm, respectively. Those results can alter materials of metasurface from conventional, transparent dielectrics (TiO2, GaN, etc) to hydrogenated amorphous silicon. Also, the high adjustability of the complex refractive index of silicon with simple steps can be useful for low-cost fabricatable, versatile metasurfaces. At last, the experimental demonstration was also conducted to verify high-efficiency metasurface composed of optimized materials. Optimized refractive index with suitable geometrical parameters achieves 64% at the wavelength of 635 nm, 65% at the one of 532 nm, and 42% at one of 450 nm, which have been not reported yet. Considering the simple fabrication steps with adjustability compared to other dielectrics, hydrogenated amorphous silicon will be a promising material for the practical application of metasurfaces.

Electrically-Controlled Digital Metasurface Device for Light Projection Displays Na Liu[1,2]; [1]University of Stuttgart, Germany; [2]Max Planck Institute for Solid State Research, Germany

The fast development of nanophotonics urges breakthrough concepts and design principles to create functional devices for diverse optical applications. In particular, the advent of metasurfaces has revolutionized nanophotonics, enabling a variety of opportunities. Metasurfaces, which comprise subwavelength optical antennas in ultrathin layers, identify a class of flat optical devices with exceptional control over the propagation of light.[1] Despite the exciting progress, a specific research focus - dynamic optical metasurfaces,[2] which probably also provide the most important link to the real-world optical applications, still awaits endeavors. They allow for active manipulation of light beams and enable fascinating optical functions, including dynamic beam steering, focusing and shaping, as well as optical vortex generations, imaging, and sensing. However, the reported schemes have been mostly limited to simultaneous tuning of the resonance frequencies or amplitudes of all the metasurface antennas.[3, 4] They also suffer from poor device control with low intensity modulation and narrow operating band. Thus, there is still plenty of room to advance this research focus, especially at visible frequencies.
We demonstrate a strategy to realize dynamic optical metasurfaces by tailoring their spatial frequencies via modulation of both the geometric and propagation phases at visible frequencies. In particular, we showcase electrically-controlled digital metasurface devices (DMSDs) for light projection displays. The DMSD consists of metasurface pixels in an M × N array. Each metasurface pixel contains gold nanorods arranged in a rectangular lattice. In some preselected (odd or even) columns,

the nanorods are covered with a dielectric material. The sample is subsequently encapsulated in a thin liquid crystal (LC) cell. The dynamic function of the metasurface pixels is enabled by electrically controlling the relative phase between the neighboring odd and even columns via LCs on the millisecond time scale. In principle, each metasurface pixel can be designed to generate a specific dynamic holographic pattern in the far field. Particularly for light projection display applications, each metasurface pixel that can be electrically switched between '1' and '0' states is individually addressed by an electrode, forming an anomalous reflection spot that can be turned on and off with high contrast in the projection screen. As a result, programmable images are dynamically generated and displayed. [5]

Highly Reflective Subtractive Colors Based on Silver Nanodisk Metasurfaces Jolie Blake[1], Stefano Rossi[2], Oliver Olsson[1], Marika Gugole[1], Kunli Xiong[1], Magnus Jonsson[2] and Andreas Dahlin[1]; [1]Chalmers University of Technology, Sweden; [2]Linköping University, Sweden

Plasmonic structural colors generated by metasurfaces have emerged as feasible alternatives to traditional pigment-based printing. Despite extensive studies, producing structural colors from nanostructured metasurfaces in metal-insulator-metal (MIM) configuration still presents some challenges. One major hurdle is pixel fabrication that does not rely on expensive lithographic methods but can still controllably produce saturated and bright colors. We report highly reflective cyan, magenta and yellow (CMY) color pixels based on silver metasurfaces, using a wide-area fabrication technique suitable for upscaling. Through numerical simulations we demonstrate that the colors achieved are as a result of resonances more characteristic of Fabry-Pérot than gap- surface plasmon modes due to the thick spacer layer.

Multifunctional Structured Light with Flat Optics Federico Capasso and Ahmed Dorrah; Harvard University, United States

Flat optics based on metasurfaces holds promise for the design of a new class of diffractive optical component that circumvents the limits of refractive as well as Fresnel optics, in terms of control of aberrations, compactness and multifunctionality. Here we highlight the enhanced functions enabled by metasurface flat optics in structuring light. Optical elements coupling the spin and orbital angular momentum (SAM/OAM) of light have found a range of applications in classical and quantum optics. Q-plate type devices based on dielectric metasurfaces have shown superior performance in terms of singularity definition and ability to generate fractional and high OAM beams. A far more general spin to orbital angular momentum scheme has been recently demonstrated based on novel metasurface optical elements (J-plates) not limited to conjugate converted states, which are used to generate new complex structured light. The J-plate, with J referring to the photon's total angular momentum (TAM), is a metasurface device that imparts two arbitrary OAM states on an arbitrary orthogonal basis of spin states. When these J-plates are cascaded in series, they can generate several single quantum number beams and versatile superpositions thereof. Moreover, in contrast to previous spin-orbit-converters, the output polarization states of cascaded J-plates are not constrained to be the conjugate of the input states. Cascaded J-plates are also demonstrated to produce vector vortex beams and complex structured light, providing new ways to control TAM states of light

Metasurfaces hold major potential for multi-functionality, which may play a pivotal role in the next-generation compact nanodevices. OAM from lasers holds the promise for compact, at-the-source solutions to fuel applications from imaging to communications . However, conjugate symmetry between circular spin and opposite helicity OAM states from conventional spin-orbit (SO) approaches, as well as low purity modes, has meant that complete control of light's angular momentum from lasers has remained elusive. Recent work on metasurface-enhanced lasers that overcomes this limitation will be discussed, including the demonstration of new high-purity OAM states with quantum numbers reaching l= 100, and non-symmetric vector vortex beams that lase simultaneously on independent OAM states as much as $\Delta l = 90$ apart. This laser conveniently emits in the visible, producing new OAM states of light as well as all previously reported OAM modes from lasers, offering a compact and power-scalable source that harnesses intra-cavity structured metasurfaces for the creation of arbitrary chiral states of structured light.
Finally, recent work on beams with light structured along the propagation direction will be presented, where the polarization or the OAM of the beam changes along the propagation direction.

5:15 AM *F.SF03.04.02
Multifunctional Nonlocal Metasurfaces Nanfang Yu, Stephanie Malek and Adam C. Overig; Columbia University, United States

Diffractive photonic devices manipulate light via local and nonlocal optical modes. Local devices, such as metasurfaces, can shape a wavefront at multiple selected wavelengths, but inevitably modify light across the spectrum; nonlocal devices, such as grating filters, offer great frequency selectivity but limited spatial control. In this talk, I will introduce a rational design paradigm using quasi-bound states in the continuum to realize multifunctional nonlocal devices: metasurfaces that produce narrowband spatially tailored wavefronts at multiple selected wavelengths and yet are otherwise transparent.
I will show an experimental demonstration of dielectric metalenses that focus light only for narrowband resonances and leave the rest of the spectrum unaffected. Our resonant metasurfaces can be cascaded to achieve multifunctional behavior with each metasurface independently shaping the wavefront for a distinct resonance resonant wavelength.
These devices may expand the capabilities of multifunctional meta-optics to include active or nonlinear wavefront shaping. Scaled to visible wavelengths, our resonant metalenses may prove useful for augmented reality applications as compact and highly transparent multi-color see-through lenses.

5:30 AM F.SF03.04.03
Sensitivity of Plate-Lattice Metamaterials to Geometric Imperfections Fani Derveni[1], Andrew Gross[2], Kara Peterman[1] and Simos Gerasimidis[1]; [1]University of Massachusetts Amherst, United States; [2]University of South Carolina, United States

Structural requirements have pushed lightweight materials with advantageous material properties to the forefront of engineering practice. As a result, it has become necessary to enhance the breadth of design options with a new generation of lightweight materials offering high strength, high stiffness, and high energy absorption capacity. The accelerated progress of additive manufacturing has enabled the fabrication of intricate architectures which are used today to design new materials. These materials, also called architected materials, exhibit mechanical properties which are dictated primarily by their pattern rather than their composition and therefore the design of their architectures has received great attention. The fabrication capabilities gained from additive manufacturing has opened up a new space for design exploration based on these architectural forms. Until today, there have been numerous architected lattice materials with extraordinary properties such as negative Poisson's ratio, negative stiffness, multi-stability, negative thermal expansion and others. Very recently, a new generation of architected materials has emerged in the form of plate-lattice materials in which plates are patterned in different configurations to create a cellular geometry. Recent findings have shown that plate-lattice materials are not only significantly stiffer and stronger than truss-lattices, but also able to attain the theoretical Hashin Shtrikman and Suquet bounds for isotropic materials. The objective of this work is to explore the imperfection sensitivity of a variety of isotropic and anisotropic plate-lattice architectures of cubic symmetry, such as Simple Cubic (SC), Body-Centered Cubic (BCC), Face-Centered Cubic (FCC) and their isotropic combinations (SC-BCC and SC-FCC). Three-dimensional shell computational models with periodic boundary conditions are used to study the buckling behavior. Short and long wavelength buckling modes are observed by increasing the tessellation size of plate-lattices under axial compression for a range of relative densities between 0.05% (ultra-thin) and 25%. Geometric imperfections are incorporated in the model by varying imperfections of modal shapes. The main goal of this work is to provide accurate knockdown factors for plate-lattice materials with geometric imperfections and to characterize fundamental behavior of these plate-lattice metamaterials with a potential use in new generation structural applications.

5:40 AM F.SF03.04.04
Multidimensional and Multifunctional Metalenses Based on Photonic Spin Hall Effect Renchao Jin[1,2], Zheng-Gao Dong[2] and Yongmin Liu[1,1]; [1]Northeastern University, United States; [2]Southeast University, China

Metasurfaces are composed of arrays of subwavelength meta-atoms, which have demonstrated many exciting opportunities to control the amplitude, phase and polarization of incident light. Metasurfaces with circularly polarized sensitivity has attracted wide attention, because of the manifestation of the photonic spin Hall effect (PSHE)[1]. Pancharatnam-Berry (PB) phase is the frequently used method to control the phase of circularly polarized light. However, most metasurfaces based on the PB phase only work for circularly polarized light with one specific spin, hindering the simultaneous and independent control of left-handed circularly polarized (LCP) light and right-handed circularly polarized (RCP) light [2].
In this talk, we demonstrate that utilizing both the PB phase and the propagation phase, we can rationally control the phase for each spin state of light [3]. The PB phase provides opposite phase modulation for LCP and RCP light, and it is determined by the in-plane rotation angle of meta-atoms [4,5]. In contrast, the propagation phase provides the same phase modulation regardless of the polarization of incident light and rotation angle of meta-atoms. Therefore, combing the PB phase and propagation creates a flexible way to realize simultaneous phase control of LCP and RCP light. As proof-of-concept demonstrations, here we numerically and experimentally realize the independent focusing and manipulation of both spins of light by V-antenna metasurfaces. Our multidimensional metalens is able to focus light of different spins at designated positions along both transverse and longitudinal directions. It can be used as a polarization analyzer to distinguish the polarization state of incident light. In addition, our multifunctional metalens can act either as a convex lens or an axicon, depending on the spin of light. The demonstrated multidimensional and multifunctional metalens has versatile potentials in spin-dependent nanophotonics, ranging from optical imaging and micro/nano-object manipulation to optical sensing.

Design and Additive Manufacturing of Intelligent Metamaterials Xiaoyu Zheng; University of California, Los Angeles, United States

Metamaterials represent the concept of utilizing artificial material building blocks to create desirable properties derived from three-dimensional layout and compositions. While novel topologies can now be realized via additive manufacturing, the lack of processable materials, multi-material gradients, speed and scalabilities have stymied its further adoption. In this talk, I will outline a suite of new material design and manufacturing routes, enabled by additive manufacturing of topologies, multi-scale features and multi-material cues. Attention is focused on how additive manufacturing techniques will enable processing the unprocessable, from structural composites to functional and stimuli-responsive multi-materials. This unleashes new design freedoms for rapid material property discovery and product realizations; where electrical, thermo, mechanical behaviors and their couplings can be inversely designed and tailored by an end-user at will. I will present a few examples, where structural, electronic and energy transduction materials are 3D architected into a compact form factor, without requiring multiple processing stages such as printing, embedding or wiring. Next, we will present their new applications, such as ultralight and strong materials, self-sensing materials, microsystems for robotics, air and maritime sensing, transducers, wave guiding and telecommunications.

5:15 AM F.SF03.05.02
Extreme Mechanical Resilience in Nanolabyrinthine Self-Assembled Metamaterials Carlos Portela[1,2], A Vidyasagar[2], Sebastian Krödel[3], Tamara Weissenbach[3], Daryl Yee[2], Julia R. Greer[2] and Dennis Kochmann[3]; [1]Massachusetts Institute of Technology, United States; [2]California Institute of Technology, United States; [3]ETH Zürich, Switzerland

Lightweight materials with tailorable properties have attracted attention for decades, yet stiff materials that can resiliently tolerate extreme forces and deformation, while being manufactured at large scales, have remained a rare find. Bio-inspired designs such as hierarchical foams and atomic-lattice-mimicking trusses have achieved optimal combinations of mechanical parameters but suffer from limited mechanical tunability, limited long-term stability, and low throughput volumes. Most mechanical metamaterials have relied on symmetry, periodicity, and lack of defects to achieve the desired mechanical response, resulting in sub-optimal mechanical response under the presence of inevitable defects. Shell-type designs, which

can mitigate stress concentrations and flaws, have come with high densities and limited recoverability.

We exploit non-periodic ceramic shell architectures of ultralow density (reaching 4 mg/cm^3) whose engineered curvature distribution achieves close-to-optimal stiffness scaling and, moreover, whose careful combination of topology, geometry and base material results in mechanical resilience superior to previous mechanical metamaterials. We present a method for scalable fabrication of these materials, guided by natural spinodal decomposition, which results in shell-based ceramic architectures with thicknesses down to ~10 nm and overall sample volumes of up to a few cubic centimeters. We show the capability of these architectures to maintain more than 50% of their original stiffness and strength after ten cycles of compression up to 30% while exhibiting no visible permanent deformation. Guided by simulations, we show how controlling the material morphology leads to the (an)isotropic material response whose directional stiffness distribution, impressively, remains constant over a wide range of shell thicknesses, as demonstrated experimentally. Our approach highlights pathways to harness self-assembly methods in the design and scalable fabrication of novel metamaterials with both tunable high stiffness and unsurpassed recoverability, simultaneously unachievable by previously reported mechanical metamaterials.

Parametric Oscillation of Electromagnetic Waves in Momentum Band Gaps of a Spatiotemporal Crystal Seojoo Lee[1], Jagang Park[1], Hyukjoon Cho[1], Yifan Wang[2], Brian Kim[2], Chiara Daraio[2] and Bumki Min[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]California Institute of Technology, United States

Photonic crystals have revolutionized the field of photonics with their unique capabilities of dispersion and energy band gap engineering, such as the demonstration of extreme group and phase velocities, topologically-protected photonic edge states, and the control of spontaneous emission of photons. On the other hand, time-variant media have shown their distinct functionalities including nonreciprocal propagation, frequency conversion, and amplification of light. However, these phenomena in time-variant media have mostly been investigated for the cases where spatiotemporal modulation is in the form of a simple harmonic wave. Here, we extend the type of spatiotemporal modulation so that time-variant and spatially-discrete photonic crystal structures, or spatiotemporal crystals, can be analyzed. The design of spatiotemporal crystals allows the engineering of momentum band gap, within which the parametric amplification occurs. As a potential platform for the construction of a parametric oscillator, a finite-sized spatiotemporal crystal is proposed and analyzed. The parametric oscillation is initiated by the energy and momentum conversion of an incident wave and the subsequent amplification by parametric gain within the momentum band gap. The oscillation process dominates over frequency mixing interactions above a transition threshold determined by the balance between gain and loss. Furthermore, the asymmetric formation of momentum band gaps can be realized by spatial phase control of temporal modulation, which leads to the directional radiation of oscillations at distinct frequencies. The proposed structure would enable simultaneous engineering of energy and momentum band gaps and provide a guideline to the implementation of advanced dispersion-engineered parametric oscillators.

5:15 AM F.SF03.06.02
3D Chiral Self-Assembly of Spheres and Tetrahedra Daniel B. Straus and Robert J. Cava; Princeton University, United States

The design of new chiral materials usually requires stereoselective organic synthesis to create molecules with chiral centers. Less commonly, achiral molecules can self-assemble into chiral materials, despite the absence of intrinsic molecular chirality. Here, we demonstrate the assembly of high-symmetry molecules into a chiral van der Waals structure by synthesizing crystals of $C_{60}(SnI_4)_2$ from icosahedral buckminsterfullerene (C_{60}) and tetrahedral SnI_4 molecules through spontaneous self-assembly. The SnI_4 tetrahedra template the Sn atoms into a chiral cubic three-connected net of the $SrSi_2$ type that is held together by van der Waals forces. Our results represent the remarkable emergence of a self-assembled chiral material from two of the most highly symmetric molecules, demonstrating that almost any molecular, nanocrystalline, or engineered precursor can be considered when designing chiral assemblies.

Synthesis and Characterization of Nanoscale 3-Dimensional Metamaterials Grace Pakeltis[1], C. Praise Anyanwu[2], Juan C. Idrobo[3], David Masiello[2], Jason Fowlkes[1,3] and Philip D. Rack[1,3]; [1]The University of Tennessee, Knoxville, United States; [2]University of Washington, United States; [3]Oak Ridge National Laboratory, United States

Metamaterials have been of great interest in the field of photonics due to their ability to realize intriguing new properties unachievable in natural materials. Advances in metamaterial design and characterization have led to advancing from the microwave region to terahertz and optical frequency to realize artificial magnetism, negative refractive index, and superlenses. One of the most common elements in metamaterial design is the split ring resonator. While much work has been devoted to optically modeling and characterizing planar plasmonic SRR arrays, there has yet to be a robust strategy for synthesizing 3 dimensional SRR structures. Enhanced functionality should be possible by extending into the third dimension. In this study, we illustrate a nanoscale synthesis process which utilizes a hybrid of direct-write 3D nanoprinting and thin film deposition to fabricate free-standing split ring resonators for the investigation of 3D metamaterials. Focused electron beam induced deposition is used to deposit non-plasmonic 3D scaffolds, which are subsequently isolated with a conformal SiO_2 layer and coated with a plasmonic materials, specifically Au, to create functional 3D metamaterials. A variety of single coupled SRR structures were fabricated and low-loss electron energy loss spectroscopy was utilized to characterize their full plasmonic spectra with nanoscale resolution. Complementary electron discrete dipole approximation simulations were performed to elucidate the resultant consequent electric and magnetic field distributions. This work demonstrates the flexibility FEBID scaffolds offer for the advancement of new 3D devices for applications and fundamental studies of metamaterials.

SESSION F.SF03.07: Topological Photonics

5:00 AM *F.SF03.07.01
Novel Valley Manipulation in Photonic Crystals Baile Zhang; Nanyang Technological University, Singapore

The valley degree of freedom (DOF) has recently been introduced into photonic crystals as a new way to manipulate electromagnetic waves, similar to how electrons are manipulated in valleytronic materials. Compared to the photonic pseudospin that requires complex construction such as ring resonators and bianisotropic metamaterials, the valley DOF originates from the underlying lattice symmetry, which does not rely on strong spin-orbit coupling and thus can be easily integrated in a photonic crystal setup. In this talk, I will introduce some of our recent works on valley manipulation.

First of all, the topological valley edge states have been realized in many photonic crystals. We firstly implemented a valley photonic crystal at microwave frequencies based on a four band model, and demonstrated the spin-valley locking feature. A very interesting phenomenon is the perfect out-coupling of valley edge states because of the valley conservation at the zigzag interface.

Secondly, we constructed an unpaired Dirac point at a single valley. It is well known that a photonic graphene exhibits two Dirac cones at two valleys. Therefore, in order to probe features of 2D Dirac particles, special precautions must be taken to ensure that only one valley is excited. Depending on the system geometry, this is not always possible, because defects and interfaces can give rise to strong intervalley scattering. Here we will discuss the construction of an unpaired Dirac point at only one valley. Some unique photonic phenomena such as the nonreciprocal reflection and angular selectivity are discussed. This unpaired single Dirac cone is inspired by the famous Haldane model, where the inversion symmetry breaking and time reversal symmetry breaking compete to open a topological bandgap.

Thirdly, we found that another mechanism that can be utilized to manipulate valley is via loss and gain, or non-Hermiticity. By modifying the Haldane model, it can be seen that the loss/gain can participate in the completion between inversion symmetry breaking and time reversal symmetry breaking, and drive the Haldane-type topological transition. In particular, the loss/gain can displace the Dirac points in momentum space. So the modulation of loss/gain can induce a uniform effective magnetic field and thus Landau levels, similar to the effect of strain engineering, but without lattice deformation.

Finally, these valley photonic crystals have found device applications such as the on-chip communication and electrically

pumped lasers.

5:15 AM *F.SF03.07.02
Non-Hermitian Symmetry and Topology in Photonics Liang Feng; University of Pennsylvania, United States

Symmetry and topology are fundamental notions existing in all kinds of natural systems, from spiral galaxies and hurricanes to amino acids in molecules and non-trivial topologically protected electronic states in condensed matter. A stream of linearly polarized photons is typically topologically trivial, nevertheless, its full-vector nature intrinsically endows light with full capability of creating and carrying unique symmetry and topology. Most notably, the intrinsic capability of photonics of superposing non-Hermitian eigenstates through optical gain and loss provides a powerful toolbox for exploring the symmetry paradigms that were deemed challenging in condensed matter systems. Such investigations of symmetry and topology in photonics are revolutionizing the design principles in optical sciences. We have discovered new synthetic photonic materials, geometries, and field profiles that systematically enable the exploration of symmetry and topology in photonics. As such, the elusive symmetries can simplify the design of photonic meta-atoms and unit cells to reshape the density of states of photons in a topological and ultraflexible manner, which leads to on-demand meta-control of light emission, transmission, scattering and detection [1], thereby sustaining the ever-expanding information explosion for information processing, communication and computing.
For example, we have demonstrated one of the most striking benefits: the creation of eigenstate degeneracies such as exceptional points intrinsically associated with non-Hermitian Hamiltonians. This breaks the natural symmetry between reciprocal counterpropagating resonant modes in a micro-cavity to conduct unidirectional light-matter interaction carrying the large orbital angular momentum for structured light emission. Such a symmetry-driven approach allowed us to create the first microlaser source carrying the desired spin and orbital chirality as unique information carriers [2-4], giving rise to a new dimension of storing and processing information in photon's chiral degree of freedom. In addition to expanding the information dimensions to address the upcoming information explosion, flexible reconfiguration of topological pathways can offer a completely new paradigm for high-density photonics routing. However, the desired topological robustness unfortunately diminishes the hope of topological tunability. To overcome this fundamental limitation, we perform non-Hermitian symmetry to enable a new kind of topological states into the bulk of the topological insulator with a uniform topology, for the first time [5]. Without "battling" against topological protection, the new non-Hermitian topological states facilitate robust transmission links in the entire footprint to route optical signal to any desired output port. The ports-to-footprint ratio is at least 2 orders of magnitude higher than the state-of-the-art.
Hence, our research addresses grand challenges in fundamental quantum physics and also enables entirely new optical sciences and photonic technologies, which advances and benefits both fields simultaneously.

Active Topological Photonics on the Nanoscale Gennady Shvets, Minwoo Jung and Ran Gladstein Gladstone; Cornell University, United States

Topological photonics enables unusual and robust properties of electromagnetic waves, including reflections-free photon propagation along strongly curved interfaces and localization at the corners and other discontinuities of photonic structures. One of the key remaining challenges include bringing topological photonics to the nanoscale and making it active/reconfigurable. In this talk, I will describe our group's progress on using two-dimensional materials such as electrostatically-gated graphene to accomplish these goals. The concept of a metagate – a structured metallic gate used to imprint topologically-complex chemical potential landscape onto graphene – will be introduced. Examples of lower- and higher-order topological structures that, respectively, confine graphene surface plasmon polaritons to edges and corners, will be presented, and the prospects for their experimental realization will be discussed. A novel regime of quantum landscaping, where periodic patterns of chemical potential simultaneously modify electronic and photonic propagation bands, will be introduced and exemplified using meta-gated graphene.

5:00 AM *F.SF03.08.01
Revealing the Energy Spectrum of Plasmonic Hot-Carriers via Single Molecule Transport Measurements Vladimir Shalaev[1], Harsha Reddy[1], Kun Wang[2], Zhaxylyk Kudyshev[1], Linxiao Zhu[2], Shen Yan[2], Andrea Vezzoli[3], Simon Higgins[3], Vikram Gavini[2], Alexandra Boltasseva[1], Pramod Reddy[2] and Edgar Meyhofer[2]; [1]Purdue University, United States; [2]University of Michigan–Ann Arbor, United States; [3]University of Liverpool, United Kingdom

The generation of hot-carriers in plasmonic nanostructures, via plasmon decay, is of great current interest as hot-carriers play key roles in applications like photocatalysis, energy harvesting and in novel photodetection schemes that circumvent band-gap limitations. However, experimental quantification of steady-state energy distributions of hot-carriers in plasmonic nanostructures, which is critical for systematic progress, has not been possible. In this talk, we will describe our recent experimental advances that have enabled the direct measurement of hot-carrier energy distributions under steady-state conditions [1]. Specifically, we will explain how a scanning probe-based technique that records charge transport through single molecular junctions, when combined with nanoplasmonic experimental methods, can be leveraged to directly quantify hot-carrier energy distributions in a key model system—a thin gold film that supports propagating surface plasmon polaritons. Furthermore, key physical insights from our measurements on the role of Landau damping in producing hot-carriers and the contributions of different plasmonic modes towards hot-carrier generation will be discussed. Finally, we will outline how these experimental advances could potentially be leveraged to quantify hot-carrier distributions in plasmonic nanoparticles and other nanophotonic devices.

Topological Anomalies Made Visible Henning Schomerus; Lancaster University, United Kingdom

Topological photonics and mechanics aim to replicate fermionic symmetries as feats of precision engineering. Here I show how to enhance these systems via effects such as gain, loss and nonlinearities that do not have a direct electronic counterpart. This leads to a topological mechanism of mode selection [1,2,3], formation of compactons in flat band condensates [4] and sonic metamaterials [5], topological response of lasers [6] and robotic metamaterials [7], and practical applications such as for receiver protectors [8]. Common to them all are structured intensity distributions of the topological modes which are associated with topological anomalies and supersymmetry [9,10,11], normally abstract concepts that become directly visible in experiments.

A Trajectory Model of Quantum Mechanical Tunneling for Comparisons to Electromagnetic Wave Propagation Through a Barrier Kevin L. Jensen[1], Nina Riga[2], Donald Shiffler[2], Rebecca Seviour[3] and Joel L. Lebowitz[4]; [1]Naval Research Laboratory, United States; [2]Air Force Research Laboratory, United States; [3]University of Huddersfield, United Kingdom; [4]Rutgers, The State University of New Jersey, United States

Quantum mechanical (QM) tunneling and transit time effects are increasingly important to attosecond and nanoscale physics for which quasi-classical trajectory interpretations are useful [1] to characterize electron emission. Modeling electron transport with particle-based methods may possibly benefit from using a Wigner distribution function (WDF), which is a quantum distribution with a trajectory interpretation that has analogs to a classical distribution of particles. The WDF is therefore potentially useful to describing tunneling and other purely quantum mechanical behaviors like resonant transmission [2, 3]. An exploration of the trajectory interpretation, however, is made difficult because there are few analytically solvable cases on which to test the methods, investigate the trajectory behavior, and relate to dielectric structure experiments examining the relationship between QM tunneling and electromagnetic wave propagation through a barrier that are progressing in tandem and described by N. M. Riga, et al. (this conference).
In this work, the WDF for an exactly solvable system for closed boundary conditions [4] gives both analytic trajectories and time-dependent behavior, and is described. Changes in the eigenstates associated with a step-potential lead to trajectories whose tunneling behavior is examined. Open boundary conditions are required to consider current flow and are required for the emission models, but require numerical approaches to the time evolution behavior for even simple barriers (in contrast to exact solutions to Schrodinger's Eq. [5]). Our methods and findings are presented and compared to alternate methods for thin barriers using analytic models [6].

Local Valley-Hall Effect for Photons Dia'aaldin Bisharat and Dan Sievenpiper; University of California, San Diego, United States

In recent years, there has been extensive research on photonic topological insulators (PTIs), motivated by the prospect of backscattering-immune wave propagation. One way to realize PTIs is by altering the crystalline symmetry of the lattice to emulate the quantum valley-Hall effect. This relies on the valley degree of freedom (DOF) that is readily available in photonic crystals (PhCs) with C6v symmetry. Typically, however, the lattice is reduced to C3v symmetry, causing a transition of the system to the valley topological phase (characterized by half-integer Chern numbers of opposite signs associated with the positive and negative halves of the Brillouin zone, respectively). This enables the occurrence of valley-polarized modes exhibiting backscattering-immune wave propagation in the absence of inter-valley scattering disorder. Here, we propose a local-valley approach that maintains C6v symmetry yet supports robust valley-polarized modes.
To differentiate our approach form the typical valley-based approach, consider the example of a hexagonal lattice of dielectric rods. In the typical approach, the rods are usually deformed into triangular shape and the edge modes are observed at the interface between two PhCs, where the triangles in one PhC are facing the opposite way with respect to those in the other PhC. In comparison, in the proposed approach, the rods have cylindrical shape and the edge modes are observed along one row of rods that are misaligned with respect to the original lattice like in common line defect waveguides. Note that the preserved rotational symmetry of the unit cell means that the edge states in the later approach must reside in an intrinsic

bandgap of the PhC that is different than that associated with C3v symmetry.
In both approaches, the edge modes are the results of linking opposite orbital angular momentum vortices across the waveguide region. In addition, the proposed edge modes exhibit the expected unidirectional wave excitation and robust wave transmission through sharp zigzag-shaped bends. Moreover, we show that our proof-of-concept platform is in fact an analogue of bilayer graphene system with AB/BA stacking regions. Hence, we reveal that the sole criterion for supporting valley-polarized states is breaking the mirror inversion symmetry locally, i.e. only near the waveguide region. Attractively, the proposed approach leads to simple implementation, benefiting practical applications and easier fabrication at optical frequencies compared to existing valley-type PTIs.

Twisted Polaritonics Andrea Alù; City University of New York, United States

In this talk, we discuss our recent progress in the area of twistronics with light based on twisted metasurfaces or twisted van-der-Waals bilayers, which support topological transitions at photonic magic angles. The unusual interplay between coupled hyperbolic polaritons and the rotation angle between them enables unusual transitions from hyperbolic to elliptical propagation, which can be predicted by counting the number of intersections between the polariton bands of the two individual surfaces when isolated. During the talk, we discuss the unusual phenomena supported by these structures, and their opportunities for nano-imaging and information transport.

Photonics Inverse Design Jelena Vuckovic; Stanford University, United States

Combining state of the art optimization and machine learning techniques with high speed electromagnetic solvers offers a new approach to "inverse" design and implement classical and quantum photonic circuits with superior properties, including robustness to errors in fabrication and environment, compact footprints, novel functionalities, and high efficiencies. We illustrate this with a number of demonstrated devices in silicon, diamond, and silicon carbide, including wavelength and polarization splitters and converters, power splitters, couplers, nonreciprocal switches and routers, on chip laser driven particle accelerators, and efficient quantum emitter-photon interfaces.

5:30 AM F.SF03.09.03
Probabilistic Representation and Inverse Design of Metasurfaces Based on a Deep Generative Model Yihao Xu, Wei Ma and Yongmin Liu; Northeastern University, United States

Over the past decades, the study of metamaterials and metasurfaces has brought enormous success in modern photonics. With rationally designed sub-wavelength units, known as meta-atoms, one can manipulate light in a desired and prescribed manner. Although modern numerical methods can accurately simulate the optical responses of complex structures, the full-wave simulation methods such as FEM and FDTD still require a lot of time and computational resources, especially when parameter sweeping in a huge design space is required to inversely retrieve the optimal structure according to certain optical responses. In the traditional research approach, researchers need to adjust the geometric/material parameters through experience repeatedly until the simulated optical responses meet the requirements to the maximum. This process still takes enormous time even for experienced researchers when the design problem is challenging.

Very recently, data-driven approaches, such as deep learning, have been applied to design various photonic structures, including metamaterials, metasurfaces, photonic crystals and plasmonic nanostructures[1-4]. To better reveal the implicit structure-property relationship and thus facilitate metasurface designs, we proposed to represent metasurfaces and model the inverse design problem in a probabilistically generative manner with the help of variational autoencoders (VAE), which not only enable to efficiently and elegantly investigate the complex structure–optical response relationship in an interpretable way, but solve the one-to-many mapping issue that is tough in a deterministic model[2]. Moreover, to avoid vast full-wave simulation when collecting data, a semi-supervised learning strategy is developed that allows the model to utilize unlabeled

data in addition to labeled data in an end-to-end training network[5]. We demonstrate that the self-supervised deep learning model can effectively utilize randomly generated unlabeled data during training, with the total test loss and prediction accuracy improved by about 15% compared with the fully supervised counterpart. On a data-driven basis, the proposed deep generative model can serve as a comprehensive and efficient tool that prompts the design, characterization, and even novel discovery in the research domain of metasurface, and photonics in general.

5:40 AM F.SF03.09.04
Active Learning with Multi-Objective Optimization for 3D-Printed Acoustic Metamaterials Combining Simulations and Experiments Karsten Bruening[1], Wan Shou[2], Mina Konaković Luković[2], Beichen Li[2], Kui Wu[2], Xianchen Xu[3], Jun Amano[1] and Wojciech Matusik[2,2]; [1]Konica Minolta Laboratory USA, United States; [2]Massachusetts Institute of Technology, United States; [3]University of Missouri–Kansas City, United States

3D-printing and additive manufacturing enable much larger design spaces than conventional manufacturing methods (e.g. subtractive manufacturing, injection molding). This applies to the geometry as well as to the materials, with some 3D-printers offering multi-material printing with continuous variation in composition. Without the bounds from “design for manufacturing”, more complex designs become possible and are not penalized by manufacturability. In fact, complex designs are often favored over geometrically simple designs (e.g. structured infill vs. solid infill). This freedom of design leads to a vast design space which can be hard to navigate. Even simple objects with 5 to 10 design parameters, resulting in a design space of an equally large number of dimensions, require sophisticated methods to fully take advantage of the design freedom and find the design with optimum performance. Typically, the optimal design is found by searching the design space using simulation and the optimal simulated outcome is manufactured.
In this work, we add an additional layer of optimization. We use simulation to narrow down the design candidates to a set which is Pareto-optimal. Then, we take these designs as seeds for experimental optimization. The simulation as well as the experimental optimization use active learning based on multi-objective Gaussian processes Bayesian optimization. For the experimental optimization, we perform active learning in batches, filling the print volume with a set of Pareto-optimal candidate designs, which maximize the acquisition function, enabling efficient experimental iteration over candidate designs. This approach of combining simulation and experiments is particularly useful because often simulations do not accurately represent the real-life object performance, e.g. due to simplifying assumptions, difficult to characterize material parameters etc.
In this paper, we use the outlined approach to optimize the sound transmission loss (STL) spectrum of an acoustic metamaterial. The objectives are to maximize STL at certain frequencies, while keeping the material thickness in the deep subwavelength regime (e.g. 20 mm thickness, vs. 343 mm wavelength for f = 1000 Hz). We achieve the optimal design by starting with a conceptual idea, e.g. a combination of membranes with Helmholtz resonators, or using an array of multi-membrane cells producing phase shifts that lead to a desirable interference in the outgoing wave field. This conceptual idea has 5 to 10 design variables (e.g. membrane size, resonator size). These design variables are then optimized using active learning with multi-objective Gaussian processes Bayesian optimization. Our framework incorporates NSGA-II (Non-dominated Sorting Genetic Algorithm II) optimization implemented in Matlab and Python. The workflow seamlessly integrates with COMSOL simulation and creates STL files for printing. Experimental measurements are performed on an impedance tube, which is a fairly quick and simple measurement (~ 3 min per sample), such that a large number of samples can be measured.
Ultimately, we optimized acoustic metamaterials for various applications. We obtained and experimentally validated superior properties compared to state-of-the-art acoustic insulators. This optimization framework combining simulations and experiments can be adapted to various design problems in materials science.

Engineering Light-Matter Interactions in Semiconductor Nanowire Photodetectors and in Optical Nanotweezers Kenneth Crozier; The University of Melbourne, Australia

We present recent studies in which engineering the interaction between light and nanoscale materials has been pursued for applications in photodetectors and in optical tweezers.

We review our recent work that demonstrates that the absorption spectrum of a photodetector can be controlled via waveguide resonances in semiconductor nanowires [1-6]. We discuss the physical interpretation for this phenomenon [1]. We review work in which p-i-n photodiodes were incorporated into vertically oriented silicon nanowires, and then used for colour imaging [2-5]. We also review recent work on extending this concept to the short-wave infrared via Ge nanowires [6]. We describe recent work in which we demonstrated chip-scale microspectrometers based on arrays of nanowire photodetector pixels [7] and an interleaved design with a "fishnet" pattern [8].

We also describe our work on optical trapping with plasmonic nanoapertures [9] and with all-dielectric (silicon) nanoantennas [10,11]. Fluorescence microscopy is used to track the position of, and emission from, individual trapped nanoparticles. The nanoparticles consist of fluorescent polystyrene nanospheres with diameters of 20 nm and 100 nm and streptavidin-coated CdSe/ZnS quantum dots. We observe the Brownian motion of the trapped nanoparticles using fluorescence imaging. Other experiments reported include the two-photon excitation of fluorescence from trapped nanoparticles, and the trapping of multiple nanoparticles simultaneously. We also discuss our recent work on an algorithmic approach to the design of plasmonic nanoapertures for optical tweezers [12].

Experimental Investigation on an Interfacial Structure for Solar-Driven Water Desalination Xiaojie Liu, Yanpei Tian, Fangqi Chen and Yi Zheng; Northeastern University, United States

Solar-driven interfacial steam generation for desalination has attracted broad attention. However, a significant challenge still exists for achieving a fast evaporation rate and high quality of water together with the low-cost and simple-to-manufacture device to provide a feasible solar-driven steam generation system. In this study, a novel "blackest" paint Black 3.0 serving as a perfect solar absorber is introduced into the hot-pressed melamine foam networks, constructing the blackest (99% absorptance in the solar region) and self-floating evaporation device. The features of effective solar absorptance and salt-rejection capability contribute to a high evaporation rate at 2.48 kg m^{-2} h^{-1} under one sun (1 kW m^{-2}). This feature shines remarkable lights on a facilely fabricated, robust, high-efficient, and cost-effective solar steam generation system.

5:25 AM F.SF03.10.04

Assembling and Orienting Gold Nano-Triangles and Nano-Octahedra at the Vapor/Aqueous Interface and in the Bulk Solution Hyeong Jin Kim[1], Md Mir Hossen[1], Andrew C. Hillier[1], David Vaknin[1], Wenjie Wang[2] and Surya K. Mallapragada[1]; [1]Iowa State University, United States; [2]Ames Laboratory, United States

Here, we report on anisotropic nanostructure assemblies at the vapor/aqueous interface and in the bulk solution. Gold nano-triangles and octahedra were synthesized and functionalized with poly(ethylene) glycol (both polymer-grafted nanostructures are referred to as PEG-AuNSts). Synchrotron-based grazing incidence small angle X-ray scattering and liquid surface X-ray reflectivity showed that PEG-AuNSts were populated at the vapor/aqueous interface with preferred orientation at the surface by introducing salts or polyelectrolytes which can induce interpolymer complexation between grafted-polymer and polyelectrolytes at low pH level. The resulting assemblies of PEG-AuNSts were further investigated by regulating the concentration of electrolytes and solution pH. Similar strategies were also used to create the three-dimensional assemblies of PEG-AuNSts in the bulk solution. Solution small angle X-ray scattering revealed that controlled assemblies could be achieved by the interplay of temperature, salt concentration, and interpolymer complexation.

Metadevices Based on Integration of Microsystems and Metamaterials Xin Zhang; Boston University, United States

Metamaterials, a major type of artificially engineered materials, exhibits unprecedented and controllable effective properties, including electric permittivity and magnetic permeability, and have boosted the development of optical and photonic devices. Metamaterials are composed of arrays of subwavelength unit cells. The effective properties of metamaterials are mainly determined by the structural design of the constituting subwavelength unit cells rather than their chemical composition. The design-driven properties enable versatile designs of their electromagnetic properties. Recent research has shifted to construct reconfigurable, tunable, and nonlinear metamaterials towards the development of metamaterial devices via integrating actuation mechanisms and quantum materials with meta-atoms. Microelectromechanical systems (MEMS) provide a powerful platform for manipulating the effective properties of metamaterials and the integration of multiple functions with metamaterials. In this talk, I will introduce the fundamentals of metamaterials, approaches to integrate MEMS with metamaterials, functional metamaterial devices from the synergy, and outlooks for metamaterial-enabled devices. Specifically, I will talk about terahertz devices based on the tunable metamaterials for dynamic control of the magnitude, phase, wave front, and polarization by MEMS-driven metamaterial unit cells. Terahertz detectors based on nonlinear terahertz metamaterials will be introduced. In addition, I will discuss the recent advances in the metamaterials for magnetic resonance imaging (MRI) based on the controllable nonlinearity in metamaterials. The implementation of intelligent metamaterials to boost the signal to noise ratio of clinical MRI, which will be translated to improvement in image quality and efficiency. The implementation of nonreciprocal devices based on nonlinearity will also be presented. Besides electromagnetic metamaterials, I will also present the construction of acoustic metamaterials for sound wave manipulation. The acoustic lens to focus sound waves based on the horn-like space coiling structures will be discussed. The ultra-open metamaterial for noise mitigation will also be presented. The future of metamaterials will be outlooked. Based on the MEMS and advanced manufacture technology, multifunctional metamaterial in electromagnetic and acoustic domains will be developed to yield functional devices to achieve functions that are not achievable by nature materials.

5:15 AM *F.SF03.11.02
Tunable Chiral Optical Properties in Semiconductor Nanocrystals and Metamaterials Vivian Ferry; University of Minnesota Twin Cities, United States

Optical nanomaterials offer the ability to bend, twist, guide, and confine light in nanoscale dimensions. Among these materials, chiral nanostructures particularly show promise for applications ranging from polarization manipulation to 3D displays, sensing, and spin-selective transport. Compared to their molecular counterparts, chiral nanomaterials exhibit orders of magnitude stronger dissymmetry factors, but have only been realized in a limited set of materials systems. We have recently demonstrated different strategies to tune and manipulate the polarization response of chiral metamaterials that combine metallic nanostructures, dielectric materials, and semiconductor nanocrystals. By controlling the refractive index of

the dielectric components in different architectures, we show that the sign of the circular dichroism can be reversed, and the polarization and directionality of the outcoupled luminescence from nearby nanocrystals can be controlled. To create light-emitting metamaterials, it is additionally useful to create nanostructured elements comprised entirely of photoluminescent materials. We have recently developed patterning methods to transform semiconductor nanocrystals into patterned nanocrystal solids, realizing lateral feature sizes as small as 30 nm and heights in excess of 100 nm without degradation of the photoluminescence. We show that by designing the shape of the nanocrystal solid at this length scale and controlling connectivity between the nanocrystals, the refractive index and nanostructure absorptivity can be tailored. This work points to new strategies to design dynamically tunable metamaterials and control nanoscale light-matter interactions.

5:30 AM F.SF03.11.03
Aluminized Polymethylpentene Thin Film for High-Effective Radiative Cooling Yanpei Tian, Xiaojie Liu and Yi Zheng; Northeastern University, United States

The radiative cooling phenomenon relies on the atmospheric transparency window to dissipate heat from the earth into outer space, which is an energy-saving cooling technique. This work demonstrates a highly effective aluminized Polymethylpentene (PMP) thin-film thermal structure. The emissivity of aluminized PMP thin films matches perfectly to the atmospheric transparency window so as to minimize parasitic heat losses. This photon-to-cooling structure yields a highest-to-date temperature drop of 8.5 K in comparison to the ambient temperature and a corresponding radiative cooling power of 193 W/m^{2}during a one-day cycle. The easy-to-manufacture feature of an aluminized PMP thin film makes it a practically scalable radiative cooling method.

5:40 AM F.SF03.11.04
Radiative Cooling in the Earth's Glow Using Commonplace Materials Jyotirmoy Mandal[1], Sagar Mandal[2], John Brewer[1], Arvind Ramachandran[3] and Aaswath P. Raman[1]; [1]University of California, Los Angeles, United States; [2]Independent Researcher, United States; [3]Arizona State University, United States

Passive daytime radiative cooling involves solar reflection and thermal emission into the cold outer space through the atmospheric transmission windows. Due to its passive nature and net cooling effect, it is a promising alternative or complement to electrical cooling.[1-2] For efficient radiative cooling of objects, an unimpeded view of the sky is ideal. However, the view of the sky is often limited - for instance, the walls of buildings have > 50% of their field of view subtended by the earth. Moreover, objects on earth become sources of heat under sunlight. Therefore, vertical building facades with hot terrestrial objects in view experience reduced cooling or heating, even with materials optimized for heat loss into the sky.[2-3]

We show that by using materials with selective long-wavelength infrared (LWIR) emittances, walls and roofs can radiatively cool to considerably lower temperatures than achievable by using broadband thermal emitters like paints and recent designs.[2-3] Promisingly, selective LWIR emitters can be scalably manufactured from common polymers, ceramics and composites, with some being sufficiently ubiquitous to be sourced from waste. The materials are suitable for use on both opaque and transparent building envelopes, making them applicable on both walls and windows. Cooling enhancements (theoretical and demonstrated) achieved by such commonplace materials offer a remarkable opportunity for untapped energy savings in buildings.

Thermal Behaviors of Hydrocarbon-Coated Aluminum Nanoparticles as Energetic Metamaterials in Combustion Applications—A ReaxFF Molecular Dynamics Study Sungwook Hong, Roxanne Esparza and Ryan Parlier; California State University, Bakersfield, United States

Aluminum nanoparticles (ANPs) have been considered attractive additives for combustible applications because the ANPs possess a high energy density with an increased burning rate, owing to an increased surface area-to-volume ratio.[1] Unfortunately, use of the ANPs is limited by two factors: (1) ANPs can be readily sintered; and (2) ANPs can be easily oxidized, prior to the combustion process due to their high reactivity, degrading the combustion performance. To resolve this issue, synthesis of metamaterials, using ANPs and hydrocarbon has been suggested. For example, ANPs could be effectively coated by hydrocarbon precursors to improve its combustion performance.[2,3] The previous studies reported that the hydrocarbon-coated ANPs are less reactive at low temperatures and they became susceptible to the oxidation at higher temperatures, suggesting that the hydrocarbon coating is essential for the ANPs to be used as combustible materials.[4,5] However, a molecular-level understanding of thermal behaviors of the hydrocarbon-coated ANPs has yet to be achieved. Here we perform reactive molecular dynamics (RMD) simulations based on ReaxFF[6] to investigate effects of hydrocarbon coating on the combustion process of the ANPs including sintering and oxidation processes. Our RMD simulations reveal molecular-level reaction steps for the combustion process of the bare/hydrocarbon coated ANPs. As such, our RMD simulations will help guide an experimental design of a novel energetic metamaterial using ANPs and hydrocarbon, providing a valuable input for the community of solid-fuel propellants.

S.H. and R.P. acknowledge a start-up funding from School of Natural Science, Mathematics and Engineering at California State University, Bakersfield (CSUB). A.M. acknowledges a funding support from Student Research Scholar (SRS) program at CSUB.

Computational Design of Energetic Metamaterials Using Graphene-Supported Aluminum Nanoparticles—A ReaxFF Molecular Dynamics Study Ryan Parlier, Andrew Martinez and Sungwook Hong; California State University, Bakersfield, United States

Aluminum nanoparticles (ANPs) have attracted a great amount of interest owing to their high energy density, high reaction rate, earth abundance, and low toxicity.[1] ANPs have been considered effective energetic materials. Unfortunately, ANPs are easily oxidized at room temperature, leading to oxide layers on their surfaces. Those oxide layers work as a dead weight. Therefore, it is vitally important to design a novel metamaterial that improves the combustion performance of ANPs. Recent studies show that adding graphene oxide and graphene fluoride improves the combustion performance of ANPs.[2,3] This is mainly due to a synergistic effect between graphene sheets and ANPs. For example, oxygen molecules could be easily dissociated when they get closer to both graphene sheets and ANPs. As such, we hypothesize that graphene-supported ANPs, which could be considered novel energetic metamaterials, provide a remarkable combustion performance. Here we simulate the oxidation of graphene-supported ANPs using reactive molecular dynamics (RMD) simulations based on ReaxFF.[4] Our RMD simulations reveal atomic-level reaction mechanism for the improved oxidation process of graphene-supported ANPs. As such, the RMD results will help guide an experimental design of a novel energetic metamaterial using graphene sheets and ANPs, providing a valuable input for the community of energetic metamaterials.

S.H. and R.P. acknowledge a start-up funding from School of Natural Science, Mathematics and Engineering at California State University, Bakersfield (CSUB). A.M. acknowledges a funding support from Student Research Scholar (SRS) program at CSUB.

Spin-Valley Locked Edge States in Staggered Chiral Photonic Crystal Yeseul Kim, Minkyung Kim and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Topological phases of matters, firstly investigated in condensed matter physics, have been extended to other wave physics such as photonics. In this poster presentation, we present spin-valley locking of edge states in a chiral photonic crystal in the two-dimensional honeycomb lattice. Using a coupled dipole method, we demonstrate bulk band structure with a band gap, which is spanned by the spin-valley locked edge states. The staggered chirality breaks the inversion symmetry and the chirality provides the spin-valley locking characteristics.

Late News: Computational Synthesis of Novel Energetic Metamaterials Using Metal Nanoparticles and Hydrocarbon Precursors for Combustion Applications Roxanne Esparza and Sungwook Hong; California State University, Bakersfield, United States

The use of aluminum nanoparticles (ANPs) in combustion applications has attracted a great amount of attention owing to their high energy density with an increased burning rate.[1] Unfortunately, due to the nature of ANPs' high reactivity, the ANPs are easily sintered, leading to an increase in their particle size, and thus lowering the combustion efficiently. In order to tackle this issue, recent efforts have been made to synthesize novel metamaterials, using ANPs and hydrocarbon precursors. For example, ANPs could be effectively coated by hydrocarbon precursors to lower their reactivity, thus preventing sintering effects of ANPs. However, an effect of precursor types of hydrocarbon on sintering behaviors of ANPs has yet to be understood at the atomic level. Here we perform reactive molecular dynamics (RMD) simulations based on ReaxFF[2] to investigate computational synthesis of energetic metamaterials using ANPs and carbon precursors. In particular, we employed different types of carbon precursors to evaluate the sintering behaviors of ANPs. Our RMD simulations suggest detailed reaction steps for the sintering process of the bare/hydrocarbon coated ANPs. As such, our RMD simulations will help provide a valuable input for experimental synthesis of a novel metamaterial using ANPs and hydrocarbon for combustion application.

S.H. and R.E. acknowledge a start-up funding from School of Natural Science, Mathematics and Engineering at California State University, Bakersfield (CSUB).

F.SF03.12.07

Late News: Humidity-Dependent Flaw Sensitivity in the Crack Propagation Resistance of 3D-Printed Nano-Ceramics Edoardo M. Rossi[1], Jens Bauer[2] and Marco Sebastiani[1]; [1]Università degli Studi Roma Tre, Italy; [2]University of California, United States

Pyrolitic 3D-printed carbon nano-ceramics currently emerge as a class of lightweight materials with exceptional mechanical strength and stiffness, being characterized by feature-sizes well below the capabilities of the highest-resolution 3D additive manufacturing techniques alone. Despite the increasing applications, their use is hampered by the lack of knowledge on their mechanical reliability. Few studies have investigated their intrinsic mechanical properties: important characteristics, like hardness and fracture toughness, and their dependency on environmental conditions, which can be relevant for a thorough understanding of the complex mechanical behaviour of additively manufactured pyrolitic carbon structures, are unknown. In this work, we present nanoindentation splitting of TPP-DLW-derived pyrolitic carbon micro-pillar specimens, characterized by a diameter of 5.3 μm and a hight-to-diameter ratio of two, as a straight-forward method to measure the fracture toughness and nanoindentation continuous stiffness measurements for the assessment of the elastic modulus and hardness. Micro-pillars with and without SEM detectable surface flaws, absent of STEM-detectable internal defects, were tested at two extremal intervals of the environmental relative humidity, humid air was used to adjust RH at values greater than 60% and dry nitrogen at room pressure ensured RH levels below 5%, to investigate the impact of pyrolysis-induced surface flaws and the interplayed effects with the testing environment on the mechanical reliability of the 3D printed nanoceramics. We show that TPP-derived pyrolytic carbon can achieve 500% increased fracture toughness over macroscopic forms of vitreous carbon, which typically lies in the range of 0.5-1.4 $MPam^{0.5}$, with values up to 3.1 $MPam^{0.5}$. However, experiments at RH > 60% revealed a detrimental effect of high relative humidity environments on the fracture toughness of the pyrolitic carbon nano-ceramic structures, causing embrittlement due to liquid diffusion ascribed to the presence of only a few, nanometer-sized, which probably promotes crack propagation under external loading due to chemically induced structural weakening of the glassy carbon structure. While comparable effects are less relevant in macro-size ceramics, this study demonstrates that reliability and durability of micro- and nano-architected ceramic metamaterials and devices require toughening design approaches which focus on size-dependent surface effects. The observed humidity effect can have a remarkable impact on the scale-up of such nano-architected metamaterial in a wide range of applications, especially biomedical and micro-fluidics fields.

Late News: Infrared Reflecting/Transmitting Smart Glass For Energy Efficient Windows Mark Altwerger, Yashashvini Andugula, Harry Efstathiadis and Iulian Gherasoiu; SUNY Polytechnic Institute CNSE, United States

Low-e glass panes are not well adapted for use in regions where the predominant heat that passes through windows has its origin indirect solar radiation. Almost 49% of solar energy is distributed in the spectrum from 0.7-2.5μm for which low-e glass-pane reflectivity is below 10%. This is the case with 14% of the contiguous U.S. according to NREL. The metamaterial that we propose is a robust, thin-film structure that has the ability to reflect near-infrared heat radiation (NIR) with λ 0.7-10μm while transmitting more than 90% of the visible light intensity. The ability to reflect NIR and transmit selected wavelength range is obtained through the field-enhanced electron concentration of moderately doped metal oxide thin films. Approximately 48% of the total energy produced in the U.S. or 18.6 billion kWh is spent on heating and cooling. Therefore, the ability to retrofit this technology onto existing buildings is of considerable interest. Electrical and optical characterization demonstrate the synthesis of state-of-the-art materials with properties suitable for the fabrication of smart glass devices.

Hybrid Fabrication Techniques for Bioelectronics George G. Malliaras; University of Cambridge, United Kingdom

While lithography provides unparalleled control over dimensions, additive manufacturing techniques enable unique design flexibility. Here we consider the merits of hybrid fabrication involving the combined use of lithography and various additive manufacturing techniques in bioelectronics. We examine examples ranging from implantable sensors to neuromorphic transistors and discuss various fabrication strategies, showing the hybrid approaches offer several advantages.

Graphene-Templated Growth of Organic Semiconductors for Organic Electronics Kilwon Cho; Pohang University of Science and Technology, Korea (the Republic of)

High-performance organic electronic devices require organic semiconductor (OSC) thin films to possess desired microstructures. An effective approach is use of graphene as a template for controlling growth behavior of OSC crystals. Unlike on ordinary substrates, the growth modes of OSCs on graphene are not only determined by the graphitic surface structure but also electronic characteristics of graphene. In this talk, I will discuss how OSC molecules assemble on graphene surface under the influence of graphene's doping effect. Also I will discuss a result that the OSC films grown on a graphene template under an optimized condition provide favorable vertical and lateral transport pathways for charge carriers and excitons in organic transistor and photovoltaic devices

7:10 PM *F.SF04.01.08
Linking Microstructure to Transport at Several Lengthscales in Conjugated Polymers Alberto Salleo; Stanford University, United States

Carrier mobility in conjugated polymers continues to increase with recent reports of field-effect mobilities exceeding 10 cm^2/V.s. Charge transport is intrinsically dependent on processes occurring across multiple lengthscales. In order to access order parameters at the molecular scale we use charge modulation spectroscopy combined with theory. This technique allows us to further differentiate field-induced and doping-induced charges and study how their delocalization depends on local structure and disorder. Furthermore, we study the mesoscale organization of polymers using new techniques in the transmission electron microscope. By combining 4D STEM and HRTEM we are able to study the microstructure across a range of length-scales in real space and reciprocal space. These techniques are used on homopolymers and donor-acceptor copolymers and allow to extract information about the microstructure that is typically not visible by inspection. Such multiscale studies of microstructure are instrumental in guiding our understanding of charge transport in conjugated polymers.

7:30 PM *F.SF04.04.02
Amplified Spontaneous Emission and Lasing in Quasi-2D Perovskites Franky So and Kenan Gundogdu; North Carolina State University, United States

Recently, metal-halide perovskite materials are considered as a promising candidate for lasing applications. Compared to 3D and other low-dimensional perovskites, quasi-2D perovskites are a better gain media due to its unique properties such as large binding energy and self-assembled quantum wells. Specifically, efficient energy funneling from low-dimensional domains to high-dimensional domains will not only enhance the radiative recombination but also facilitate population

inversion.
In this presentation, we will discuss the fundamental requirements for population inversion in perovskites in the context of material dimensionality and morphology. We will also present our recent work on laser cavity design and processing for optimum laser performance.

7:50 PM *F.SF04.06.01
Various Solution Processing Methods for Boosting Electrical Performance of Metal-Oxide-Based Thin-Film Transistors and Phototransistors I Sak Lee, Dong Hyun Choi, Dongwoo Kim and Hyun Jae Kim; Yonsei Univ, Korea (the Republic of)

Oxide thin-film transistors (TFTs) have attracted much attention for next-generation electronics because of their superior performance compared with conventional a-Si TFTs such as high mobility and optical transmittance in the visible light. Particularly, solution process is a promising technique for the oxide TFT fabrication method for being a low-cost method with high composition controllability, high throughput, and various application. In this study, we propose various researches to improve the electrical and optical performances in oxide TFTs. Furthermore, we suggest a solution-processed oxide absorption layer (SAL) to enable detection of visible light for oxide phototransistors.

Voltage-Based Ambi-Ionic Migration (VAM) for Modulating Active Layer
The voltage-based ambi-ionic modulation (VAM) technique allows specific ions to migrate into the active layer by applying bias, easily modulating the active layer. Also, the potassium superoxide (KO^2) solution is employed in oxide thin-film transistors (TFTs) as a source of potassium (K^+) ions and highly reactive superoxide radical (O_2^{*-}) ions. By applying external bias, the K^+ and O_2^{*-} ions rapidly migrate into the active layer, directly changing its electrical properties and chemical composition. Through the VAM technique, various metal-oxide-based devices such as oxide TFTs can perform better.

Multifunctional Heterogeneous Organic (MHO) Passivation Layer for Oxide TFT
We propose a highly flexible and reliable multifunctional heterogeneous organic (MHO) passivation layer composed of stacked diketopyrrolopyrrole (DPP)-polymer and parylene-C films for improving the stability of oxide TFTs under various ambient environments and mechanical stress. The presented MHO passivation layer leads to high-performance oxide TFTs by: (1) protecting them from external reactive molecules, (2) blocking light to the oxide layer, and (3) improving their electrical characteristics. As a result, oxide TFTs with MHO passivation layer exhibit higher stability in ambient environment and under light. Moreover, since the MHO passivation layer can be deposited at room temperature and exhibits high mechanical stability, it could be practical in the fabrication of flexible/wearable devices.

Selective modulation of electrical characteristics by electro-hydro-dynamic printing
A simple fabrication method for homojunction-structured Al-doped indium–tin oxide (ITO) thin-film transistors (TFTs) using an electro-hydro-dynamic (EHD) jet-printed Al_2O_3 passivation layer with a specific line (W_{Al2O3}) is proposed. After EHD jet-printing, the specific region of ITO where Al_2O_3 is printed changes from a conducting film to a semiconducting film while Al_2O_3 acts as passivation layer. The channel length of the fabricated TFTs is defined by W_{Al2O3} which is easily changed with varying EHD jet printing conditions, replacing masks with varying patterns. Consequently, the proposed approach is promising as a low-cost and flexible manufacturing system for multi-item small-lot-sized production of Internet of Things devices.

Solution-Processed Oxide Absorption Layer (SAL) for Visible-Light Detecting Phototransistor
We propose a solution-processed oxide absorption layer (SAL) for visible-light (532 and 635 nm) detection for indium−gallium−zinc oxide (IGZO) phototransistors. The SAL was deposited onto the sputtered IGZO using precursor solutions composed of the same atomic configuration of sputtered IGZO, resulting in superior interface characteristics. We artificially generated sub-gap states in the SAL using a low temperature (200°C) annealing, minimizing the degradation of the electrical characteristics of TFT. These sub-gap states in SALs improved the photoelectron generation under long-wavelength visible-light despite the wide bandgap of IGZO (over 3.0 eV). As a result, the IGZO phototransistors with SALs have both superior optoelectronic characteristics and high optical transparency.

8:10 PM *F.SF04.05.03
Design Requirements for Flexible TFT-Based Logic Applications Kris Myny[1,2]; [1]imec, Belgium; [2]KU Leuven, Belgium

In last decades, the research on flexible logic circuits based on thin-film transistors (TFTs) have been increasingly growing as technologies tend to stabilize enabling application-oriented research. Although backplane applications such as active matrix displays and 2-D imager arrays are the main driver for technology developments, logic applications also benefit from

increased performance. In this invited presentation, I will elaborate on several design requirements for TFT-based logic circuits and link them to technology and material requirements.

The focus of this work will be in the direction of flexible IoT applications, ranging from radio-frequency communication chips to sensor readout circuitry to monitor vital parameters. All demonstrated flexible integrated circuits have been realized in a dual-gate self-aligned a-IGZO TFT technology. The main advantage of a self-aligned transistor is the strongly reduced parasitic overlap capacitance between gate and source-drain contacts, enabling faster circuit blocks consuming less power. Consequently, we have demonstrated a flexible IGZO-based NFC communication tag connecting to an NFC-enabled smartphone [1]. In recent work, we have been updating our design libraries with substantially lower power consumption and realized a capacitive tag that communicates directly with the touchscreen of a smartphone as an enabler for the Internet-of-Everything [2]. This tag has been made self-powered by integrating a flexible Perovskite photovoltaic cell that captures the energy from the smartphone screen which powers the chip.

The dual-gate self-aligned transistor provides a designer with an additional benefit, namely the presence of an extra gate. The backgate can be employed for several different purposes: to increase the transconductance, to improve the output resistance or to control the threshold voltage. Most of these design considerations are mainly interesting for analogue circuits, for example to improve the gain of an operational amplifier. As a third case in this presentation, I will discuss our recent achievements on a flexible ECG patch with NFC compatibility for healthcare monitoring patches [3]. Finally, as the newest technology developments move in the direction of increased charge carrier mobilities, matching p-types and low-temperature polysilicon and oxides (LTPO), I will elaborate on the future enabling opportunities for TFT-based logic circuits and applications.

Flexible Semiconductors Films by Molecular Design, Nanostructure Synthesis and Porous Morphologies Antonio Facchetti[1,2]; [1]Northwestern University, United States; [2]Flexterra Corp, United States

In this presentation we report the development of novel semiconductors, as well as thin-film engineering, for flexible and stretchable organic and inorganic (electrochemical)transistors and sensors. In particular we show that “ultra-soft” polymers comprising naphthalenediimide units co-polymerized with “rigid” and “flexible” organic units can change how charge transport is affected by mechanical stress, demonstrating that polymer backbone composition is more important that film degree of texturing. Furthermore, molecular design of polymers enables plasticization of a small molecule semiconductor film used in thin-film transistors. In addition, we report new “soft” transistor architectures using porosity as key element enhancing mechanical flexibility and tuned charge transport. Finally, metaloxide semiconductor nanostructures are fabricated in a very simple way and enable TFT and several types of sensors which can be monolithically integrated. These devices can better sense analytes, intercalate ions, and be chemically doped.

2:05 PM *F.SF04.02.01
Water-Based and Defect-Free 2D-Inks for Printed Electronics Cinzia Casiraghi; University of Manchester, United Kingdom

2-Dimensional materials (2DMs) are very attractive building blocks for the next generation electronics, which require low cost and flexible devices that can be easily integrated onto substrates such as paper and plastic. The atomically thin nature of 2DMs enables mechanical flexibility, high sensitivity, easy functionalization, and allows one to stack together different 2DMs to fabricate multifunctional heterostructure-based devices.
In this talk I will show a general formulation approach to make water-based, defect-free and biocompatible 2DM-based inks suitable for fabrication of a wide range of fully printed devices, such as photodetectors, capacitors and transistors, on paper and plastic [1-3].
Furthermore, printed 2DM-based devices can be easily coupled with printed RFID tags made of graphene, enabling the development of a wireless and battery-free multisening platform on paper [4-6]. Finally, the inks can be easily combined with polycrystalline 2DMs produced by chemical vapour deposition, allowing quick fabrication of complex circuits on paper, such as high-gain inverters, logic gates and current mirrors [7].
If time allows, I will also introduce a new C-based, highly resilient and flexible substrate for printed electronics, specifically designed for applications that involve repeated strain, where paper cannot be used because the incresing fatigue in the cellulose substrate leads to failure of the device. We will show that this highly resiliant substrate can sustain over 50k bending cycles without failure, in contrast to paper, which starts failing already after 5k cycles [5].

2:25 PM *F.SF04.02.02
Progress Towards Reproducible, Robust, and Recyclable Printed Electronics Aaron D. Franklin; Duke University, United States

The promises of a printed electronics revolution continue to be hindered by challenges in the performance, reproducibility, and broad utility of printed devices. Inks from nanoscale materials have received increasing attention for their potential to overcome some of these hurdles, particularly in yielding direct-printed thin films meeting target electrical performance, air stability, and process compatibility. While many commercial options now exist for conducting inks, accessibility of versatile and robust semiconducting and insulating inks remains a challenge. In this talk, the recent progress on, and benefits of, semiconducting carbon nanotube (CNT) inks will be reviewed, particularly in the context of direct-write, aerosol jet-printed electronic devices. Proper control of ink properties and printing process, including factors such as ink temperature and printing time, can yield semiconducting CNT thin films with relatively high mobility, uniformity, and reproducibility. In addition, two attractive options for direct-write printed insulating inks will be discussed: hexagonal boron nitride (hBN) and crystalline nanocellulose (CNC). It will be shown how the appropriate design of these nanomaterial-based inks can enable the printing of fully recyclable electronics, where the constituent nanomaterials can be reclaimed and reused after initial printing and use in electronic devices.

2:45 PM *F.SF04.03.01
Laser Printing of Functional Materials Oana D. Jurchescu; Wake Forest University, United States

The past decades have witnessed a commendable progress in the development of materials for low-cost flexible electronics. New products that are beyond reach with current technologies can soon become a mainstay in our lives if these materials reach the necessary standards for performance and stability. The development of processing techniques that can address the manufacturability – scalability – sustainability – performance balance represents the next key step in the integration of these materials into next-generation electronic devices. In this presentation, I will introduce the use of laser printing, a rapid, scalable, environmentally friendly and low-cost manufacturing technique for deposition and patterning of various functional materials on flexible substrates. The first example focuses on organic semiconductors, and I will discuss the fabrication and characterization of organic thin-film transistors placed on plastic and paper. Aerosol spray laser lithography was used to

define the electrodes, in conjunction with different metal inks: the pattern was created using a regular toner, which was subsequently selectively removed. We created a grid of transistor devices with variable channel lengths and widths and obtained good charge carrier mobilities and an excellent tolerance to bending. Next, I will describe the use of laser printing for the fabrication of metal halide perovskite films. The electrical properties of the laser printed films were comparable with those of the spin-coated layers, despite the fact that the microstructure consists of randomly oriented crystallites. The current-voltage characteristics exhibit negligible hysteresis and the electrical properties of the films are very stable under ambient conditions due to the fact that a vertical separation of the toner components results in an encapsulating the perovskite layer by the other toner components. Our work introduces an exciting new avenue for the fabrication of stable perovskite devices that is scalable and devoid of hazardous solvents.

3:05 PM *F.SF04.03.02
Processing Fundamentals for Self-Aligned Flexible Printed Electronics Krystopher Jochem, Motao Cao, Panayiotis Kolliopoulos, Xiaochen Ma, Satish Kumar, Daniel Frisbie and Lorraine F. Francis; University of Minnesota Twin Cities, United States

Continuous, roll-to-roll (R2R) printing processes are attractive for manufacturing of flexible electronics. Two common challenges with R2R are reaching small feature sizes and achieving precise registration of multiple functional layers in devices such as transistors. This presentation will cover our efforts to overcome these issues using Self-Aligned Capillarity-Assisted Lithography for Electronics (or SCALE). SCALE has two steps. In the first step, R2R imprinting is used to create a multilevel open network of reservoirs, capillaries and device structures into a UV-curable coating deposited on a flexible substrate. In the second step, electronically functional inks are then delivered sequentially into the reservoirs on this imprinted substrate by inkjet printing, and capillarity pulls inks into capillaries and device structures. Since the imprint stamps are fabricated from high-resolution, Si master patterns created by photolithography, the features created in the imprint resin are also high-resolution, at the micron scale. The single imprinting step also simultaneously creates all the structural features needed to control the flow and deposition of multiple inks, resulting in self-alignment of multiple materials in complex multilayer devices.

To-date we have developed SCALE methods to create conductive networks, resistors, capacitors, diodes and transistors. For example, to manufacture high aspect ratio (thickness/width) SCALE conductive networks, we used a combination of inkjet delivery of a silver particle-free ink into reservoirs of the imprinted substrate, followed by capillary flow and thermal annealing to convert the ink to a silver seed layer and lastly electroless copper plating to build conductor thickness in capillary channels. By optimizing processing conditions and understanding the fundamentals of capillary flow, narrow (e.g., 10 μm), high aspect ratio (>1), low resistance (~1 ohm per cm of conductor length) embedded conductive traces were created. This presentation will show advances in device architecture and performance, and explore the key processing steps. Special attention will be given to continuous roll-to-roll processes.

3:25 PM *F.SF04.04.01
Organic Infrared Sensors and Energy Storage Capacitors Based on Narrow Bandgap Polymers Tse Nga Ng[1], Ning Li[1], Lulu Yao[1], Kaiping Wang[1] and Jason D. Azoulay[2]; [1]University of California San Diego, United States; [2]University of Southern Mississppi, United States

Narrow bandgap polymers are used to realize infrared photodetectors that is relevant to a variety of applications including environmental monitoring and medical diagnosis. To achieve high detectivity in detectors, it is critical to reduce the device noise. This talk presents experimental and modeling studies on the noise current in exemplar organic bulk heterojunction photodiodes, with 10 donor–acceptor combinations spanning wavelength between 800 and 1600 nm. A significant reduction of the noise and higher detectivity were found in devices using non-fullerene acceptors (NFAs) in comparison to those using fullerene derivatives. The low noise in NFA blends was attributed to a sharp drop off in the distribution of bandtail states, as revealed by variable-temperature density-of-states measurements. Taking disorder into account, we developed a general physical model to explain the dependence of thermal noise on the effective bandgap and bandtail spread.

The narrow bandgap polymers are also Faradaic materials for energy storage and present opportunities to create energy dense supercapacitors. The vast majority of conducting polymers are p-type, and here we present promising n-type polymers that are stable when operating within a large potential window (3V), with a best-in-class energy densities (30.4 Wh/kg at a 1 A/g discharge rate), and a long cycle life (90% capacitance retention after 5000 cycles) critical to energy storage and management. This work demonstrates the application of a new class of stable and tunable redoxactive material to realize high-endurance energy storage devices for flexible printed systems.

Material, Process and Device Issues in Solution Processed Semiconductor Products Yue Kuo; Texas A&M Univ, United States

The general trend in semiconductor fabrications is the low thermal budget because of limitations on the minimum device dimension or the substrate material. For example, in IC fabrication, the process temperature can change the dopant redistribution, which directly affects the junction and interface properties. In large area flat panel displays, the glass substrate can only tolerate a low temperature, i.e., below the softening temperature. Since the solution process method can deposit thin films at a low temperature, it is compatible with various rigid or flexible substrates. Currently, there are many efforts in applying the solution process method to fabricate semiconductor products.

Among many types of low temperature prepared devices, thin film transistors (TFTs) are probably most popular because they have been critical components in the flat panel displays for 3 decades [1]. TFTs can also be used in a broad range of non-display products, such as chemical, gaseous, solution, bio, magnetic, and optical sensors as well as imagers, memories, and circuit drivers [2,3]. In TFTs, the semiconductor layers can be made of small or large organic molecules or inorganic silicon, metal oxide, or compound materials. The dielectric layer can also be made of organic or inorganic materials. However, in spite of many reports on solution process fabricated TFTs, no commercial products are available on the market. In this paper, a detailed analysis of some critical issues in this kind of device will be presented. For the device performance part, the bulk and interface defects, which may be of chemical or physical nature, are key factors to be improved. For the reliability part, the long-term stability, such as shifts of characteristics under the operation condition, will be addressed. Many disadvantageous material properties in the low temperature solution processed thin films and stacked structures can be improved with a low thermal budget pulsed rapid thermal annealing process [4,5]. A discussion on this method will be included in this presentation, too.

Narrowband-Absorption-Type Organic Photodetectors Based on Solution-Processed Fullerene-Free Bulk Heterojunctions Vincenzo Pecunia, Kai Xia and Yang Cao; Soochow University, China

Organic semiconductors have attracted considerable interest for spectrally-selective light sensing (i.e., narrowband

photodetection), which is relevant to manifold applications—e.g., colorimetry, healthcare monitoring, biology, chemical fingerprinting.[1] The attractiveness of organic semiconductors for narrowband photodetection is especially due to the capability of many such compounds to absorb light precisely over the spectral range of interest, thereby enabling filterless narrowband-absorption-type organic photodetectors (OPDs). However, it has been generally challenging to date to realize such OPDs while achieving good spectral selectivity. This has been primarily due to the widespread use of fullerenes as electron acceptors, which bring along a detrimental shallow absorption tail through the visible range.[2] Additionally, while solution-based methods have been recognized as key to developing low-cost and/or free-form photodetectors and imagers, narrowband-absorption-type OPDs comprising solution-based active layers have thus far struggled to deliver high photoconversion efficiency.[3]

In this study we show that non-fullerene acceptors (NFAs) provide an attractive route to high-performance solution-processed OPDs with narrowband-absorption-type capability. We discuss the viability and general applicability of this approach by presenting the NFA-based solutions we have developed for narrowband-absorption-type OPDs selectively responding in the green range and the far-red range. In particular, we have studied two solution-processible NFAs: a benzodithiophene-based compound with narrowband absorption in the far-red range (solid-state spectral absorbance width of 132 nm) and a subphthalocyanine-based compound with narrowband absorption in the green range (solid-state spectral absorbance width of 80 nm). In both cases, we have explored solution-deposited photoactive layers consisting of bulk-heterojunctions in which the NFAs are combined with donors that are either transparent or that also selectively absorb in the target spectral range.

By tailoring our solution-processed NFA-based photoactive layers, we have achieved narrowband-absorption-type photodetection with cutting-edge performance. In self-powered operation, our NFA-based OPDs for the far-red range deliver the highest specific detectivity to date (1.4×10^{13} Jones) of all narrowband-absorption-type far-red-selective OPDs, and concurrently achieve the narrowest spectral width (141 nm) of all solution-processed implementations.[4] Moreover, our green-selective NFA-based OPDs deliver a spectral with of 130 nm with an external quantum efficiency up to 40%, which is the highest to date for green-selective solution-processed narrowband-absorption-type OPDs. Our OPDs additionally show a linear response over an optical power range greater than four orders of magnitude, and exhibit a fast response compatible with a wealth of relevant applications. The versatility of our NFA-based narrowband-absorption-type approach marks an important step in the realization of solution-processible OPDs towards high-performance and low-cost colour sensors and imagers, and additionally motivate dedicated synthetic efforts in NFA research targeting narrowband OPD applications.

Graphene-Templated Growth of Organic Semiconductors for Organic Electronics Kilwon Cho; Pohang University of Science and Technology, Korea (the Republic of)

High-performance organic electronic devices require organic semiconductor (OSC) thin films to possess desired microstructures. An effective approach is use of graphene as a template for controlling growth behavior of OSC crystals. Unlike on ordinary substrates, the growth modes of OSCs on graphene are not only determined by the graphitic surface structure but also electronic characteristics of graphene. In this talk, I will discuss how OSC molecules assemble on graphene surface under the influence of graphene's doping effect. Also I will discuss a result that the OSC films grown on a graphene template under an optimized condition provide favorable vertical and lateral transport pathways for charge carriers and excitons in organic transistor and photovoltaic devices

Understanding Printing Physics for Controlled Conformation, Aggregation and Alignment of Conjugated Polymers Ying Diao; University of Illinois at Urbana-Champaign, United States

Controlled morphology evolution via directed assembly has played a central role in the development of modern electronic, optical and clean energy materials. In comparison to conventional 'hard' materials, organic electronics can be easily processed into diverse form factors by low-cost, high-throughput methods such as roll-to-roll printing and 3D printing. The printing conditions intimately couple with the assembly process and sensitively modulate the solid-state properties in the

fabricated devices. A major challenge in this field lies in controlling the nucleation, growth, aggregation and alignment of conjugated polymers during solution printing and coating, which critically impact the printed device performance by orders of magnitude. The rapid printing process creates a complex environment with coupled physics that drive the polymer assembly far from equilibrium. Yet little is known of the non-equilibrium molecular assembly pathways and the printing physics so essential to tuning molecular conformation and multiscale morphology and the resulting intrachain and interchain charge transport properties of printed organic semiconductors.

In our work, we elucidate fundamental printing physics through finite element simulations and free energy modeling. By doing so, we are able to decipher non-equilibrium assembly pathways and control multi-scale assembly of semiconducting polymers. We further establish processing-structure-property relationship by performing printing experiments, morphology and device characterizations. We observe unexpected flow-induced morphology and electronic transition that accompanies change in printing regimes. We elucidate that printing flow in a moving, drying meniscus can drastically alter the polymer assembly pathways by flow-induced conformation change. We further design bioinspired assembly processes learning from biosystems, allowing molecules to put themselves together cooperatively into highly ordered structures otherwise not possible. High degree of morphology control from molecular to device scale further enables new insights into charge transport properties of semiconducting polymers and realizes advanced electronic devices such as printed 2D monolayer devices and ultrasensitive chemical sensors.

Monolithic Integration of Organic Light-Emitting Transistors and Organic Photodiodes for a New Class of Optoplasmonic Devices in Biosensing Mario Prosa[1], Emilia Benvenuti[1], Michael Toerker[2], David Kallweit[3], Paola Pellacani[4], Laura Lopez-Sanchez[4], Margherita Bolognesi[1], Lucia Fornasari[4], Franco Marabelli[5] and Stefano Toffanin[1]; [1]Consiglio Nazionale delle Ricerche (CNR), Italy; [2]Fraunhofer FEP, Germany; [3]CSEM, Switzerland; [4]Plasmore Srl, Italy; [5]University of Pavia, Italy

The implementation of different organic optoelectronic devices in a single architecture may represent a winning approach for the development of compact, highly-sensitive and -selective sensors.
Here, the monolithic integration of organic photodiodes (OPDs) onto organic light-emitting transistors (OLETs) is demonstrated, discussed and validated as a new platform for biosensing. While OLETs combine electrical switching characteristics with light generation capability, the deposition of OPDs directly onto the source electrodes of the OLETs provides the light-sensing ability to the whole multifunctional system, as a result of the spectral compatibility between OLETs and OPDs.
The potential of the platform is demonstrated in a real sensing application by depositing a nanoplasmonic grating on the top side of the encapsulating glass of the OLET+OPD chip. The nanoplasmonic thin film, which has been suitably designed and developed, has the ability to change the spectral reflectivity if a variation of the refractive index occurs on the top surface. The effectiveness of the new detection scheme is validated by proving that the OPD photocurrent, generated as a consequence of the light emitted by the OLET and then reflected by the nanoplasmonic grating, changes by a factor 10^{-9} A when exposing the sensing surface from water to alcoholic solutions at different concentrations.

6:20 AM F.SF04.01.07
A sub 150-nm, Ultrathin, Ultraflexible, Fully Solution Processed Organic Field Effect Transistor Fabrizio A. Viola and Mario Caironi; Istituto Italiano di Tecnologia - IIT, Italy

In recent decades, a rising interest in flexible electronic devices has led to an increasing request for novel fabrication technologies for a large set of possible applications such as prosthetics, human-robot interaction, and rehabilitation. In this field, one of the major goals is the fabrication of flexible electronic devices by means of unconventional and highly compliant materials. In particular, organic materials have attracted significant interest in the scientific and industrial community due to their intrinsic mechanical characteristics and to the possibility to process them at very low temperatures at low costs, enabling new potential applications not achievable with inorganic counterparts.
In this work, we demonstrate that is possible to fabricate an all solution processed organic field effect transistor with a total thickness lower than 150 nm, which is the thinnest organic transistor ever fabricated, by adopting an approach based on solution-assisted delamination of freestanding ultra-thin layers of a well-known polymer insulator, namely poly(vinyl formal) (PVF). Thanks to the peculiar characteristics of the employed materials, the device shows an excellent transparency, together with an extremely high level of conformability. In fact, the proposed device is able to sustain bending to extremely small curvature radii and to conform on complex 3D surfaces, such as human skin, which makes it non-invasive and completely imperceptible, opening to a multitude of possible applications of our approach in several fields, from wearable electronics to implantable-electronics. The device fabrication relies entirely on solutions process techniques (such as spin-coating and ink-

jet printing) and can be potentially up-scaled to an industrial size. Moreover, the devices show very reliable electrical performances, with mobility up to 0.18 cm^2/Vs, and a very good reproducibility, which are requirements particularly challenging when large-area fabrication techniques and solution processed materials are employed.

6:30 AM *F.SF04.01.08
Linking Microstructure to Transport at Several Lengthscales in Conjugated Polymers Alberto Salleo; Stanford University, United States

Carrier mobility in conjugated polymers continues to increase with recent reports of field-effect mobilities exceeding 10 $cm^2/V.s$. Charge transport is intrinsically dependent on processes occurring across multiple lengthscales. In order to access order parameters at the molecular scale we use charge modulation spectroscopy combined with theory. This technique allows us to further differentiate field-induced and doping-induced charges and study how their delocalization depends on local structure and disorder. Furthermore, we study the mesoscale organization of polymers using new techniques in the transmission electron microscope. By combining 4D STEM and HRTEM we are able to study the microstructure across a range of length-scales in real space and reciprocal space. These techniques are used on homopolymers and donor-acceptor copolymers and allow to extract information about the microstructure that is typically not visible by inspection. Such multiscale studies of microstructure are instrumental in guiding our understanding of charge transport in conjugated polymers.

6:45 AM *F.SF04.01.09
Thermoelectric Energy Conversion Devices of Electrochemically Doped Polymer Films Taishi Takenobu; Nagoya University, Japan

Thermoelectric energy conversion is one of the key technologies for energy harvesting devices to convert waste heat into electric power, and vice versa. Particularly, for IoT (Internet of Things) society based on wearable electronics, flexible large-scale thermoelectric conversion devices are highly required. Therefore, as the active semiconductors of these devices, organic conducting polymers are strong candidates due to their low-temperature solution processability, compatibility with large-area deposition techniques, and intrinsic robust mechanical properties. However, the thermoelectric transport mechanism of these materials is still unclear due to their unique disordered nature, in particular the poor interconnectivity between crystalline domains. Here, we investigated their thermoelectric and carrier transport properties using the electrochemical doping technique and successfully maximized their performances [1].

In thermoelectric energy conversion devices, the Seebeck coefficient (= thermopower, S), which is the proportional constant to the voltage generation against an induced temperature gradient, is a significant factor in designing thermoelectric devices. Importantly, according to the Mott equation, S is proportional to the energy derivative of the electronic density of states at around Fermi energy; therefore, it is critically important to control the energy band filling. Conventionally, the band filling is tuned by chemical doping and, in most materials, it is very difficult to establish precisely controllable doping methods. Another important factor for thermoelectric energy conversion devices is the thermoelectric power factor $S^2\sigma$ (σ is conductivity). It should be strongly emphasized that the power factor has to be optimized to maximize the electric power output of thermoelectric devices. Consequently, this is a key parameter for applications. However, it is widely known that there is a trade-off between S and σ in terms of carrier density, n. Although σ is almost linearly proportional to n, S decreases with increasing n. Therefore, again, it is necessary to maximize $S^2\sigma$ by tuning n.

To overcome this limit, we developed electrochemical doping technique [2-6] and combined this technique with thermoelectric measurements [1, 7-12]. In particular, we applied this method into semicrystalline PBTTT and donor-acceptor copolymers [1]. As the results, we successfully maximized their power factor and clarified the behind physics.

Physical Image of Organic Vertical Transistors with Conductive-Network Electrodes Chuan Liu, Zihao Chen, Kairong Huang, Sujuan Hu and Xiaoci Liang; Sun Yat-sen University, China

Organic vertical transistors with conductive-network electrodes composed of carbon- or metal-based nanowires or meshes have been gaining increasing attention in recent years and several comprehensive reviews have been published [1, 2]. Differing from planar field-effect transistors (FETs) or thin-film transistors (TFTs), the conduction of the carriers in such devices occurs through vertical channels that are controlled by the gate field from the gaps between the nanowires or from the holes within the metal films [3]. Because of their submicron channel length, vertical transistors based on organic semiconductors (e.g., polymers or small molecules) with carbon-nanotube electrodes or metal meshes exhibit a large current density that can be used to drive light-emitting diodes [4]. The device structure also show great potential on flexibility, high degree of intergration. In addition, the layer-by-layer structure can be deposited by state-of-the-art printing technologies in industrial printing lines established for organic light-emitting diodes. However, the devices lack concise physical images to understand the operations and explicit design rules to achieve the necessary performance, such as sharp subthreshold swing, a large on: off ratio and and saturation in the high drain voltage (V_D).
Here, we develop a device theory with concise physical images, which are generally applicable for devices with organic or inorganic semiconductors. The simplified solution of Poisson's equation reveals that the electrostatic potential at the semiconductor-dielectric interface is controlled by both the gate and drain field, behaving like a plucked string. The spacing between electrodes and the capacitance ratio between dielectrics and semiconductors are critical for achieving strong gate tunability of the interfacial potential, which can be maximized to achieve a sharp turn-on property toward the Boltzmann limit in the subthreshold regime. Above the threshold, the conduction channels in devices with Schottky contacts can change from the "L type" to "I type", or vice versa, during scanning and the current-voltage relations can be well described by modifying classical transistor equations. The derived theories and equations agree well with the numerically simulated devices and reported experiments, revealing the physical images and providing explicit rules for designing, fabricating, and characterizing such transistors.

7:10 AM F.SF04.01.11
Soft Electronics and Materials for Ear to Brain Engineering Georgios Spyropoulos; Ghent University, Belgium

Responsive modulation of neural networks is increasingly being used to treat patients with auditory-neurological disorders and neuropsychiatric diseases. Yet, current technology burdens neurostimulation tools with bulky, non-biocompatible electrical components that require rigid encapsulation for long-term implantation in body. Recently, we created a novel transistor architecture (internal ion-gated organic electrochemical transistors; IGT) that can be an efficient building block for integrated bioelectronics. These transistors include all the key features required for safe, efficient, and prolonged use of transistors in biological environments: i) they are made out of biocompatible and stable materials; ii) they are soft and conformable; iii) they show high speed and amplification to detect potentially low-amplitude ionic signals of the body; iv) they can perform certain computations.
Here, I am presenting the vision of our newly founded lab towards designing, based on that emerging technology, and developing novel fully implantable, contained and responsive neural interface devices that will allow long-term acquisition and closed-loop manipulation of neural circuits with high spatiotemporal resolution over extended period of time to reveal neural dynamics in the auditory-neurological pathway.

Monolayer Organic Field-Effect Transistors with Extremely High Current Density Paddy K. L. Chan; University of Hong Kong, Hong Kong

In this talk, I will focus on the high performance monolayer organic crystal and utilize it to develop an OFET with record high current density. The semiconductor is based on the solution processable DNTT derivatives and the deposition method is solution shearing. Among the four derivates, the best performance for the contact resistance is 25 ohm-cm at V_{DS} = -1 V, under a gate bias of -85V. The monolayer crystal could conduct unprecedently high density of current up to 19 μA/μm per channel width which is corresponding to 1.2 MA/cm^2 normalized by channel cross-section area. This current density is significantly higher than the reported values of other OFETs and also comparable with the inorganic transistors. Operating the OFETs with a high current density, however, would induce significant heating effect and a temperature rise of 110 K is obtained in the channel area. This inevitable wasted heat in the high power operation would lead to the thermal damage in the OFETs especially at the metal/organic contact interface. To suppress the thermal damage, a reduced voltage pulse width down to 10 μs and duty cycle down to 1% would still operate the device properly. Our work suggests that (i) monolayer crystal is a favored configuration in lowering the contact resistance; (ii) molecularly thin semiconductor could still conduct enormous amount of current; and (iii) thermal management is critical for future studies on OFETs, especially those with outstanding performance. Lastly, I will demonstrate how can use this high current density OFETs to drive different electronic devices such as LEDs and buzzers.

Printing Blends of Small Molecule Semiconductors with Insulating Polymers to Fabricate High Performing and Stable OFETs for Sensing Applications A. Tamayo[1], Tommaso Salzillo[1], Antonio Campos[1], Inés Temiño[1], Sergi Riera-Galindo[1], Simona Ricci[1], Adara Babuji[1], Raul Santiago[2], Stefan T. Bromley[2], Carmen Ocal[1], Esther Barrena[1], Remy Jouclas[3], Christian Ruzie[3], Guillaume Schweicher[3] and Marta Mas-Torrent[1]; [1]Institut de Ciència de Materials de Barcelona (ICMAB-CSIC), Spain; [2]Universitat de Barcelona, Spain; [3]Université Libre de Bruxelles (ULB), Belgium

Printing organic small molecule semiconductors by solution shearing for the fabrication of highly performing organic field-effect transistors (OFETs) is currently of major technological interest. However, two challenging issues remain unsolved in order to implement these devices in real applications: reproducibility and long-term stability. The blending of the organic semiconducting molecules (OSC) with insulating binding polymers has proved to be an efficient route to ensure the formation of homogenous films over large areas with high device-to-device reproducibility. However, since molecules are bound together through weak van der Waals interactions, they are prone to polymorphism. Slight differences between polymorphs can lead to dramatic changes in their mobilities. Further, some technologically desirable polymorphs are metastable but can degrade with time to the most thermodynamically stable form, thus impacting device performance. Recently, we have shown that the use of blends of OSCs with polymers by Bar-Assisted Meniscus Shearing (BAMS) gives rise to highly crystalline films.[1] In addition, the control of the deposition parameters (coating speed and temperature) as well as the modification of the ink formulation can be used as tools to tune the thin films morphology and the formation of thermodynamic and Kinetic polymorphs.[2] In a recent publication, we have also demonstrated that the blending approach can also be exploited to trap metastable polymorphs, which can lead to devices with both improved performance and long-term stability.[3]
The devices fabricated with this methodology have been applied for the development of X-ray detectors [4], biosensors[5] and for recording the activity of cells[6].

The first [BEDT-TTF = bis(ethylenedithio)- tetrathiafulvalene based quasi-twodimensional organic superconductor β-$(BEDT\text{-}TTF)^2I_3$ was first reported back in 1984.[1] Soon it became clear that ion radical salts (IRSs) derived from BEDT-TTF exhibit tuneable electronic band structures; therefore, such molecules are excellent building blocks for engineering a rich and diverse family of organic crystalline metals and semiconductors. Electronic band structures of BEDT-TTF-based molecular conductors originate from ordered arrangements, such as stacks and layers, leading to metallic charge-transfer salts with partially filled bands.[2]
One interesting characteristic of BEDT-TTF-based crystalline conductors is the very deformable molecular and crystal structure with strong electron−electron and electron−phonon couplings. Thanks to this, their anisotropic electronic structures exhibit many fascinating electronic and structural phase transitions caused by lattice deformations, which can be controlled by external stimuli such as light, temperature, strain, pressure, and humidity, among others. Nevertheless, it is necessary to engineer these crystals into a proper material for sensing applications. This was done by forming polycrystalline layers of IRSs, derived from BEDTTTF-based conductors, in nanocomposite bilayer (BL) films a strategy that allows combining electrical properties of IRSs with classical properties of insulating polymers, like flexibility, transparency, and solution processability.
Developing smart materials that can respond to an external stimulus is of major interest in artificial sensing devices able to read information about the physical, chemical and/or biological changes produced in our environment. Additionally, if these materials can be deposited or integrated on flexible, transparent substrates, their appeal is greatly increased. Such properties can be further tuned by choosing the nature of the IRSs enabling high sensitivity towards strain, pressure, temperature or even contactless radiation sensing i.e. bolometers.[3,4] In a very recent example, bilayer films, composed of conducting polycrystalline layers of two dimensional BEDT-TTF-IRSs, hydroresistive sub-micron sized crystals on top of a polymeric host matrix permit to electrically monitor relative humidity in a stable and fully reversible fashion.[5] This sensor platform enables the combination of high electrical performance of single crystals with processing properties of polymers towards a simple, low-cost and highly sensitive platform for applications in robotics, biomedicine and human health care.

Printed Polymer Field-Effect Transistors and Rectifiers Operating at Radio-Frequencies Mario Caironi; Istituto Italiano di Tecnologia, Italy

Organic electronics has been developed for many novel applications towards large area and flexible electronics, but it has been traditionally considered only for low frequency applications. However roadmaps towards GHz operation have been

recently proposed, exploiting improved electronic properties and optimized electronic device architectures. Such frequency range would be appealing for example to enable local area networks interconnecting large-area distributed and wearable sensors. Towards such applications, manufacturing processes comprising high-throughput printing techniques would be very appealing, although limitations in spatial resolution and in the control of electronic properties add a further obstacle to an already very challenging roadmap. In this contribution I will report on our progress in developing printed electronic devices capable of operating at radio-frequencies, targeting the High-Frequency range. In particular, I will show direct-written polymer field-effect transistors (FETs) operating above 20 MHz at low-voltage on plastic substrates, and fully inkjet printed diodes enabling rectifiers on plastic at 13.56 MHz. Finally, I will show recent results on FETs targeting the Ultra-High Frequency range, where local communication would be feasible.

Water-Based and Defect-Free 2D-Inks for Printed Electronics Cinzia Casiraghi; University of Manchester, United Kingdom

2-Dimensional materials (2DMs) are very attractive building blocks for the next generation electronics, which require low cost and flexible devices that can be easily integrated onto substrates such as paper and plastic. The atomically thin nature of 2DMs enables mechanical flexibility, high sensitivity, easy functionalization, and allows one to stack together different 2DMs to fabricate multifunctional heterostructure-based devices.
In this talk I will show a general formulation approach to make water-based, defect-free and biocompatible 2DM-based inks suitable for fabrication of a wide range of fully printed devices, such as photodetectors, capacitors and transistors, on paper and plastic [1-3].
Furthermore, printed 2DM-based devices can be easily coupled with printed RFID tags made of graphene, enabling the development of a wireless and battery-free multisening platform on paper [4-6]. Finally, the inks can be easily combined with polycrystalline 2DMs produced by chemical vapour deposition, allowing quick fabrication of complex circuits on paper, such as high-gain inverters, logic gates and current mirrors [7].
If time allows, I will also introduce a new C-based, highly resilient and flexible substrate for printed electronics, specifically designed for applications that involve repeated strain, where paper cannot be used because the incresing fatigue in the cellulose substrate leads to failure of the device. We will show that this highly resiliant substrate can sustain over 50k bending cycles without failure, in contrast to paper, which starts failing already after 5k cycles [5].

Progress Towards Reproducible, Robust, and Recyclable Printed Electronics Aaron D. Franklin; Duke University, United States

The promises of a printed electronics revolution continue to be hindered by challenges in the performance, reproducibility, and broad utility of printed devices. Inks from nanoscale materials have received increasing attention for their potential to overcome some of these hurdles, particularly in yielding direct-printed thin films meeting target electrical performance, air stability, and process compatibility. While many commercial options now exist for conducting inks, accessibility of versatile and robust semiconducting and insulating inks remains a challenge. In this talk, the recent progress on, and benefits of, semiconducting carbon nanotube (CNT) inks will be reviewed, particularly in the context of direct-write, aerosol jet-printed electronic devices. Proper control of ink properties and printing process, including factors such as ink temperature and printing time, can yield semiconducting CNT thin films with relatively high mobility, uniformity, and reproducibility. In

addition, two attractive options for direct-write printed insulating inks will be discussed: hexagonal boron nitride (hBN) and crystalline nanocellulose (CNC). It will be shown how the appropriate design of these nanomaterial-based inks can enable the printing of fully recyclable electronics, where the constituent nanomaterials can be reclaimed and reused after initial printing and use in electronic devices.

5:30 AM F.SF04.02.03
Ambipolar Printed-Carbon-Nanotube Transistors with Self-Assembled-Monolayer Nanodielectrics for Low-Power and Low-Voltage Electronics Luis Portilla[1,2], Jianwen Zhao[2] and Vincenzo Pecunia[1]; [1]Soochow University, China; [2]Suzhou Institute of Nanotech and Nano-bionics, China

Easy-to-fabricate, low-power and low-voltage thin-film-transistors (TFTs) that allow robust (complementary/complementary-like) circuit integration are highly sought-after for the development of off-the-grid smart sensors for the Internet of Things (IoT) ecosystem (*1*). Semiconducting single walled carbon nanotubes (sc-SWCNT) are a promising semiconductor material for TFTs with high field-effect mobilities and capable of low-voltage operation (*2*). However, fabricating sc-SWCNT TFT electronics with complementary (CMOS) characteristics typically requires complex fabrication processes, due to the several materials solutions (e.g. selective doping, different contact metals, multiple capping layers) required to this end, which also result in extra process steps (*3*). In this talk, we present our findings on the capability of ambipolar semiconducting single-walled carbon nanotube network (sc-SWCNTN) TFTs to deliver electronics that is easy-to-fabricate, low-power, (ultra-)low-voltage, and complementary-like. Our ambipolar TFTs comprise a sc-SWCNTN active layer deposited and patterned via aerosol-jet printing—with a maximum processing temperature of 120 °C—atop self-assembled monolayer (SAM)/AlO_x hybrid nanodielectrics. These TFTs exhibit symmetric ambipolar characteristics with balanced electrons and hole mobilities in the neighborhood of 10 $cm^2 V^{-1} s^{-1}$, along with an onset voltage near 0 V and threshold voltages of < 1 V, all which enables these devices to operate within a voltage range of ~ 1 V.

The significance of our ambipolar sc-SWCNTN devices for low-voltage TFT electronics is assessed both experimentally and theoretically. We firstly discuss the impact of two key TFT parameters—subthreshold slope and flatband voltage—on the voltage and power requirements of circuits based on our ambipolar sc-SWCNTN TFTs. Moreover, by connecting our sc-SWCNTN TFTs in CMOS fashion, we demonstrate experimentally that the resultant inverters and NAND gates deliver CMOS-like performance with positive noise margins at supply voltages (V_{DD}) as low as 0.5 V and up to 2 V. On the high end of this V_{DD} range, inverter gates achieve gains > 80 V/V and bandwidths exceeding 100 kHz. Additionally, on the low end of this V_{DD} range, inverters are able to operate with subnanowatt static power dissipation, which is well aligned with the power requirements of off-the-grid applications. Importantly, in addition to its cutting-edge capabilities, our CMOS-like integration comes with the inherent advantage of using one single semiconductor for both *n*-channel and *p*-channel conduction, which allows a streamlined fabrication process compared to alternative approaches reported in the literature (e.g., involving dopants, different capping layers, different source and drain contact materials). In summary, we demonstrate that the combination of printed sc-SWCNTs and hybrid SAM nanodielectrics provides an attractive route to the realization of ambipolar sc-SWCNT TFT CMOS-like circuits for low-voltage/(ultra-)low power electronics.

Laser Printing of Functional Materials Oana D. Jurchescu; Wake Forest University, United States

The past decades have witnessed a commendable progress in the development of materials for low-cost flexible electronics.

New products that are beyond reach with current technologies can soon become a mainstay in our lives if these materials reach the necessary standards for performance and stability. The development of processing techniques that can address the manufacturability – scalability – sustainability – performance balance represents the next key step in the integration of these materials into next-generation electronic devices. In this presentation, I will introduce the use of laser printing, a rapid, scalable, environmentally friendly and low-cost manufacturing technique for deposition and patterning of various functional materials on flexible substrates. The first example focuses on organic semiconductors, and I will discuss the fabrication and characterization of organic thin-film transistors placed on plastic and paper. Aerosol spray laser lithography was used to define the electrodes, in conjunction with different metal inks: the pattern was created using a regular toner, which was subsequently selectively removed. We created a grid of transistor devices with variable channel lengths and widths and obtained good charge carrier mobilities and an excellent tolerance to bending. Next, I will describe the use of laser printing for the fabrication of metal halide perovskite films. The electrical properties of the laser printed films were comparable with those of the spin-coated layers, despite the fact that the microstructure consists of randomly oriented crystallites. The current-voltage characteristics exhibit negligible hysteresis and the electrical properties of the films are very stable under ambient conditions due to the fact that a vertical separation of the toner components results in an encapsulating the perovskite layer by the other toner components. Our work introduces an exciting new avenue for the fabrication of stable perovskite devices that is scalable and devoid of hazardous solvents.

5:15 AM *F.SF04.03.02
Processing Fundamentals for Self-Aligned Flexible Printed Electronics Krystopher Jochem, Motao Cao, Panayiotis Kolliopoulos, Xiaochen Ma, Satish Kumar, Daniel Frisbie and Lorraine F. Francis; University of Minnesota Twin Cities, United States

Continuous, roll-to-roll (R2R) printing processes are attractive for manufacturing of flexible electronics. Two common challenges with R2R are reaching small feature sizes and achieving precise registration of multiple functional layers in devices such as transistors. This presentation will cover our efforts to overcome these issues using Self-Aligned Capillarity-Assisted Lithography for Electronics (or SCALE). SCALE has two steps. In the first step, R2R imprinting is used to create a multilevel open network of reservoirs, capillaries and device structures into a UV-curable coating deposited on a flexible substrate. In the second step, electronically functional inks are then delivered sequentially into the reservoirs on this imprinted substrate by inkjet printing, and capillarity pulls inks into capillaries and device structures. Since the imprint stamps are fabricated from high-resolution, Si master patterns created by photolithography, the features created in the imprint resin are also high-resolution, at the micron scale. The single imprinting step also simultaneously creates all the structural features needed to control the flow and deposition of multiple inks, resulting in self-alignment of multiple materials in complex multilayer devices.

To-date we have developed SCALE methods to create conductive networks, resistors, capacitors, diodes and transistors. For example, to manufacture high aspect ratio (thickness/width) SCALE conductive networks, we used a combination of inkjet delivery of a silver particle-free ink into reservoirs of the imprinted substrate, followed by capillary flow and thermal annealing to convert the ink to a silver seed layer and lastly electroless copper plating to build conductor thickness in capillary channels. By optimizing processing conditions and understanding the fundamentals of capillary flow, narrow (e.g., 10 μm), high aspect ratio (>1), low resistance (~1 ohm per cm of conductor length) embedded conductive traces were created. This presentation will show advances in device architecture and performance, and explore the key processing steps. Special attention will be given to continuous roll-to-roll processes.

Ink Engineering for Color–Selective Printed Organic Photodiodes and Filterless Multichannel Visible Light Communication Noah Strobel[1,2], Nikolaos Droseros[3], Wolfgang Köntges[4], Mervin Seiberlich[1,2], Manuel Pietsch[1,2], Stefan Schlisske[1,2], Rasmus Schroeder[4], Ulrich Lemmer[1,2], Martin Pfannmöller[4], Natalie Banerji[3] and Gerardo Hernandez-Sosa[1,2]; [1]Karlsruhe Institute of Technology, Germany; [2]InnovationLab, Germany; [3]University of Bern, Switzerland; [4]Universität Heidelberg, Germany

Organic photodiodes (OPDs) are particularly well suited for future optical sensing technologies in the fields of mobile, wearable and skin-like electronics as they enable chemically tunable optoelectronic performance and fabrication by digital printing techniques on mechanically compliant substrates.(1) However, OPDs have typically utilized active layers developed for photovoltaic applications exhibiting broad absorption range and lacking the spectral selectivity necessary in fields like imaging or communication which require optical detectors that can distinguish between different wavelengths. To solve this, common approaches have relied on device engineering methods which result in devices with increased fabrication complexity.

This work introduces a general solution for inkjet-printing wavelength-selective bulk-heterojunction (BHJ) photodetectors through engineering of the ink formulation and demonstrate its potential for Visible Light Communication (VLC).(2) Non-fullerene acceptors (NFAs) are incorporated in a transparent semiconductor polymer donor matrix to narrow and tune the response in the visible range without optical filters or light-management techniques. In this approach, the device spectral response solely depends on the choice of the NFA while the polymer donor dictates the rheological properties of the ink. Thus, this approach effectively decouples the optical response from the viscoelastic ink properties, simplifying process development. A thorough morphological and spectroscopic investigation of the novel BHJ systems finds excellent charge-carrier dynamics enabling responsivities up to 230 mA W^{-1}. This state-of-the-art response combined with high bandwidths >1.5 MHz, allows effective application in a VLC system. In this system, the complementary color-selectivity of the devices enables successful demultiplexing of simultaneously transmitted optical signals without the need of any additional optical filters or light-management techniques.

Late News: High Yield Manufacturing of Fully Screen Printed Organic Electrochemical Transistors Marzieh Zabihipour[1], Roman Lassnig[2], Jan Strandberg[2], Magnus Berggren[1], Simone Fabiano[1], Isak Engquist[1] and Peter Andersson Ersman[2]; [1]Linköping University, Sweden; [2]RISE Research Institutes of Sweden, Sweden

The potential of the screen printing method for large-scale production of organic electrochemical transistors (OECTs), combining high production yield with low cost, is here demonstrated. Fully screen printed OECTs of 1 mm^2 area, based on poly(3,4-ethylenedioxythiophene) doped with poly(styrensulfonate) (PEDOT:PSS), have been manufactured on flexible PET substrates. The goal of this project effort has been to explore and develop the printing processing to enable high yield and stable transistor parameters, targeting miniaturized digital OECT circuits for large scale integration (LSI). Of the 760 OECTs manufactured in one batch on a PET sheet, only 2 devices were found malfunctioning, thus achieving an overall manufacturing yield of 99.7 %. A drain current ON/OFF ratio at least equal to 400 was applied as the strict exclusion principle for the yield, motivated by proper operation in LSI circuits. This consistent performance of low-footprint OECTs allows for the integration of PEDOT:PSS-based OECTs into complex logic circuits operating at high stability and accuracy.

Organic Infrared Sensors and Energy Storage Capacitors Based on Narrow Bandgap Polymers Tse Nga Ng[1], Ning Li[1], Lulu Yao[1], Kaiping Wang[1] and Jason D. Azoulay[2]; [1]University of California San Diego, United States; [2]University of Southern Mississppi, United States

Narrow bandgap polymers are used to realize infrared photodetectors that is relevant to a variety of applications including environmental monitoring and medical diagnosis. To achieve high detectivity in detectors, it is critical to reduce the device noise. This talk presents experimental and modeling studies on the noise current in exemplar organic bulk heterojunction photodiodes, with 10 donor–acceptor combinations spanning wavelength between 800 and 1600 nm. A significant reduction of the noise and higher detectivity were found in devices using non-fullerene acceptors (NFAs) in comparison to those using fullerene derivatives. The low noise in NFA blends was attributed to a sharp drop off in the distribution of bandtail states, as revealed by variable-temperature density-of-states measurements. Taking disorder into account, we developed a general physical model to explain the dependence of thermal noise on the effective bandgap and bandtail spread.

The narrow bandgap polymers are also Faradaic materials for energy storage and present opportunities to create energy dense

supercapacitors. The vast majority of conducting polymers are p-type, and here we present promising n-type polymers that are stable when operating within a large potential window (3V), with a best-in-class energy densities (30.4 Wh/kg at a 1 A/g discharge rate), and a long cycle life (90% capacitance retention after 5000 cycles) critical to energy storage and management. This work demonstrates the application of a new class of stable and tunable redoxactive material to realize high-endurance energy storage devices for flexible printed systems.

5:15 AM *F.SF04.04.02
Amplified Spontaneous Emission and Lasing in Quasi-2D Perovskites Franky So and Kenan Gundogdu; North Carolina State University, United States

Recently, metal-halide perovskite materials are considered as a promising candidate for lasing applications. Compared to 3D and other low-dimensional perovskites, quasi-2D perovskites are a better gain media due to its unique properties such as large binding energy and self-assembled quantum wells. Specifically, efficient energy funneling from low-dimensional domains to high-dimensional domains will not only enhance the radiative recombination but also facilitate population inversion.
In this presentation, we will discuss the fundamental requirements for population inversion in perovskites in the context of material dimensionality and morphology. We will also present our recent work on laser cavity design and processing for optimum laser performance.

5:30 AM F.SF04.04.03
Solution-Processed Photoelectrochemical (PEC)-Type Photodetectors Based on Layered Metal Monochalcogenides (GaS, GaSe, GeSe) Gabriele Bianca[1,2], Marilena I. Zappia[3,4], Sebastiano Bellani[1,3], Michele Serri[1], Leyla Najafi[1,3], Nicola Curreli[1], Beatriz Martin-Garcìa[1], Reinier Oropesa-Nunez[3], David Sedmidubsky[5], Vittorio Pellegrini[1,3], Zdenek Sofer[5], Anna Cupolillo[4] and Francesco Bonaccorso[1,3]; [1]Istituto Italiano di Tecnologia, Italy; [2]Università degli Studi di Genova, Italy; [3]Bedimensional Spa, Italy; [4]Università della Calabria, Italy; [5]University of Chemistry and Technology Prague, Czechia

The conversion of light energy into electricity and chemical fuels through photoelectrochemical (PEC) cells represents a powerful strategy for sustainable fuel and chemical generation, environmental remediation (*i.e.*, pollutant degradation), advanced analytical systems (*i.e.*, chemical sensors) for environmental and biological monitoring, as well as innovative self-powered photodetectors. In particular, aqueous PEC cells, including water splitting ones, are emerging for the development of cheap, easily fabricated, environmentally friendly self-powered photodetectors with high spectral responsivity. In this context, two-dimensional (2D) materials, including either single- and few-layer flake forms, are continually attracting utmost interest as potential advanced photo(electro)catalysts. Recently, group-III and group-IV transition metal monochalcogenides, which can be exfoliated in 2D form due to their low cleavage energy (typically < 0.5 J m^{-2}), have been theoretically predicted to be water splitting photocatalysts. In fact, their 2D nature intrinsically guarantees that the charge carriers are directly photogenerated at the interface with the electrolyte, where redox reactions take place before they recombine. Moreover, their electronic structure can be tuned by controlling the number of the layers to fulfil the fundamental requirements for water splitting photocatalysts, *i.e.*: 1) conduction band minimum (CBM) energy (E_{CBM}) > reduction potential of H^+/H_2 ($E(H^+/H_2)$); 2) valence band maximum (VBM) energy (E_{VBM}) < reduction potential of O_2/H_2O ($E(O_2/H_2O)$). Among them, low-cost and environmentally friendly layered gallium sulfide (GaS), gallium selenide (GaSe) and germanium selenide (GeSe) are promising materials candidate for optoelectronic devices due to their properties: tunable electronic structure, strong visible-light absorbance, significant photoresponse due to direct-bandgap transitions, photoferroelectricity and environmental stability. Here, we report the first experimental characterization of the PEC water splitting activity of single-/few-layer flakes of GaS, GaSe and GeSe produced in form inks by scalable liquid-phase exfoliation (LPE) approach in non-toxic solvents. The as-produced dispersions were deposited by spray-coating technique to conceive solution-processed self-powered PEC-type photodetectors. The PEC behaviour of MCs-based photoelectrodes was evaluated in different aqueous media, ranging from acidic to alkaline solutions: 0.5 M H_2SO_4 (pH 0.3), 1 M Na_2SO_4 (pH 6), 1 M KCl (pH 6.5), 1 M KOH (pH 14) under different illumination wavelengths in the visible spectral range, namely 455, 505 and 625 nm. Moreover, due to its large band gap, GaS was also tested under UV radiation (275 nm) obtaining an UV photodetector without using any visible light filter. Instead, GaSe and GeSe photoelectrodes show a responsivity up to ~0.16 A W^{-1} and ~0.32 A W^{-1}, respectively, upon 455 nm illumination at light intensity up to 63.5 μW cm^{-2}. The obtained performances are superior to those of several self-powered and low-voltage solution-processed photodetectors, approaching the ones of self-powered commercial UV-Vis photodetectors. Our results can open the way towards the use of 2D metal monochalcogenides in innovative PEC systems, (bio)sensors and other innovative optoelectronics devices.

5:40 AM F.SF04.04.04
Mantis-Shrimp Inspired Multispectral and Polarimetric Imaging Achieved Using Highly Polarized Organic

Photodetectors Harry Schrickx[1], Ali Altaqui[1], Pratik Sen[1], Jeromy Rech[2], Jin-Woo Lee[3], Michael Escuti[1], Wei You[2], Bumjoon J. Kim[3], Robert Kolbas[1], Michael Kudenov[1] and Brendan T. O'Connor[1]; [1]North Carolina State University, United States; [2]University of North Carolina at Chapel Hill, United States; [3]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Multispectral and polarimetric imaging provides invaluable information undetectable by the human eye, leading to significant advancements in fields that include biomedical imaging, astronomy, and agriculture. Current methods for snapshot multispectral and polarization imaging require an array of adjacent pixels to create a super-pixel, where each pixel serves to measure a subset of the optical information. However, this super-pixel suffers from significant spatial and sampling error. To overcome these limitations, we introduce a new detector strategy inspired by stomatopods, or mantis shrimp. Mantis shrimp display one of the most intricate vision systems in nature, featuring 16 types of photoreceptor cells capable of perceiving light ranging from UV to far-red, as well as polarized light. We refer to our sensor as a Stomatopod-Inspired Multispectral and POLarization (SIMPOL) sensor. The SIMPOL sensor leverages two key technologies: (1) polarization sensitive semitransparent organic photovoltaics (P-OPVs), and (2) folded retarder (FR) films. The FRs enable finely tuned polarization rotation for different wavelengths of light. The P-OPVs then preferentially sense light polarized with a specific orientation. By pairing the P-OPVs and FRs, we create a versatile sensing platform for narrow optical bandwidth detection and polarization sensing. The SIMPOL detector design consists of a cascading series of P-OPVs and FRs and share many features of the mantis shrimp eye, enabling the realization of multispectral and polarization sensing in a single pixel for the first time.

The function of the SIMPOL sensor is critically dependent on the performance of the P-OPVs, which are required to be highly polarized, and highly transparent along the non-absorbing electric field orientation. The polarization sensitivity of these devices is achieved by orienting the polymer semiconductors in the plane of the film. Here, we introduce a strategy of high temperature rubbing on a low molecular weight all-polymer bulk heterojunction film to achieve a high degree of in-plane alignment. We demonstrate a blend of PBnDT-FTAZ and P(NDI2OD-T2) subjected to the high temperature rubbing results in dichroic ratios of over 18 and photocurrent ratios of over 7 when under orthogonally polarized illumination. This represents the most polarization sensitive OPVs demonstrated to date. The SIMPOL sensor consists of six stacked P-OPVs enabling the detection of four spectral channels with a spectral resolution of up to 16.9 nm, while simultaneously measuring the linear polarization state of the light. We demonstrate the potential of the SIMPOL detector by imaging a scene that includes broad spectral and polarization features, representing a significant advancement in spectral and polarization imaging.

Renect Progress in the Design of Shape Free Displays Jongho Hong, Jae Min Shin, Sang-Woo Kim, Jangyeol Yoon, Sung-Chan Jo, Changhee Lee and Jinoh Kwag; Samsung Display, Korea (the Republic of)

Recently, the development of the existing flat panel display technology has reached an extreme level, interest in the new display form factor has been increased more than ever. Since those researches began, foldable display, which has been successful in establishing itself in the mobile display market since 2019. In additon to the design aspect, it succeeded in receiving the customer’s choice in terms of functionality, such as the expansion of the screen, and is expected to continue to develop in the future. Rollable display technology is also expected to be applied to various products in near future beyond the research level.
In the last decade, stretchable display technologies have attracted much attention as a next step after foldable and rollable displays. A stretchable display capable of realizing a free-form that is impossible with exisiting display technology is expected to be applied as a field of new products. Free-form display, as a high potential and challenging research field, have brought interest to the issue of how to make stretchable behavior that offer both durable and reliable characteristics with conventional and/or newly developed electronic materials. Although there were several efforts to make intrinsic stretchable display based on soft materials with stretchable electronics, the resolution of pixel images and long-life stablity should be improved.
We report on the latest advances in stretchable display based on OLED technology and discuss the recent progress in the design of stretchable display by comparing the key design consideration in terms of substrate, materials, and geometries. We will also introduce the freeform stretchable display based on low temperature poly-silicon (LTPS) active-matrix OLED

(AMOLED) technology. This research has introcuced a stretchable display that operates normally without degradation of image quality even after convex or concave static formed shaping using a low-temperature vacuum thermoforming process. In addition, repetitive deformation was applied in a vertical direction to stretch the center of the display panel while the panel was in operation. After applying tensile elongation up to 50,000 cycles using a repetitive stretching machine, no significant difference was observed in the color coordinate measurement depending on the deformation.

5:15 AM *F.SF04.05.02
Conformable Imager for Biometric Data Measurement Tomoyuki Yokota and Takao Someya; The University of Tokyo, Japan

With the rapid aging of Japanese society, how to increase quality of life (QoL) while controlling rising medical expenses has become an urgent issue. To solve this difficult issue, the acquisition and utilization of biological information using new technologies such as wearable devices is more expected. In particular, self-care and home medical care, in which patients and their families are responsible for their own health, are considered as one of the way to solving the issues of a super-aging society. Indeed, wearable sensors that can constantly monitor health conditions and home-use blood pressure monitors with communication functions are being introduced to the market one after another to prepare for the advent of a self-care era. On the other hand, when designing a new insurance system or incentive system using biometric information from wearable sensors, it is important issue how to confirm whether data measured at home is the patient's own. Furthermore, the risk of patient mix-ups must be reduced as more wearable devices come to be used in hospitals and welfare facilities in the future. Therefore, measuring vital signs simultaneously with biometric authentication of the user is an urgent issue.
We have developed a sheet-type image sensor that enables high-resolution and high-speed reading. This sheet-type image sensor can take the high-resolution image of fingerprints and veins used for biometric authentication. In addition, the same sheet-type imager can measure the pulse wave which is one of the vital signs, and its distribution.
Although there are many reports of sheet-type image sensors, it has not been achieved both high-resolution imaging and high-speed readout, and static biometric data and dynamic vital signs cannot be measured by one sheet-type image sensor. This is because high-sensitivity photodetectors and high-speed switching elements could not be integrated on a polymer substrate without damaging of the switching elements.
The developed sheet-type image sensor is fabricated by densely integrating a high-efficiency readout circuit using an active matrix of a low-temperature polysilicon thin film transistor and a photodetector that uses a highly efficient organic semiconductor as a photosensitive layer. The resolution of the image sensor achieves 508 dots per inch (dpi) required for fingerprint authentication, and the organic photodetector consists of bulk hetero structure organic layer which has high photosensitivity to near infrared light with a wavelength of 850 nanometers (external quantum efficiency of 50% or more). It it easy to integrate the sheet-type image sensor into equipment and attach it to curved surfaces due to the thickness of the polymer base material is 10 micrometers, and the total thickness of the sheet-type image sensor is 15 micrometers (Figure 1). By developing a process technology that integrates photodetectors and thin-film transistors without damage to each other, it has become possible to realize a sheet-type image sensor that achieves both high-resolution imaging and high-speed reading. Evaluation of vein and fingerprint images taken by this sheet-type image sensor showed that the contrast difference of the veins was less than 5% compared to images using a general CMOS imager. We confirmed that the conformable imager has high image quality equivalent to that of conventional CMOS imagers.
Since the sheet-type image sensor is thin and bendable, it can be easily integrated into wearable devices, and it is possible to measure health condition and perform biometric authentication at the same time. As a result, it is expected that prevention of “spoofing” and patient from being mixed up.

5:30 AM *F.SF04.05.03
Design Requirements for Flexible TFT-Based Logic Applications Kris Myny[1,2]; [1]imec, Belgium; [2]KU Leuven, Belgium

In last decades, the research on flexible logic circuits based on thin-film transistors (TFTs) have been increasingly growing as technologies tend to stabilize enabling application-oriented research. Although backplane applications such as active matrix displays and 2-D imager arrays are the main driver for technology developments, logic applications also benefit from increased performance. In this invited presentation, I will elaborate on several design requirements for TFT-based logic circuits and link them to technology and material requirements.

The focus of this work will be in the direction of flexible IoT applications, ranging from radio-frequency communication chips to sensor readout circuitry to monitor vital parameters. All demonstrated flexible integrated circuits have been realized in a dual-gate self-aligned a-IGZO TFT technology. The main advantage of a self-aligned transistor is the strongly reduced parasitic overlap capacitance between gate and source-drain contacts, enabling faster circuit blocks consuming less power.

Consequently, we have demonstrated a flexible IGZO-based NFC communication tag connecting to an NFC-enabled smartphone [1]. In recent work, we have been updating our design libraries with substantially lower power consumption and realized a capacitive tag that communicates directly with the touchscreen of a smartphone as an enabler for the Internet-of-Everything [2]. This tag has been made self-powered by integrating a flexible Perovskite photovoltaic cell that captures the energy from the smartphone screen which powers the chip.

The dual-gate self-aligned transistor provides a designer with an additional benefit, namely the presence of an extra gate. The backgate can be employed for several different purposes: to increase the transconductance, to improve the output resistance or to control the threshold voltage. Most of these design considerations are mainly interesting for analogue circuits, for example to improve the gain of an operational amplifier. As a third case in this presentation, I will discuss our recent achievements on a flexible ECG patch with NFC compatibility for healthcare monitoring patches [3]. Finally, as the newest technology developments move in the direction of increased charge carrier mobilities, matching p-types and low-temperature polysilicon and oxides (LTPO), I will elaborate on the future enabling opportunities for TFT-based logic circuits and applications.

Patchable 3D Motion Tracking Magneto-Interactive Electroluminescence Display Seung Won Lee, Chanho Park, Hyeokjung Lee, Kyuho Lee and Cheolmin Park; Yonsei University, Korea (the Republic of)

Development of a human-interactive display that enables the simultaneous sensing, visualisation, and memorisation of a magnetic field has attracted significant attention because it offers control and easy access to information that is rarely available. This study demonstrates a magneto-interactive electroluminescent display patchable on skin, which is capable of sensing, visualising, and storing magnetic field information, thereby enabling 3D motion tracking. For this purpose, a magnetic field-dependent conductive gate is employed in an alternating current electroluminescent (EL) display, which is used to produce non-volatile and rewritable magnetic field-dependent EL display. By constructing mechanically flexible arrays of non-volatile magneto-interactive EL displays, a skin-patchable and pixelated platform is realised. The unique feature of magnetic field varying along the z-axis enables the 3D motion tracking (monitoring and memorisation) on 2D pixelated display. This 3D motion tracking display is successfully used as a non-destructive surgery-path guiding display, wherein a pathway for a surgical robotic arm with a magnetic probe is visualised and recorded on a display patched on the abdominal skin of a rat, thereby helping the robotic arm to find an optimal pathway without damage incurred on the path to the surgery spot.

Various Solution Processing Methods for Boosting Electrical Performance of Metal-Oxide-Based Thin-Film Transistors and Phototransistors I Sak Lee, Dong Hyun Choi, Dongwoo Kim and Hyun Jae Kim; Yonsei Univ, Korea (the Republic of)

Oxide thin-film transistors (TFTs) have attracted much attention for next-generation electronics because of their superior performance compared with conventional a-Si TFTs such as high mobility and optical transmittance in the visible light. Particularly, solution process is a promising technique for the oxide TFT fabrication method for being a low-cost method with high composition controllability, high throughput, and various application. In this study, we propose various researches to improve the electrical and optical performances in oxide TFTs. Furthermore, we suggest a solution-processed oxide absorption layer (SAL) to enable detection of visible light for oxide phototransistors.

Voltage-Based Ambi-Ionic Migration (VAM) for Modulating Active Layer
The voltage-based ambi-ionic modulation (VAM) technique allows specific ions to migrate into the active layer by applying bias, easily modulating the active layer. Also, the potassium superoxide (KO^2) solution is employed in oxide thin-film transistors (TFTs) as a source of potassium (K^+) ions and highly reactive superoxide radical (O_2^{*-}) ions. By applying external bias, the K^+ and O_2^{*-} ions rapidly migrate into the active layer, directly changing its electrical properties and chemical composition. Through the VAM technique, various metal-oxide-based devices such as oxide TFTs can perform better.

Multifunctional Heterogeneous Organic (MHO) Passivation Layer for Oxide TFT
We propose a highly flexible and reliable multifunctional heterogeneous organic (MHO) passivation layer composed of stacked diketopyrrolopyrrole (DPP)-polymer and parylene-C films for improving the stability of oxide TFTs under various ambient environments and mechanical stress. The presented MHO passivation layer leads to high-performance oxide TFTs by: (1) protecting them from external reactive molecules, (2) blocking light to the oxide layer, and (3) improving their electrical characteristics. As a result, oxide TFTs with MHO passivation layer exhibit higher stability in ambient environment and under light. Moreover, since the MHO passivation layer can be deposited at room temperature and exhibits high mechanical stability, it could be practical in the fabrication of flexible/wearable devices.

Selective modulation of electrical characteristics by electro-hydro-dynamic printing
A simple fabrication method for homojunction-structured Al-doped indium–tin oxide (ITO) thin-film transistors (TFTs) using an electro-hydro-dynamic (EHD) jet-printed Al_2O_3 passivation layer with a specific line (W_{Al2O3}) is proposed. After EHD jet-printing, the specific region of ITO where Al_2O_3 is printed changes from a conducting film to a semiconducting film while Al_2O_3 acts as passivation layer. The channel length of the fabricated TFTs is defined by W_{Al2O3} which is easily changed with varying EHD jet printing conditions, replacing masks with varying patterns. Consequently, the proposed approach is promising as a low-cost and flexible manufacturing system for multi-item small-lot-sized production of Internet of Things devices.

Solution-Processed Oxide Absorption Layer (SAL) for Visible-Light Detecting Phototransistor
We propose a solution-processed oxide absorption layer (SAL) for visible-light (532 and 635 nm) detection for indium−gallium−zinc oxide (IGZO) phototransistors. The SAL was deposited onto the sputtered IGZO using precursor solutions composed of the same atomic configuration of sputtered IGZO, resulting in superior interface characteristics. We artificially generated sub-gap states in the SAL using a low temperature (200°C) annealing, minimizing the degradation of the electrical characteristics of TFT. These sub-gap states in SALs improved the photoelectron generation under long-wavelength visible-light despite the wide bandgap of IGZO (over 3.0 eV). As a result, the IGZO phototransistors with SALs have both superior optoelectronic characteristics and high optical transparency.

Electron and Hole Transport in Methyl Ammonium Lead Iodide Mohammad Sajedi Alvar, Gert-Jan Wetzelaer and Paul W. Blom; Max Planck Institute for Polymer Research, Germany

Hybrid organic-inorganic perovskites are promising materials for the application in solar cells and light-emitting diodes. However, the basic current-voltage behavior for electrons and holes is still poorly understood in these semiconductors due to their mixed electronic-ionic character. To develop an experimentally-validated numerical device model, it is therefore necessary to isolate individual physical phenomena. We investigate the dynamics of ion motion in methyl ammonium lead iodide ($MAPbI_3$) by impedance spectroscopy and electric displacement as a function of frequency. The displacement response is fully reproduced by a numerical device model that enables us to determine the frequency-dependent dielectric constant, the ion concentration and the ion diffusion coefficient. These validated ion dynamics are applied to analyze space-charge-limited electron and hole currents in $MAPbI_3$. We demonstrate that the frequency dependence of the permittivity plays a crucial role in the analysis of space-charge-limited currents and their dependence on voltage scan rate. Our mixed electronic-ionic device model accurately reproduces the current-voltage characteristics of single-carrier devices, showing that in $MAPbI_3$ transport of electrons dominates over holes.

High-Performance Carbon-Free Solution-Processed Oxide TFTs Fabricated by Direct Patterning Masashi Miyakawa, Mitsuru Nakata, Hiroshi Tsuji and Yoshiki Nakajima; NHK Science & Technology Research Laboratories, Japan

Facile solution-processing of metal oxide thin-film transistors (TFTs) is a promising alternative to conventional vacuum-processing and offers various advantages, such as low cost, large-area fabrication capability, and process simplicity.[1] The patterning of such films is necessary for device integration; however, most solution-processing is still conducted using traditional photolithographic patterning processes. A simple and reliable direct patterning method is a key technological requirement to maximize the advantages of solution-processing.[2] We have previously reported a direct patterning method for an aqueous In-Ga-Zn oxide (IGZO) precursor.[3]
A direct patterning method to obtain high-performance carbon-free oxide TFTs using In-Zn oxide (IZO) and In-oxide (InO) will be presented. Direct patterning is achieved by selective photoreaction of water molecules as a precursor solvent and nitrate ligands under ultraviolet irradiation without organic photosensitive additives. This environmentally-friendly chemical etching process uses a non-toxic organic acid (citric acid), followed by annealing at 350 °C, to obtain carbon-free oxide films of IZO and InO. TFTs with these oxide films on SiO_2 dielectrics that were fabricated by the direct patterning method and with sputtered Mo electrodes exhibited high mobilities of 11.5±1.6 cm^2/Vs for IZO and 39.0±1.9 cm^2/Vs for InO. The InO TFTs with solution-processed dielectrics using siloxane materials also exhibited good switching characteristics and a mobility of more than 30 cm^2/Vs. X-ray reflectivity and X-ray diffraction analysis of the InO film density and crystallinity indicated denser and larger crystallinity in the photo-patterned oxide films. Efficient photooxidation by optimization of the deposition conditions and precursor concentrations during UV exposure resulted in higher quality solution-processed oxide films.

Low-Voltage IGZO Thin-Film Transistors Using SAM Surface Modification on Ta_2O_5 as the Gate Dielectric Navid Mohammadian and Leszek A. Majewski; The University of Manchester, United Kingdom

Low-voltage, high-performance thin-film transistors (TFTs) have been getting tremendous attention over recent years due to the increasing demand for low-power, portable electronic devices and sensor arrays. However, reducing the power consumption of TFTs is an extremely challenging task [1]. High-κ dielectric materials are thought to play an essential role in applications where a low-power device operation is needed.
In particular, tantalum pentoxide (Ta_2O_5) is a very promising candidate due to the high dielectric constant in the bulk (κ_{bulk} ~27) and as a thin-film ($\kappa_{thin\text{-}film}$ ~20). These values are at least two times larger than that of Al_2O_3 (κ_{bulk} ~9) and five times larger than that of SiO_2 (κ_{bulk} ~3.9) [2]. As a result, Ta_2O_5 has been abundantly used in electrolytic capacitors, DRAM devices, and recently in solution-processed inorganic semiconductor thin-film transistors as a promising gate dielectric for low-power electronics [3].
whereas high-k insulators introduce undesirable effects at the semiconductor-insulator interface which generally leads to increased trapping which causes a rise of V_{TH} and SS, as well as lowers the field-effect mobility of charge carriers in TFTs [4]. To overcome both issues in low voltage organic thin-film transistors (OTFTs) passivating of the high-k metal oxides surfaces with self-assembled monolayer (SAM) compounds is routinely used [5]. Although modification of ultra-thin ($d \leq 20$ nm) metal oxide gate dielectrics with SAMs is currently a common process in organic TFTs [6], this approach has not yet been explored in metal oxide semiconductor transistors.
In this talk, low-voltage a-IGZO TFTs using solution-deposited, OTS-modified Ta_2O_5 operating at 1 V are presented. The optimised devices display threshold voltages V_{TH} around 0.4 V, subthreshold swings (SS) below 90 mV/dec, current on/off ratios larger than 10^5, and field-effect mobility in excess of 2.3 cm^2/Vs. The morphology and dielectric properties of both

pristine and OTS-treated thin Ta_2O_5 films have been studied. It is shown that the proposed approach has a high potential to enable the design of stable, low-voltage organic semiconductor circuitry in a highly reproducible manner.

Direct Langmuir-Blodgett Deposition of Few-Layered 2H WSe_2 Flakes for Electrical Characterization Madina Telkhozhayeva[1], Rajashree Konar[1], Eti Teblum[1], Hagit Aviv[1], Maria Tkachev[2], Olga Girshevitz[2], Yaakov Tischler[1] and Gilbert D. Nessim[1]; [1]Bar-Ilan University, Israel; [2]Institute of Nanotechnology and Advanced Materials, Bar-Ilan University, Israel

Two-dimensional (2D) semiconductors have attracted extensive research interest due to their unique size, atomic thickness and band structure. In this respect, transition metal di-chalcogenides (TMDCs) are leading candidates because of strong in-plane chemical bonds and out-of-plane weak interactions. This allows them to be exfoliated into so-called 2D flakes, which can be micrometers wide but less than a nanometer thick. Among them, 2H-WSe_2 as a layered 2D material demonstrates remarkable properties such as low thermal conductivity, high carrier mobility, and direct band-gap, thus offering a suitable platform for next generation nanoscale devices [1-2].
Liquid-phase exfoliation (LPE) of bulk TMDCs can yield high-quality semiconducting flakes dispersed in commonly used solvents. Although a considerable number of research with LPE methods towards 2H-WSe_2 has been conducted, there are lack of reports on controlled organization of these exfoliated flakes on substrates. This step is crucial since produced 2H-WSe_2 flakes tend to restack into a bulk structure via van der Waals interactions, which significantly limit device applications. Langmuir-Blodgett (LB) assembly is an effective and easily integrated approach for arranging 2D flakes into highly ordered single-layer and multilayered films with controllable thickness, well-defined structure, and homogeneity.
Here, we present a cost-effective and facile technique for the controlled processing of 2D 2H-WSe_2 dispersions into uniform close-packed flakes via the LB method. Bulk 2H-WSe_2, synthesized using an atmospheric-pressure chemical vapor deposition (AP-CVD) technique, was exfoliated into mono- to few-layered 2H-WSe_2 flakes using low-boiling solvent (ethanol) at high-frequency bath sonication system. The compression of the liquid-exfoliated WSe_2 flakes on the water sub-phase was used to form a continuous layer, which was subsequently transferred onto a pretreated substrate. UV-Vis, Raman, AFM, HRSEM and HRTEM prove that the as-deposited material is successfully exfoliated from bulk 2H-WSe_2 into mono- to few-layered flakes. Furthermore, we studied the electrical properties of the FIB-fabricated 2H-WSe_2 flake device using a two-probe current versus voltage (I-V) measurements. The proposed technique provides a simple path to assemble structures of solution-processed 2D semiconductors avoiding the challenges related to high cost and high temperature processing for further applications in electronics and optoelectronics.

Effect of DUV Curing on Low-Temperature Synthesis of IZO Semiconductor-Based TFTs Alessio Mancinelli[1], Sami

Bolat[2], Jaemin Kim[1], Yaroslav E. Romanyuk[2] and Danick Briand[1]; [1]EPFL, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Solution processing is an attractive alternative to standard vacuum fabrication techniques for the large-area manufacturing of metal-oxide (MO_x) based electron devices. In this frame, thin-film transistors (TFTs), which serve as the essential electronics building blocks, have to be primarily addressed. Furthermore, when these TFTs are realized on flexible substrates, many potential applications such as displays, chemical sensors, and conformable wearable devices, could be envisioned. However, the need for high-temperature sintering processes (T > 350 °C) has restrained thus far their commercial diffusion. The necessity for temperature-resistant polyimide as a substrate has restrained their field of application mainly to displays (e.g. indium gallium zinc oxide (IGZO) on polyimide). More economic and environmental-friendly substrates such as PET, cellulose, and biopolymers will become essential in future daily life applications requiring cheap and perhaps disposable devices. Among others, smart label sensors for temperature and chemical monitoring of food, realized directly in the packaging could be enabled. Accordingly, the development of a production process compatible with such thermosensitive substrates has to be addressed.

One of the key challenges for the full exploitation of these devices is the reduction of the thermal budget required for the MO_x synthesis. Our approach is based on the use of deep ultraviolet light (DUV) to promote the sol-gel synthesis reaction and therefore reduce the thermal budget of the process. The energetic photons generated by the DUV lamp are used to photo-activated the chemical reactions and initiating the M–O–M bond formation inside the deposited thin film. The quality of the MO_x layer is further enhanced by the heat treatment which eliminates the undesired reaction residuals and densifies the film. Similar photonic processes for solution-processed metal-oxide transistors have been mainly based on indium oxide (InO_x) as semiconductor material. The more convenient chemistry of InO_x facilitates its solution processing at low-temperature. However, the films obtained from these compounds can suffer from unstable behaviour and operation at negative voltages. We report on TFTs based on a solution-processed indium zinc oxide (IZO) semiconductor utilizing a DUV enhanced curing, which enables a reduction of the processing temperature. A parametric analysis of the curing parameters has been carried out in to investigate the minimal conditions required to achieve performing devices. In this frame, we compared the efficiency of a post-annealing step in with in-situ combined DUV exposure and heating). Furthermore, the curing processes have been investigated using two different DUV light sources evaluating the different outcomes: a single-wavelength (172 nm) emitting excimer lamp and a broader emitting DUV lamp (184 nm/253 nm). The electrical characteristics of the TFT have been extracted and used to establish optimal curing conditions. Notably using DUV, short curing times as low as 10 minutes at 200 °C (e.g. 5 min DUV + 5 min post-annealing @ 200 °C) achieved mobility of 3 cm^2/Vs. Higher mobility values (>15 cm^2/Vs) have been achieved with prolonged processes (>80 min). While a temperature reduction to 180 °C yielded ~1 cm^2/Vs. The effects of the different curing protocols on the chemical composition of the IZO films have been studied using Fourier-transform infrared spectroscopy and X-ray photoelectron spectroscopy. The IZO semiconductor has been eventually paired with a printed high-k MO_x dielectric film, cured using the same methodology, to realize fully solution-processed MO_x TFTs, with as ultimate goal producing full printed TFTs. The identification of the most effective tool, combined with a fine-tuning of the parameters, allows to the DUV enhanced curing to diminish the thermal budget required to process IZO TFTs, paving the way for its further implementation on temperature-sensitive substrates.

F.SF04.07.04
Uniform and Stable Aerosol-Jet Printing of Carbon Nanotube Thin-Film Transistors Shiheng Lu, Joanne Zheng, Jorge Cardenas, Nicholas Williams, Yuh-Chen Lin and Aaron D. Franklin; Duke University, United States

Carbon nanotube thin-film transistors (CNT-TFTs) have attracted intensive attention due to their potential use in various applications, including display backplanes and sensing systems. Device uniformity, which is largely determined by the homogeneity and reproducibility of CNT thin films, is essential for large-scale manufacturing and practical applications. Here, we demonstrate an aerosol-jet printing approach to realizing CNT-TFTs with device characteristics that are among the most uniform of CNT-based transistors to date. The key enabling factors include proper ink formulation, polymer surfactant removal via rapid thermal anneal (RTA), and careful ink temperature control. Terpineol was added as a secondary solvent, and both optical and atomic force microscopy (AFM) reveal that the addition of this nonvolatile and viscous component efficiently suppresses the unwanted coffee-ring effect. The effectiveness of RTA-based polymer removal was supported by AFM results. It was discovered that a lower CNT ink temperature during printing offers higher ink output, increased CNT density, larger field-effect mobility, as well as enhanced device uniformity. This ink temperature-device uniformity relationship was further examined by fabricating batches of CNT-TFTs at a range of different ink temperatures, which revealed that low ink temperature (e.g., 8 °C) not only benefits uniformity of devices printed within a short period of time (~ 70 s), but also improves long-term (~1 h) printing stability. A set of several dozen CNT-TFTs printed from a CNT ink at 8 °C exhibited a mobility of 12.5 ± 0.5 $cm^2\ V^{-1}\ s^{-1}$, with a relative standard deviation $\sigma(\mu_h) / \mu_h$ as small as 4%. These results unveil

the role that ink temperature and other critical processing factors play in aerosol jet printed films and have the potential to address device uniformity issues that have previously plagued the utility of printed CNT thin films.

F.SF04.07.05
Fine-Tuning of Molecular Conformations for High-Speed Organic Photodetectors with Enhanced Charge Transport Jisoo Shin, Sungyoung Yun, Hye Sung Choi, Taejin Choi, Younhee Lim, Seon-Jeong Lim, Kyung-Bae Park and Sunghan Kim; Samsung Advanced Institute of Technology, Korea (the Republic of)

Organic semiconductors have the advantages of high absorption coefficients and wavelength selectivity compared with those of inorganic materials. As such, organic photodetectors (OPDs) are emerging as the next candidates for commercialized organic electronic devices, organic CMOS image sensors (OCISs). Wavelength-selective OPDs are applicable to the three-dimensional (3D) stacked structure that can replace the existing CMOS image sensors for the expansion of the light-input surface area by maximizing the photons absorbed effectively by each pixel, leading to high sensitivity and resolution since they can absorb selective wavelength from incident light without color filters.
To realize these advantages, systematic approach for molecular design of OPDs and optimized device architecture has been reported by our group recently. Noteworthy, through recent years of research on OPDs, the improvement of charge transport properties is also indispensable for commercialization of high-speed image sensors. Compared to silicon CMOS image sensors, some charges are slowly transported and remain in organic layer, then slow decays of photocurrent induced image lags closely related to remaining charges (RCs) in OCISs.
Here, combined with simulation and experiment, we designed and synthesized novel push-pull type molecules with different moieties by tuning the molecular conformations, which showed improved optical properties as well as charge carrier mobility. According to the improved device performance, we experimentally find out that charge transport properties including RCs are closely related to molecular structure with introduction of carbon-bridge and various types of side group. The effect of molecular conformations on the optoelectronic properties of high-speed OPDs will be discussed in detail.

F.SF04.07.06
Unsubstituted and Fluorinated CoPc Nanowires, Ultrathin Films and Composites for Room Temperature ppb Environmental Gas Monitoring in Highly Humid Terrains Soraya Flores[1], Jean Gonzalez[1], Juan Cintron[1], Dalice M. Piñero Cruz[1], Jose Hernandez[1], Nerida deJesus[2], Ruben E. Diaz-Rivera[2] and Luis F. Fonseca[1]; [1]University of Puerto Rico at Río Piedras, United States; [2]University of Puerto Rico at Mayagüez, United States

Metallo Phthalocyanines (MPc) have been widely studied as promising material to develop sensitive gas sensor devices. In particular, its electrical response when exposed to gas analytes encourages its use in chemiresistors. This is so because they show some characteristics that can be exploited for the development of very sensitive gas sensors. When compared with other semiconductors, such as metal oxides, their baseline resistivity is relatively high and can change orders of magnitude when exposed to the sensing gas, which can be easily tuned through the incorporation of substituents in the periphery of the Pc platform. Moreover, there is little difference between their room temperature and higher temperature response. Recent publications report reproducible single digit parts-per-million sensitivities at room temperature, usually when preparing the material at the nanoscale.
This work summarizes advances in the synthesis, solution preparation, and gas sensing applications of CoPc and fluorinated CoPc nanowires and films with thicknesses below 20nm. In this case, room temperature parts-per-billion response is reported. Novel sensors prototypes based on F_{16}CoPc composites activated with Pt nanoclusters show significant reduction in their sensor response time. The report includes a systematic comparison with unsubstituted CoPc, and the response to different reducing and oxidizing gases. These new prototypes will be optimized for the detection of environmental contaminants in areas with high atmospheric relative humidity.

F.SF04.07.07
Metal Oxide Nanostructure Patterns via Modified Immersion Transfer Printing for Internal Light Extraction of Quantum Dot Light-Emitting Diodes Moohyun Kim, Eugene Cho, Jeong Min Shin, Min Seok Jang and Yeon Sik Jung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Quantum dot light-emitting diodes (QLEDs) are considered as next-generation displays due to the outstanding advantages of quantum dots (QDs) such as large color gamut by narrow emission, high brightness, solution-processability and potential long term stability. The performance of QLED is characterized by external quantum efficiency (EQE), which is the multiplication of internal quantum efficiency (IQE) and light out-coupling efficiency (EQE = IQE×light out-coupling efficiency). Recent progress has improved EQE of QLEDs for red, green and blue color to about 20%, which is on the level of commercial phosphorescent organic light-emitting diodes (OLEDs). Considering that the light out-coupling efficiency of a

typical multilayer structure device is 20%, it can be seen that the IQE of QLEDs reached 100%. Therefore, research on light out-coupling efficiency or light extraction of QLEDs has been gaining attention to further improve the EQE.
In OLEDs, light is commonly extracted through corrugated structure or photonic crystal like internal light extraction nanostructure. Generally, these nanostructures are located between the multilayer structure and transparent electrode to interact with the target wavelength. However, applying this strategy for enhancement of QLEDs has difficulty even though the structural similarity of the multilayer structure. This is because multilayer structure of QLEDs is fabricated based on solution process while OLEDs are fabricated through vacuum deposition. Therefore, in QLED, the light extraction nanostructure strongly effects the morphology of the multilayer device causing degradation of the operation characteristic. Furthermore, very narrow QDs emission with 30nm of full-width at half maximum (FWHM) suggests the need for more advanced technique with finer and more precise nanostructures.
In this study, we demonstrate a metal oxide (MoO_3) nanostructure fabricated by modifying immersion transfer printing (iTP) method for internal light extraction of QLEDs. MoO_3 was applied as the internal light extraction material on the basis of high refractive index value (n) of 2.1 at 520 nm and semiconducting properties as a hole transport layer in optoelectronic devices. iTP is introduced as the fabrication method for its compatibility with the solution processed QLEDs and capability for forming high resolution MoO_3 nanostructure. Previous reported iTP, which uses hydrophobic particles, was modified to compensate for the incompatibility between hydrophilic MoO_3 particles and PDMS brushed substrates. PDMS-PS co-brush system was applied to control the surface affinity as a way to achieve MoO_3 incorporation onto the Si template. In addition, PDMS/PS bilayer was used as the picking carrier polymer to increase the transfer yield of the MoO_3 nanostructure. As a result, nanoscale line patterns with widths of 1000, 350, and 50 nm in large areas are well demonstrated. Finite-difference time-domain (FDTD) simulations are conducted to help design the precise size and shape of the pattern for light extraction to optimize the QLED internal light extraction. QLED was fabricated based on this design and showed improvement in the performance of the QLED device.

F.SF04.07.10
Examining the Impact of Air Exposure and Temperature Variation on N- and P-Type Polymer Charge Transport for Transistor and Photovoltaic Applications Samantha Brixi and Benoit Lessard; University of Ottawa, Canada

Enhancing device stability is essential to the widespread commercial adoption of organic electronic devices. Interactions of organic semiconductors with their environment often lead to degradation of device performance; therefore, it is important to understand how such devices as organic thin-film transistors and organic photovoltaics are affected by these interactions. This allows scientists and engineers to both choose appropriate applications for these materials and guide the development of new materials with enhanced stability. Polymers are of particular interest due to their capacity to be processed in solution for a new generation highly scalable and inexpensive electronic devices from sensors to solar cells. We have studied the stability of p- and n-type materials of interest for transistor and photovoltaic applications in environments relevant to commercial applications of these materials, including exposure to air, vacuum, and varied temperatures. In all cases, significant degradation could be observed. After 18 days of air exposure for p-type materials P3HT and PBDB-T, a 95% loss in hole mobility (μ_h) was observed for P3HT, while PBDB-T only experienced a μ_h loss of 42%.[1] For n-type polymers studied, a loss in electron mobility (μ_e) of 99% was observed for N2200 exposed to air for two weeks, while an 84% μ_e loss was observed for PIBDFBT-37.[2] Preliminary studies on polymers in organic photovoltaics indicate similar trends, but the degradation of charge transport properties does not give the full picture. We plan to further explore the impact of polymer degradation and charge transport on the stability of organic photovoltaics and transistors.

Dielectrophoretic Assembly of Single Nanowires for Advanced Characterisation Nanoscale Standards Maxim Shkunov[1], Sebastian Wood[2], Ruth Rawcliffe[1], Filipe Richheimer[2], Tomas Peach[1] and Fernando Castro[2]; [1]University of Surrey, United Kingdom; [2]National Physical Laboratory, United Kingdom

Nano-characterisation techniques, including confocal microscopy, atomic force microscopy (AFM) and tip enhanced Raman scattering (TERS), rely on the ability of each instrument to resolve nano-scale features without distortions and artefacts, however, reference samples allowing to perform fully quantitative characterisation of their responses are not available. Calibration of lateral and depth resolution of advanced scanning-probe microscopy methods is currently very challenging and calls for the development of nanoscale standards with features in 10-200 nm range with various morphological and optoelectronic characteristics.
We demonstrate the development of solution-based, single-nanowire-based reference samples, where easily identifiable

device positions each contain a semiconducting nanowire with a particular set of properties. Key parameters that are considered include: diameter and length, Raman response, photoluminescence and conductivity. The devices are self-assembled from a wide range of solution-processed semiconducting nanowires, including Si, Ge, InAs, InP, GaN, Ge/Si. Individual nanowires are positioned in pre-defined locations using electric-field assisted process, dielectrophoresis (DEP), by applying controllable DEP signal voltage and frequency. Nanowires are characterised, and various response metrics are analysed using conducting-AFM, confocal Raman, TERS and other techniques to establish which nanowire materials provide highly distinguishable responses, necessary for reference standards. Challenges in identifying most suitable nanowire materials, including their spectroscopic characteristics (e.g. Raman) and morphological features (e.g. diameters) are discussed and several reference samples for the characterisation of lateral and vertical resolution of nanoscale scanning probe techniques are suggested.

Effect of Oxygen Pressure on Optical and Electrical Properties of Single-Crystalline Cu_2O Fabricated by Pulsed Laser Deposition Jan Lancok, Lenka Volfova, Premysl Fitl and Michal Novotny; Czech Academy of Sciences, Czechia

Copper oxide Cu_2O is an important and well known p-type transition metal oxide semiconductor material, which has already been employed in the fabrication of electronic devices. For example Cu_2O has been used in thin photovoltaic devices, resistive switching, transistors, gas sensors or catalysts. The films were fabricated by Pulsed Laser Deposition from CuO ceramic target by means of Nd:YAG laser operated at 266 nm wavelength. MgO(100) substrates were mounted on substrate holder 5 cm away from the target and maintained at temperature in the range 500-700 °C. Our attention was mainly focused on the influence of the oxygen pressure, which was varied between 10^{-5} Pa and 1 Pa, on the structural and following on optical and electrical properties. The investigation of the plasma was carried out by Optical emission spectroscopy. The surface morphology and composition were characterised by AFM and XPS, respectively. The crystalline quality of the films were characterised by means of XRD and following by TEM and HRTEM, which confirmed the epitaxial grown of the films in low oxygen pressure up to 0.1 Pa. When the oxygen pressure exceeded 0.1 Pa the growing films started to be polycrystalline and the CuO phase also appeared. Because we focused on utilization of the Cu2O films as gas sensors, the near ambient pressure photoelectron spectroscopy was carried out to investigation of surfaces composition in the presence of gasses and vapours such as ethanol, hydrogen and NO2.

F.SF04.07.14

Thermal Dedoping of Doped Poly (3-hexylthiophene) for Multimodal Temperature Sensing Hemanth Maddali[1] and Deirdre O'Carroll[1,2]; [1]Rutgers, The State University of New Jersey, United States; [2]Rutgers University, United States

Conjugated polymers have a wide range of applications in optoelectronic devices and in numerous sensing technologies. Conjugated polymers that have thermally activated optical or electrical responses have garnished interest due to their potential as thermal sensors. These thermochromic properties are often introduced via doping. In this study, we investigate the use of electrochemically doped poly(3-hexylthiophene) (P3HT) thin films as multimodal temperature sensors. P3HT thin films spin coated on indium-tin oxide coated glass substrates are electrochemically doped using tetrabutylammonium perchlorate (TBAP) dissolved in acetonitrile. The pristine P3HT thin films, which are purple in color, exhibit a color change to blue, upon doping. The doped P3HT thin films are then heated under vacuum at 140^0 C and the color of the thin films reverts from blue to purple indicating thermally activated dedoping. UV-visible absorbance spectra of pristine, doped and dedoped P3HT thin films show that the change in optical absorption properties upon doping is reversed due to thermally activated dedoping. Energy dispersive X-ray spectroscopy (EDS) reveal the presence of dopant molecules (TBAP) distributed throughout the doped P3HT film. Upon dedoping, the EDS maps show almost negligible levels of the dopant molecules. This further proves that heating of doped P3HT thin films triggers dedoping and causes the distinctive thermochromic response, i.e., a color change from blue to purple. The electrical properties of doped and dedoped films are also expected to result in a significantly different current upon application of voltage. This warrants fabrication of a current-based temperature sensor that would perform colorimetrically and electrically.

F.SF04.07.15

A 13.56 MHz Rectifier Based on Fully Inkjet Printed Organic Diodes Fabrizio A. Viola and Mario Caironi; Istituto Italiano di Tecnologia - IIT, Italy

The increasing diffusion of portable and wearable technologies results in a growing interest in electronic devices having features such as flexibility, lightness-in-weight, transparency and wireless operation. Organic electronics was proposed as a potential candidate to fulfill such needs, in particular targeting pervasive Radio-Frequency (RF) applications. Still, limitations in terms of device performances at RF, particularly severe when large-area and scalable fabrication techniques are employed,

have largely precluded the achievement of such an appealing scenario. In this work, we demonstrate a high-frequency rectifier based on fully inkjet printed organic Schottky diodes fabricated through scalable large-area methods on plastic. The inkjet printing of the organic semiconductor, the core of the diode structure, has been carefully optimized in order to obtain a low series resistance, which is mandatory to improve the diode cut off frequency. Moreover, the employed materials in the presented device have been chosen to finely tune the barriers formed at metal-semiconductor interface, in order to increase the rectification ratio of the diode: the obtained value is higher than 10^6 which is, to the best of our knowledge, the highest value ever reported with a fully printed structure. Furthermore, we show, as a proof-of-concept, how a rectifier circuit integrating the fully printed diode, can successfully supply power to a polymer micro-electronic circuit printed on a plastic foil with a similar process. In particular, by rectifying a 13.56 MHz AC voltage the rectifier enables the correct operation of a D-Flip Flop, which is a fundamental logic building block for serialization elements. The possibility of harvesting electrical power from RF waves and delivering it to a cheap flexible substrate through a simple printed circuitry paves the way to a plethora of appealing distributed electronic applications.

F.SF04.07.16
Thermally Stable Au Decorated Silica-Titania Mesoporous Nanocomposite for pH Sensing Evaluation Shumaila Islam and Adil Alshoaibi; King Faisal University, Pakistan

Herein, doping/decoration of gold nanoparticles (AuNPs) within mesoporous silica-titania nanocomposite is achieved via a facile and co-assembly sol-gel method. Polyethylene glycol is used as a co-structure-directingagent. For sensing analysis, a mixture of organic dyes i.e., bromophenol blue, phenol red, and cresol red is encapsulated in the AuST nanocomposite matrix. FESEM/EDX analysis shows a crack-free surface, porous network and uniform distribution of Au, Ti, Si, along with dye species. FTIR and XRD suggested the heterogeneous chemical bonding and crystallite size 24 nm after encapsulation. AuST nanocomposite shows thermally stable behavior after 450 °C even after co-dyes encapsulation. High surface area 322 ± 2.5 m2/g, pore diameter 30.2 Å, and pore volume 0.24 cm3/g, average surface roughness 10 nm, and refractive index 1.29 is advantageous for good sensing response at pH 1–12. The sensitivity is measured as 10 counts/pH at 441 nm. Moreover, good reversible response, fast response time 2.1 sec in acidic media, and 0.9 sec in basic media is observed.

Late News: Hybrid Surface Treatment of Elastomer Substrates for Robust and Reliable Integration of Rigid Components with Inkjet-Printed Stretchable Circuits Hyungsoo Yoon, Byeongmoon Lee, Sujin Jeong and Yongtaek Hong; Seoul National University, Korea (the Republic of)

Stretchable electronics has emerged as a next-generation technology that goes beyond rigid and flexible electronics to enable novel form-free devices and provide advanced user-experiences. Integration of rigid integrated circuit (IC) chips and inkjet-printed circuits on pre-strained elastomers has been regarded as one of the most powerful methods for fabricating stretchable multifunctional systems due to their unique advantages such as a facile and low-cost process, and a high degree of customizability. However, direct inkjet-printing on elastomers is challenging due to their low surface energy that causes dewetting. Furthermore, the super-hydrophobic surface shows poor adhesion with inkjet-printed metal films as well as conductive adhesives for chip bonding, significantly limiting system stability under deformation. Therefore, appropriate surface modification is indispensable for the robust implementation of inkjet-printing-based stretchable hybrid electronic system. Surface modification of elastomers has been realized by oxygen-plasma or ultraviolet/ozone (UVO) treatments. Both methods render the surface of the elastomers wettable by creating a large number of hydrophilic groups on it, where well-defined patterns can be formed by inkjet-printing. However, the methods have several limitations when applied to inkjet-printing on pre-strained elastomers. Plasma-treated elastomers undergo fast hydrophobic recovery due to the molar migration from the bulk to the surface, resulting in unstable wettability, uneven patterns, and poor adhesion. Alternatively, the UVO treatment provides improved stability and uniformity. However, a thick layer of the elastomer from the surface is stiffened by UV energy, which causes a large strain mismatch between the thick stiff surface and soft bulk. Consequently, the pre-stretched elastomer cannot completely return to its original dimension, restricting the maximum stretchability of the system far behind compared to the applied pre-strain. Therefore, a new surface modification strategy that simultaneously offers stable wetting and a high level of adhesion without compromising their stretchability is highly required.
In this work, we demonstrate robust stretchable hybrid electronic system based-on inkjet-printing and hybrid surface modification of polydimethylsiloxane (PDMS). The surface treatment offers stable wettability and great adhesion and preserves the substrate stretchability. Specifically, the pre-strained PDMS (mixed at 10:1) is exposed with oxygen-plasma to form hydroxyl groups and poly-L-lysine (PLL) solution (aqueous solution, 0.1% (w/v) in H_2O) is sequentially drop-casted on the plasma-treated PDMS. After that, the PDMS is rinsed with deionized (DI) water. Abundant amine groups functionalized on the surface of the PDMS enable stable wetting and good adhesion for inkjet-printing process. Furthermore, the modified

surface shows remarkable adhesion with conductive epoxy, allowing robust IC chip bonding on the printed stretchable circuits. To investigate the effect of the hybrid surface treatment, we compare three biaxially pre-stretched PDMS substrates that undergo UVO, oxygen-plasma, and oxygen-plasma with PLL treatments, respectively. The plasma-treated PDMS results in uneven patterns and poor adhesion due to its instability and fast hydrophobic recovery. While the UVO-treated PDMS only shows stretchability of 19% when it is pre-stretched ~70%, the PDMS with hybrid surface treatment restores its original dimension, *i.e.*, it shows the same stretchability as the pre-strain value. Finally, a series of stretchable hybrid electronic systems are demonstrated with their mechanical robustness, including stretchable LED displays, which proves the superiority of our hybrid surface treatment. The detailed methods and results will be discussed at the conference.

Late News: Implementing ITO-Free Transparent Conductive Electrodes in Flexible Organic and Hybrid Light-Emitting Diodes Felix Hermerschmidt[1], Lukas Kinner[1,2], Theodoros Dimopoulos[2] and Emil List-Kratochvil[1,3]; [1]Humboldt-Universität zu Berlin, Germany; [2]Austrian Institute of Technology, Austria; [3]Helmholtz-Zentrum Berlin, Germany

We utilize 25% of our total electricity consumption for lighting and display applications. To address this consumption, several efficient lighting technologies have been targeted. Inorganic solid-state lighting together with organic light-emitting diodes (OLEDs) are the candidates spearheading the lighting revolution of the 21st century. However, while OLEDs have shown commercial success in rigid display applications, a number of challenges remain to be overcome in order to fulfil their full potential.
Among these are the continued quest for stable emitter materials and to improve strategies for the outcoupling of light from the device. Additionally, energy, temperature and cost efficient processing methods need to be targeted in order to fabricate the transparent conductive electrodes (TCEs) needed for device operation.
Today, transparent conductive oxides, and in particular indium tin oxide (ITO), represent the dominant class of TCEs. ITO combines high transparency (>85% in the visible wavelength range) with low sheet resistance (ca. 10 Ω sq^{-1}) when deposited on glass. As a result, most optoelectronic devices utilize ITO as the transparent electrode. However, ITO has some inherent limits in its range of applications. It is mechanically unstable upon bending, while its scarcity translates to a volatile and high price. It is therefore desirable to replace ITO with other transparent conductive electrodes [1].
Of particular interest are low temperature processes (<130 °C), since these are compatible with the use of temperature-sensitive and low cost flexible substrates, such as polyethylene terephthalate (PET). In this contribution we highlight our recent work on the design, fabrication and characterization of a number of different low temperature processes using, among others, inkjet printing and spray coating to produce TCEs [2,3]. These approaches are based on Ag and Cu nanoparticle, particle-free and nanowire inks. We will show that the developed ITO-free electrodes on PET show superior optical, electrical and mechanical performance compared to PET/ITO reference samples.

Late News: Organic Radiation Dosimeter for X-Ray, Gamma and Neutron Detection Zachary Lamport[1], Marco R. Cavallari[2], Michael Bardash[3] and Ioannis Kymissis[1]; [1]Columbia University, United States; [2]Federal University for Latin American Integration, Brazil; [3]QEL System Services, Inc., United States

In many professions, ionizing radiation is either a by-product of some process or is itself utilized, posing a significant hazard to those in the surrounding area. Workers will usually be required to wear a personal radiation dosimeter which measures and integrates the cumulative radiation dose experienced such that either prolonged or flash exposures are recorded and analyzed for the safety of the wearer. For personal dosimeter badges, the sensing element is usually made of relatively high-Z elements which absorb radiation differently than the lighter elements found in the human body.[1,2] An all-organic radiation dosimeter could more closely approximate the effect of radiation on biological tissues. Another added benefit of such organic-based devices is that they can be made quite cheaply and on a lightweight, flexible substrate. These factors together with the burgeoning IoT systems could allow for a more robust detector network in areas relevant to homeland security. Here, we report on an all-organic radiation dosimeter using the conducting polymer poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS)[3] as both the detector region and conductive traces patterned on a polyethylene napthalate (PEN) substrate. Ionizing radiation incident on a central PEDOT:PSS pad induces a static charge in the air, the PEDOT:PSS itself, and the underlying PEN substrate that is measured as a voltage by the connected op-amp voltage

follower.[4–6] Two organic field-effect transistors (OFETs) with the PEDOT:PSS source and drain, respectively, connected to the central PEDOT:PSS region allow for an initial biasing of the central pad, as the semiconductor 6,13-bis(triisopropylsilylethynyl) pentacene (TIPS-pentacene) functions as two very large resistors. The OFETs allow for a very small amount of current to flow through the ungated semiconductor in order to place the central pad at a desired voltage, from which any deviations are measured. To clear the charge from the central pad, one or both of the OFETs can be turned on through the respective PEDOT:PSS gate electrode underneath a parylene dielectric. We show reproducible and reliable measurements of the radiation dosimeters subjected to a wide range of exposure energies of both X-ray and gamma rays using wide and focused beams resulting in an approximate detection limit of 5 mRad/hour. In addition, there is very strong evidence that the PEDOT:PSS-based devices can detect neutrons from a shielded and unshielded beryllium-encased plutonium source at a dose of 620 mRad/hour. This represents a significant step forward in the production of cheap, reusable radiation dosimeters made with materials of similar radiation cross-section to the human body.

Late News: Highly Conformable Pressure-Sensitive Thin-Film Transistors Using Capacitance Modulation via Nanostructured Surface Morphology of AgNWs Hayun Kim, Byeongmoon Lee, Hyunuk Oh, Hyunjun Yoo and Yongtaek Hong; Seoul National University, Korea (the Republic of)

Electronic skin that can map pressure distribution on arbitrary surfaces has gained tremendous significance for its wide range of use in various fields such as skin prosthesis, artificial nerve systems for soft robotics, and advanced human-machine interfaces. To keep pace with these trends, many studies have focused on reporting high-performance pressure sensors and their passive-matrix array using novel materials and structures. Among various types of pressure sensors, capacitive pressure sensors with engineered microstructures offer significant potential owing to their high sensitivity, fast response time, and great mechanical flexibility. However, previous works on capacitive pressure sensors mainly focused on the performance of a single sensor, and their application to a high-resolution array was challenging because of their complex structure and fabrication process. Therefore, reported sensor arrays using capacitive pressure sensors generally showed low spatial fidelity due to the crosstalk among pixels and low pixel density. Furthermore, to exploit the capacitance change in practical applications, the circuit requires a capacitance-to-current converter that can limit the design freedom and make the system unstable on complex 3-dimensional surfaces. Therefore, device-scale integration between capacitive pressure sensors and thin-film transistors(TFTs) is highly desirable for capacitance-to-current conversion and further active-matrix applications. Although a few studies have reported pressure-sensitive thin-film transistors, they usually suffer from complex fabrication processes and limited flexibility due to their sophisticated structures such as sidewall spacers to make air gaps in dielectric layers.
In this work, we propose a facile and large-area compatible method for pressure-sensitive TFTs (PSTFTs) and their application to flexible sensor arrays. Our PSTFT is based on all-inkjet-printed single-wall carbon nanotube(SWCNT) TFTs, where a silver nanowire (AgNW) gate electrode with nanostructured surface morphology softly touch the top surface of the dielectric layer. The fabrication process of the PSTFT is fairly simple, highly customizable, and cost-effective. The SWCNT active channel, silver (Ag) source and drain electrodes, and poly(4-vinylphenol) (PVP) dielectric layer were sequentially inkjet-printed on a surface-engineered polyethylene naphthalate (PEN) substrate. The AgNW gate electrode was then formed on another flexible substrate by spray-coating. The 3D nanostructures in the AgNW random network form nano-scale air gaps between the gate electrode and dielectric. These nanoscale air gaps are key to the capacitance modulation in the PSTFTs. When the vertical pressure is applied to the top gate electrode, as the air gaps disappear and the contact area between the gate electrode and dielectric increased, the capacitance between the gate electrode and active layer drastically

increases without any supporting spacer. Our PSTFT showed well-split transfer curves with on-off ratios of from 1 to $1.3*10^4$ according to the applied pressure. When the pressure reached 700 kPa, the TFT showed $1.3*10^4$ on/off ratio. We further demonstrate the feasibility of our approach by mounting the highly conformable sensor array on human skin to read out the change of the pressure such as finger touch and joint flexure. This study provides a new pathway to map pressure distribution using capacitive pressure sensors without any crosstalk among adjacent pixels, which can be further applied to any type of deformable substrates with potential applications such as skin-mounted device, deforming soft robotics, and display. The detailed methods and results will be discussed later.
This work was supported by the Technology Innovation Program (No.20008801, Development of muscular function management solution based on electronic skin with EMG IMU and Strain sensor) funded By the Ministry of Trade, Industry & Energy(MOTIE, Korea).

Aqueous Synthesis of 3D Nano-architected Ceramics and Metals—Nano-Architected TiO_2 PhCs Julia R. Greer; California Institute of Technology, United States

Additive manufacturing (AM), or 3D printing, represents a set of processes that enable layer-by-layer fabrication of complex structures using a wide range of materials that include ceramics, polymers, and metals. AM has allowed exploiting novel material properties, especially those that arise at the nano-scale, that do not occur in conventional materials, revolutionizing the production of complex parts for aerospace, military, automotive, optial, and medical applications. Facilitating these technologies requires a fabrication process to create a variety of functional materials in 3D, however the material choice for AM at the nano- and micro-scale is limited. A conspicuous example is a lack of AM processes for high refractive index (n), low absorption materials with nano-sized dimensions, which are typically required for microoptics and device applications. To harness the beneficial properties of 3D nano-architected meta-materials, it is critical to assess their properties at each relevant scale while capturing overall structural complexity. We present the fabrication and synthesis of nano- and micro-architected materials using 3D (two-photon and interference) lithography, as well as characterization of their properties as a function of architecture, constituent materials, and microstructural detail. We focus on additive manufacturing of complex, multi-component and multi-material architectures comprised of metal oxides, metals, and hydrogels that are derived from (metal) salt-based, aqueous photoresin synthesis. The discussion will focus on each representative materials system (metals, oxides, and hydrogels), with a detailed overview of titanium dioxide, with critical feature dimensions between 150 and 600 nm and <1% porosity. Using the described methodology, we created 3D dielectric photonic crystals (PhCs) out of rutile TiO2 patterned into woodpile face-centered tetragonal (FCT) architectures with beam dimensions of 300-600nm and lateral periods

of 0.8-1.5 μm. We use Plane Wave Expansion (PWE) simulations and Fourier Transform Infrared Spectroscopy (FTIR) to demonstrate the full photonic bandgaps centered at 1.8-2.9 μm. This fundamental research provides insights into the range of possible, often *transient* attainable chemical compositions, microstructures and architectures of chemically-derived, 3D-archtiected ceramics and metals, enabling advances in multiple technologies, i.e. 3D MEMS, micro-optics, and prototyping of 3D PhCs.

3D Printing Functional Materials and Devices Michael C. McAlpine; University of Minnesota Twin Cities, United States

The ability to three-dimensionally interweave biological and functional materials could enable the creation of devices possessing personalized geometries and functionalities. Indeed, interfacing active devices with biology in 3D could impact a variety of fields, including biomedical devices, regenerative biomedicines, bioelectronics, smart prosthetics, and human-machine interfaces. Biology, from the molecular scale of DNA and proteins, to the macroscopic scale of tissues and organs, is three-dimensional, often soft and stretchable, and temperature sensitive. This renders most biological platforms incompatible with the fabrication and material processing methods that have been developed and optimized for functional electronics, which are typically planar, rigid and brittle. A number of strategies have been developed to overcome these dichotomies. Our approach is to utilize extrusion-based multi-material 3D printing, which is an additive manufacturing technology that offers freeform, autonomous fabrication. This approach addresses the challenges presented above by (1) using 3D printing and imaging for personalized device architectures; (2) employing ‘nano-inks’ as an enabling route for introducing a diverse palette of functionalities; and (3) combining 3D printing of biological and functional inks on a common platform to enable the interweaving of these two worlds, from biological to electronic. 3D printing is a multiscale platform, allowing for the incorporation of functional nanoscale inks, the printing of microscale features, and ultimately the creation of macroscale devices. This blending of 3D printing, functional materials, and ‘living’ inks may enable next-generation 3D printed devices.

5:15 AM *F.SF05.02.03
Manufacturing Molecules for the New Carbon Economy Eric B. Duoss; Lawrence Livermore National Laboratory, United States

Material properties are governed by the chemical composition and spatial arrangement of constituent elements at multiple length scales. This fundamentally limits material properties with respect to each other creating trade-offs when selecting materials for a specific application. For example, strength and density are inherently linked so that, in general, the denser the material, the stronger it is in bulk form. We are combining advanced micro-architected design with additive manufacturing techniques to create material systems and devices with previously unachievable property combinations. We have demonstrated designer properties resulting from architected materials in polymers, metals, ceramics, and combinations thereof for unprecedented control of structural, mechanical, thermal, chemical, and functional properties. Our manufacturing techniques can generate designed structures which are highly three-dimensional and composed of micro- and nano-scale features with multiple constituent materials in the same structure. In this talk, I will discuss our advanced modeling, materials, and manufacturing methods with focus on applying these approaches to cellular fluidics—a novel 3D fluidic control and delivery platform—and printed electrochemical reactors for CO2 reduction reactions.
This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

5:30 AM F.SF05.02.04
3D Printed Electrodes with Periodic Pores for Fast Bubble Transport During High-Rate Alkaline Water Electrolysis Tianyi Kou; University of California, Santa Cruz, United States

Water electrolysis has been gaining century-long attention as a hydrogen production technique due to its simplicity and effectiveness. Coupling with renewable energy, water electrolysis paves the way for clean and sustainable hydrogen generation without worsening the depletion of fossil fuels and degradation of ecosystems. Particularly, alkaline water

electrolysis (AWE) is one mature industrial strategy, and megawatt-level stacks have been well established in the market recently owing to many of the following advantages. The less corrosive nature of alkaline electrolyte compared to acid media allows for the use of non-platinum catalysts which significantly lowers the cost of AWE. In addition, the low vapor pressure of alkaline media is helpful in realizing high-purity hydrogen gas production. AWE generally exhibits a decent energy efficiency of about 80-85% at mid-high current densities of 100-200 mA/cm^2, but the efficiency drops significantly when increasing the current to 400 mA/cm^2 or higher. The considerable energy efficiency loss is related with the both limited intrinsic and extrinsic activity of electrodes. In spite of recent efforts in developing intrinsically active electrodes for AWS with facile proton-coupled electron transfer (PCET) and fast reaction kinetics, it is equally urgent to promote the extrinsic activity of electrodes at high current densities. Three-dimensional (3D) porous electrodes, such as commercial Ni foam, have been routinely used for as AWS electrode substrate because of their high surface area and ability in enhancing the mass diffusion of electrolyte. Nonetheless, the large amount of gas bubbles generated at high current densities are unfavorable to be released out of the 3D Ni foam due to the disordered pore arrangement. The sluggish bubble transport and release behavior of gas bubbles in 3D Ni foam block the efficient reactant diffusion and cause high ohmic loss, leading to substantial high overpotentials and low energy efficiency. Through an additive manufacturing strategy, we prepared a 3D printed Ni electrode with periodical pore structures as the substrate of AWS electrodes. The pore channels aligning with the buoyancy direction is believed to facilitate the upward movement of gas bubbles, and therefore enhance their diffusion and release out of the 3D electrodes. By growing intrinsically active AWS catalyst of carbon doped NiO on the 3D printed Ni, the electrodes exhibit much higher extrinsic activity than the counterparts supported on Ni foam. A high current density of 1000 mA/cm^2 can be obtained in 1.0 M KOH at low overpotentials of 245 and 425 mV for HER and OER, respectively. The work provides a new strategy of enhancing extrinsic activity of AWS electrodes at practically high current densities through pore structure engineering.

3D Printed Self-Supporting Elastomeric Structures for Multifunctional Microfluidics Ruitao Su[1], Jiaxuan Wen[1], Qun Su[1], Michael S. Wiederoder[2], Joshua R. Uzarski[2], Steven Koester[1] and Michael C. McAlpine[1]; [1]University of Minnesota Twin Cities, United States; [2]U.S. Army Combat Capabilities Development Command Soldier Center, United States

Due to the advantages of small sample volumes and well-controlled microenvironments, microfluidic devices have enabled exciting applications such as lab-on-a-chip diagnostics, point-of-care systems, organ-on-a-chip, nanomaterial synthesis, and bioassays. Soft lithography is a widely employed device fabrication method that can achieve sub-micron resolution using the elastomer polydimethylsiloxane (PDMS). Yet, the requirement of microfabrication facilities, stamp distortions, as well as time-consuming manual steps such as PDMS molding, layer alignment and bonding imposes constraints on the use of soft lithography to produce ubiquitous and widely deployable microfluidic devices. Additive manufacturing, or 3D printing, techniques have recently emerged as promising complements or alternatives to augment the manufacturability of microfluidic devices. 3D printing methods such as stereolithography (SL) and multi-jet modeling (MJM) utilize photo-curable polymers to create well-defined micro channels with feature sizes below 100 μm and a range of components for fluid manipulation. However, due to the potential for contamination from either the residual precursor resins or sacrificial supporting materials, directly printing microfluidic structures onto substrates that contain pre-deposited 3D structures or electronic sensing elements is challenging for SL and MJM. The degree of automation of SL and MJM is also compromised due to necessary post-processing steps to remove residual precursor and supporting materials from the channels. In addition, microfluidic devices printed by SL and MJM with photo-curable polymers have low elasticity and cannot be aligned to existing structures. Microfluidic device fabrication methods can be further enhanced by directly integrating microfluidic structures with electronic sensors and curvilinear surfaces as well as improving automation.

Here, we introduce an automatable extrusion-based printing methodology that can directly align and print elastomeric microfluidic structures onto planar and curvilinear substrates with minimal post-processing. By selecting a silicone-based ink of proper viscosity and controlling the profiles of printed overhung structures, self-supporting walls were realized and further enclosed to form hollow structures such as channels and chambers. Since the microfluidic spanning distance is in the sub-millimeter regime, a sufficiently small bending moment results that the as-printed walls can withstand, rendering this method highly suitable for printing microfluidic structures. Printing toolpaths can then be specifically designed to create leakage-free transitions between channels and chambers, T-shaped intersections and overlapping channels. The mechanical equilibrium states of the 3D printed silicone structures eliminate the need for supporting materials and rigid exterior covers that are conventionally required to build hollow structures with viscoelastic materials. Multi-material mixers were fabricated by integrating printed herringbone ridges to achieve high mixing efficiency in an enclosed microfluidic channel. Further, seamless integration of microfluidics and sensing microelectrodes was realized via synchronous alignment and printing onto the micro-chip. High-throughput and real-time impedance measurements of NaCl solutions were demonstrated with the 3D printed salinity sensor array. Most compellingly, we conformably printed 3D microfluidic networks that were integrated with valves on a spherical surface, demonstrating a novel device form-factor that can be potentially extended to freeform surfaces

such as the human body as microfluidics-based wearable health sensors. The devices demonstrated in this work serve as a proof of concept for the automatable capabilities of extrusion-based 3D printing to fabricate self-supporting and aligned multifunctional microfluidic structures.

5:50 AM F.SF05.02.07
3D Printed Soft Robots with Self-Healing, Reconfigurable and Conducting Capabilities Eliot Gomez[1], Shiwanka Wanasinghe[2], Obed Dodo[2], Michael F. Durstock[3], Dominik Konkolewicz[2] and Carl Thrasher[3]; [1]UES, Inc., United States; [2]Miami University, United States; [3]Wright-Patterson Air Force Base, United States

3D printing with light-based vat photopolymerization (VP-3DP) can make challenging geometries (e.g. overhangs, cavities, channels) with soft elastic materials, resulting in great strides in soft robotics. As printing speeds and resolution improve, soft robotics still face challenges to produce large-scale features via VP-3DP due to a limited build area and the need for structural supports for complex features. In an effort to bridge this gap, we have developed tunable photopolymerizable resin systems amenable to VP-3DP to produce self-healing elastomers. Materials consist of dynamically exchangeable moieties that can be printed with wide-ranging moduli (e.g. elastic to rigid). Printed parts have high elongations (up to 2,000% strain); the capacity to self-heal to elastic or rigid parts; and reset permanent shape via bond exchange with applied heat. By printing these materials into small modular structures and utilizing their capacity for dynamic bond exchange, we demonstrate the facile construction of highly complex, reconfigurable, and macro-sized soft robotic actuators. We then combine these soft robotic actuators with self-healing conductors in the form of bulk liquid metal or Polymerized Liquid Metal Networks for embedded strain sensing, joule heating, and power delivery in a self-healable soft robot.

6:00 AM F.SF05.02.08
3D Printing of 0D/1D/2D Materials into Complex Architectures Kun Fu; University of Delaware, United States

Carbon nanomaterials, including 0D carbon nanopowders, 1D carbon nanotubes, and 2D graphene, exhibit scaling effect and exceptional properties with great interest in structural and functional applications. The integration of carbon nanomaterials and architectural features at multiple length scales into structural mechanics and functional materials has significantly shifted the paradigm of materials engineering toward materials by design with structural and functional capabilities. Three-dimensional carbon multiscale architectures featuring the characteristics of both the constituent CNT material, which brings the effects of its feature nanoscale resolution and properties, as well as the structures across multiscale lengths offer breakthrough advances in many applications including ultra-light structural materials, energy storage, and biomedical devices. However, there is no effect approach to assemble those carbon nanomaterials into macro-scale structures with desired architecture while ensuring scaling properties. Therefore, it is highly anticipated to develop new manufacturing technology to handle nanomaterials and assemble them into large-scale structure with complex architectural features in a fast and efficient way.
In my talk, I will introduce our recent work on additive manufacturing of three-dimensional carbon-based multiscale architectures, and demonstrate its applications in electrochemical energy storage. Our method will retain the properties of carbon nanomaterials and there no additional binder or polymer in the final 3D components. We have demonstrated that carbon nanomaterials, including 0D carbon nanopowders, 1D carbon nanotubes, and 2D graphene, could be all processed into complex three-dimensional multiscale carbon architectures.

6:10 AM F.SF05.02.09
3D-Printed Pseudocapacitive Electrodes Enable Efficient Electron and Ion Transport at High Mass Loadings Bin Yao[1], Marcus A. Worsley[2] and Yat Li[1]; [1]University of California, Santa Cruz, United States; [2]Lawrence Livermore National Laboratory, United States

High mass loading and efficient charge transport are two crucial but often mutually exclusive characteristics of supercapacitors. 3D printing has emerged as a new tool to fabricate high-performance electrodes for energy storage devices. The interconnected conductive pathways in the printed 3D structures allow efficient electron transport. The periodic large pores in the 3D printed structures provide a short cut for electrolyte ions to the electrode surface. This efficient electron transport and ion diffusion in 3D printed electrodes enables fast charging and discharging even for thick electrodes at high mass loadings without sacrificing their gravimetric and volumetric capacitive performance, which successfully addresses the long-term challenge in this area. In this talk, I will present a millimeter-thick 3D-printed graphene aerogel electrode that could support pseudocapacitive manganese oxide (MnO_2) up to 180 mg cm^{-2}. The ultrahigh mass loading and efficient kinetic process enable them a record-high areal capacitance of 44.13 F cm^{-2} for supercapacitors. More importantly, the 3D-printed graphene/MnO_2 electrode can simultaneously achieve excellent capacitance normalized to area, gravimetry, and volume,

which is the trade-off for most electrodes. Furthermore, by pairing the 3D-printed graphene aerogel/MnO_2 as a cathode and surface-functionalized graphene aerogel as an anode, the assembled asymmetric supercapacitor (ASC) could further be extended to 2V. This high mass loading-ASC could achieve a remarkable energy density of 0.65 mWh cm^{-2} at an ultrahigh power density of 164.5 mW cm^{-2}, outperforming all the previously reported supercapacitor devices operated at the same power density. These works have successfully proved the feasibility of fabricating pseudocapacitive electrodes *via* a 3D printing method, which might revolutionize the conventional fabrication process of commercial supercapacitors.

6:20 AM F.SF05.02.10
A Low-Maintenance Soil Moisture Sensor Fabricated with Ecofriendly and Biodegradable Materials Yongkun Sui[1], Madhur Atreya[1], Subash Dahal[2], Rajiv Khosla[2] and Gregory L. Whiting[1]; [1]University of Colorado Boulder, United States; [2]Colorado State University, United States

Every year in the United States, hundreds of billions dollars are spent on farm production. The two largest farming costs are related to crop input and labor. The cost on labor can be reduced by mechanization. However, because of the heterogeneity of farmlands, farmers face a challenge of reduced resource efficiency after switching to large-scale farming. To further reduce the cost by improving the resource efficiency, precision agriculture (PA) technologies has been widely adopted since the early 1990s. PA technologies use various sensors to measure temporal and site-specific environment, soil, and crop data. The currently available commercial sensors fabricated using conventional components are cost-prohibitive, therefore the deployment density and data resolution are limited.
Recently, additive manufacturing (AM), owing to its reduced material wastage, fast prototyping, and lower equipment cost features, has been used to fabricated sensors for PA applications. Various AM techniques such as inkjet-printing, screen-printing, stencil-printing, and extrusion-printing have been used to fabricate soil and environment sensors. Of the two, soil sensors probably benefit the most from low fabrication costs because accommodating the spatial and temporal heterogeneity of soil requires a high sensor density. For instance, soil moisture level could be different between two sampling spots at 2.5 m apart. Deploying sensors at this high density is obviously infeasible. In reality, only 1 sensor is deployed per hectare which is insufficient for high-resolution PA applications.
Researches have tried several printing approaches to reduce the fabrication cost of soil moisture sensors in order to improve the measuring resolution. Most printed soil moisture sensors use interdigitated electrodes to measure the dielectric constant of soil at different moisture levels. The electrodes are typically printed using silver or copper inks on polymer substrates. These printed sensors have demonstrated reliable performances in laboratory environments; however, still pose two challenges: (1) the sensors are made of non-degradable materials therefore require labor-intensive retrievals to avoid accumulation in the field, (2) the conductive components (i.e. silver or copper) are toxic to soil microbes and crops.
In this work, we report on a printed soil moisture sensor made of biodegradable and ecofriendly materials. The sensor is comprised of a slowly degradable hydrophobic encapsulant and rapidly degradable functional components (i.e. the electrodes and substrates). This combination of materials allows the sensor to function in soil for an extended period then rapidly fail after the encapsulant is decomposed by soil microbes. The rapid breakdown facilitates easy assessment of each sensor's service life so that the maintenance effort can be reduced. The sensor will eventually decompose completely hence eliminates the needs of labor-intensive retrievals. Ecotoxicity tests show that the sensor materials do not hinder the crop growth. Sensors with encapsulants of different thickness were fabricated and their sensitivities as a function of volumetric water content (VWC) were measured. The long-term stability of the sensor was assessed by accelerating the degradation under controlled temperature. Finally, the breakdown of the sensor was characterized with an extended accelerated test.

6:30 AM F.SF05.02.11
Developing Ceramic AM to Unlock Enhanced Thermal Storage by Swirling Two-Phase Flow in a Package Integrated Cyclone COoler (PICCO)—A Case Study Cathleen A. Hoel[1], Rinaldo Miorini[1], Hendrik De Bock[1] and Darin Sharar[2]; [1]GE Research, United States; [2]U.S. Army Research Laboratory, United States

Power electronic devices have a driving demand to both decrease in size and weight while increasing in performance, which requires next generation thermal management methods. GE Research and the US Army Research Lab have teamed up to explore the concept of utilizing a 3D printed ceramic cooling channel with an internal swirler to enable efficient use of two-phase flow in a Package Integrated Cyclone COoler (PICCO). This work will describe the challenges and learnings associated with 3D printing the ceramic swirler in alumina by stereolithography. Processing effects were evaluated including printing orientation, substrate effects, and slurry grade. Design effects were evaluated including support structures, addition of fillets and geometric non-uniformities.
Research was sponsored by the U.S. Army Research Laboratory's Sensors and Electron Devices Directorate (SEDD) and was accomplished under Cooperative Agreement Number W911NF1920276. Metallic 3D Printing—Implications to Customized Prosthetic Implants Sze Yi Mak[1] and Ching Hang Bob Yung[2]; [1]The University of Hong Kong, Hong Kong; [2]Koln 3D Technology (Medical) Limited, Hong Kong

Medical devices such as artificial implants and prostheses are commonly made of metallic materials, for instance, Cobalt-Chromium alloy, Titanium alloy and stainless steel, for they demonstrate satisfactory biomechanical properties and biocompatibility. The introduction of additive manufacturing has brought the design and fabrication of medical device into a new era, customizing not only shape but also porosity, internal design and surface finishing. Here we present the use of novel Integrated Machining Direct Metal Laser Sintering (IM-DMLS) 3D printing technology to enable hybrid fabrication of prosthetic implant customizing to specific bone anatomy to a dimensional accuracy of ±O(10) microns. Subsequent fine polishing results in a surface roughness (Ra) in micron to submicron range. Tailoring the internal structure of prosthetic implant reduces the weight of implant while preserving good biomechanical properties. Furthermore, we demonstrate the feasibility to form Cobalt-Chromium alloy scaffolds with tunable lattice size and porosity in the biological-relevant range which allows osseointegration. Our work has prominent potential in medical applications of customized medical devices that benefits patients in terms of better bone-implant integration in long term and improved patient experience of size fitting and weight reduction.

3D Printing of Aerogels Dong Lin, Halil Tetik and Nasrullah Shah; Kansas State University, United States

Aerogels are highly porous structures produced by replacing the liquid solvent of a gel by air without causing a collapse in the solid network. Unlike conventional fabrication methods, additive manufacturing has been proposed to fabricate aerogels having complex geometries with designed pore morphologies, which can be advantageous for various applications. However, the fabrication of Aeroges with tailored macrostructures by scalable and controllable methods remains a big challenge. The vision of tailoring the architecture of aerogels for broad applications, including separation, all-solid-state batteries, micro pressure sensors, electrodes, and electrochemical catalyst templates, has stimulated the research on 3D printing of aerogels. Herein, we propose a printing methodology that combines multi-nozzle drop-on-demand inkjet printing of nanomaterials suspension with freeze casting for rapid printing of 3D aerogels architectures to achieve several key qualities, namely, pure, continuous, boundary-free, controlled microstructure, and truly 3D architectures (e.g., 3D truss with overhang structures). To date, we have successfully printed world's lightest material via 3D printing through the proposed technique.

5:15 AM *F.SF05.03.02
Electrochemically Active Architected Materials by Additive Manufacturing Xiaoxing Xia[1], Julia R. Greer[2], Claudio V. Di Leo[3], Carlos M. Portela[2], Dennis Kochmann[4], Eric B. Duoss[1] and Sarah E. Baker[1]; [1]Lawrence Livermore National Laboratory, United States; [2]California Institute of Technology, United States; [3]Georgia Institute of Technology, United States; [4]ETH Zürich, Switzerland

Architected materials are a new class of engineered materials with carefully controlled internal structures that give rise to properties that differ from or surpass those of their constituent materials. Additive manufacturing provides an extraordinary opportunity to rationally design the structure and the chemical composition of architected materials across multiple length scales to optimize properties and functionalities for a variety of applications. These functional architected materials are capable of decoupling critical trade-offs to reach new regions of the material property space and enabling exotic properties that rarely exist in classical materials. Electrochemistry describes the mutual interaction between electricity and chemical reactions, which enables electrically controlled and oftentimes reversible release/storage of energy through electrochemical reactions in, for example, batteries, fuel cells and electrodeposition processes. Designing an electrochemical system is a multi-faceted engineering challenge with trade-offs and constraints such as ion transport through electrolyte, electron

transport inside both electrodes, active electrode surface area, chemical reversibility, and mechanical/chemical stability of electrodes and products during reaction. Recent development in high resolution additive manufacturing has enabled an unprecedented degree of structural control at length scales relevant to electrochemical transport kinetics and thus open up possibilities to rationally design material architectures that improve the performance of these electrochemical systems.

Recently, we created additively manufactured architected materials that can response to and facilitate electrochemical reactions in the local environment. We developed novel fabrication methods based on a suite of 3D printing methods such as two-photon lithography and stereolithography and various physical and chemical post-processing techniques to create architected materials with multi-level design freedom including feature sizes, structural geometries, and material compositions, which resonates with the entangled challenges in electrochemical systems. We demonstrated that additive manufacturing provides a new platform to design 3D-architected electrodes for batteries and electrochemical reactors for CO_2 reduction with enhanced transport kinetics and mechanical stability. Furthermore, we presented a new class of electrochemically reconfigurable architected materials that could transform their structures in a programmable, reversible and non-volatile fashion, which provide new vistas for designing mechanical metamaterials with tunable phononic bandgaps and deployable micro-devices for biomedical applications. The multi-scale and multi-physics nature of these electrochemically active architected materials prompted us to develop a toolset of in situ microscopy techniques and various simulation frameworks to capture and analyze their dynamic behaviors undergoing electrochemical reactions in order to provide an in-depth understanding of the underlying mechanisms as well as design principles generalizable for other functional architected material systems.

5:30 AM *F.SF05.03.03
Multi-Functional Materials for Additive Manufacturing—Electromechanical Materials for Self-Sensing and Actuation Xiaoyu Zheng; University of California Los Angeles, United States

While considerable progress has made in additive manufacturing of structural materials, including polymer, metal and ceramics, adding multi-functionality into the material pallet is compelling. However, such efforts has been challenged by the trade-off between active properties and manufacturablility. In this talk, I will present the additive manufacturing of a suite of electro-mechanical coupling materials (e.g. piezoelectric materials and electronic integration) for energy transduction, where electrical and mechanical behaviors and their couplings can be inversely designed and tailored by an end-user at will. This unleashes new design freedoms for rapid material property discovery and functional product realizations. I will discuss a suite of all-in-one transducers and their new applications, including self-sensing autonomous materials, microsystems for robotics, as well as air and maritime self-sensing system.

5:45 AM F.SF05.03.06
3D Printing of Hydroxypropyl Cellulose Liquid Crystal—Towards Tunable and Sustainable Photonic Structures Chun Lam Clement Chan, Iek Man Lei, Yan Yan Shery Huang and Silvia Vignolini; University of Cambridge, United Kingdom

As we move towards more sustainable manufacturing systems, cellulosic materials are extremely promising due to their biocompatible and sustainable characteristics. Hydroxypropyl cellulose (HPC) is a biocompatible cellulose derivative capable of self–assembling into a lyotropic chiral nematic phase in aqueous solution, which can then reflect vibrant colourations.

We report here a functionalised photocrosslinkable HPC ink compatible with 3D printing. We demonstrate that we can 3D print solid materials with a large variety of shapes, and that the HPC retains its liquid crystalline state and therefore, its colouration after the printing. The final colour of the material can be tuned on–line during printing either by changing the amount of water in the ink formulation or by altering the temperature at which the ink is photo–crosslinked. Our developed system, therefore, allows us to extend beyond the limits of traditional multi-color printing systems based on dyes, as it allows to create materials with colours across the visible range using a single feedstock.

5:55 AM F.SF05.03.08
Additive Manufacturing of Functional Materials via Photopolymer Complex Synthesis Daryl Yee and Julia R. Greer; California Institute of Technology, United States

Over the past decade, additive manufacturing has emerged as one of the most powerful manufacturing tools available today. Vat photopolymerization techniques, in particular, are especially promising as they are capable of achieving high resolutions

and throughputs. However, the fabrication of non-polymeric materials with this technique still remains a challenge in the field — ceramics can be fabricated using vat photopolymerization but are often either based on photosensitive slurries that can be challenging to use and have poor resolutions or on inorganic-organic photoresins that are limited in composition achievable and require some complex synthesis. Metals, in general, have not been explored with vat photopolymerization techniques.

To address these, we introduce the concept of architected "chemical reactors" and demonstrate how we can use this general idea to adapt the field of materials chemistry to additive manufacturing. We present a novel technique called photopolymer complex synthesis that combines solution combustion synthesis with vat photopolymerization to address the issues mentioned above and enable the additive manufacturing of both complex metal oxides and metals. In brief, aqueous metal-ion containing homogenous photoresins are prepared and used with photolithography, in conjunction with post-processing techniques to fabricate architected metal oxide or metal structures. As examples of this technique, we fabricated and characterized zinc oxide (ZnO) and lithium cobalt oxide (LCO) architected structures with sub-micron and sub-millimetre features respectively. Compression of the ZnO structures resulted in an electromechanical response, and electrochemical cycling of the LCO structures showed efficient performance as a lithium ion battery cathode. We also demonstrate the fabrication and characterization of metal structures made from copper and cupronickel alloys. Characterization of these structures using X-ray diffraction, energy-dispersive spectroscopy and transmission electron microscopy indicate that the structures are indeed comprised of the appropriate material, highlighting the utility of photopolymer complex synthesis as a facile and accessible method for the fabrication of these metal oxide and metal materials.

6:05 AM F.SF05.03.10
Aerosol Jet Printing of Battery Separator Membranes Andrew L. Fassler[1,2], Ryan R. Kohlmeyer[1,2,3], Gregory Horrocks[1] and Michael F. Durstock[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc, United States; [3]Xerion Advanced Battery Corp, United States

Additive manufacturing of batteries offers great potential for the future of power integration into electronics and devices, such as in thin film and flexible devices where battery packaging physically prevents intimate incorporation. Additionally, printing technologies open up new design spaces for batteries such as in distributed power supplies and utilization of unused negative space around other features within a device. To achieve this, additive manufacturing approaches must be developed that permit the deposition of battery component materials with fine feature sizes and with control over complex 3D topologies and thin film morphologies.
We demonstrate the use of aerosol jet printing approaches for the deposition and control of 3D printed battery component materials. The printed ink is atomized into micro-droplets and entrained into a flowing carrier gas. This flow is then focused at the printing nozzle where it exits in a high speed collimated stream. This process couples high resolution feature sizes (10-100 μm) with a large working distance, making it ideal for incorporating batteries into minute spaces and on non-planar structures. However, the complexity of the aerosol jet process puts specific constraints on the inks in order to maintain proper atomization.
Here we focus on controlling the separator/electrolyte membrane morphology, which is known to be one of the most critical challenges in 3D printed battery systems. A relatively high level of separator porosity is required to maintain a high ionic conductivity, however these features must be small enough in size to prevent dendritic growth and shorting. We achieve this porosity control through a drying induced phase separation process. A mixed solvent system with carefully controlled relative evaporation rates is used together with a variety of polymer/nanoparticle host materials. This leads to instability in the ink upon drying thereby causing phase separation into polymer poor and polymer rich phases, creating porosity upon solidification. This approach enables the deposition of extremely uniform separator films with fine porosity control. In this study, we examine printing the separator material both on flat substrates and directly onto rough graphite anodes as a means of printing Li-ion batteries. We explore how the printing processes directly impacts battery performance and demonstrate how intimate contact between the electrode and separator at this interface and can impact dendrite growth, a key safety concern in Li-ion batteries.

6:15 AM F.SF05.03.12
Bamboo Fibre-Reinforced Mycelium Composites for Sustainable Structures Hortense Le Ferrand[1], Nazanin Saeidi[2,3], Eugene Soh[1] and Zhi Yong Chew[1]; [1]Nanyang Technological University, Singapore; [2]ETH Zürich, Singapore; [3]KIT, Germany

Mycelium-bound composites are promising materials for sustainable packaging, insulation, fashion, architecture. They consist in exploiting a living organism, a fungus, to develop its intricate mycelium network to form a composite material. To date, moulding is the main fabrication process explored for mycelium-bound composites that strongly limits the ability to

design complex shapes that could widen the range of applications. As an alternative, extrusion printing is a facile and low energy-cost process that has not been explored yet but that could offer with design freedom and structural properties. In this study, we combine bamboo microfibres, chitosan, and mycelium from *Ganoderma Lucidum* to establish a composite mixture that is workable, extrudable and buildable. All those components are issued from agricultural waste, which is key in obtaining interesting composites that are also sustainable. We studied the impact of bamboo fibre size, chitosan concentration, pH and ratio to determine the optimum growth condition for the mycelium as well as highest mechanical stiffness and building capability. The resulting materials that we fabricated have thus low energy costs, are sustainable, and present mechanical properties that makes the process promising for structural applications. The printing method now allows the investigation of complex structures for more optimal mycelium growth thanks to the design of 3D porous structures allowing spreading of the loads and high surface contact with oxygen.

SESSION F.SF05.04: Bioprinting
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-SF05

5:00 AM *F.SF05.04.01
3D Bioprinting Using UNIversal Orthogonal Network (UNION) Bioinks Sarah C. Heilshorn; Stanford University, United States

Three-dimensional (3D) bioprinting is a promising technology to produce living, tissue-like structures, but a current lack of diversity in bioink materials is a major limitation. A cell's phenotype is directly influenced by its surrounding microenvironment; thus, ideally each cell type would be printed in its own customizable bioink. To fulfill this need for a universally applicable bioink strategy, we developed a versatile, bioorthogonal crosslinking mechanism that is completely cell compatible and works with any type of biopolymer. We term this family of materials UNIversal, Orthogonal Network (UNION) bioinks. To prepare these materials, the biopolymer backbone is modified with either an azide or a bicyclononyne (BCN) group. The functionalized polymer is mixed with cells to create a bioink, and then extruded into a support bath containing soluble, multifunctional crosslinkers modified with the partner bioorthogonal reactive group. As demonstration of UNION bioink versatility, gelatin, hyaluronic acid (HA), recombinant elastin-like protein (ELP), and polyethylene glycol (PEG) were each used as backbone polymers to create inks with storage moduli spanning 200 to 10,000 Pa. Because UNION bioinks are crosslinked by a common chemistry, multiple materials can be printed together to form a unified, cohesive structure. This approach is compatible with any support bath that enables diffusion of the UNION crosslinker. Both matrix-adherent human corneal mesenchymal stromal cells and non-matrix-adherent human induced pluripotent stem cell-derived neural progenitor spheroids were printed with UNION bioinks. The cells retained high viability and expressed characteristic phenotypic markers after printing. Thus, UNION bioinks are a versatile strategy to expand the toolkit of customizable materials available for 3D bioprinting.

5:15 AM *F.SF05.04.02
3D Printing of Engineered Bacteria for the Production of Biofilms-on-a-Chip Anne S. Meyer; University of Rochester, United States

In order to create crisp, defined patterns of biologically-created materials, new technologies need to be developed and implemented. The Meyer lab is developing first-of-their-kind DIY bacterial 3D printers that can deposit engineered bacteria in specific three-dimensional patterns using simple devices and chemistries. Our affordable, easy-to-build bacterial 3D printers have fully automated, coordinated control of the pumps and printhead, allowing for high spatial resolution (<mm-scale) printing of bacteria onto wet or dry surfaces. Our printers mix an alginate-containing bacterial culture with a calcium chloride solution upon printing, triggering cross-linking of the alginate molecules to form a stable, biocompatible scaffold to support the bacteria. After printing, the bacteria survive for several weeks and can be induced to produce a variety of biomaterials. We are applying our printer to the fabrication of engineered biofilms, groups of bacteria that live within a spatially structured polymer matrix. We use our 3D printer to deposit engineered *E. coli* that are able to produce CsgA fibrils, or curli fibrils, the major protein component of biofilm polymer matrices. These engineered bacteria can stick to the printing surface even upon attempting to dissolve the printing scaffold, creating free-standing, stably patterned biofilms. Our patterned biofilms develop emergent properties analogous to those seen in natural biofilms, including resistance to anti-bacterial treatment and oxygen depletion within the biofilm interior. These model biofilms will be crucial for future development of anti-biofilm strategies, for which no reproducible model biofilm test system is currently available, as well as

for the reliable production of beneficial living materials, which could be applied for water and soil purification or mineral extraction.

5:30 AM *F.SF05.04.03
Additively Manufactured Architected Synthetic Biofilms William Hynes, Karen Dubbin, Javier Alvarado and Monica Moya; Lawrence Livermore National Laboratory, United States

Bio-active materials integrated with living cells are capable of sensing and responding to a wide range of environmental stimuli and show great promise in biological and chemical sensing applications. The field of bioprinting has typically been geared towards mimicking biology for the purpose of creating human ex-vivo tissues and little work aimed at engineering materials to perform a synthetic function. In this work we engineer hybrid materials composed of living and non-living materials to structure and support the viability and function of living microbes through the fabrication of artificial biofilms

We have previously demonstrated the ability to additively manufacture three-dimensional living tissues using optimized scaffolding materials that sustain the long-term viability of living cells and are amenable to creating diverse living constructs with high degrees of cellular organization. Using the 3D structuring capabilities of LLNL's BioPuSL system (a custom-built biological projection micro-stereolithography), we demonstrate the viable patterning and subsequent growth of *E. coli* bacteria within 3D bioprinted, bacterial-laden engineered biofilms. We show how altering biofilm 3D architecture influences the mass-transport to govern the target application of metal ion absorption. This approach of incorporating sensing cells within novel substrates and architecture designs can enable the development of a new generation of biological generated functional materials with many applications from biosensors to the production of biofuels and bioproducts.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNLCONF-760584.

5:45 AM *F.SF05.04.04
Electrohydrodynamic Printing to Achieve the Next Generation of Functional Biomaterials Miguel Castilho[1,2]; [1]UMC Utrecht, Netherlands; [2]Eindhoven University of Technology, Netherlands

AM technology is a rapidly growing biomaterial processing technique that has an enormous potential for (bio)medical applications such as tissue engineering and regenerative medicine, however greater resolution is required for the next generation of biomedical materials. Melt electro (spinning) writing (MEW) is one such unique AM process that has gained the spotlight in regenerative medicine due to its potential to engineer highly-ordered fibrous scaffolds, capable of replicating extracellular microenvironment functions. Highly resolved porous constructs fabricated in this manner have great utility for both *in vitro* and *in vivo* applications and represents the cutting-edge of 3D printing in biomedical applications. This talk will highlight some of latest developments in such high-resolution 3D MEW processing. This includes developments in processing parameters, functional designs, modelling biomechanics of MEW fibre constructs, and bioactive and hydrogel-based materials for MEW. A particular focus will be placed on the application of MEW constructs for cartilage and cardiac muscle regeneration. The second part of the presentation discusses an even more enticing feature in advancing MEW technology: the convergency of MEW with other 3D printing technologies, e.g. extrusion-based printing, in a single printing platform. The simultaneous use of MEW with other complementary 3D printing processes allows the strategic arrangement of multiple material compositions and operation at different length scales, from sub-micron to centimetre scale, not possible with any single component deposition method. Applications of this novel multitechnology fabrication in soft tissue engineering will be discussed.

6:00 AM F.SF05.04.05
3D Printing of Living Microbial Fuel Cell Anode Megan Freyman, Tianyi Kou, Shanwen Wang and Yat Li; University of California, Santa Cruz, United States

3D printing helps to provide further control on electrode design. By using 3D printing to tune the geometry, porosity and dimensions of the structure, mass transport to functional microbes or sites in the structure can be improved. By embedding living microbes directly into the ink we can create 3D printed structures to help harness the activity of microbes and use them in functional devices. Here we demonstrate the incorporation of the living bacteria Shewanella Oneidensis MR-1 (S. Oneidensis MR-1) directly into an ink used for creating 3D printed structures. By incorporating S. Oneidensis MR-1 into a sodium alginate-cellulose ink we showed that S. Oneidensis MR-1 survives the 3D printing process through the prominent degradation of methyl orange azo dye from the surrounding solution in the presence of the living 3D printed structure. The viability was further confirmed using confocal microscopy. By incorporating carbon black into this ink we further

demonstrate the direct printing of a living microbial fuel cell (MFC) anode. Electrochemical measurements showed there was good charge transfer between the S. Oneidensis MR-1 and the electrode surface. To our knowledge, this is the first report on implementing 3D printed bacteria structure as a living electrode for an MFC system. The capability of printing living and functional 3D bacterial structure could open up new possibilities in design and fabrication of microbial devices as well as fundamental research on the interaction between different bacterial strains, electrode materials, and surrounding environments.

6:10 AM F.SF05.04.06
High Fidelity 3D Printable Materials with Spatio-Temporally Tunable Degradation for Tissue Engineering Archish Muralidharan, Robert McLeod and Stephanie Bryant; University of Colorado Boulder, United States

In order to advance the state-of-the-art of tissue engineering, there is a need for degradable materials with adequate mechanical properties, tunable degradation, and the ability to form biologically relevant complex geometries. The overarching goal of this work is to 3D print personalized stiff structural scaffold which can be infilled with a soft cellular niche hydrogel, satisfying the conflicting design requirement of both a soft matrix to promote neo-tissue growth and a stiff scaffold to withstand physiological loads. To achieve this goal, mechanical integration of these two materials is needed to enable transfer of biomechanical cues and prevent delamination at the interface and engineer the scaffold to degrade at pre-engineered rates.

In our previous study, a relationship between the exposure conditions during 3D printing and the local mesh size of the network formed was established *(Muralidharan et. al. Adv. Mater Technol. 2019)*. Control over mesh size of the 3D printed polymer network ranging from 1.3nm to 11.5nm was achieved. Mesh size ultimately controls the transport of second material (soft hydrogel) into the printed network, and integration distances ranging from 10s of microns to millimeters in 3D printed parts were demonstrated.

This study aimed to develop 3D printable degradable materials with high fidelity and predictable properties through two specific objectives: ***1) Design and develop 3D printable materials with controlled degradation.*** The synthesis of traditional multifunctional macromers that form degradable networks commonly involves multiple functionalization and purification steps, which makes the development of large numbers of polymers with diverse properties difficult. Poly (β-amino esters) (PBAEs) are an attractive biomaterial for degradable materials that has one-step synthesis with no further purification steps and tunable degradation. Linear macromers based on diacrylate-terminated PBAEs were synthesized by reacting 1^{o} amines (RNH_2) with diacrylates. 3D printable poly (β-amino ester) based acrylate terminated macromers were subsequently photopolymerized and characterized for degradation. Through rational selection of acrylates and amines used to synthesize the PBAEs, the hydrophobicity of the network can be controlled. This directly influences the degradation mechanism (i.e. bulk vs surface degradation). We demonstrate degradation profiles with an exponential decay in mechanical properties over time, evident of bulk erosion, to networks with minimal change in mechanical properties, evident of surface erosion. Mass loss was measured over time in an accelerated degradation solution of 1M NaOH. The degradation profiles ranged from linear mass loss to systems where mass loss is slow at early times and accelerates as the network degrades. The polymers with similar modulus of 8-10MPa, exhibited a wide range of degradation rate from 100% mass loss within 90 min to 100% mass loss in 10 days to minimal mass loss over 45 days. These variations, achieved through simple chemical modifications, illustrate the versatility of these PBAE based polymers. ***2) High resolution 3D printing using PBAE macromers***. Through high resolution projection microstereolithography based 3D printing, customized medical image derived geometries with precisely prescribed microarchitectures can be produced. The high molecular weight macromers limit the diffusion of propagating radical into dark during 3D printing, thus allowing high fidelity features as low as 20μm. Moreover, the spatio-temporal degradation control was demonstrated with three orders of magnitude variation in degradation rates. In summary, with an advanced toolbox of synthetic and manufacturing methodologies in hand, we can rationally design and manufacture polymer materials with specific properties.

6:20 AM F.SF05.04.07
High-Throughput Methods for Materials Creation, Selection and Identification Leading to the Production of Personalised Cell Instructive Biomedical Devices via Ink Jet Based 3D Printing Ricky Wildman, Yinfeng He, Morgan Alexander, Derek Irvine, Paul Williams, Zuoxin Zhou, Richard Hague, Christopher Tuck, Jeni Luckett, Jean Dubern and Andrew Hook; University of Nottingham, United Kingdom

3D printing has been widely investigated for biomedical applications and attracted considerable attention as a cost-effective manufacturing technique to produce bespoke devices for patients. However, it is still facing many challenges for realizing this target due to a lack of suitable materials. At the University of Nottingham, we have developed a methodology that allows

us to rapidly identify printable formulations for use with inkjet 3D printing, selected from libraries of materials with cell instructive behaviour. We show how we can exploit this high throughput approach to quickly identify useful, printable materials with potential for scale up and for the production of multimaterial, multifunctional devices. We will show how we used this method to produce devices composed of formulations that can inhibit biofilm formation (*Pseudomonas Aeruginosa* and *Staphylococcus aureus*) by more than 90% in comparison with commonly used devices made from silicone rubber. We go on to show how the design and manufacture of these multimaterial devices can be coupled to design optimisation approaches that generate compositional maps of materials that tell us where to put which materials in order to get a precise mechanical response. As a result, we are able to show that we can select for material, shape and the distribution of material composition to create bespoke implants or other devices that offer significantly reduced infection mortality rate during application, as well as offering all the personalisation benefits that come with 3D printing. We have carried out a range of characterizations that show our devices are capable of safe use and retain their efficacious properties both *in vitro* and *in vivo*.

6:30 AM F.SF05.04.08
Microstructural Control of Polymers Achieved Using Controlled Phase Separation During 3D Printing with Oligomer Libraries—Dictating Drug Release for Personalized Subdermal Implants Laura A. Ruiz Cantu, Gustavo F. Trindade, Zuoxin Zhou, Vincenzo Taresco, Laurence Burroughs, Elizabeth Clark, Felicity Rose, Morgan Alexander, Christopher Tuck, Richard Hague, Clive J Roberts, Derek Irvine and Ricky Wildman; The University of Nottingham, United Kingdom

In developing 3D printed implants, we face considerable challenges in defining which materials to utilize and what combinations to adopt to personalize their performance. A pertinent example is the long-term subdermal contraceptive implant. This is usually cylindrical with a size (maximum diameter 2 mm, length range 1 to 4 cm) defined by a combination of implantation method and anatomical positioning. Currently, such devices are manufactured by a process which heats a blend of polymer and active pharmaceutical ingredient (API) to around 100°C, However, current systems are not personalizable, nor is it possible to combine multiple drugs into a single treatment. One route to achieving personalization is through 3D printing. Ink jet based 3D printing, offers multiple benefits including its scalability, high resolution and importantly, drop by drop deposition that can provide both control over material properties at the microscale as well as the ability to co-deposit multiple materials (drugs).

In this study, we show that ink jet 3D printing of polymer blends gives rise to controllable phase separation that can be used to tailor the release of drugs. We predicted phase separation using high throughput screening combined with a model based on the Flory-Huggins interaction parameter, and were able to show that drug release from 3D printed structures can be predicted from observations based on single drops of mixtures.

Here, we report the creation of a library of multicomponent biodegradable inks, whose diversity of physicochemical properties allows for the range of phase separation behaviour required for tailoring drug release. We show that, by understanding the mechanisms that drive formation of this microstructure, we can predict microstructure that arises out of the ink jet printing process and reliably design and manufacture implants for tailored release.The screen considers the behavior of formulations designed for the release of drugs from 3D printed constructs and uses single drops screening (SDS) to characterize behavior in large, printed constructs.

We observed microstructure in larger-scale printed material that is similar to the drops but not evident in cast materials. We show that, by understanding both this microstructuring and the material composition characteristics, we can design and manufacture implants exhibiting tailored release that does not require varying the implant geometry. This is an important advance for implants that need to be delivered by cannula, where the shape is highly constrained and thus the usual geometrical freedoms associated with 3D printing cannot be exploited, bringing a hitherto unseen level of understanding to emergent material properties of 3D printing.

6:40 AM F.SF05.04.09
Multifunctional Artificial Artery from Direct 3D Printing with Built-In Ferroelectricity and Tissue-Matching Modulus for Real-Time Sensing and Occlusion Monitoring Jun Li, Yin Long, Fan Yang and Xudong Wang; University of Wisconsin–Madison, United States

Treating vascular grafts failure often requires complex surgery procedures and associates with a high mortality rate. Real-time monitoring vascular system could enable quick and reliable identification of complications and initiate safer treatments in the early stage. In this work, electric field-assisted 3D printing technology was developed to fabricate *in situ*-poled ferroelectric artificial arteries that offered battery-free real-time blood pressure sensing and occlusion monitoring capability.

The complex functional artery architecture was made possible by the development of a printable ferroelectric bio-composite which could be quickly polarized during printing and reshaped into devised objects. Synergistic effect from the ferroelectric potassium sodium niobate (KNN) particles and the ferroelectric polyvinylidene fluoride (PVDF) polymer matrix yielded a superb piezoelectric performance (bulk-scale $d_{33} > 12$ pC N^{-1}, confirmed by piezometer) on a par with that of commercial ferroelectric polymers. The sinusoidal architecture brought the mechanical modulus down to the same level of human blood vessels. The desired piezoelectric and mechanical properties of the 3D-printed artificial artery provided an excellent sensitivity to pressure change (0.306 mV/mmHg, $R^2 > 0.99$) within the range of human blood pressure (11.25 to 225.00 mmHg). The high pressure sensitivity and the ability to detect subtle vessel motion pattern change enabled early detection of partial occlusion (e.g., thrombosis), allowing for preventing grafts failure. This work demonstrated a promising strategy of incorporating multi-functionality to artificial biological systems for smart healthcare systems.

6:50 AM F.SF05.04.10
Support-Enabled Three-Dimensional Printing of Bacteria Marco Riccardo Binelli, Patrick A. Rühs, Giovanni Pisaturo and André R. Studart; ETH Zürich, Switzerland

The three-dimensional localization of bacterial cultures provides a valuable tool for studying the behavior of microbes and for generating engineered living materials, but remains a challenging feat to achieve. Recent efforts have been made to confine bacteria into printable hydrogel matrices, mainly focusing on sustaining the growth of microbes while ensuring adequate material properties for 3D printing. At times, though, the rheological features required for conventional direct ink writing do not match the needs of the bacterial strain of choice and hinder the growth of the microorganisms. To circumvent this obstacle, we developed a 3D printing approach that allows us to directly deposit bacteria suspensions into a matrix that both supports free-form printing and allows oxygen diffusion. In our approach, we choose bacteria that have a potential for functional applications or for the synthesis of materials. Amongst these, bacteria capable of synthesizing bacterial cellulose such as *G. xylinus* are of particular interest as they are able to produce personalized biomaterials with outstanding properties such as biocompatibility, tensile strength, and high chemical purity. The rheological behavior of the matrix selected to host such bacteria must prevent the shape-distorting effects of surface tension and gravity. Moreover, when a needle ploughs through the support matrix, it is necessary to ensure a rapid closure of the groove behind the tip to maintain the resolution of the print. Using this approach, we are able to print freeform bacteria suspensions and, when using *G. xylinus*, directly form complex 3D cellulose structures. The use of bacteria to directly grow functional materials in accurate 3D shapes opens the way to a new generation of tailorable living materials, which do not only perform the designed function but also retain the ability to regenerate and respond to environmental stimuli. We envision this new paradigm to be of interest for a wide variety of applications as, for instance, wound dressing and drug delivery.

SESSION F.SF05.05: Developments in AM Materials, Techniques and Processes

5:00 AM *F.SF05.05.01
Additive Manufacturing of Hierarchical Materials Using Self-Assembly Inks André R. Studart; ETH Zurich, Switzerland

Additive manufacturing (AM) offers new opportunities to shape functional materials into complex three-dimensional geometries that are not accessible via conventional fabrication technologies. The layer-by-layer approach used in AM processes also allows us to build artificial structures in a similar way to the methods used by living organisms to grow complex hierarchical materials with unusual sets of properties. Living organisms strongly rely on self-assembly processes to create such functional hierarchical structures. In this talk, I will show how additive manufacturing can be combined with self-assembly processes to fabricate macroscopic functional objects with structural features spanning over multiple length scales. The underlying concept is to exploit the shaping capabilities of AM to define the structure of the object at the macroscale (> 1mm), while implementing self-assembly strategies within the feedstock ink to achieve structural control at the sub-millimeter scale. Alike biological materials, the 3D objects manufactured through this approach exhibit properties that emerge primarily from the hierarchical structure rather than the specific chemistry of its constituents. This provides an attractive route towards the design and fabrication of functional materials with enhanced performance using more sustainable chemical resources.

5:15 AM *F.SF05.05.02

Complex Materials Design for Multidimensional Additive Processing Subramanian Ramakrishnan and Tarik Dickens; Florida Agricultural and Mechanical University, United States

The ability to pattern multiple materials, on micrometer length scales, in three dimensions is critical for several technological applications including composites, microfluidics, photonics, and tissue engineering. The aim of the recently established NSF CREST Center at Florida A&M University is to promote additive manufacturing of novel device structures with an effort towards ab-initio fundamental understanding of material-property relationships that govern the working forces behind high-rate processing applications, and thus low-cost energy products. It is our goal to develop a materials-to-manufacturing framework for research in 3D printing of structures and devices for a wide variety of applications. We aim to (1) gain a fundamental understanding of the materials assembly and additive processing through a combination of experiments and theory; (2) develop and use novel processing/characterization tools for the proposed materials/devices; and (3) use AM to layer-by-layer process these structures/devices. The three main subprojects in the center include - (1) Nanostructured lightweight magnetic materials for shielding/sensing applications. (2) Nanostructured materials for energy applications and (3) Nanostructured Materials for Biological Applications. In this talk, I will detail recent developments in the CREST on these particular sub projects – flow and field assisted processing of multifunctional nanocomposites – where we use combined flow and magnetic fields to orient nickel nanorods, direct printability and performance of 3D conductive graphite structures – where we use extrusion printing to fabricate graphitic structures with enhanced electrical and thermal conductivities, microscopic origin of elasticity and yielding in colloidal gels – where we use a combination of rheology and x-ray scattering to get a microscopic view of macroscopic properties and characterization and printability of Sodium alginate-Gelatin hydrogel for bioprinting non small cell lung cancer cells (NSCLC) co-culture. Research is tightly integrated with education of minority students at FAMU which is the only HBCU to offer a PhD in chemical and industrial engineering.

5:30 AM *F.SF05.05.03
Novel Inks Based on Capillary Suspensions for Additive Manufacturing with 2D Materials Brian Derby; University of Manchester, United Kingdom

Current state-of-the-art graphene inks for extrusion based additive manufacturing (AM) typically contain large quantities of polymers and other additives that require removal through post processing heat treatment to allow access to many functionalities of the 2D materials. Alternative routes, e.g. freeze casting, require complex multiple steps under thermal control to allow printability. Here, an alternative route to additive manufacturing with 2D materials is proposed, based on the concept of the capillary suspension. Capillary suspensions can form when a solid phase is suspended in a mixture of two immiscible solvents, one of which (the minor phase of the mixture) strongly wets the particles in suspension. The microstructure of a capillary suspension leads to a Bingham bevavior, with low resistance to flow above a critical stress when the capillary bridges within the suspension are ruptured and is thus ideally suited to extrusion based AM. A capillary suspension containing 20 wt.% graphene in aqueous suspension, with carboxymethyl cellulose as dispersant, is transformed to a capillary suspension through the addition of 5% octanol. The resulting ink has fluid properties compatible with 3D printing and simple lattice structures are produced with strength sufficient strength for handling after air drying. Similar inks and demonstrator structures with 2D BN in suspension have also been produced. The graphene structures have open porosity of 69%, a compression strength of 1.3 MPa and electrical conductivity of 250 Sm^{-1}. The stability of the ink is shown to be controlled by the relative wetting angle with the two fluids and particle size and aspect ratio.

5:45 AM F.SF05.05.04
3D Printable Sustainable Biocomposites from Corn Starch and Husks Yijie Jiang and Md. Nurul Islam; University of North Texas, United States

There are increasing research interests in natural materials and composites for sustainable additive manufacturing. Natural materials, such as cellulose fibers, have been used as reinforcement fillers in petroleum-based matrix polymers. However, the hydrophilic cellulose fibers are incompatible with many synthetic hydrophobic polymers, leading to weak interfacial bonding and poor mechanical properties. More importantly, the majority of these composites remains not recyclable or degradable. Manufacturing pure natural materials into mechanically-robust engineering materials can benefit in both environmental and economic perspectives associated with the replacement of petroleum-based materials. The natural resources are renewable, biodegradable, and inexpensive. For example, corn is the largest agricultural product in the US with an annual output over 300 million tons. Processing this large amount of corn results in more than 200 million tons of waste, such as husks and cobs. Although there are emerging researches using natural materials, such as rice and protein, to develop 3D printable materials, limitations on printable materials and their mechanical properties exist. Here, we develop 3D printable biocomposites entirely from corn products and waste, namely starch and cellulose fibers from husks. We extract cellulose microfibrils from corn

husks via an alkalization process to achieve controlled dimension and structures. The cellulose fibers are distributed into compatible matrices derived from corn starch, to formulate 3D printable biocomposites using an extrusion-based direct ink writing (DIW) method. We perform a systematic design of experiments to investigate the ink formula, processing steps, and resulted mechanical properties to establish process-structure-property relationships and obtain the optimal mechanical properties. The results indicate comparable stiffness and strength compared with other 3D printed thermoplastics. Since our biocomposites consist of purely natural components, they have potential applications in medical and food area.

5:55 AM F.SF05.05.05
4D Printing of High-Performance Shape-Memory Isotropic Thermoset via Fused Deposition Modelling—Print the Unprintable Qiyi Chen and Rigoberto Advincula; Oak Ridge National Laboratory, United States

Fused deposition modeling (FDM), as one of the most dominant 3D printing techniques, has been increasingly applied in various fields, yet it suffers from the anisotropic performance in the printed materials and the difficulty to print thermoset polymer. Here, we present an unprecedented 4D printing process that achieves, for the first time, FDM printability of highly isotropic thermoset polymer with excellent shape memory behavior and superb thermo-mechanical performance. A specially modified Epoxy-benzoxazine/carbon nanotube hybrid resin was formulated that behaves as a low-temperature thermoplastic allowing FDM printing, and a high-temperature thermoset achieving covalently crosslinked structure. The cross-layer reaction fuses individual layers into an integrity, thus eliminating layer delamination induced by FDM to offer isotropic mechanical properties regardless of the printing orientations. The highly crosslinked epoxy-benzoxazine network offers excellent shape memory behavior with fast recovery rate (full recovery in 80 s) and large recovery degree (98%), as well as outstanding mechanical strength and thermal stability that are superior over most FDM printed polymer.

6:05 AM F.SF05.05.06
A Time-Saving and Cost-Effective Method to Process New Alloys by Laser Powder Bed Fusion Paolo Fino, Alberta Aversa, Alessandra Martucci, Fabrizio Marinucci, Federico Bosio, Federica Bondioli, Diego Manfredi and Mariangela Lombardi; Politecnico di Torino, Italy

Nowadays, there are only a limited number of commercial alloy systems for Laser Powder Bed Fusion (LPBF) , i.e. pure titanium and Ti6Al4V alloys, stainless steels, nickel-based superalloys, Al-Si alloys, cobalt chromium and recently high-entropy alloys. At the same time, developing new alloy compositions is now becoming a key challenge to address in the additive manufacturing field. However, the development of new alloys for LPBF generally requires high economical investments. In fact, the starting powders have a high cost because of they must present highly sphericity and specific particle size distribution to guarantee good flowability and to prevent the formation of porosities in the final parts. In addition, finding the right window for the main process parameters is a core procedure for adopting novel alloy compositions for LPBF. There are many process parameters that can affect the final density of the parts:
considering a fixed value for the layer thickness, selected on the basis of the powder mean size and distribution, part quality depends from laser power, scan speed, hatching distance and scanning strategy. The traditional Design Of Experiment (DOE) approaches for defining the operating process windows are time consuming and expensive requiring the manufacturing of several matrices of massive samples.
Recently in literature it has been demonstrated that the proper P and v values for can be determined via the Single Scan Tracks (SSTs) approach, which requires small quantity of powders with respect to the manufacturing of massive samples. In fact, SSTs are useful for the evaluation of the melting and consolidation behaviour of the material by changing laser power and scan speed, but without considering the effect of the hatching distance. For this reason, according to the traditional approaches SST analyses must be followed by matrices of massive samples with different hatching distances with a consequent increase of the employed powders.
In this work, a novel method to define LPBF process parameter of new alloys through SSTs is proposed. At first, a power - speed operating window is easily defined. Then, the proper hatching distance is designed considering to have an optimum overlap among adjacent scan tracks. In this way, massive samples can be directly produced by using the best *P*-*v*- combinations, avoiding many experiments. In particular, in the first jobs a range of P-v values for which stable and regular SSTs are identified. For the SST characterization an automated and fast method is set up by developing a code for analysing SST images, also avoiding the subjectivity of each researcher in measuring SST features. After that, the measurement of SST width allows to directly select the hatching distance to ensure a good overlapping. In this way the manufacturing of dense samples can be easily carried out by employing a small quantity of powder and time.

6:15 AM F.SF05.05.07
Additive Manufacturing of Conductive Polymer Using Stereolithography—Effects of Multi-Walled Carbon Nanotubes Reinforcement on Electrical Properties and Dimensional Accuracy Daniel D. Lim[1,2], Jaemin Lee[1] and

Wonjoon Choi[1]; [1]Korea University, Korea (the Republic of); [2]University of California, Berkeley, United States

Stereolithography (SLA) 3D printing is often used to fabricate complex 3D structures requiring precise and clean surface finish due to its geometrical accuracy compared to other additive manufacturing methods. However, photopolymer resin used in the SLA has limited mechanical, electrical, and thermal properties. Nanofibers or nanoparticles were used as fillers to improve these properties, and studies showed that adding Carbon Nanotubes (CNT) as reinforcement enhanced the electrical conductivity of the resin, but these lacked in the analysis of the geometrical accuracy performance.
In this study, we evaluated the effect of CNT concentration on electrical conductivity, curing conditions, and dimensional accuracy. Polyurethane acrylate resin was mixed with varying MWCNT concentration from 0 weight percentage (wt%) to 0.8 wt%, and structures were printed using a desktop masked SLA 3D printer. Electrical conductivity was measured using a four-point probe method and dimensional accuracy was evaluated with the geometrical benchmark model.
From the measured data, 0.6 wt% was the maximum concentration of MWCNT that performed a high precision level of SLA method, which also showed 0.033 S/m of electrical conductivity. We applied these findings to fabricate complex multi-material 3D circuit and capacitive sensor.

6:25 AM F.SF05.05.08
Electrohydrodynamic Redox 3D Printing—Broadening the Materials Range for Multi-Material Additive Manufacturing at the Submicron Scale Alain Reiser, Lukas Koch, Maxence Menétrey, Mirco Nydegger and Ralph Spolenak; ETH Zurich, Switzerland

Many emerging applications in microscale engineering require the fabrication of three-dimensional architectures in inorganic materials. Small-scale additive manufacturing (AM) aspires to provide access to these geometries with feature sizes in the micro- and submicrometer range. Yet, the synthesis of device-grade inorganic materials is still a challenge for AM [1] – a major handicap for its incorporation in advanced micro- and nanofabrication processes.
Here, we present our latest advances in electrohydrodynamic redox printing (EHD-RP), focusing on the broadening of the materials range and the optimization of the deposited microstructure. EHD-RP has previously been shown to enable the direct, ink-free fabrication of polycrystalline multi-metal 3D structures with a resolution of 250 nm and a feature size of ≈100 nm [2]. The electrochemical concept can result in excellent as-printed materials quality printed at speeds that outperform alternative electrochemical techniques by one order of magnitude. Additionally, as a most unique feature, EHD-RP has demonstrated nanoscale multi-metal printing with unprecedented detail. Yet, until now, the materials available to EHD-RP have been limited to copper, silver, and gold.
In this talk, we will discuss our latest findings on microstructure optimization in copper. Further, we will present our efforts to expand the printable materials palette to different metals, including alloys and magnetic metals, as well as semiconductors and insulators. We will show that the method is compatible with different sources of ions (sacrificial anodes and salt solutions) and will discuss the role of the solvent. The results present a further step towards the additive deposition of inorganic materials of high quality by microscale AM.

Engineering a Biodegradable, Electrically Conductive Polymer Nanocomposite via 3D Printing Yiwei Fang, Xianghao Zuo, Yuan Xue, Yichen Guo and Miriam H. Rafailovich; Stony Brook University, United States

The consistent growth of electronic devices is one poses one of the most serious ecological challenges of the decade. The rapid pace of innovation correlates with rapid obsolescence of existing devices. Disposal of these devices often poses problems since the electronic circuitry is often printed using toxic heavy metals and other hazardous chemicals which are harmful to both global environment and human health. To address these issues we have engineered a new degradable,

environmentally sustainable, and electronically and thermally conductive nanocomposite, which could be extruded into filaments and used for 3-D printing of circuits and antennas. We blended poly (butylene adipate-co-butylene terephthalate) (PBAT) with a semi-crystalline harder polymer, poly (lactic acid) (PLA), and added graphene nano-platelets (GNPs) as filler. PLA and PBAT are incompatible and phase segregate, but the interfacial tension between GNPs and PLA is even higher than that of the two polymers, and hence the GNPs are sequestered only within the PBAT phase, and do not segregate at the polymer interfaces. The blend is also ductile and easily extruded into filaments for 3-D printing. TEM imaging of the filaments showed that the additional confinement during extrusion further aligned the GNPs allowing them to form percolated rope-like structures within the matrix. Electrcial and thermal conductivity measurements indicated that samples formed via 3D printing had better thermal and electrical properties than those formed via molding, without sacrificing the mechanical performance. Compared with molded PBAT/PLA/GNPs at 20% graphene loading, printed electrical conductivity significantly increased from 2.49S/m to 597 S/m, thermal conductivity increased from 0.664W/mK to 1.794W/mK, while the Young's Modulus increased from 867MPa to 1258Mpa.

Ink Design Strategies for the Direct Ink Writing of Energy Devices Stefano Tagliaferri, Apostolos Panagiotopoulos, Heather Au, Pierpaolo Modugno, Magdalena Titirici and Cecilia Mattevi; Imperial College London, United Kingdom

3D printing is gaining importance for the fabrication of energy devices with superior performance, controllable dimension and customized shape. The complex architectures enabled by printing processes are able to enhance electron and mass transport and provide high surface area, which constitute fundamental features for energy systems. Among extrusion-based techniques, Direct Ink Writing offers the possibility to print a wide range of different materials, and it is suitable for the multi-material deposition of full energy devices, such as supercapacitors and rechargeable batteries.
Despite the great potential held by 3D printing processes, the fabrication of full devices via Direct Ink Writing is bound to the formulation of printable inks from energy materials. Inks must meet specific rheological requirements to be printable, which include high shear-thinning behaviour during flow, solid-like response at rest and fast recovery of the elastic properties after extrusion. The ink design strategy must be carefully optimized to simultaneously obtain high printability and achieve favourable electrochemical properties.
Here the most common ink formulation strategies for energy devices are discussed, highlighting the role played by the different ink components to achieve high printability and their impact on the electrochemical performance of the final device. Viable ink formulations for the fabrication of sodium-ion batteries are presented, giving insight into the connection between rheological behaviour and printability.

6:55 AM F.SF05.05.12
PDMS-Rich Domain on the Electrical Properties of 3D-Printed CNT/PDMS Foam Nanocomposites Chao Liu and Junjun Ding; Alfred University, United States

The carbon nanotube (CNT)/polydimethylsiloxane (PDMS) composite has been studied and fabricated as soft electronics, such as strain sensors, supercapacitors, and electrodes, due to its excellent flexibility and electrical conductivity. An engineered foam structure provides the capability of large-scale deformation as stretchable devices and also affects the percolation threshold of CNT concentration in the CNT/PDMS foam composites. It has been investigated that PDMS-rich domains form at the surface of the composites, where limited reinforcements distribute in this region. However, little research has been focused on the influence of this domain on the electrical conductivity of composites. In this work, we present the effect of the PDMS-rich domain on the CNT/PDMS foam nanocomposites. The material extrusion 3D printing method is used to fabricate the composites due to its advantage of free design to form the scaffold model. The foam structure is built by introducing a foaming agent into CNT/PDMS composite ink as feedstock for material extrusion 3D printing. Electrical pathways formed by interconnected CNTs increase due to PDMS-rich regions at the surface of micropores in the foam structure. Therefore, we hypothesize that the percolation threshold of CNT concentration in the foam composites decreases compared to that in the solid composites. The percolation threshold is inversely proportional to the density of micropores in the foam structure. It is also noted that the electrical conductivity of CNT/PDMS foam composites is higher than the solid composites at identical CNT concentrations. We will compare this hypothesis to our achieved foam structure fabricated using a sacrificial material (sodium chloride). This study provides a broader insight into the mechanism of electrical conductivity in polymer-based foam nanocomposites.

Process Development of WC-Ni Cemented Carbide Composites via Laser Powder Bed Fusion B. Reeja Jayan, Jack Beuth and Edgar Mendoza Jimenez; Carnegie Mellon University, United States

In this work, laser powder bed fusion (LPBF) is used for the additive manufacturing of composite samples consisting of tungsten carbide particles with a nickel binder. Such process can become a viable low-energy alternative to the conventional production of ceramic-metal composites for applications including tooling, electronics, and wear components. Single track experiments are used to evaluate the melting behavior of the composite material. Samples are then printed with of process parameters that adequately melted the material. The density, microstructure, and functional properties of these samples are measured. Highly dense (>98%) samples are successfully manufactured and analyzed as a function of LPBF parameters. Macro- and microdefects resulting from the laser processing are also discussed. A methodical approach to evaluate an acceptable processing region is presented and used to investigate the feasibility of additively manufacturing tungsten carbide-nickel composites via LPBF.

7:15 AM F.SF05.05.14
Selective Laser Melting of Metal Matrix Composites Ethan Parsons; MIT Lincoln Laboratory, United States

Aluminum metal matrix composites (MMCs) are highly desirable materials for precision aerospace applications, where stiffness and low mass are critical, but they are rarely used because of their cost and machining difficulty. In these applications, components typically have complex geometries and are produced in small numbers. Therefore, processing metal matrix composites additively would be the ideal solution, but MMCs with high ceramic content are not commercially available for AM. Here, using purely mechanical methods and readily available constituent powders, we fabricate composite feedstock powders optimized for laser powder bed fusion in a cost-effective, scalable manner. We demonstrate that these powders can be laser consolidated to nearly 100% relative density, providing a potential pathway for the broader adoption of these high-performance yet underused materials.

7:25 AM F.SF05.05.15
Structure and Tensile Behavior of Nanocrystalline Laminar Composites Fabricated by Ultrasonic Additive Manufacturing Austin A. Ward[1] and Zachary Cordero[2,1]; [1]Rice University, United States; [2]Massachusetts Institute of Technology, United States

Ultrasonic additive manufacturing combines layer-by-layer ultrasonic welding of foils with CNC machining to produce net-shape components without melting the feedstock. The solid-phase nature of ultrasonic additive manufacturing makes it attractive for building bulk nanocrystalline metals; however, the high hardness of nanostructured materials makes it difficult to achieve the plastic flow necessary for welding without excessive frictional heating, which could compromise their grain structure. Here, we circumvent this processing challenge by creating laminar composites comprising nanocrystalline NiCo feedstock alternated with soft Al interlayers which accommodate the deformation required for bonding. During the layer deposition process, the NiCo grain structure was preserved and the Al asperities completely conformed to the NiCo surface. TEM chemical analysis of the NiCo/Al interfaces combined with thermodynamic calculations reveals a 100 nm interdiffusion zone containing several intermetallic phases. Tensile testing of the composites and the monolithic NiCo shows that an improved energy absorption in the laminates is realized in part through delocalized damage mechanisms. Ultimately, we couple this experimental work with process models that quantitatively illustrate the tradeoff between frictional heating induced- grain growth and interfacial plastic flow, theoretically validating the addition of softer interlayers as a processing strategy for nanostructure preservation.

7:35 AM F.SF05.05.16
Voxel-Scale Conversion Mapping Informs Intrinsic Resolution in Stereolithographic Additive Manufacturing Tobin Brown, Callie Higgins and Jason Killgore; National Institute of Standards and Technology, United States

In stereolithography (SLA), diffusion of reactive species between light and dark regions of the printing plane limits the achievable resolution. Partially crosslinked macromolecules diffuse away from initiating regions, leading to overpolymerization in dark zones and loss of print fidelity. Additionally, gradients within polymerized regions cause mechanical heterogeneity in the final part. These processes occur on the individual voxel scale and below, so bulk measurement techniques such as photorheology and infrared spectroscopy are unable to adequately measure them, and new measurement techniques are needed. As resolution requirements for new applications push the limits of scalable single-photon processes, the ability to meet this demand hinges on an increased understanding of the fundamental photopolymerization processes involved.

In this talk, I will describe an atomic force microscopy (AFM) technique to directly map the generation and diffusion of

polymeric species during stereolithography. We use an AFM cantilever with a nanocylinder extending from the tip, and when the cylindrical probe is inserted into a resin, the drag on the cylinder can be used to measure to the local viscosity of the liquid, and in turn, the local extent of reaction. Vibrating the cantilever at one of its resonance frequencies (10^4 Hz - 10^7 Hz) affords high temporal resolution. Computational fluid dynamics modeling indicates that the fluid motion induced by the oscillating cantilever is localized within 1 μm of the probe. Employing a custom-built instrument, we can direct arbitrary light patterns from a spatial light modulator to the imaging plane of the AFM to achieve photopolymerization. By translating the tip and light pattern relative to one another, the full spatial evolution of the reaction profile can be measured.

We employed this technique to measure the reaction dynamics during SLA photopolymerization of a thiol-ene resin. The thiol-ene click reaction has some advantages over the photopolymerization of acrylate resins, including reduced shrinkage stress and insensitivity to oxygen inhibition. We find a non-reciprocal dependence of the reaction on light intensity; increasing the light intensity decreases the efficiency of the reaction, likely by increasing the bi-radical termination rate. Thus, at constant light dose, lower light intensities lead to increased conversion in the reaction volume, even accounting for increased time for diffusion. This disproves a common assumption in stereolithography, namely that gelation depends solely on the light dose, often referred to as the "critical dose."

Mapping the spatial evolution of the polymer conversion profile also allows us to easily identify the diffusion length scales during the reaction, and we measure polymer accumulation 20 μm away from the illuminated region within one second of light exposure, identifying the relevant length scale of our process. We then created an open ring test structure (inner diameter = 15 μm, outer diameter = 45 μm) based on this finding to determine the effect that diffusion plays on the resolution of a printed part. Consistent with our measurements of the reaction profile, we observe significant overpolymerization in the ring center, leading to gelation and loss of fidelity to the projected mask. This new technique provides adequate spatial (1 μm) and temporal (<1 ms) resolution for modern stereolithography applications, and it can be used to predict the ultimate printing resolution and rapidly determine the optimal exposure conditions for a given resin.

Late News: Additive Manufacturing of Reversible Covalent Polymer Networks for Self-Healing Soft Robotic Applications Joost Brancart, Ellen Roels, Seppe Terryn, Bram Vanderborght and Guy Van Assche; Vrije Universiteit Brussel, Belgium

Dynamic covalent chemistries have attracted much attention to create reversibly crosslinked covalent polymer networks that show improved processability compared to irreversibly crosslinked networks. Two types of dynamic covalent mechanisms exist: (i) dissociative reversible reactions where the covalent bonds dissociate upon application of the corresponding stimulus, such as heat or light and (ii) associative exchange reactions where a certain functional group can exchange bonds with existing covalent bonds. These dynamic covalent chemistries have also become very popular to create self-healing materials that are able to reform broken bonds to recover the functional properties of materials and hence increase the service lifetime of structures and systems by recovering their functional performance.
The thermally reversible Diels-Alder cycloaddition reaction between furan and maleimide functional groups is a widely studied reversible covalent chemistry for creating thermally reversible covalent polymer networks. While scientific articles reporting synthesis of new reversible polymer networks are numerous, accurate knowledge of the reaction kinetics and thermodynamics of the dynamically reversible equilibrium reaction and the structure and property development of derived stimuli-responsive materials are much less widespread. Such knowledge allows to design and optimize the functional properties of the materials in view of intended applications and to tailor the processability of the reversible polymer networks. Heating the thermally reversible polymer networks based on the Diels-Alder reaction shifts the reaction equilibrium towards the gradual breaking of the cycloadduct crosslinks in the network. At a certain point so many bonds are broken that the material undergoes a solid-liquid transition, referred to as degelation, as the network structure is broken down. This reversible gel transition was employed to create filaments for the 3D printing of 3D structures for flexible, compliant components for a self-healing soft robotic gripper.
The dynamically reversible chemistry, choice of monomers and resulting polymer network architecture determine the (thermo)mechanical properties, thermoresponsive behaviour and healing capabilities of the created reversible covalent polymer networks. Optima need to be sought between (i) reasonably fast reaction kinetics for fast and efficient damage healing at moderate temperatures, (ii) reasonable processing and manufacturing conditions and (iii) adequate mechanical properties and structural stability required for the intended application. Stress relaxation is desirable property to make materials tougher, relieving stress before microscopic defects can grow into macroscopic cracks and ultimately lead to failure, while creep behaviour during application can't be allowed. Recycling and reprocessing of materials are desirable from an ecological viewpoint, while the materials should also be able to withstand static and dynamic loading in a considerable range of environmental conditions.

7:55 AM F.SF05.05.19
Late News: Direct-Write 3D Printing from Solution for Tunable Structural Color of Bottlebrush Block Copolymers Bijal Patel and Ying Diao; University of Illinois at Urbana-Champaign, United States

Additive manufacturing of functional polymers remains limited by the challenge of precisely controlling multiscale hierarchical assembly during processing. In this work, we address this challenge by integrating nonequilibrium self-assembly of densely grafted bottle brush block copolymers with a highly versatile direct-write 3D printing approach. We demonstrate that programmatic variation of printing conditions enables control of peak reflected wavelength for bottlebrush photonic crystals across a range of 403 to 626 nm (blue to red) with a single ink material. We further demonstrate spatial and functional patterning of photonic crystals to achieve colorful prints of chameleon patterns through on-the-fly tuning of assembly kinetics during printing. Via scanning electron microscopy and synchrotron small-angle X-ray scattering analysis of printed films, we then clarify the microstructural underpinning of this phenomena as tuning of lamellar domain d-spacing (total thickness of A+B block) over a range of greater than 30 nm, which we attribute to modulation of polymer conformation during printing. Finally, we establish the role of kinetic trapping of metastable microstructures as the mechanism for domain size control based on *in situ* optical microscopy and solvent-vapor annealing experiments. Thus, we demonstrate a new method for tunable block copolymer photonics without synthetic variation. Furthermore, we present a hardware and software integrated 3D printing scheme that can serve as a test bed for functional property modulation for a variety of functional polymeric and material systems.

Aqueous Synthesis of 3D Nano-architected Ceramics and Metals—Nano-Architected TiO_2 PhCs Julia R. Greer; California Institute of Technology, United States

Additive manufacturing (AM), or 3D printing, represents a set of processes that enable layer-by-layer fabrication of complex structures using a wide range of materials that include ceramics, polymers, and metals. AM has allowed exploiting novel material properties, especially those that arise at the nano-scale, that do not occur in conventional materials, revolutionizing the production of complex parts for aerospace, military, automotive, optial, and medical applications. Facilitating these technologies requires a fabrication process to create a variety of functional materials in 3D, however the material choice for AM at the nano- and micro-scale is limited. A conspicuous example is a lack of AM processes for high refractive index (n), low absorption materials with nano-sized dimensions, which are typically required for microoptics and device applications. To harness the beneficial properties of 3D nano-architected meta-materials, it is critical to assess their properties at each relevant scale while capturing overall structural complexity. We present the fabrication and synthesis of nano- and micro-architected materials using 3D (two-photon and interference) lithography, as well as characterization of their properties as a function of architecture, constituent materials, and microstructural detail. We focus on additive manufacturing of complex, multi-component and multi-material architectures comprised of metal oxides, metals, and hydrogels that are derived from (metal) salt-based, aqueous photoresin synthesis. The discussion will focus on each representative materials system (metals, oxides, and hydrogels), with a detailed overview of titanium dioxide, with critical feature dimensions between 150 and 600 nm and <1% porosity. Using the described methodology, we created 3D dielectric photonic crystals (PhCs) out of rutile TiO2 patterned into woodpile face-centered tetragonal (FCT) architectures with beam dimensions of 300-600nm and lateral periods of 0.8-1.5 μm. We use Plane Wave Expansion (PWE) simulations and Fourier Transform Infrared Spectroscopy (FTIR) to demonstrate the full photonic bandgaps centered at 1.8-2.9 μm. This fundamental research provides insights into the range of possible, often *transient* attainable chemical compositions, microstructures and architectures of chemically-derived, 3D-archtiected ceramics and metals, enabling advances in multiple technologies, i.e. 3D MEMS, micro-optics, and prototyping of 3D PhCs.

5:15 AM F.SF05.06.02
Bridging Micro-Mechanical and Macromechanical Properties of Titanium Alloys Made by Additive

Manufacturing Yu Zou; University of Toronto, Canada

Dual-phase titanium alloys, incorporating α and β phases with contrasting mechanical properties, exhibit balanced and comprehensive mechanical performance, which is suitable for many structural applications, especially in aerospace and biomedical sectors. Laser melting deposition (LMD, one of the primary additive manufacturing methods) provides an ideal method to efficiently fabricate metallic components with complex geometries, as well as controlling microstructure. The complex phases, microstructure, and related phase/grain boundaries significantly influence the deformation and fracture behavior of AM-produced titanium parts. So far, the correlation between the microscale mechanics of individual phases/grains and global mechanics of AM-produced parts has been poorly understood. This thesis will focus on analyzing the micromechanical properties of α+β titanium alloys, including hardness/modulus in different phases, micro-compression/tension/bending tests, towards a better understanding the role of micromechanical properties of each phase and interfaces on plastic deformation and damage behavior of bulk materials. Thus, the goal of this work is to bridge the microscale and macroscale mechanical properties in additive manufactured titanium alloys.

5:25 AM F.SF05.06.04
Electromechanical Behavior of Additively Manufactured Polycrystalline Zinc Oxide Rebecca Gallivan[1], Daryl Yee[1], Julia R. Greer[1], Zachary Aitken[2], Antoine Chamoun-Farah[3] and Yong-Wei Zhang[2]; [1]California Institute of Technology, United States; [2]Institute of High Performance Computing, A*STAR, Singapore; [3]Washington University, United States

Sub-micron resolution oxide materials have immense potential in the fabrication of various nanotechnologies. Zinc oxide (ZnO) is of particular interest due to its piezoelectric properties and its application as sensors in microelectromechanical systems (MEMS). We have recently developed a technique called Photopolymer Complex Synthesis that enables the creation of nano-architected polycrystalline ZnO with feature sizes of 250nm. We achieve this by first patterning zinc ion-containing aqueous photoresins using two-photon lithography and subsequently calcining them at a variety of temperatures to give ZnO. *In-situ* microcompression experiments with concurrent electrical measurements on these architected ZnO structures demonstrate an electromechanical response, i.e. a voltage drop is observed during compression of the structure. Since ZnO exhibits an intrinsic piezoelectricity effect primarily along the c-axis of the crystal, some net crystallographic alignment is necessary for any piezoelectric effect to be observed in polycrystalline ZnO. However, TEM analysis of these polycrystalline ZnO architectures show that they have a homogeneous random crystal orientation. Thus, a more in-depth study of this material and its microstructure-property relationship is necessary to understand the emergence of the observed electromechanical properties.

By adopting a statistical approach that accounts for the random nature of this microstructure, we show through analytical models and experimental results the role of relative length scales, i.e. the microstructure grain size compared to the architecture feature size, in this observed phenomenon. Our findings also demonstrate that microstructure can be used to tune the piezoelectric response of these structures and highlights the possibility of exploiting localized strain in complex architectures. Investigation of this unique processing of ZnO demonstrates not only the specific properties of this architected material, but highlights the importance of microstructural investigation in novel micro-scale 3D printing materials. Additionally, this fundamental exploration provides an insight into the underlying mechanisms of electromechanical behavior in intrinsic polycrystalline peizoelectrics and lays the foundation for future design and engineering of these materials at the nanoscale.

5:35 AM F.SF05.06.05
Limits of Mechanical Stability in Nanoscale Direct Laser Writing Elaheh Sedghamiz, Modan Liu and Wolfgang Wenzel; Karlsruhe Institute of Technology, Germany

Three-dimensional direct laser writing (3D-DLW) is an indispensable tool to high accuracy structuring and fabricating of 3D micro- and nano-objects via polymerization processes induced by direct laser writing[illegible]. Over the past decade, this technology has become a well-established lithography tool for fabricating 3D geometries directly on functional substrates. This capability provided the possibility for a wide range of applications in photonics, microfluidics[illegible], mechanical microstructures[illegible], and cell scaffolds.
As the dimensions of the printed structures shrink it remains a challenge to control the stiffness of the fabricated structure by changing the many conditions influencing direct laser writing condition. We therefore developed a nanaoscale simulation approach as an alternative to physical experiments to optimize the 3D writing process and reduce the number of experiments. This approach enables a systematic studies of how various writing parameters affect the structure and stiffness of the fabricated polymer network. We employ a coarse grained molecular dynamics (MD) method to simulate direct laser writing

of 3D polymer networks from a monomer pool, where monomers react irreversibly according to reaction rate constants, which results in 3D objects being printed voxel by voxel.
Simulations show that the degree of monomer conversion increases with higher laser power or, correspondingly, higher exposure times and saturates towards high writing powers/ high exposure times. Nonetheless, the laser power has a more pronounced effect on the degree of monomer conversion and mechanical properties than exposure time. We investigate the physical parameters and mechanical stability of the resulting structures and find optimize the parameters to write 3D polymer networks with high mechanical stability. This approach allows us to tune the mechanical properties of the 3D printed objects exploiting the fine interplay between laser power, exposure time and also aspect ratio of the printed objects to meet the requirements for different applications.

5:45 AM F.SF05.06.06
Mechanical Properties of 3D-Printed Elastomeric Foams Ali Alperen Bakir[1] and Sezer Ozerinc[2]; [1]The University of Nottingham, United Kingdom; [2]Middle East Technical University, Turkey

Fused deposition modeling (FDM) is one of the most widely used additive manufacturing techniques for the production of plastic parts. Until recently, prototyping activities had been the main application of FDM, where mechanical properties of printed structures are of minor importance. However, with the decreasing costs of FDM-based manufacturing, and improvements in filament technologies, the manufacturing of functional load-bearing components has become feasible for many applications. This new application route requires a better understanding of the process-mechanical property relationships in FDM-produced parts. Parameters such as nozzle temperature, raster orientation, print orientation, and infill ratio directly affect the strength and ductility of FDM parts. There have been many studies on this topic in the last decade, mostly focusing on the widely used filament materials such as ABS and PLA. In the meantime, new advances in filament technology have made elastomers available for FDM. Low stiffness and extreme elongation capabilities of elastomers provide new 3D printing opportunities for a wide range of structural applications. Further advancement in the field has recently enabled the printing of elastomeric foams by using the readily available FDM printers. Mechanical properties conventional elastomeric foams are well-characterized in the literature; however, there is no study in the literature about the mechanical behavior of 3D-printed elastomeric foams to our knowledge.
In this work, we investigate the process-property relationships of an elastomeric filament designed to foam during extrusion, providing a low-density and porous structure. We focused on the effect of infill ratio, layer thickness, feed rate, and nozzle temperature on the mechanical properties. An Ultimaker 2+ FDM printer produced tensile dogbone specimens by using Varioshore TPU natural filament manufactured by Colorfabb (Netherlands). Scanning electron microscopy characterized the microstructure of the specimens, and conventional tensile mechanical testing quantified the mechanical properties. Increasing nozzle temperature, increasing layer thickness, and decreasing feed rate promote foaming and provides a lower density structure. As the extent of foaming increases, the elastic modulus, strength, and elongation at failure decrease. After the characterization step, we combined the excellent capability of FDM in producing custom cellular structures with the intrinsically low stiffness of the elastomeric foam and demonstrated the fabrication of extremely compliant cellular structures. Compression testing results of these model structures demonstrate the enormous potential of the foaming filament technology for the generation of novel compliant structures.

5:55 AM F.SF05.06.07
Microstructure Modeling of Uniform Droplet Sprayed Deposits for Mg Alloy-Based Additive Manufacturing Nikolaos Kostoglou[1], Hiroki Fukuda[2], Emre I. Gunduz[3], Claus Rebholz[4], Teiichi Ando[5] and Charalabos C. Doumanidis[6]; [1]Montanuniversitat Leoben, Austria; [2]Fukuda Metal Foil & Powder Co Ltd, Japan; [3]Naval Postgraduate School, United States; [4]University of Cyprus, Cyprus; [5]Northeastern University, United States; [6]Vin University, Viet Nam

This article addresses modeling of the solidifying material structure during 3D welding/printing of fully dense Mg alloy products by fused deposition of molten droplets from a uniform droplet spray source on a motorized X-Y table substrate. The resulting crystallite size distribution is simulated by a solidification model consisting of nucleation/fragmentation and constrained growth description, calibrated via structural data from a single droplet splat. This is enabled by a semi-analytical thermal modeling framework, based on superposition of moving Green's and Rosenthal functions for the temperature field from a Gaussian source distribution, in which the deposit solid geometry and heat transfer boundary conditions are accounted for by mirror source images of modulated efficiency. The simulation model is implemented for layered ellipsoidal deposit sections on planar substrates by multi-pass spraying, and its predictions are validated against measured crystal size by image analysis of experimental micrographs of a $Mg_{97}ZnY_2$ alloy, to an error margin of $\pm$15%. The computationally efficient simulation provides insight to the deposit microstructure, and is intended as a process observer in a closed-loop, adaptive control scheme based on infrared temperature measurements.

6:05 AM F.SF05.06.08
Multi-Modal Synchrotron Analysis for the Design of Corrosion Resistant Additively Manufactured Stainless Steels David J. Sprouster, Gary P. Halada and Jason R. Trelewicz; Stony Brook University, United States

Additive manufacturing processes produce materials with hierarchical microstructures containing fusion boundaries at the macroscale, irregular grains and grain boundaries at the microscale, and subgrain dislocation structures at the nanoscale. In 316L stainless steels, corrosion performance has been discussed in the context of chemical heterogeneities formed in the presence of these hierarchical microstructures. However, the large variability in reported measurements underscores the need for statistically significant microstructural data, which is often difficult to access via electron microscopy alone. In this presentation, we explore multi-modal synchrotron x-ray techniques for quantifying hierarchical microstructures and their connection to the underlying chemical distribution in 316L stainless steel. Our results show that the dislocation density depends on the printing conditions and ultimately influences chemical distribution at the nanoscale with implications for the formation of deleterious second phases from a corrosion perspective. On this basis, corrosion rates and pit densities are discussed to build a connection between printing conditions and corrosion performance vis-à-vis microstructural and chemical information from correlative electron microscopy and synchrotron characterization experiments. A decreased pitting potential and loss of passive behavior accompanied by elongated regions of pitting attack were attributed to Cr depletion degrading passive film formation with Mn carbides serving as initiation sites for localized attack.

6:15 AM F.SF05.06.11
The Effect of Part Printing Angle Normal to the Print Bed for Fused Filament Fabrication of 17-4 PH Stainless-Steel Metal Additive Manufacturing Tawaddod Alkindi, Mozah Alyammahi and Rahmat Agung Susantyoko; DEWA R&D Center, Dubai Electricity and Water Authority, United Arab Emirates

Additive Manufacturing (AM) has been developed expeditiously in the past years, and the application domain and material range are broadening steadily. The 3D printing era has started in 1987 when the first commercial 3D printer was released utilizing stereolithography technique. Ever since, new AM processes are introduced and implemented to face current challenges and accommodate the new requirements in the manufacturing field along the way of 3D printing development.
In opposition to subtractive manufacturing techniques that include material removal to obtain the desired shape, additive manufacturing (AM) is a process where joining of materials takes a place to create three-dimensional (3D) objects from 3D model data. The printed designs are made by adding subsequent layers generated from computer-aided design. The ultimate advantage of AM is that it gives the user the ability to create bespoke designs of both different geometric and different materials. However, AM is a very diversified term that comprises different methods such as direct metal laser sintering, fused filament fabrication (FFF), stereolithography, powder bed fusion, selective laser melting (SLM), and binder jetting.
The 3D printing of metallic materials is based on the layered consolidation of feedstock materials in the form of: i) powder, ii) wire, or iii) sheet while using various energy sources to form complex structures and designs. Metal printing methods are categorized as electron- beam-based, arc-based, laser-based, welding-based, and ultrasonic. However, the most common energy sources for metal 3D printing are electron beams and lasers. Laser-based metal 3D printing processes are classified into laser sintering (LS), laser melting (LM), and laser metal deposition (LMD). LS is a powder bed fusion technique where a scanning laser is used to consolidate the layers of metal powder sequentially. The LM is another powder bed fusion technique involving the consolidation of metal powders using high-intensity lasers. All equipment setup, configuration, and processing methodology are similar in LS and LM, but in LM, the powder is almost or completely melted to produce a dense structure. LM enables the production of metal parts with a considerably high level of microstructural homogeneity when compared with LS. In LMD, the feedstock material is either a wire or powder. In powder-based LMD, a pressurized gas transfers the powder through a nozzle into a melt pool created by a laser beam on a substrate. The laser and powder integrated system deposits the material while following a specified path. In wire-based LMD, a wire is continuously fed into the path of the laser, while the tip of the wire is continuously melted to make deposits on a substrate.
The FFF technique for printing metallic parts is a particular interest in the investigation of this work due to acceptable printing resolution and relatively low-cost process compared to LS,LM, and LMD costs. To our knowledge, no one has reported the effect of printing angles to the tensile property for metal FFF process. We will use the Markforged Metal X 3D printer using 17-PH stainless steel material in this work. The 3D printing consists of 3 steps: FFF 3D printing of metal-binder filament, washing to remove the binder, and sintering to achieve metal mechanical property. We will use Eiger software to import and slice the STL file of the sample design. We will use standard tensile test sample ASTM D638 V.
This work will investigate the effect of 3D printing angles on the mechanical properties of the printed samples. The default orientation in the printer is zero for X, Y, and Z, which corresponds to sample X0Y0Z0. We will do experiments of five different print angles of 0, 30, 45, 60, and 90 degrees normal to the surface. Finally, we will measure and discuss the tensile properties (stress, strain, Young's modulus and yield) of the 17-4 PH stainless steel using Instron 3367 apparatus.

6:25 AM F.SF05.06.13
Late News: Mechanical Testing of Stereolithographically Fabricated Polymer-Graphene Composites Kalaimani Markandan and Changquan Lai; Nanyang Technological University, Singapore

The emergence of 3D printing has allowed for the rapid prototyping of complex geometries that were previously inaccessible using traditional manufacturing techniques. Amongst these additive manufacturing techniques, stereolithography stands out in terms of the surface smoothness, isotropy in properties and fabrication speed it can provide. The materials that can be 3D printed with stereolithography, however, are limited and fairly weak in mechanical properties. Here, we aim to improve the mechanical performance of stereolithographically printed polymers through the addition of graphene fillers. The effects of filler concentration, post-fabrication baking and loading direction on the quasistatic and dynamic mechanical properties of the composite were investigated. It was found that the graphene platelets were selectively aligned along the print axis, the graphene platelets were well-dispersed up to a concentration of ~ 0.05 wt% and post-print bake has the effect of increasing the degree of cure in the PMMA polymer resin up to 120°C, beyond which it would begin to degrade. As a result of such optimization, polymers reinforced with as little as 0.02 wt. % graphene were found to increase their stiffness by 88.3 % and strength by 115.2 %. Split-Hopkinson pressure bar tests also showed that these composites had higher specific strengths and specific energy absorption compared to other lightweight materials such as syntactic ceramic foams and Al alloys (in both bulk and foam form factors).

Tunable Elongation-at-Break of Tensile Mechanical Properties of Stereolithography Additive Manufacturing Through Control of Printing Orientations Mozah Alyammahi, Rahmat Agung Susantyoko and Tawaddod Alkindi; DEWA R&D Center, Dubai Electricity and Water Authority, United Arab Emirates

Additive manufacturing (AM) spread widely not only for prototyping but also for the production of end-use products. Quality control is a vital importance in the production of parts. One of the challenges of quality control in AM technology - such as fused deposition modeling (FDM) - is that the mechanical strength of the 3d-printed part could be anisotropic (not uniform). The part's printing orientation could affect the mechanical strength of 3d-printed parts. Among the AM technology spectrum, the stereolithography (SLA) process is known to be able to produce parts with relatively uniform mechanical strength (isotropic).
Many studies were done using FFF 3D printing method. However, to our knowledge, only very few studies had done to investigate the effect of printing orientation on the elongation-at-break of 3d-printed parts using SLA technology. Moreover, previous studies only experimented with a limited amount of samples and orientations. Therefore, strength and elongation-at-break need to be examined in detail and with more variations of print orientation. For this purpose, this study investigated the influence of part's printing orientation to the tensile mechanical properties (tensile-stress-at-max-load, tensile-strength-at-break, tensile-stress-at-yield, young-modulus, elongation-at-break) of SLA technology. This work covered a large number of orientations (27 printing orientations) testing five different mechanical properties.
We used Form 2 3D printer to 3D print with White photopolymer resin of FLGPWH04 material. We used Preform 3.03.1 software to set the sample positions. The samples were oriented with respect to x, y, and z axes according to the software axes. Permutation-with-repetition of 3 different angles (0°, 45°, and 90°) with respect to 3 different axes resulted in 27 part's printing orientations. Furthermore, we printed 3 samples for each orientation with for a total of 81 samples for all orientations. The printed samples were washed in isopropyl alcohol (IPA) for 20 minutes. Afterward, we carefully removed the support structures from the samples using a tweezer; followed by drying and curing process at 60 °C for a total of 20 minutes (samples were flipped every 10 minutes).
We followed the ASTM D638 V standard tensile test design. Each printed sample was kept at the same time (13 days) before the tensile testing to avoid time impact on the properties. Then we performed the tensile testing using Instron 3367. In Bluehill LE 3.77 software, the sizes were entered for each sample. It took the measurements while the test was running and calculated the strain, stress, modulus, and yield. The raw data from the samples compiled in Microsoft Excel.
The results showed relatively uniform isotropy of the tensile-stress-at-max-load and it has 3.8% relative standard deviation.

In addition, tensile-strength-at-break, tensile-stress-at-yield, and young-modulus has 4.15%, 5.67% and 7.94% relative standard deviation, respectively. In contrast, a relatively large anisotropy of elongation-at-break has been observed with 21% relative standard deviation. The sample printed vertically (90 degrees normal to the bed) elongated to an average of 10% whereas the sample printed horizontally (0 degrees normal to the bed) elongated to an average of 15%. One hypothesis that explains this behavior is that printing vertically created many layers comparing to printing horizontally. Thus, the high number of interfaces layers make the part elongate less. The results show that the elongation-at-break could vary and could be tuned in SLA technology; a new finding in this research field.
We recommend that the designer of SLA parts to consider the part's printing orientation depending on the possible application (whether the application requires large elongation-at-break or short elongation-at-break). By knowing the effect of printing orientation, high-quality parts could be produced consistently according to the application's requirement.

Enhanced Toughness in Ceramic-Reinforced Polymer Composites with Herringbone Architectures Robert Zando, Ataollah Mesgarnejad, Chunzhou Pan, Sandra Shefelbine, Alain Karma and Randall M. Erb; Northeastern University, United States

A common design rule in synthetic particle-filled composites is to align all reinforcing particles parallel with the primary stress and thereby perpendicular to a likely fracture. Doing so can often result in crack deflection, which is commonly touted as evidence that a material has enhanced fracture toughness. In reality, as soon as the crack deflection occurs, the material is fracturing along an "easy axis". Much better is for the crack not to deflect and be forced to propagate forward along a "hard axis" spending much more energy to grow. Geometric conditions alone can create T-stress that confine the crack to propagate straight along a hard-direction. However, real-world applications of filled composites often dictate geometric design and put toughness at risk. Instead, designed texturing of reinforcing particles has the potential to steer cracks along a "hard axis" without reliance on geometric loading conditions. Recent advances in the field of composite manufacturing techniques, make such architectures possible, allowing the creation of microstructures which can locally tune the fracture toughness anisotropy. In the studies presented, we explore a unique variant of this principle through the creation of an alignment architecture reminiscent of the spine of a herringbone fish, designed to trap a fracture along the boundary between two regions of distinct particle alignment. This robs the fracture of a preferred direction of initial fracture deflection, delaying the initiation of fracture formation, and forces it along a "hard" direction of fracture initiation, effectively raising both its initial and overall fracture resistance significantly beyond monolithically aligned composite polymer systems. However, while this custom microstructure proved successful in demonstrating this method of boosting mechanical performance over traditional monolithic systems in principle, it remains limited in application by the necessity of a fracture initiating at or near the boundary between two alignment regions. Without filling this pre-condition, the fracture would initiate in a manner similar to a monolithic alignment system.
To overcome this limitation, we applied these principles to generate a new class of beautiful herringbone mosaics that provide isotropic toughness in 2D. This structure was composed of a series of hexagonal unit cells, further divided into a series of triangular sub-cells, each with herringbone patterns. Mechanical testing of these samples determined that this structure not only demonstrated superior initial fracture toughness to monolithic samples, but that this effect was approximately isotropic, showing superior mechanical performance over the highest performing monolithic samples regardless of the direction of the tensile force relative to the microstructure placement. In applications in which the geometric design of a particle-filled composite is constrained, texturing materials with herringbone mosaics provide a meaningful route toward boosting isotropic toughness through microstructural design alone.

Lightweight Cellular Metal Composites with Zero and Tunable Thermal Expansion Enabled by Ultrasonic Additive Manufacturing Ethan Parsons; MIT Lincoln Laboratory, United States

In aerospace applications, variations of temperature caused by changing environmental conditions or generation of heat is a common problem. The resulting thermal strains cause separation and alignment errors in optical systems, and stresses due to mismatches of thermal expansion at material interfaces cause failure of components and structures. Because minimizing weight, cost, and lead time are also critical requirements, lightweight, easily machined metals are attractive for aerospace applications, but these materials all have substantial coefficients of thermal expansion. Previous work has shown that the superposition of two metals with dissimilar coefficients of thermal expansion in periodic cellular configurations can result in a composite material with zero effective thermal expansion. However, fabrication of these material architectures typically is either impossible or requires manual assembly. Here, we propose methods to design and fabricate cellular metal composites with tunable thermal expansion and optimized specific stiffness that can be manufactured at useful scales entirely with automated methods. Samples were manufactured with ultrasonic additive manufacturing and computer-controlled machining,

and thermal expansion was measured optically. The results demonstrate the practical fabrication of cellular metal composites with zero or negative thermal expansion in one direction, tunable thermal expansion in a second direction, and structural performance indices competitive with the indices of conventional aerospace alloys.

The Effects of Solidification Rates on Grain Refinement Capacity of TiC in Directionally Solidified Ti6Al4V Alloy Naoki Date[1], Shunya Yamamoto[1], Yoshimi Watanabe[2], Shizuka Nakano[3,4], Naoko Sato[3] and Shinsuke Suzuki[1,1]; [1]Waseda University, Japan; [2]Nagoya Institute of Technology, Japan; [3]National Institute of Advanced Industrial Science and Technology, Japan; [4]Henry Monitor Inc., Japan

In additive manufacturing, a titanium alloy Ti6Al4V is the most widely used and was reported to form columnar grains during process. However, columnar grains are generally regarded to be unfavorable since their presence can impart solidification defects and mechanical property anisotropy. Therefore, fine equiaxed microstructures are desired. Recently more or less 0.3vol% addition of TiC particles resulted in grain refinement of Ti6Al4V during Laser-based powder bed fusion of metals[1]. Furthermore it was clarified that TiC particles partially melted in molten Ti6Al4V and the residual TiC particles generated fine and equiaxed grains from the heterogeneous nuclei during directional solidification of Ti6Al4V[2]. Although equiaxed grains can be obtained at high solidification rates in general, the effect has not been clear in an alloy with TiC. In this study, as a fundamental research for additive manufacturing, we aimed to reveal the effects of solidification rate, which varies the amount of melted TiC and the degree of constitutional undercooling.

Ti6Al4V powder (with 2.0vol% TiC and without TiC) in a Ti6Al4V sheath was melted and directionally solidified with a floating zone melting method at various solidification rates V(=1,3,5,10,15mm/min). During the process, the temperature around the melt pool was measured using a two-color pyrometer. Microscopic images on the cross section through the center of directionally solidified samples were obtained to evaluate the numbers and equivalent diameter of the prior β grains. The area fractions of the precipitate and matrix were analyzed by an image processing software, and the carbon contents in them were analyzed by Electron Probe Micro Analyzer(EPMA) to estimate the amount of the melted TiC. Also using phase field method, microstructure evolution of Ti6Al4V during solidification was simulated and constitutional undercooling around solidification front was estimated.

From microstructural observations, the number of fine equiaxed prior β grains increased by TiC addition except at 1mm/min and the total number of grains increased as solidification rate increased. Also with TiC added microstructure, precipitation appeared in the prior β grains regardless of solidification rates. EPMA analysis results showed that the precipitation was Ti_2C and the area percentage of Ti_2C decreased with increasing solidification rate. Estimating carbon amount from Ti_2C fraction, carbon amount derived from melted TiC is 0.262 mass% at 1mm/min and 0.178 mass% at 15mm/min. Considering total carbon amount 0.270 mass% from 2.0vol% added TiC, carbon amount derived from melted TiC is smaller when solidification rate is higher. From phase field simulation, constitutional undercooling around solidification front was larger as solidification rates increased. From above, it is considered that at a higher solidification rate, the amount of melted TiC particles is smaller, and the amount of residual potent heterogeneous nucleus TiC particles is larger at a large constitutional undercooling .

4D Printing with Elastic Hinge Using Shape Memory Polymer and Elastomer via Fused Deposition Modeling 3D Printer Shunsuke Yamamura and Eiji Iwase; Waseda University, Japan

Recently, many researchers have studied 4D printing by fused deposition modeling (FDM)-3D printer using thermoplastic material including shape memory polymer (SMP) [1]. 4D printing is 3D printing with shape-shifting-function triggered by material shrinkage and/or expansion. A conventional 4D-printed device by FDM-3D printer is, however, difficult to deform after shape-shifting, because thermoplastic material is rigid below the glass transition temperature. Therefore, a conventional 4D-printed device is not possible to use as an origami stretchable device which is deformed by origami-deformation of elastic hinges [2].

In this study, we proposed a 4D printing device with a hybrid hinge. The hybrid hinge has a structure in which a self-folding hinge made of SMP and soft hinges made of elastomer are arranged in series. By applying heat to the 3D printed device with

a hybrid hinge, the self-folding hinge works to form a folded structure. The elastic deformation after self-folded can be realized not by a self-folded hinge but by soft hinges made of an elastomer with wide elastic range. In order to confirm the elasticity of hybrid hinge, we evaluated a change of folding angle when the devices were repeatedly bent. As a comparison to our proposed device with a hybrid hinge, we prepared a device without a hybrid hinge, i.e. without soft hinges. In the device without a hybrid hinge, we confirmed that the folding angle changed at one cycle bending due to plastic deformation of SMP. On the contrary, the bending angle of the device with a hybrid hinge did not change by a repetition of bending deformation. Finally, we demonstrated an origami stretchable device with multiple hybrid hinges. We fabricated miura-ori as origami stretchable device. Unlike a previous demonstration of miura-ori using 4D printing via FDM-3D printer, our fabricated device can be deformed from folded shape to deployed shape by external force even under room temperature at 25°C.

In conclusions, our proposed hybrid hinge was confirmed as an effective way to realize the 4D printing with elastic hinge. We believe that our proposed way will accelerate the development of stretchable origami device.

3D Printing of Poly-Ether-Ether-Ketone (PEEK) and Reinforced Peek Materials and Its Mechanical Properties with Post Heat Treatments Kyung-hyun Kim, Hyeon-Sik Ahn, Dong-Hwan Kim, Ae-Sun Oh and Hyun-Cheol Bae; Electronics and Telecommunications Research Institute, Korea (the Republic of)

3D printing or additive manufacturing has great attention in recent years as it allows the manufacturing of complex shapes and various geometries. Specially, these techniques have various application fields, which are making prototypes for electronics, aerospace, automotive, and so on. For 3D printing technology to be applied to electric vehicles, it needs to be light, high strength and high thermal stability. Many researchers are working on high-temperature, high-strength materials such as PEEK and composites to increase strength.
Therefore, we have designed a hybrid organic-inorganic composite material, which are glass fiber, carbon fiber, and modified PEEK, for high-temperature, high-strength materials stability. We successfully made organic-inorganic 3D printing filaments using a mini-extruder machine for fused deposition modelling (FDM) printer. Also, we studied thermal and mechanical properties of 3D printed samples with or without post heat treatment at 250oC for 1 hr. These printed samples were measured by thermal mechanical analyzer (TMA), bending strength and tensile strength with micro-universal testing machine. Surface morphology and the crystallinity of PEEK of those are measured by scanning electron microscope (SEM) and the Differential Scanning Calorimetry (DSC) method.
We will present the detailed experiment results and other analysis results for improved 3D printed samples.
This work was partly supported by the National Research Council of Science & Technology (NST) grant by the Korea government (MSIP) (No. CRC-19-02-ETRI) and the Technology Innovation Program (No. 20005139) funded by the Ministry of Trade, Industry & Energy(MOTIE, Korea)

Synthesis of Polyetherimide(PEI)-Based Photocurable Resin for Biocompatible DLP Stereolithography 3D Printing Process Jae hwan Chung, Hee Jeong Park, Hyejin Kim and Dong hyun Lee; Dankook University, Korea (the Republic of)

3D printing, commonly known as additive manufacturing, is a manufacturing process of producing three dimensional objects having complex features through layer by layer printing. The 3D printing technique has been developed rapidly and applied to various industrial fields since it was proposed in 1980s. Even though there are many 3D printing techniques introduced so far, the photocuring 3D printing which is based on photopolymerization of photo-sensitive materials is becoming more important due to its high printing speed, high precision and smooth surface of products. However, the materials which are mainly utilized in the photocuring 3D printing often encounter limited mechanical properties which are originated from their own nature. Thus, it is necessary to design photo-sensitive materials satisfying the requirements. Recently, poly(ethylene glycol) diacrylate(PEGMA) which is commonly a highly biocompatible photocurable material is widely used in the photocuring 3D printing for biomaterials, dental materials, biomimetics, and tissue engineering and so on despite its poor mechanical and thermal properties. Thus, there are many demand to overcome the disadvantages of PEGDA and to find suitable materials for the fields. Here, we report the polyetherimide-based photocurable resin for biocompatible 3D printing. Polyetherimide(PEI) is one of engineering plastics, which has superior mechanical strength, long-term thermal stability, excellent chemical resistance and good biocompatibility. By integrating those properties of polyetherimide to advanced biocompatible 3D printing, we synthesized a polyetherimide-based photocurable resin for DLP stereolithography 3D printing. To synthesize the polyetherimide-based resin condensation reaction between dianhydrides of BPADA and diamines

of 3,5-diaminobenzoic aicd under the nitrogen flow are conducted to produce amic acid groups in chain backbones and chain ends. As thermal imidization of the reactants is then proceeded in sequential 3 steps of 60°C for 2 hours, 110°C for 2hours and 205°C for 4 hours, the amic acid groups are successfully converted to imide linkages. It is noted that the carboxylic acid of diamono acid are still remained after the imidization. After cooling down to the 30°C, glycidil methacrylate (GMA) is additionally grafted to the PEI molecules by the reaction with the carboxylic acids in presence of tetraethylammonium bromide (TEAB), triethylamine and hydroquinone under the nitrogen flow of 100°C. The GMA groups impart the photochemical reactivity to in the PEI molecules. After the precipitation in distilled water and filtration, PEI-g-GMA powder is obtained and dried in vacuum oven at 40°C for 24hours. To prepare the photocurable resin for 3D printing, the synthesized PEI-g-GMA is mixed with crosslinkers(PEGDA), reactive diluents(1-vinyl-2-pyrrolidinone(NVP) and photo initiators(Igarure819®). To test the biocompatible property of our resins, three dimensional specimens are printed with the photocurable resins prepared here, by precisely adjusting light dosage and compositions of the mixtures. It is found that the specimens are printed in 0.4 seconds of exposure time and 30 μm of layer thickness. The printed specimens are rinsed with isopropanol and post-cured in a UV light chamber. The photocurable resin and the printed specimens are characterized by using universal test machine(UTM), differential scanning calorimeter(DSC), thermal gravimetric analysis(TGA), FT-IR and H^1-NMR spectroscopy. In addition, the molecular weight of PEI-g-GMA is estimated by end group analysis based on H^1-NMR data.

***In Situ* Microbeam X-Ray Scattering and Infra-Red Imaging of Polypropylene/Graphene Nanoplatelet Nanocomposites During Additive Manufacturing**

Yu-Chung Lin[1], Aniket M. Raut[1], Yuval Shmueli[1], Steve N. Nitodas[1], Guillaume Freychet[2], Mikhail Zhernenkov[2] and Miriam H. Rafailovich[1]; [1]SUNY Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

The fused deposition modeling (FDM) is an advanced 3D printing technique in which the thermoplastic polymer is melted and extruded by the shear force coming from the nozzle to create layer by layer structure according to the user input file. Compared to the conventional molding, a major challenge of the FDM process is the highly nonequilibrium thermal gradients that impact the filament fusion and the thermo-mechanical and electrical integrity of the materials produced. Furthermore, since these gradients are poorly understood, tructure/property models predicting the outcome of printing have been difficult to establish. In order to visualize the gradients, while probing the internal structure of the printed samples, we designed an apparatus which can simultaneously profile both macrostructure and microstructure during printing, as a function of time, using synchrotron X-ray scattering, and together with infrared thermal imaging. This information is then combined with Raman spectroscopy, rheology, and DMA studies, in order to understand the evolution of the internal structure and its corresponding influence on the properties of the materials. We had previously applied these techniques to crystalline polymers, PLA and iPP [1]. Here, we extend these measurements to the study of the internal structure of FDM printed Polypropylene (PP)/Graphene Nanoplatelet (GNPs) nanocomposites. Micro-beam wide-angle scattering analysis showed that the GNPs cluster towards the center of the filament during extrusion from the nozzle when the GNP concentration is higher than 10%. Previous studies had demonstrated that iPP interacts strongly with graphene [2], and hence the segregation of the GNP away from the interface facilitates chain diffusion across the interfaces, consistent with the high impact toughness observed. Thermal imaging confirms the non-uniform distribution, with the highest conductivity, 267% increase, occurring along the center of the fibers. Hence incorporation of GNP and the subsequent alignment enables the printing or oriented thermal or conductors. In operando time-dependent small angle scattering analysis of the filament during extrusion shows the interesting correlated motion of the GNPs, which stops abruptly once the temperature is below the melting point. This confirms the gel-like state which occurs with the GNP in the iPP melt state and drives the particles along the velocity gradient in the moving nanocomposite stream.

Optimizing the Mechanical Properties of 3D Printed Binary Mixtures of PLA and Polyolefins

Yu-Chung Lin[1], Larry J. Huang[2], Richard Li[3], Addison Liu[4], Nikita Salunke[5], Zimei Du[1], Amhed Shata[1], Henry Takizawa[1], Mustafa Zaidi[1], Daniel Luo[6], Yuval Shmueli[1], Miriam H. Rafailovich[1] and Steve N. Nitodas[1]; [1]SUNY Stony Brook University, United States; [2]Wilton High Svhhol, United States; [3]Conestoga High School, United States; [4]Unionville High School, United States; [5]Evergreen Valley High School, United States; [6]Monroe-Woodbury High School, United States

Polylactic acid (PLA) is commonly used for 3D-printing, nevertheless it is characterized by poor self-adhesion. The quick cooling rate of PLA does not allow enough time for the fibers in the filament to properly penetrate across an interface and form strong polymer chains. As a result, adhesion is inhibited and the overall strength of prints is reduced, making 3D-printed

PLA a nonviable material for load bearing applications. This work aims at tackling this problem with a binary polymer blend of PLA combined with a polyolefin, more specifically high-density polyethylene (HDPE) or isotactic polypropylene (iPP). HDPE has superior self-adhesive properties to PLA and a lower surface energy than PLA. This coupled with its low glass transition temperature causes the HDPE to segregate towards the surface of the filament, forming an outer shell during extrusion. We hypothesized that a shell thickness of three radii of gyration will provide a polymer chain long enough to enhance the interpenetration of fibers between layers while keeping phase separation to a minimum. Three radii of gyration are theoretically found at a mass composition of 0.36 wt% HDPE/99.64 wt% PLA. The binary composite showing the highest improvement in mechanical properties, as compared to neat PLA, was 0.25 wt% HDPE/99.75 wt% PLA. This supports the hypothesis that the addition of a small loading of HDPE can improve the mechanical properties of a 3D-print by manipulating the polymer structure via migration of HDPE to the surface of PLA, as also verified by water contact angle measurements and secondary-ion mass spectrometry. Improved interlayer diffusion was also observed when adding low concentrations of iPP to PLA. The inherent immiscibility of PLA and iPP, as a result of the lower surface energy of the latter, allows for an enhanced filament structure: when present at low concentrations, iPP migrates to the surface of the extruded PLA matrix as well, creating a filament characterized by a PLA core and an iPP shell, as confirmed by water contact angle goniometry. Mechanical testing showed that in comparison to the pure PLA control, an optimized filament of 99 wt.% PLA/1 wt.% iPP displayed a 66% increase in toughness. Optical microscopy validated this data, revealing indistinguishable filament-to-filament interfaces in the optimized composite as opposed to pure PLA

Late News: Rheological Study of 3D Printable Thermoelectric Inorganic Materials Hyejin Ju, Jung-Eun Lee and Han Gi Chae; Ulsan National Institute of Science and Technology, Korea (the Republic of)

The thermoelectric(TE) generator is a solid-state device that directly converts the flow rate (temperature difference) into electrical energy. This TE energy transformation offers a unique solution for producing electricity from waste heat. For enhancing the efficiency of the TE generator, 3d printing method to produce TE materials are needed with geometries suitable for heat sources. Herein, in order to attain high-quality 3D printing of TE inorganic materials, a comprehensive evaluation of appropriate rheological properties and methodologies for formulating inorganic inks is required. For 3D printing, the most important feature is the thixotropy that implies time-dependent shear thinning property.
In this study, we analyzed the rheological behavior of the Bi_2Te_3-based and Cu_2Se-based TE inorganic inks to assess printability and 3D structural retention concerning the content of ion binder which has a strong electrostatic interaction among their particles. Moreover, for evaluating the thixotropy, 3D printing was imitated using a rheometer by three-interval thixotropy test (3ITT) under the nonlinear viscoelastic region.
In static state, the inks showed Bingham plot and it becomes solid like property with increasing ion binder content. Especially, the 3ITT indicated that in Bi_2Te_3 based ink without ion binder, storage modulus(G') increased dramatically when subjected to stress over the 10 Pa. It implied that the particles are aggregated and turned into unstable states. Using quantitative functions such as degree of structural deformation(De), Degree of structural recovery(Rec), we numerically examined the degree of ink recovery after high shear stress. Both inks have generally shown similar rheological characteristics. Phase stability is improved when binder content increases, but above a certain binder concentration the particle aggregation occurs, and recovery rate and printability are reduced. Thus, it is essential to find the optimum ion binder concentration of inorganic ink suitable for 3D printing. These results were able to demonstrate that ion binder of 25wt% in Bi_2Te_3-based ink and 50wt% in Cu_2Se-based ink were the optimized ion binder conditions for high-quality 3d printing TE materials.

Late News: Direct Ink Writing of Dehydrofluorinated Poly(vinylidene difluoride) to Fabricate Porous Films Beenish Imtiaz, Nick A. Shepelin, Sandra Kentish and Amanda V. Ellis; The University of Melbourne, Australia

Poly(vinylidene fluoride) (PVDF) has been used extensively as a membrane material for water treatment. It can be easily processed into porous films with high mechanical strength directly from the solution. However, the chemical instability of PVDF remains an issue, particularly in the caustic environments found during the membrane cleaning process, which consequently decreases the lifetime of PVDF membranes. Despite possessing high mechanical strength, PVDF membranes exhibit decreased applicability for low-fouling piezoelectric separation applications, owing to a low electroactive phase following deposition. For the use as piezoelectric membranes, it is important to maximize the electroactive phase, in order to produce vibrations through the application of AC voltage. Moreover, the techniques currently used to enhance the electroactive phase in PVDF, such as poling, mechanical stretching, and quenching, result in the instability and hinder high-temperature separation applications in piezoelectric PVDF membranes.
To overcome these issues, PVDF can be chemically modified to make dehydrofluorinated PVDF (dPVDF). This

modification has multiple benefits. The primary advantage of this modified material is the presence of pendant alkene moieties, which can be used for further post modification strategies to fabricate smart and reactive membranes that respond to external stimuli, such as pH, temperature or electric potential, in order to mitigate fouling. An additional advantage of this material is an increased electroactive phase relative to PVDF, which makes it a promising candidate for low-fouling piezoelectric membrane applications.
Here, for the first time, we present the fabrication of porous dPVDF films by direct ink writing (DIW) and subsequent phase inversion. The dPVDF solutions in *N,N*-dimethylacetamide (DMAc) exhibited Bingham behavior at polymer concentrations between 7 wt% and 15 wt%, and thus could be DIW to produce continuous films. The dPVDF inks (dPVDF (15 wt% in DMAc), and 5, 15, 30 wt% PVP), were subsequently DIW into continuous films, and phase inverted in deionized water (non-solvent) to produce porous films. The porosity of the dPVDF films was confirmed using helium beam ion microscopy. The presence of alkene moieties in the dPVDF and dPVDF porous films was confirmed through attenuated total reflection – Fourier transform infrared (ATR-FTIR) spectroscopy and Raman spectroscopy. An increase in electroactive phase fraction was observed in the DIW films, confirming the enhancement in piezoelectric characteristics. The DIW porous dPVDF membranes presented herein show exceptional promise for the production of piezoelectric membranes and the subsequent utilization as separation membranes in harsh environments.

Late News: Investigating and Comparing the Resistance to Tensile Testing of Molded and 3D Printed PLA/PP Polymer Blends Daniel Luo[1,2], Yu-Chung Lin[2] and Miriam H. Rafailovich[2]; [1]Monroe Woodbury High School, United States; [2]Stony Brook University, The State University of New York, United States

When 3D printing, the quick cooling rate of PLA does not allow enough time for the filament to properly diffuse across an interface[1], which inhibits adhesion and reduces the overall strength of prints. We aimed to tackle this problem by adding low concentrations of polypropylene (PP) to PLA to create a 3D-printing filament with improved interlayer diffusion.[2] Our hypothesis is when a PLA/PP blend is formed through 3D printing, PP migrates to the surface of the filaments due to its lower surface energy and lower glass transition temperature, forming a core-shell structure that produces pseudo-"self-healing"[2] by fusing fibers. Due to PP's lower surface tension compared to PLA (30.7 mN/m vs 44 mN/m)[5], PP will travel to the surface of the fibers when extruded, displacing air pockets formed when the fibers crack.[3,4] Previous testing shows that 1% PP blends are the most resistant to tensile testing, and this study seeks to determine if the PP/PLA blend produced by molding or 3D printing is more effective, and which concentration of PP is most resistant to tensile testing.
To find how the core-shell structure impacted the physical properties of the blends, the ratio of the Volume of the Shell vs. Volume of the Fiber and Shell thickness were both plotted against the Volume fraction of PP. Radius of gyration (R_g) of PLA and PP were also calculated. By using the thickness of the shell and the diameter of the fiber, the number of R_gs of PLA and PP in each core-shell sample was found.
5 groups differing in PP % by weight were used to compare which concentration of PP in a PLA/PP blend best resisted tensile testing: 0%, 0.5%, 1%, 2.5%, and 5%. After preparation, the Young's Modulus, UTS (Ultimate Tensile Strength), and Elongation at Break were analyzed. The Young's Modulus of the molded samples showed that the Pure PLA had the highest Young's Modulus, meaning that the molded samples did not exhibit "self-healing". The results for the 0.5% PP, 1% PP, 2.5 % PP, 5% PP, and Pure PLA 3D printed samples indicate that 0.5% PP has a higher Young's Modulus compared to 1% and Pure PLA, making it more reliable for 3D printing. The contact angle measurements indicate that even a small % of PP in a blend produces a contact angle similar to pure PP, meaning that adding PP lowers the surface tension of the blend, therefore in the 3D printed blends PP travels to the fibers' surface and produces "self-healing".
In conclusion, this study shows that the optimal concentrations for making a PLA/PP blend for 3D printing is 99.5% PLA/0.5% PP. It also shows that compared to the 3D printed blends, the molded blends do not strengthen the blends to the same extent during tensile testing.

Late News: A Design of 3D-Printable, Biodegradable, Flame Resistant Polymer/Clay Nanocomposite Yiwei Fang[1], Christian Apostol[2], Jiale Lu[3], Lawrence Zhao[4], Yuan Xue[1], Yichen Guo[1] and Miriam H. Rafailovich[1]; [1]Stony Brook University, United States; [2]Ward Melville High School, United States; [3]Princeton International School of Mathematics and Science, United States; [4]University Laboratory High School, United States

Here we designed a non-toxic and environmental sustainable polymer nanocomposite PLA/PBAT/APP/RDP-Clay which achieved good flame resistance and balanced mechanical properties with the addition of 3wt% ammonium phosphate (APP) and 2wt% resorcinol diphenyl phosphate (RDP)-coated montmorillonite clays (C-Na^+). Polylactic acid (PLA) received attention due to its biodegradability and mechanical properties. However, its poor impact strength and flammability largely limits its application in wide range of areas. In our previous study[1], APP was found to be rigid and made the impact strength of PLA even worse. We were able to increase the ductility without affecting flammability of the PLA/APP composite by decreasing the APP concentration to only 2 wt% with the addition of only 0.12wt%RDP. Hence, poly(butylene adipate-*co*-butylene terephthalate)(PBAT), a ductile and biodegradable polymer, is introduced to balanced impact strength. But PBAT was found to be a poor efficient carbon source in APP intumescent system. For PLA/PBAT(75/25) over 10wt% APP/RDP is required to make PLA/PBAT(75/25) resisted to combustion, while pure PLA only need 2wt%APP/RDP. The huge increase for the use of APP not only increase the cost but also sacrificing the desired impact strength. According to Contact Angle Measurement and work of adhesion (W_a) between related materials, APP is more affinity to PBAT than PLA which possibly draw part of APP into PBAT phase and decrease the overall flame retardancy. In order to minimize this effect, 2wt%RDP coated sodium clay(C-Na+) is added to reduce the interfacial energy between PLA and PBAT which decrease PBAT domain size. Compatibilization was further confirmed by observation of a 32% decrease (from 2.53μm to 1.73μm) in PBAT domain size via Scanning Electron Microscopy. With 2wt%RDP-clay into the composites, we achieved a V-0 designation with a low loading of APP(3wt%). This was attributed to the decreased PBAT domain size, increasing the efficiency of APP to decrease the heat release in the combustion at a reduced overall concentration. From Thermogravimetric Analysis (TGA) result, the reaction mechanism was confirmed by the presence of intumescent char. Which is a byproduct of the reaction in the solid state. The increased ductility below Tg and viscosity in the melt enables fiber drawing and comparison of the combustibility upon FDM printing, which will be discussed.

Tunable Elongation-at-Break of Tensile Mechanical Properties of Stereolithography Additive Manufacturing Through Control of Printing Orientations Mozah Alyammahi, Rahmat Agung Susantyoko and Tawaddod Alkindi; DEWA R&D Center, Dubai Electricity and Water Authority, United Arab Emirates

Additive manufacturing (AM) spread widely not only for prototyping but also for the production of end-use products. Quality control is a vital importance in the production of parts. One of the challenges of quality control in AM technology - such as fused deposition modeling (FDM) - is that the mechanical strength of the 3d-printed part could be anisotropic (not uniform).

The part's printing orientation could affect the mechanical strength of 3d-printed parts. Among the AM technology spectrum, the stereolithography (SLA) process is known to be able to produce parts with relatively uniform mechanical strength (isotropic).
Many studies were done using FFF 3D printing method. However, to our knowledge, only very few studies had done to investigate the effect of printing orientation on the elongation-at-break of 3d-printed parts using SLA technology. Moreover, previous studies only experimented with a limited amount of samples and orientations. Therefore, strength and elongation-at-break need to be examined in detail and with more variations of print orientation. For this purpose, this study investigated the influence of part's printing orientation to the tensile mechanical properties (tensile-stress-at-max-load, tensile-strength-at-break, tensile-stress-at-yield, young-modulus, elongation-at-break) of SLA technology. This work covered a large number of orientations (27 printing orientations) testing five different mechanical properties.
We used Form 2 3D printer to 3D print with White photopolymer resin of FLGPWH04 material. We used Preform 3.03.1 software to set the sample positions. The samples were oriented with respect to x, y, and z axes according to the software axes. Permutation-with-repetition of 3 different angles (0°, 45°, and 90°) with respect to 3 different axes resulted in 27 part's printing orientations. Furthermore, we printed 3 samples for each orientation with for a total of 81 samples for all orientations. The printed samples were washed in isopropyl alcohol (IPA) for 20 minutes. Afterward, we carefully removed the support structures from the samples using a tweezer; followed by drying and curing process at 60 °C for a total of 20 minutes (samples were flipped every 10 minutes).
We followed the ASTM D638 V standard tensile test design. Each printed sample was kept at the same time (13 days) before the tensile testing to avoid time impact on the properties. Then we performed the tensile testing using Instron 3367. In Bluehill LE 3.77 software, the sizes were entered for each sample. It took the measurements while the test was running and calculated the strain, stress, modulus, and yield. The raw data from the samples compiled in Microsoft Excel.
The results showed relatively uniform isotropy of the tensile-stress-at-max-load and it has 3.8% relative standard deviation. In addition, tensile-strength-at-break, tensile-stress-at-yield, and young-modulus has 4.15%, 5.67% and 7.94% relative standard deviation, respectively. In contrast, a relatively large anisotropy of elongation-at-break has been observed with 21% relative standard deviation. The sample printed vertically (90 degrees normal to the bed) elongated to an average of 10% whereas the sample printed horizontally (0 degrees normal to the bed) elongated to an average of 15%. One hypothesis that explains this behavior is that printing vertically created many layers comparing to printing horizontally. Thus, the high number of interfaces layers make the part elongate less. The results show that the elongation-at-break could vary and could be tuned in SLA technology; a new finding in this research field.
We recommend that the designer of SLA parts to consider the part's printing orientation depending on the possible application (whether the application requires large elongation-at-break or short elongation-at-break). By knowing the effect of printing orientation, high-quality parts could be produced consistently according to the application's requirement.

Enhanced Toughness in Ceramic-Reinforced Polymer Composites with Herringbone Architectures Robert Zando, Ataollah Mesgarnejad, Chunzhou Pan, Sandra Shefelbine, Alain Karma and Randall M. Erb; Northeastern University, United States

A common design rule in synthetic particle-filled composites is to align all reinforcing particles parallel with the primary stress and thereby perpendicular to a likely fracture. Doing so can often result in crack deflection, which is commonly touted as evidence that a material has enhanced fracture toughness. In reality, as soon as the crack deflection occurs, the material is fracturing along an "easy axis". Much better is for the crack not to deflect and be forced to propagate forward along a "hard axis" spending much more energy to grow. Geometric conditions alone can create T-stress that confine the crack to propagate straight along a hard-direction. However, real-world applications of filled composites often dictate geometric design and put toughness at risk. Instead, designed texturing of reinforcing particles has the potential to steer cracks along a "hard axis" without reliance on geometric loading conditions. Recent advances in the field of composite manufacturing techniques, make such architectures possible, allowing the creation of microstructures which can locally tune the fracture toughness anisotropy. In the studies presented, we explore a unique variant of this principle through the creation of an alignment architecture reminiscent of the spine of a herringbone fish, designed to trap a fracture along the boundary between two regions of distinct particle alignment. This robs the fracture of a preferred direction of initial fracture deflection, delaying the initiation of fracture formation, and forces it along a "hard" direction of fracture initiation, effectively raising both its initial and overall fracture resistance significantly beyond monolithically aligned composite polymer systems. However, while this custom microstructure proved successful in demonstrating this method of boosting mechanical performance over traditional monolithic systems in principle, it remains limited in application by the necessity of a fracture initiating at or near the boundary between two alignment regions. Without filling this pre-condition, the fracture would initiate in a manner similar to a monolithic alignment system.
To overcome this limitation, we applied these principles to generate a new class of beautiful herringbone mosaics that

provide isotropic toughness in 2D. This structure was composed of a series of hexagonal unit cells, further divided into a series of triangular sub-cells, each with herringbone patterns. Mechanical testing of these samples determined that this structure not only demonstrated superior initial fracture toughness to monolithic samples, but that this effect was approximately isotropic, showing superior mechanical performance over the highest performing monolithic samples regardless of the direction of the tensile force relative to the microstructure placement. In applications in which the geometric design of a particle-filled composite is constrained, texturing materials with herringbone mosaics provide a meaningful route toward boosting isotropic toughness through microstructural design alone.

Lightweight Cellular Metal Composites with Zero and Tunable Thermal Expansion Enabled by Ultrasonic Additive Manufacturing Ethan Parsons; MIT Lincoln Laboratory, United States

In aerospace applications, variations of temperature caused by changing environmental conditions or generation of heat is a common problem. The resulting thermal strains cause separation and alignment errors in optical systems, and stresses due to mismatches of thermal expansion at material interfaces cause failure of components and structures. Because minimizing weight, cost, and lead time are also critical requirements, lightweight, easily machined metals are attractive for aerospace applications, but these materials all have substantial coefficients of thermal expansion. Previous work has shown that the superposition of two metals with dissimilar coefficients of thermal expansion in periodic cellular configurations can result in a composite material with zero effective thermal expansion. However, fabrication of these material architectures typically is either impossible or requires manual assembly. Here, we propose methods to design and fabricate cellular metal composites with tunable thermal expansion and optimized specific stiffness that can be manufactured at useful scales entirely with automated methods. Samples were manufactured with ultrasonic additive manufacturing and computer-controlled machining, and thermal expansion was measured optically. The results demonstrate the practical fabrication of cellular metal composites with zero or negative thermal expansion in one direction, tunable thermal expansion in a second direction, and structural performance indices competitive with the indices of conventional aerospace alloys.

The Effects of Solidification Rates on Grain Refinement Capacity of TiC in Directionally Solidified Ti6Al4V Alloy Naoki Date[1], Shunya Yamamoto[1], Yoshimi Watanabe[2], Shizuka Nakano[3,4], Naoko Sato[3] and Shinsuke Suzuki[1,1]; [1]Waseda University, Japan; [2]Nagoya Institute of Technology, Japan; [3]National Institute of Advanced Industrial Science and Technology, Japan; [4]Henry Monitor Inc., Japan

In additive manufacturing, a titanium alloy Ti6Al4V is the most widely used and was reported to form columnar grains during process. However, columnar grains are generally regarded to be unfavorable since their presence can impart solidification defects and mechanical property anisotropy. Therefore, fine equiaxed microstructures are desired. Recently more or less 0.3vol% addition of TiC particles resulted in grain refinement of Ti6Al4V during Laser-based powder bed fusion of metals[1]. Furthermore it was clarified that TiC particles partially melted in molten Ti6Al4V and the residual TiC particles generated fine and equiaxed grains from the heterogeneous nuclei during directional solidification of Ti6Al4V[2]. Although equiaxed grains can be obtained at high solidification rates in general, the effect has not been clear in an alloy with TiC. In this study, as a fundamental research for additive manufacturing, we aimed to reveal the effects of solidification rate, which varies the amount of melted TiC and the degree of constitutional undercooling.

Ti6Al4V powder (with 2.0vol% TiC and without TiC) in a Ti6Al4V sheath was melted and directionally solidified with a floating zone melting method at various solidification rates V(=1,3,5,10,15mm/min). During the process, the temperature around the melt pool was measured using a two-color pyrometer. Microscopic images on the cross section through the center of directionally solidified samples were obtained to evaluate the numbers and equivalent diameter of the prior β grains. The area fractions of the precipitate and matrix were analyzed by an image processing software, and the carbon contents in them were analyzed by Electron Probe Micro Analyzer(EPMA) to estimate the amount of the melted TiC. Also using phase field method, microstructure evolution of Ti6Al4V during solidification was simulated and constitutional undercooling around solidification front was estimated.

From microstructural observations, the number of fine equiaxed prior β grains increased by TiC addition except at 1mm/min and the total number of grains increased as solidification rate increased. Also with TiC added microstructure, precipitation appeared in the prior β grains regardless of solidification rates. EPMA analysis results showed that the precipitation was Ti_2C and the area percentage of Ti_2C decreased with increasing solidification rate. Estimating carbon amount from Ti_2C fraction, carbon amount derived from melted TiC is 0.262 mass% at 1mm/min and 0.178 mass% at 15mm/min. Considering total carbon amount 0.270 mass% from 2.0vol% added TiC, carbon amount derived from melted TiC is smaller when

solidification rate is higher. From phase field simulation, constitutional undercooling around solidification front was larger as solidification rates increased. From above, it is considered that at a higher solidification rate, the amount of melted TiC particles is smaller, and the amount of residual potent heterogeneous nucleus TiC particles is larger at a large constitutional undercooling .

4D Printing with Elastic Hinge Using Shape Memory Polymer and Elastomer via Fused Deposition Modeling 3D Printer Shunsuke Yamamura and Eiji Iwase; Waseda University, Japan

Recently, many researchers have studied 4D printing by fused deposition modeling (FDM)-3D printer using thermoplastic material including shape memory polymer (SMP) [1]. 4D printing is 3D printing with shape-shifting-function triggered by material shrinkage and/or expansion. A conventional 4D-printed device by FDM-3D printer is, however, difficult to deform after shape-shifting, because thermoplastic material is rigid below the glass transition temperature. Therefore, a conventional 4D-printed device is not possible to use as an origami stretchable device which is deformed by origami-deformation of elastic hinges [2].

In this study, we proposed a 4D printing device with a hybrid hinge. The hybrid hinge has a structure in which a self-folding hinge made of SMP and soft hinges made of elastomer are arranged in series. By applying heat to the 3D printed device with a hybrid hinge, the self-folding hinge works to form a folded structure. The elastic deformation after self-folded can be realized not by a self-folded hinge but by soft hinges made of an elastomer with wide elastic range. In order to confirm the elasticity of hybrid hinge, we evaluated a change of folding angle when the devices were repeatedly bent. As a comparison to our proposed device with a hybrid hinge, we prepared a device without a hybrid hinge, i.e. without soft hinges. In the device without a hybrid hinge, we confirmed that the folding angle changed at one cycle bending due to plastic deformation of SMP. On the contrary, the bending angle of the device with a hybrid hinge did not change by a repetition of bending deformation. Finally, we demonstrated an origami stretchable device with multiple hybrid hinges. We fabricated miura-ori as origami stretchable device. Unlike a previous demonstration of miura-ori using 4D printing via FDM-3D printer, our fabricated device can be deformed from folded shape to deployed shape by external force even under room temperature at 25°C.

In conclusions, our proposed hybrid hinge was confirmed as an effective way to realize the 4D printing with elastic hinge. We believe that our proposed way will accelerate the development of stretchable origami device.

3D Printing of Poly-Ether-Ether-Ketone (PEEK) and Reinforced Peek Materials and Its Mechanical Properties with Post Heat Treatments Kyung-hyun Kim, Hyeon-Sik Ahn, Dong-Hwan Kim, Ae-Sun Oh and Hyun-Cheol Bae; Electronics and Telecommunications Research Institute, Korea (the Republic of)

3D printing or additive manufacturing has great attention in recent years as it allows the manufacturing of complex shapes and various geometries. Specially, these techniques have various application fields, which are making prototypes for electronics, aerospace, automotive, and so on. For 3D printing technology to be applied to electric vehicles, it needs to be light, high strength and high thermal stability. Many researchers are working on high-temperature, high-strength materials such as PEEK and composites to increase strength.
Therefore, we have designed a hybrid organic-inorganic composite material, which are glass fiber, carbon fiber, and modified PEEK, for high-temperature, high-strength materials stability. We successfully made organic-inorganic 3D printing filaments using a mini-extruder machine for fused deposition modelling (FDM) printer. Also, we studied thermal and mechanical properties of 3D printed samples with or without post heat treatment at 250oC for 1 hr. These printed samples were measured by thermal mechanical analyzer (TMA), bending strength and tensile strength with micro-universal testing machine. Surface morphology and the crystallinity of PEEK of those are measured by scanning electron microscope (SEM) and the Differential Scanning Calorimetry (DSC) method.
We will present the detailed experiment results and other analysis results for improved 3D printed samples.
This work was partly supported by the National Research Council of Science & Technology (NST) grant by the Korea

government (MSIP) (No. CRC-19-02-ETRI) and the Technology Innovation Program (No. 20005139) funded by the Ministry of Trade, Industry & Energy(MOTIE, Korea)

Synthesis of Polyetherimide(PEI)-Based Photocurable Resin for Biocompatible DLP Stereolithography 3D Printing Process Jae hwan Chung, Hee Jeong Park, Hyejin Kim and Dong hyun Lee; Dankook University, Korea (the Republic of)

3D printing, commonly known as additive manufacturing, is a manufacturing process of producing three dimensional objects having complex features through layer by layer printing. The 3D printing technique has been developed rapidly and applied to various industrial fields since it was proposed in 1980s. Even though there are many 3D printing techniques introduced so far, the photocuring 3D printing which is based on photopolymerization of photo-sensitive materials is becoming more important due to its high printing speed, high precision and smooth surface of products. However, the materials which are mainly utilized in the photocuring 3D printing often encounter limited mechanical properties which are originated from their own nature. Thus, it is necessary to design photo-sensitive materials satisfying the requirements. Recently, poly(ethylene glycol) diacrylate(PEGMA) which is commonly a highly biocompatible photocurable material is widely used in the photocuring 3D printing for biomaterials, dental materials, biomimetics, and tissue engineering and so on despite its poor mechanical and thermal properties. Thus, there are many demand to overcome the disadvantages of PEGDA and to find suitable materials for the fields. Here, we report the polyetherimide-based photocurable resin for biocompatible 3D printing. Polyetherimide(PEI) is one of engineering plastics, which has superior mechanical strength, long-term thermal stability, excellent chemical resistance and good biocompatibility. By integrating those properties of polyetherimide to advanced biocompatible 3D printing, we synthesized a polyetherimide-based photocurable resin for DLP stereolithography 3D printing. To synthesize the polyetherimide-based resin condensation reaction between dianhydrides of BPADA and diamines of 3,5-diaminobenzoic aicd under the nitrogen flow are conducted to produce amic acid groups in chain backbones and chain ends. As thermal imidization of the reactants is then proceeded in sequential 3 steps of 60°C for 2 hours, 110°C for 2hours and 205°C for 4 hours, the amic acid groups are successfully converted to imide linkages. It is noted that the carboxylic acid of diamono acid are still remained after the imidization. After cooling down to the 30°C, glycidil methacrylate (GMA) is additionally grafted to the PEI molecules by the reaction with the carboxylic acids in presence of tetraethylammonium bromide (TEAB), triethylamine and hydroquinone under the nitrogen flow of 100°C. The GMA groups impart the photochemical reactivity to in the PEI molecules. After the precipitation in distilled water and filtration, PEI-g-GMA powder is obtained and dried in vacuum oven at 40°C for 24hours. To prepare the photocurable resin for 3D printing, the synthesized PEI-g-GMA is mixed with crosslinkers(PEGDA), reactive diluents(1-vinyl-2-pyrrolidinone(NVP) and photo initiators(Igarure819®). To test the biocompatible property of our resins, three dimensional specimens are printed with the photocurable resins prepared here, by precisely adjusting light dosage and compositions of the mixtures. It is found that the specimens are printed in 0.4 seconds of exposure time and 30 μm of layer thickness. The printed specimens are rinsed with isopropanol and post-cured in a UV light chamber. The photocurable resin and the printed specimens are characterized by using universal test machine(UTM), differential scanning calorimeter(DSC), thermal gravimetric analysis(TGA), FT-IR and H^1-NMR spectroscopy. In addition, the molecular weight of PEI-g-GMA is estimated by end group analysis based on H^1-NMR data.

***In Situ* Microbeam X-Ray Scattering and Infra-Red Imaging of Polypropylene/Graphene Nanoplatelet Nanocomposites During Additive Manufacturing** Yu-Chung Lin[1], Aniket M. Raut[1], Yuval Shmueli[1], Steve N. Nitodas[1], Guillaume Freychet[2], Mikhail Zhernenkov[2] and Miriam H. Rafailovich[1]; [1]SUNY Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

The fused deposition modeling (FDM) is an advanced 3D printing technique in which the thermoplastic polymer is melted and extruded by the shear force coming from the nozzle to create layer by layer structure according to the user input file. Compared to the conventional molding, a major challenge of the FDM process is the highly nonequilibrium thermal gradients that impact the filament fusion and the thermo-mechanical and electrical integrity of the materials produced. Furthermore, since these gradients are poorly understood, tructure/property models predicting the outcome of printing have been difficult to establish. In order to visualize the gradients, while probing the internal structure of the printed samples, we designed an apparatus which can simultaneously profile both macrostructure and microstructure during printing, as a function of time, using synchrotron X-ray scattering, and together with infrared thermal imaging. This information is then combined with Raman spectroscopy, rheology, and DMA studies, in order to understand the evolution of the internal structure and its corresponding influence on the properties of the materials. We had previously applied these techniques to crystalline polymers, PLA and iPP [1]. Here, we extend these measurements to the study of the internal structure of FDM printed Polypropylene (PP)/Graphene Nanoplatelet (GNPs) nanocomposites. Micro-beam wide-angle scattering analysis showed that

the GNPs cluster towards the center of the filament during extrusion from the nozzle when the GNP concentration is higher than 10%. Previous studies had demonstrated that iPP interacts strongly with graphene [2], and hence the segregation of the GNP away from the interface facilitates chain diffusion across the interfaces, consistent with the high impact toughness observed. Thermal imaging confirms the non-uniform distribution, with the highest conductivity, 267% increase, occurring along the center of the fibers. Hence incorporation of GNP and the subsequent alignment enables the printing or oriented thermal or conductors. In operando time-dependent small angle scattering analysis of the filament during extrusion shows the interesting correlated motion of the GNPs, which stops abruptly once the temperature is below the melting point. This confirms the gel-like state which occurs with the GNP in the iPP melt state and drives the particles along the velocity gradient in the moving nanocomposite stream.

Optimizing the Mechanical Properties of 3D Printed Binary Mixtures of PLA and Polyolefins Yu-Chung Lin[1], Larry J. Huang[2], Richard Li[3], Addison Liu[4], Nikita Salunke[5], Zimei Du[1], Amhed Shata[1], Henry Takizawa[1], Mustafa Zaidi[1], Daniel Luo[6], Yuval Shmueli[1], Miriam H. Rafailovich[1] and Steve N. Nitodas[1]; [1]SUNY Stony Brook University, United States; [2]Wilton High Svhhol, United States; [3]Conestoga High School, United States; [4]Unionville High School, United States; [5]Evergreen Valley High School, United States; [6]Monroe-Woodbury High School, United States

Polylactic acid (PLA) is commonly used for 3D-printing, nevertheless it is characterized by poor self-adhesion. The quick cooling rate of PLA does not allow enough time for the fibers in the filament to properly penetrate across an interface and form strong polymer chains. As a result, adhesion is inhibited and the overall strength of prints is reduced, making 3D-printed PLA a nonviable material for load bearing applications. This work aims at tackling this problem with a binary polymer blend of PLA combined with a polyolefin, more specifically high-density polyethylene (HDPE) or isotactic polypropylene (iPP). HDPE has superior self-adhesive properties to PLA and a lower surface energy than PLA. This coupled with its low glass transition temperature causes the HDPE to segregate towards the surface of the filament, forming an outer shell during extrusion. We hypothesized that a shell thickness of three radii of gyration will provide a polymer chain long enough to enhance the interpenetration of fibers between layers while keeping phase separation to a minimum. Three radii of gyration are theoretically found at a mass composition of 0.36 wt% HDPE/99.64 wt% PLA. The binary composite showing the highest improvement in mechanical properties, as compared to neat PLA, was 0.25 wt% HDPE/99.75 wt% PLA. This supports the hypothesis that the addition of a small loading of HDPE can improve the mechanical properties of a 3D-print by manipulating the polymer structure via migration of HDPE to the surface of PLA, as also verified by water contact angle measurements and secondary-ion mass spectrometry. Improved interlayer diffusion was also observed when adding low concentrations of iPP to PLA. The inherent immiscibility of PLA and iPP, as a result of the lower surface energy of the latter, allows for an enhanced filament structure: when present at low concentrations, iPP migrates to the surface of the extruded PLA matrix as well, creating a filament characterized by a PLA core and an iPP shell, as confirmed by water contact angle goniometry. Mechanical testing showed that in comparison to the pure PLA control, an optimized filament of 99 wt.% PLA/1 wt.% iPP displayed a 66% increase in toughness. Optical microscopy validated this data, revealing indistinguishable filament-to-filament interfaces in the optimized composite as opposed to pure PLA

Late News: Rheological Study of 3D Printable Thermoelectric Inorganic Materials Hyejin Ju, Jung-Eun Lee and Han Gi Chae; Ulsan National Institute of Science and Technology, Korea (the Republic of)

The thermoelectric(TE) generator is a solid-state device that directly converts the flow rate (temperature difference) into electrical energy. This TE energy transformation offers a unique solution for producing electricity from waste heat. For enhancing the efficiency of the TE generator, 3d printing method to produce TE materials are needed with geometries suitable for heat sources. Herein, in order to attain high-quality 3D printing of TE inorganic materials, a comprehensive evaluation of appropriate rheological properties and methodologies for formulating inorganic inks is required. For 3D printing, the most important feature is the thixotropy that implies time-dependent shear thinning property.
In this study, we analyzed the rheological behavior of the Bi_2Te_3-based and Cu_2Se-based TE inorganic inks to assess printability and 3D structural retention concerning the content of ion binder which has a strong electrostatic interaction among their particles. Moreover, for evaluating the thixotropy, 3D printing was imitated using a rheometer by three-interval thixotropy test (3ITT) under the nonlinear viscoelastic region.
In static state, the inks showed Bingham plot and it becomes solid like property with increasing ion binder content. Especially, the 3ITT indicated that in Bi_2Te_3 based ink without ion binder, storage modulus(G') increased dramatically when subjected to stress over the 10 Pa. It implied that the particles are aggregated and turned into unstable states. Using

quantitative functions such as degree of structural deformation(De), Degree of structural recovery(Rec), we numerically examined the degree of ink recovery after high shear stress. Both inks have generally shown similar rheological characteristics. Phase stability is improved when binder content increases, but above a certain binder concentration the particle aggregation occurs, and recovery rate and printability are reduced. Thus, it is essential to find the optimum ion binder concentration of inorganic ink suitable for 3D printing. These results were able to demonstrate that ion binder of 25wt% in Bi_2Te_3-based ink and 50wt% in Cu_2Se-based ink were the optimized ion binder conditions for high-quality 3d printing TE materials.

F.SF05.07.19

Late News: Direct Ink Writing of Dehydrofluorinated Poly(vinylidene difluoride) to Fabricate Porous Films Beenish Imtiaz, Nick A. Shepelin, Sandra Kentish and Amanda V. Ellis; The University of Melbourne, Australia

Poly(vinylidene fluoride) (PVDF) has been used extensively as a membrane material for water treatment. It can be easily processed into porous films with high mechanical strength directly from the solution. However, the chemical instability of PVDF remains an issue, particularly in the caustic environments found during the membrane cleaning process, which consequently decreases the lifetime of PVDF membranes. Despite possessing high mechanical strength, PVDF membranes exhibit decreased applicability for low-fouling piezoelectric separation applications, owing to a low electroactive phase following deposition. For the use as piezoelectric membranes, it is important to maximize the electroactive phase, in order to produce vibrations through the application of AC voltage. Moreover, the techniques currently used to enhance the electroactive phase in PVDF, such as poling, mechanical stretching, and quenching, result in the instability and hinder high-temperature separation applications in piezoelectric PVDF membranes.
To overcome these issues, PVDF can be chemically modified to make dehydrofluorinated PVDF (dPVDF). This modification has multiple benefits. The primary advantage of this modified material is the presence of pendant alkene moieties, which can be used for further post modification strategies to fabricate smart and reactive membranes that respond to external stimuli, such as pH, temperature or electric potential, in order to mitigate fouling. An additional advantage of this material is an increased electroactive phase relative to PVDF, which makes it a promising candidate for low-fouling piezoelectric membrane applications.
Here, for the first time, we present the fabrication of porous dPVDF films by direct ink writing (DIW) and subsequent phase inversion. The dPVDF solutions in *N,N*-dimethylacetamide (DMAc) exhibited Bingham behavior at polymer concentrations between 7 wt% and 15 wt%, and thus could be DIW to produce continuous films. The dPVDF inks (dPVDF (15 wt% in DMAc), and 5, 15, 30 wt% PVP), were subsequently DIW into continuous films, and phase inverted in deionized water (non-solvent) to produce porous films. The porosity of the dPVDF films was confirmed using helium beam ion microscopy. The presence of alkene moieties in the dPVDF and dPVDF porous films was confirmed through attenuated total reflection – Fourier transform infrared (ATR-FTIR) spectroscopy and Raman spectroscopy. An increase in electroactive phase fraction was observed in the DIW films, confirming the enhancement in piezoelectric characteristics. The DIW porous dPVDF membranes presented herein show exceptional promise for the production of piezoelectric membranes and the subsequent utilization as separation membranes in harsh environments.

F.SF05.07.20

Late News: Investigating and Comparing the Resistance to Tensile Testing of Molded and 3D Printed PLA/PP Polymer Blends Daniel Luo[1,2], Yu-Chung Lin[2] and Miriam H. Rafailovich[2]; [1]Monroe Woodbury High School, United States; [2]Stony Brook University, The State University of New York, United States

When 3D printing, the quick cooling rate of PLA does not allow enough time for the filament to properly diffuse across an interface[1], which inhibits adhesion and reduces the overall strength of prints. We aimed to tackle this problem by adding low concentrations of polypropylene (PP) to PLA to create a 3D-printing filament with improved interlayer diffusion.[2] Our hypothesis is when a PLA/PP blend is formed through 3D printing, PP migrates to the surface of the filaments due to its lower surface energy and lower glass transition temperature, forming a core-shell structure that produces pseudo-"self-healing"[2] by fusing fibers. Due to PP's lower surface tension compared to PLA (30.7 mN/m vs 44 mN/m)[5], PP will travel to the surface of the fibers when extruded, displacing air pockets formed when the fibers crack.[3,4] Previous testing shows that 1% PP blends are the most resistant to tensile testing, and this study seeks to determine if the PP/PLA blend produced by molding or 3D printing is more effective, and which concentration of PP is most resistant to tensile testing.
To find how the core-shell structure impacted the physical properties of the blends, the ratio of the Volume of the Shell vs. Volume of the Fiber and Shell thickness were both plotted against the Volume fraction of PP. Radius of gyration (R_g) of PLA and PP were also calculated. By using the thickness of the shell and the diameter of the fiber, the number of R_gs of PLA and PP in each core-shell sample was found.

5 groups differing in PP % by weight were used to compare which concentration of PP in a PLA/PP blend best resisted tensile testing: 0%, 0.5%, 1%, 2.5%, and 5%. After preparation, the Young's Modulus, UTS (Ultimate Tensile Strength), and Elongation at Break were analyzed. The Young's Modulus of the molded samples showed that the Pure PLA had the highest Young's Modulus, meaning that the molded samples did not exhibit "self-healing". The results for the 0.5% PP, 1% PP, 2.5 % PP, 5% PP, and Pure PLA 3D printed samples indicate that 0.5% PP has a higher Young's Modulus compared to 1% and Pure PLA, making it more reliable for 3D printing. The contact angle measurements indicate that even a small % of PP in a blend produces a contact angle similar to pure PP, meaning that adding PP lowers the surface tension of the blend, therefore in the 3D printed blends PP travels to the fibers' surface and produces "self-healing".
In conclusion, this study shows that the optimal concentrations for making a PLA/PP blend for 3D printing is 99.5% PLA/0.5% PP. It also shows that compared to the 3D printed blends, the molded blends do not strengthen the blends to the same extent during tensile testing.

Late News: A Design of 3D-Printable, Biodegradable, Flame Resistant Polymer/Clay Nanocomposite Yiwei Fang[1], Christian Apostol[2], Jiale Lu[3], Lawrence Zhao[4], Yuan Xue[1], Yichen Guo[1] and Miriam H. Rafailovich[1]; [1]Stony Brook University, United States; [2]Ward Melville High School, United States; [3]Princeton International School of Mathematics and Science, United States; [4]University Laboratory High School, United States

Here we designed a non-toxic and environmental sustainable polymer nanocomposite PLA/PBAT/APP/RDP-Clay which achieved good flame resistance and balanced mechanical properties with the addition of 3wt% ammonium phosphate (APP) and 2wt% resorcinol diphenyl phosphate (RDP)-coated montmorillonite clays (C-Na^+). Polylactic acid (PLA) received attention due to its biodegradability and mechanical properties. However, its poor impact strength and flammability largely limits its application in wide range of areas. In our previous study[1], APP was found to be rigid and made the impact strength of PLA even worse. We were able to increase the ductility without affecting flammability of the PLA/APP composite by decreasing the APP concentration to only 2 wt% with the addition of only 0.12wt%RDP. Hence, poly(butylene adipate-*co*-butylene terephthalate)(PBAT), a ductile and biodegradable polymer, is introduced to balanced impact strength. But PBAT was found to be a poor efficient carbon source in APP intumescent system. For PLA/PBAT(75/25) over 10wt% APP/RDP is required to make PLA/PBAT(75/25) resisted to combustion, while pure PLA only need 2wt%APP/RDP. The huge increase for the use of APP not only increase the cost but also sacrificing the desired impact strength. According to Contact Angle Measurement and work of adhesion (W_a) between related materials, APP is more affinity to PBAT than PLA which possibly draw part of APP into PBAT phase and decrease the overall flame retardancy. In order to minimize this effect, 2wt%RDP coated sodium clay(C-Na+) is added to reduce the interfacial energy between PLA and PBAT which decrease PBAT domain size. Compatibilization was further confirmed by observation of a 32% decrease (from 2.53μm to 1.73μm) in PBAT domain size via Scanning Electron Microscopy. With 2wt%RDP-clay into the composites, we achieved a V-0 designation with a low loading of APP(3wt%). This was attributed to the decreased PBAT domain size, increasing the efficiency of APP to decrease the heat release in the combustion at a reduced overall concentration. From Thermogravimetric Analysis (TGA) result, the reaction mechanism was confirmed by the presence of intumescent char. Which is a byproduct of the reaction in the solid state. The increased ductility below Tg and viscosity in the melt enables fiber drawing and comparison of the combustibility upon FDM printing, which will be discussed.

We gratefully acknowledge support from the Louis Morin Charitable Trust.

Construction of an EAM Type Inter-Atomic Potential Model for Describing Metallic Polytype Structures Shinya Ogane[1], Taku Miyakawa[2,1] and Koji Moriguchi[1,2]; [1]Graduate School of Environmental Studies, Tohoku University, Japan; [2]R&D Laboratories, Nippon Steel Corporation, Japan

Polytypism is a special case of polymorphism when the two polymorphs differ only in the stacking of identical two-dimensional sheets or layers. The polytypes are characterized by a stacking sequence with a given repeating unit along a directional axis (c-axis) and are theoretically possible to have endless permutations of the sequences. Among these polytypes, the crystalline systems composed of close-packed (CP) layers have especially attracted attention on their fundamental and technological properties for many years. While these polytypes are often experimentally observed in wide-bandgap semiconductors, SiC systems are particularly known to show several hundred polytypes [1]. Since some SiC polytypes located around the ground state are energetically degenerated with about $\Delta T = 2K$ [1], it is difficult to control the phase stability during the growth of single crystals with the desired stacking polymorphism. For this reason, a variety of physical perspectives are being investigated in order to establish better single crystal growing techniques [2, 3]. In addition, the long period stacking ordered (LPSO) Mg alloys with light weight, high specific strength, and high heat resistance are also recently drawing attention as a metallic system with similar polytypism to that in SiC [4, 5].

We have proposed a computational method coupled with three theoretical tools (PGA: polytype generation algorithm; FPC-DFT: first-principles calculations based on the density functional theory; and ANNNI: axial next-nearest-neighbor Ising model), which can make us possible to efficiently investigate the structural energetics for diverse nonequivalent polytypes [1]. In our recent study [5], we have systematically evaluated the static energetics of metallic polytypes for a wide variety of elements based on the same computational method proposed by the authors [1]. For all these elemental systems, the atomistic geometry, energetics, and electronic structure for all polytypes with up to the periodic stacking length of L=13 (165 kinds of polytypes in total) have been carefully calculated based on the DFT within the GGA [5]. Using the ANNNI model extracted from the GGA calculations, we have shown from the perspective of static structural energetics that the interlayer interaction among CP layers is one of the important factors for the polytype formation [5].

Not only the static energetics but also the dynamical aspect generally affects the polytype selection during the crystal growth processes [2, 3]. It is, therefore, important to elucidate the polytype formation mechanism from the viewpoint of dynamics associated. Since the molecular dynamics (MD) simulations have become a powerful computational tool to understand and predict the structural, thermodynamic and dynamic properties of materials, the direct MD observation of dynamical aspects for the polytype growth is expected to greatly advance our understanding on the polytype selection. While the state-of-the-art potentials are often fitted to many databases including a large set of atomic configurations calculated by FPC-DFT [6], we have found that the potential models proposed so far cannot describe the accurate polytypes energetics. In the present study, we are, therefore, developing an Embedded Atom Method (EAM) type potential [6] which can be used for the dynamical simulations of metallic polytype structures focusing on the lanthanum (La) system. The basic properties and transferability of the EAM type potential model constructed in the present work will be discussed.

Phase Equilibria and Crystal Structures of Highly Ordered Intermetallic Compounds of Fe_2Al_5 Phases with the Framework Structure of η-Fe_2Al_5 Phase Tetsuya Hamada, Ryutaro Sakai, Kodai Niitsu and Haruyuki Inui; Kyoto University, Japan

Hot dipped Zn-Al alloy coated steel is widely used in the field of automobile. It is well known that the coated layer is mainly composed of the Fe_2Al_5 intermetallic compound. This compound has been considered to be the orthorhombic η phase (space

group *Cmcm*). On the other hand, our group has recently found that the layer phase often crystallizes into highly ordered atomic arrangement most likely termed as the η''' phase even during short-term dipping. Besides, recent researches address there exists several ordered phases similar to the η''' phase with the framework structure of η phase[1]. According to Burkhardt's study[2], the η phase is composed of a full occupied framework structure (4 Fe and 8 Al atoms) and partially occupied chains along the *c*-axis (6 Al sites). The *c*-axis chain is considered to allow chemical tenability and various kinds of atomic orderings; the formation of various kinds of ordered phases is considered to be responsible for how Fe and Al atoms order in the *c*-axis chain sites. However, the crystal structures of some of these ordered phases are still controversial and phase equilibrium among them are not consolidated.
In this study, we have examined the phase equilibrium among these phases and refined their crystal structures. Experiments are carried out with scanning electron microscope, energy dispersive spectroscopy, X-ray diffraction, transmission electron microscope, scanning transmission electron microscope and synchrotron X-ray diffraction. There are some invariant reactions : the η phase is found to dissolve into the η''' and η^m phases at around 350 °C while the η phase has been thought to be stable at low temperature. Some of the other phases are found to have highly ordered long-period structures with periodic antiphase boundaries.

ANNNI Model Descriptions on Structural Energetics for a Wide Variety of Metallic Polytypes Composed of Close-Packed Layers Koji Moriguchi[1,2], Taku Miyakawa[2,1], Shinya Ogane[1], Kazumasa Tsutsui[2] and Yuta Tanaka[2]; [1]Tohoku University, Japan; [2]Nippon Steel Corporation, Japan

The local inhomogeneity such as defect, surface, interface, and nanostructure often assumes an important role for developing sophisticated materials since the functionalities of materials usually originate from the spatial inhomogeneity in the associated systems. In this work, among the many phenomena related to inhomogeneity in materials, we will report our computational research on the phenomenon called "Polytypism". Polytypism is a special case of polymorphism where two polymorphs differ only in the stacking sequences of the same two-dimensional sheets or layers.

Many crystalline compounds can be considered to be composed of one or more structural units. When these units can be stacked in different ways to form stable or metastable phases, the resulting phases are known as polytypes. Among the polytypes for these compounds, the silicon carbide (SiC) systems have been the most attractive and motivated tremendous amounts of theoretical and experimental investigations on their fundamental and technological properties for many years. Many SiC polytypes located around the ground state have been found to be energetically degenerated with energy of about $\Delta T = 2K$ [1]. It is, therefore, very difficult to control the phase stability during the growth of a single crystal in order to obtain the desired stacking polytype in SiC systems. For this reason, a variety of physical perspectives are being investigated in order to establish better single crystal growing techniques [2]. In addition, the long period stacking ordered (LPSO) Mg alloys with light weight, high specific strength, and high heat resistance are also recently drawing attention as a metallic system with similar polytypism to that in SiC [3]. For both systems, the physical mechanism behind polytype selection is not yet fully understood and remains challenging issues to be solved.

In this situation, we have proposed a computational method coupled with three theoretical tools (PGA: polytype generation algorithm; FPC-DFT: first-principles calculations based on the density functional theory; and ANNNI: axial next-nearest-neighbor Ising model), which can make us possible to efficiently investigate the structural energetics for diverse nonequivalent close-packed(CP) polytypes [1, 4]. In the present work, the static energetics of a wide variety polytypes for 17 kinds of metallic elements (M=Be, Mg, Sc, Y, Co, Zn, Cu, Ag, Au, Ni, Pd, Pt, Al, Ca, Sr, Ba, and La) is systematically evaluated based on the same computational method proposed by the authors [1, 4]. For all these elemental systems, the atomistic geometry, energetics, and electronic structure for all polytypes with up to the periodic stacking length of L=13 (165 kinds of polytypes in total) have been carefully calculated based on the DFT within the GGA. The equilibrium theories based on the ANNNI model that is well known in the field of statistical mechanics have played an efficient role in the study of the origins of polytypism [5, 6]. In this work, the ANNNI model including interactions up to the third-nearest neighbor layer with the four-spin term [6] is adopted for the systems considered. Using the ANNNI model extracted from the GGA calculations, we will describe the inter-layer interactions, the phase diagrams of ANNNI model with interactions up to third-nearest neighbor, and the stability of stacking faults for each element. The relation to polytypism in the metallic systems considered will be also discussed.

Microstructure Characterization of As-Cast and Directionally Solidified Near-Eutectic Mo–Si–B Alloys Linye Zhu[1], Shuntaro Ida[1], Georg Hasemann[2], Manja Krueger[2] and Kyosuke Yoshimi[1]; [1]Tohoku University, Japan; [2]Otto-von-Guericke University Magdeburg, Germany

Mo–Si–B-based alloys have been developed as ultrahigh temperature material candidates for high-pressure turbine blades. Recently, Hasemann et al. reported that a Mo–Si–B alloy with Mo_{ss} + T_2 + Mo_3Si eutectic prepared by directional solidification (DS) has substantially improved creep resistance compared with a powder metallurgy (PM) processed alloy. It was found that a homogenous microstructure with preferentially orientated grains through DS can ameliorate mechanical performance, however, the effect of DS on the microstructure evolution of Mo–Si–B alloy is still not clear. In this study, phase constitution and microstructure of as-cast and directionally solidified near-eutectic Mo–Si–B alloys are investigated to clarify the microstructure evolution caused by DS.
Alloys with the nominal composition of Mo–17Si–7B (at.%) corresponding to the Mo_{ss} + T_2 + Mo_3Si eutectic point were prepared by arc-melting (as-cast alloy) and crucible-free zone melting (directionally solidified alloy) in an Ar atmosphere. The microstructure of the as-cast alloy consisted of primary Mo_{ss} dendrites and two eutectics of Mo_3Si + T_2 and Mo_{ss} + Mo_3Si + T_2 in cellular or dendritic growth, while the directionally solidified alloy was almost composed of a uniform and well-aligned Mo_{ss} + Mo_3Si + T_2 eutectic phase in cellular growth. The electron backscatter diffraction (EBSD) results showed that in the as-cast alloy only <100> orientation of the T_2 phase preferentially grew along the solidification direction while the other Mo_{ss} and Mo_3Si phases had no apparent orientation. However, the <001> growth direction of Mo_3Si phase parallel to the solidification direction became much stronger by the directional solidification. The coupled growth of <001>Mo_{ss}//<100>T_2//<001>Mo_3Si in the directionally solidified alloy presumably had an effect on the mechanical properties because of the texture. No habit relationship between the phases was found in both alloys possibly because the lattice parameters of constituent phases are greatly different and the system cannot minimize interfacial energy by atomic arrangement.

Energy Barrier of the Initial Stage Microstructure Formation in Martensitic Transformation of TiNi Shape Memory Alloy Kazuya Nagahira, Takeshi Teramoto and Katsushi Tanaka; Kobe University, Japan

The self-accommodation microstructure, which is the martensitic microstructure of the shape memory alloy, is constructed by a plate-like martensite variant. Recently, formation process of the self-accommodation microstructure during the martensitic transformation have been reported in the several shape memory alloy systems. In TiNi shape memory alloy, specific variant pairs including {11−1} type-I twinning interface are frequently observed in the initial stage of martensitic transformation. In this study, we refer the variant pair that formed in the initial stage of martensitic transformation as initial stage microstructure (ISM). This result suggests that there is a selection rule for the self-accommodation microstructure in the initial stage of martensitic transformation. The selection rule of ISM is important for understanding self-accommodation microstructure because it represents a mechanism of variant selection in the absence of the influence of other variants. In the present study, we have performed evaluations of energy barrier of the formation of ISM in order to elucidate the factors that determine the selection rule of ISM in TiNi shape memory alloy.
The energy barrier of the formation of ISM is the sum of the interfacial energy of the twin interface included in ISM and the elastic strain energy for the ISM formation. In the TiNi shape memory alloy, 8 types of twin orientation relations and corresponding variant pairs exist. It is considered that the variant pair with the smallest energy barrier is selectively formed as ISM. The interfacial energy of twin interface was evaluated by the first-principles calculation using VASP (Vienna Ab initio Simulation Package) code. The elastic interaction energy to form a variant pair was evaluated by a micro-mechanics proposed by Eshelby.
Since interfacial energy of {11−1} type-I twin and elastic interaction energy of the variant pair including {11−1} type-I twin are relatively small among the twin interfaces considered, it is supposed that the energy barrier of the variant pair including {11−1} type-I twin is smaller than others. These results indicate suggests that the variant pair with a small energy barrier is selectively formed as the initial stage of martensitic transformation.

Transient Liquid Phase Bonding of Bi-Ni Intermetallics for High-Temperature Electronics Hamid Fallahdoost and Junghyun Cho; State University of New York at Binghamton, United States

Transient liquid phase bonding (TLPB) has been used as a bonding process that joins dissimilar materials by employing an interlayer that provides a lower melting process. It shows the potential to be used in high temperature electronics (operated or exposed over 200°C), where there are no clear lead (Pb)-free solder options available. During the reflow process for electronics components, the interlayer melts and the constituents of the interlayer and its joining materials diffuse each other, subsequently making a homogenous intermetallic bond via isothermal solidification. Once formed, it results in a higher melting point than the bonding temperature. This research investigates such a TLPB system made of a nickel (Ni) bonding surface and a bismuth (Bi) interlayer, which can serve as a Pb-free solder alternative for high-temperature electronics. Upon melting of Bi on Ni, intermetallic phases (Bi_3Ni, BiNi) nucleate and grow by consuming a Ni layer on the substrate or the die side. Intermetallic reactions and microstructure developments were studied under various reflow conditions including temperature and time on three sets of the sandwiched assemblies: 1) Si die Sputtered Ni (1 μm-thick)/Bi/Si die; 2) Si die/Bi/Ni foil (0.5 mm-thick); 3) Ni foil/Bi/Ni foil. As such bonds constitute the structural joints in electronic packaging, mechanical properties of the intermetallic bonds and their long-term microstructural developments under high temperature aging and thermal cycling (-55°C to 200°C) were investigated by shear testing and cross-sectional microstructure analyses of the sandwiched samples. It was shown that temporal evolution of two intermetallic phases composed of faster Bi_3Ni and slower BiNi, along with the remaining Bi, are responsible for mechanical performances of TLPB. This presentation will also discuss about optimal microstructure development for the TLPB, which is critical to offset the defects and brittleness of the intermetallic phases.

Microstructure and Crystallographic Orientation Relationships in Directionally Solidified $NbSi_2/Nb_5Si_3$ Eutectic Composites with Mo Addition Haruka Uemura, Kosei Takeda, Kyosuke Kishida and Haruyuki Inui; Kyoto University, Japan

Eutectic composites composed of intermetallics and/or ceramics with very high eutectic temperatures have been considered as attractive materials for ultra-high temperature structural applications because of their high melting temperature, high structural stability and good mechanical properties. Recently, we have systematically investigated microstructure-property relationship of $MoSi_2/Mo_5Si_3$ eutectic composites with very high eutectic temperature of 1900 °C and have revealed that their high-temperature strength and room-temperature fracture toughness can be improved simultaneously by optimization of microstructure and interface properties through controlling growth condition and ternary/quaternary alloying. These previous results open a new possibility to develop novel structural materials endowed with excellent high-temperature strength and good room-temperature fracture toughness by utilizing interphase boundaries. In the present study, we focused on $NbSi_2/Nb_5Si_3$ eutectic composites (eutectic temperature ~1900 °C for binary) as a new target system and investigated microstructure variation of directionally solidified (DS) ingots of the eutectic composites as a function of ternary Mo addition. When Mo is alloyed more than 2 at. %, DS ingots are conformed to composed of C40-$(Nb,Mo)Si_2$ and $D8_m$-$(Nb,Mo)_5Si_3$, which indicates that the $D8_m$ (high temperature) to $D8_l$ (low temperature) phase transformation that occurs in binary Nb_5Si_3, is suppressed by the Mo addition. A fine eutectic microstructure of the so-called script-lamellar type, which is similar to those observed in $MoSi_2/Mo_5Si_3$ DS eutectic composites, is confirmed to develop for the Mo-alloyed $NbSi_2/Nb_5Si_3$ DS eutectic composites. Crystallographic orientation relationships between C40 and $D8_m$ phases as well as their preferential growth directions are identified by electron backscattered diffraction (EBSD) in scanning electron microscopy and transmission electron microscopy (TEM).

Evaluation of Mechanical Properties for Constituent Phases by Nano-indentation Method in γ-TiAl Alloys Sota Taniguchi, Yotaro Okada, Ryosuke Yamagata, Hirotoyo Nakashima and Masao Takeyama; Tokyo Institute of Technology, Japan

Nano-indentation method is a powerful tool to evaluate the mechanical properties of each phase in materials consisting of multi-phase microstructures. If the mechanical properties of each phase can be evaluated correctly, then we can predict the mechanical properties of bulk materials having different amounts of the phases, which would allow us to construct the design principle for materials integration (MI) to solve invers problems. However, there are a number of factors affecting the properties by this method, since the machine is so sensitive to the specimen itself such as surface conditions, as well as the machine itself such as specimen set-ups and tip of the indenters. In this study, titanium aluminide alloys were selected to evaluate the mechanical properties of the constituent phases since the alloys consists of three phases of b-Ti (bcc), a_2-Ti_3Al

($D0_{19}$ with hcp based) and g-TiAl ($L1_0$ with fcc based). In addition, we recently revealed that the introduction of an appropriate amount of the b phase is effective in improving the fracture toughness as well as tensile properties. Thus, it is very important to build up the mechanical property database for each phase in equilibrium each other in order to construct the construction of MI platform for inverse problems. The alloy studies are Ti-Al-Cr ternary alloys. These alloys were homogenized first in the b single phase region, and then heat treated in the three-phase region at 1173 K to reach the equilibrium state, based on our phase diagram study. The specimens were mechanically polished, followed by electro-polishing. Before and after the indentation test, the microstructure and orientation analysis of each phase were performed by FE-SEM and EBSD. Nano-indentation tests were performed to evaluate the Young's modulus and hardness using a continuous stiffness measurement (CSM) method with a frequency of 110 Hz using a Berkovich type indenter made of diamond. The advantage of the CSM method allows us to evaluate the properties continuously as a function of indentation depth. The results were compared with those obtained from the Oliver-Pharr method. Both properties are found to be sensitive to the indentation depth and sampling distance, depending on the phases as well as orientation. The details of the appropriate conditions will be discussed, in conjunction with the O-P method. This work was supported by Council for Science, Technology and Innovation (CSTI), Cross-ministerial Strategic Innovation Promotion Program (SIP), "Material Integration" for revolutionary design system of structural materials.

F.SF07.06.09
Effect of Si in Solution on the Crystal Structure of σ Phase (*tP*30) in Fe-Cr Binary Alloys Eitaro Maeda and Masao Takeyama; Tokyo Institute of Technology, Japan

FeCr-σ with a crystal structure of *tP*30 (ordered tetragonal phase) is one of the TCP phases and often observed in heat resistant materials. This phase is considered as a harmful phase to deteriorate mechanical properties of the materials. However this phase could be a strengthening phase, just like Laves phase, if the phase stability can be increased by alloying. In the previous study, we have found that the lattice parameters of both *a* and *c* become either larger or smaller by the addition of M in solution, depending on the size of atomic radius of M relative to those of Fe (r_{Fe}=1.274 Å) and Cr (r_{Cr}=1.282 Å) as usual, except Fe addition. In case of the excess addition of Fe in solution, the *a* axis becomes smaller whereas the *c* axis becomes larger. We attributed the unusual anisotropic lattice parameter change to the site occupancy change in five sub-lattice sites (M1, M2, M3, M4, M5) of the σ phase, based on the Rietveld analysis; the occupancy of Cr atom in M5 sub-lattice site increase with increasing excess Fe atoms. In this study, we picked up non-transition element Si as the third element since it has larger atomic radius (r_{Si}=1.322 Å) and is known as strong σ stabilizer, and investigated the lattice parameter change with Si in solution.
The alloys studies are Fe-(50-x/2)Cr-xSi (at. %) where x=5, 10. They were prepared by arc melting to 30g button ingot, and homogenized in the σ single-phase region. Phase identification was conducted by powder XRD techniques and the lattice parameters were calculated from obtained XRD profiles. The obtained XRD profiles were further analyzed by means of Rietveld method to determine the structural change of σ phase as well as site occupation of the elements. Microstructures were examined by SEM and hardness was measured by micro Vickers hardness machine. We confirmed that both alloys with 5 and 10 at.% Si exhibit σ single phase with almost the same hardness of 12 GPa. It is interesting to note that, just like Fe addition, the anisotropic behavior of the lattice parameters was obtained; the *a* axis decreases whereas the *c* axis increases with increasing in Si content. However, Rietveld analysis suggested that this anisotropic behavior is different from that in Fe case related to the site occupancy change of M5 sub-lattice site. The detailed mechanism of this anisotropic behavior and the crystal structure change will be discussed in conjunction with the *c*/*a* ratio and unit cell volume of the σ phase.

F.SF07.06.10
Towards High-Throughput First-Principles High-Temperature Thermodynamic Modeling Siya Zhu and Axel van de Walle; Brown University, United States

We demonstrate how widely used high-throughput first-principles calculation frameworks for novel phase discovery can be augmented to enable phase stability predictions above absolute zero and yield informative phase diagrams at a fraction of the computational cost of traditional methods. The approach is based on a combination of (i) the special quasirandom structures formalism, extended to account for possible short-range order, (ii) carefully selected lattice dynamics calculations (iii) efficient molecular dynamics modeling of liquid phases that leverage high-quality experimental thermodynamic for elemental liquids and (iv) the CALPHAD approach for free energy modeling. As an example, we investigate the Ni-Re system, where earlier calculations predicted the presence of novel $D0_{19}$ and $D1_a$ phases. We find that, in spite of their stability at 0K, these intermetallic compounds become unstable at high temperature. These findings also prove helpful in guiding the search for alloys that provide cost effective substitutes for rhenium as a structural material.

F.SF07.06.11

Development of a Thermodynamic Database for CALPHAD Simulations of CoNiCrAlY Metallic Coatings Marlena Ostrowska[1], Yao Wang[1,2] and Gabriele Cacciamani[1]; [1]University of Genoa, Italy; [2]Centre of Excellence for Advanced Materials, China

High temperature materials, such as superalloys, are often covered with metallic coatings in order to protect the substrate from oxidation and to extend its working life. The phases present in the coatings, partly determined by the alloy composition, play an important role in the material properties. Among them, several are beneficial for the properties while some phases are detrimental during service. Co and Ni are the major elements in the metallic coatings. The appropriate amounts of Al, Cr and Y are added to improve their overall performance and to meet the demanding industrial requirements. In general Al-Co-Cr-Ni alloys are adopted as the main coatings for superalloys and small amounts of Y are added to improve oxide scale adherence. However, it is very difficult to predict how phase stabilities are affected by the addition of each element in multi-component alloys, without performing computational simulations.
A reliable thermodynamic database containing Al, Co, Cr, Ni and Y has been developed to support the design of CoNiCrAlY coatings, following the CALPHAD approach. All binary and ternary subsystems are included in the database. Most of the ternary subsystems, due to the lack of consistent thermodynamic description in the literature, were assessed by our group, namely Al-Co-Ni [1], Al-Cr-Ni [2], Co-Cr-Ni [3] and several ternary systems containing yttrium, such as Al-Co-Y, Al-Cr-Y, Al-Ni-Y and Co-Ni-Y (paper in preparation).
The new database was used to simulate a few commercial alloys used as metallic coatings protecting gas turbine blades. The calculated phase compositions were then confronted with the available experimental data from the literature for the following coatings: PWA270 (Ni-21%Co-18%Cr-12.7%Al-0.17%Y), PWA286 (Ni-21.1%Co-17.1%Cr-12.7%Al-0.61%Y) at 1000°C [4] and the Co-based coating Co-28.6Ni-21.2Cr-15.6Al-0.4Y at 1150°C [5] (in at%). The good agreement between calculated and experimental data was evident, therefore, the present database can be reliably used to predict phase equilibria in alloy coatings already in use or to support the design of new alloys with improved performance. In particular, to find the temperature range in which undesired phases (e.g. σ) are stable and investigate the influence of each element on the phase stability.

Influences of Loading Axis Orientation and Specimen Shape on Kink-Band Formation in Single Crystals of Mg-Zn-Y LPSO Phase Investigated by Micropillar Compression Tests Kohei Okage, Kyosuke Kishida and Haruyuki Inui; Kyoto University, Japan

Mg-TM(transition metal)-RE(rare earth) ternary alloys containing a precipitation phase with a long-period stacking-ordered (LPSO) structure have received considerable attentions as a new light-weight structural material endowed with high strength and good ductility simultaneously. Such attractive mechanical properties are believed to be caused by heavily kinked structure of platelet precipitates of Mg-LPSO phase developed during hot extrusion process. Formation of the kinked structure in HCP metals with a relatively high c/a ratio has been interpreted generally with the dislocation-based kink band formation mechanisms such as the Hess and Barrett model, Frank-Stroh model, and Gilman model, which considered different trigger mechanisms for the activation of basal slip when the loading axis is (nearly) parallel to the basal planes, i.e., elastic buckling, stress concentration caused by pre-existing or pre-introduced defects, and a slight tilt of basal plane, respectively. However, the actual controlling factors for the kink-band formation in Mg-LPSO phases have not been fully clarified yet. In the present study, we investigated compression deformation behavior of Mg-LPSO single crystals as a function of loading axis orientation, specimen shape and stacking sequence of the LPSO structure (18*R* and 14*H*-type) by utilizing micropillar compression methodology in order to clarify the dominant controlling factors for the kink-band formation in Mg-LPSO phases.

F.SF07.06.13

The Effect of Forming Internal Electric Field in Seebeck Effect Momoka Sakamoto[1], Rikuto Sasaoka[2], Chiho Inoue[2] and Shinji Munetoh[2]; [1]Chikushigaoka High School, Japan; [2]Kyushu University, Japan

In the Seebeck effect in p-type semiconductor, the voltage can be generated by the diffusion of excited career in high temperature side to low temperature side in impurity level. However, careers in a valence band rediffuse to high temperature side because of electric potential difference, and the value of voltage drop at equilibrium. On the other hand, the block of rediffusing career can generate larger the value of voltage. In this study, we combined two different fermi level of p-type semiconductors, the light boron doped silicon and the heavy boron doped silicon, in order to form internal electric field in the interface with Spark Plasma Sintering. This process has formed the barrier of energy for prevention of career rediffusion. We found that the synthesized sample's voltage increased in comparison with the light boron doped silicon and the heavy boron doped silicon. It is indicated that voltage can increase by forming internal electric field, with the sample combined different fermi level p-type semiconductors.

Late News: The Influence of the Powder Metallurgy Precursor on the Microstructure and Mechanical Properties of a Porous Cu-Al-Ni Alloy Maria T. Malachevsky[1,2], Alberto Baruj[1,2], Graciela Bertolino[1,2] and Ignacio Papuccio[3]; [1]Centro Atomico Bariloche - CNEA, Argentina; [2]CONICET, Argentina; [3]Facultad de Ciencias Exactas -UNCPBA, Argentina

Shape memory alloys are able to stand large deformations and to recover their shape afterwards. Depending on the temperature, the shape recovery could take place after heating or by the so-called pseudoelastic behavior. These particular properties make these smart materials good candidates for applications such as damping or actuation. Cu-based shape memory alloys are commercially attractive due to their relatively low cost compared to Ni-Ti alloys. Multiple research efforts have focused on expanding their potential applications by adding features that can improve the material. Porous shape memory alloys were developed in an effort to combine the shape recovery and energy dissipation properties with reduced density and weight. However, most polycrystalline Cu-based shape memory alloys are prone to intergranular fracture both in compact and porous samples. Reducing the material grain size could decrease the stress concentration at grain boundaries and help to avoid fracture. This can be achieved by alloying with other elements or by selecting an appropriate manufacturing method. As a possible fabrication route, we used powder metallurgy starting from a small particle size.
Among Cu-based shape memory alloys, Cu-Al-Ni alloys are an alternative with good properties and low cost. In this work, we explored the fabrication of porous Cu-14Al-3Ni by conventional powder metallurgy, starting from mechanically pre-alloyed powder and a mixture of the elemental metal powders. For preparing the pre-alloyed powder, we employed a high-energy Fristsch Pulverissette 7 planetary mill, processing under Argon at 700 rpm for 3 hours. The resulting powder was analyzed by means of X-Ray Diffraction (XRD). The XRD pattern showed no presence of Al or Ni while the Cu peaks were shifted to lower angles indicating the solid solution of both Al and Ni in the structure. The Cu peaks were also significantly widened due to the strain resulting from the high-energy milling. Some peaks of γ-Cu_9Al_4 were detected, as well as small CW peaks resulting from the milling media contamination. The other precursor was prepared by hand mixing the elementary powders in an agate mortar. Both precursors were mixed with 1 wt.% mixture of PVA and PVB as a binder and, after drying, 30 vol.% ammonium bicarbonate was added as space holder. Cylindrical samples were prepared by uniaxial cold pressing at 700 MPa. After sintering at 1000 °C, the samples were solution-treated for 24 h at 900 °C under Ar. After the treatment, they were water-quenched to obtain the martensitic phase.
The samples prepared with the milled powder were investigated by XRD. After sintering, the phases detected were α, γ-Cu_9Al_4 and AlNi. The heat treated samples consisted of the shape memory phase 18R accompanied by α and AlNi. The presence of AlNi in the sintered sample suggests that the alloy resulted short of both elements and consequently the solution treatment was performed in the α-β two-phase field. After quenching, α remained as a secondary phase. Meanwhile, the samples prepared with the hand mixed precursor consisted of the 18R and 2H shape memory phases.
X-ray microtomography images of the porous samples were acquired with an Xradia Micro XCT-200 microscope. The samples prepared with the pre-alloyed precursor presented internal cracks indicating that the presence of the brittle γ-Cu_9Al_4 phase reduced the powder compressibility. The lower density prevented their mechanical characterization. On the other hand, samples prepared with the hand mixed precursor were well sintered allowing their complete characterization. Compression uniaxial tests were performed and the shape memory behavior was corroborated. Samples recovered 100% from a 7% strain and 98.56% from 11.5% strain when heated to 140 °C. The obtained grain size is about 30 µm.

F.SF07.06.16

Computational Study of Radiation Damage in Bilayer Nanostructures Cameron Hopper[1], Raghuram Santhanpuram[1], Elton Chen[2], Remi Dingreville[2] and Arun K. Nair[1]; [1]University of Arkansas–Fayetteville, United States; [2]Sandia National

Laboratories, United States

Neutron and ion radiation damage materials used in radioactive environments, such as nuclear reactors. This type of radiation can cause atoms to be moved around in the atomic structure or removed entirely, causing defects and damage to accumulate in the material, which leads to lower mechanical strength. Since these defects are on the atomic level, it can be hard to detect. We propose examining two different types of interfaces: bilayer interfaces, specifically Silicon-Aluminum and Silicon-Gold, as well as crystalline-amorphous interfaces to investigate whether these types of interfaces can help develop radiation-resistant materials. Using molecular dynamics, we will model these bilayer and amorphous structures as well introduce radiation in the form of Frenkel pairs to our system. To analyze the mechanical strength at different levels of radiation damage, yield surface calculations will be performed by subjecting the samples to biaxial and uniaxial tension and compression tests to determine the yield points. Different defect absorption mechanisms at the interface will also be discussed.

F.SF07.06.17
Late News: Understanding the Interaction Between Grain Boundary Precipitation and Creep Cavitation of Type 316H Stainless Steel During In-Service Aging Siqi He[1], Hao Shang[1], Antonio Fernandez-Caballero[2], Alexander Warren[1], David Knowles[1], Peter Flewitt[1] and Tomas Martin[1]; [1]University of Bristol, United Kingdom; [2]University of Oxford, United Kingdom

Creep cavitation is an important degradation mechanism for metallic components used at an elevated temperature. Stress, temperature and microstructure all play a role in the initiation of creep cavities, and the formation mechanism of cavities can depend heavily on local phase and chemistry. In this work, the relationship between microstructural evolution due to long term thermal ageing and creep cavitation is explored in an ex-service AISI type 316H stainless steel sample from an advanced gas-cooled nuclear reactor boiler header after 65,000 hours at 490 to 530°C. The microstructure of the ex-service specimen has been investigated by secondary electron microscopy, focused-ion beam cross sectioning, electron backscatter diffraction and transmission electron microscopy. $M_{23}C_6$ precipitates, α-ferrite precipitates and creep cavities are observed at grain boundaries, with increased precipitation and cavitation at random grain boundaries, and an absence of creep cavities at coincidence site lattice (CSL) 3 boundaries. The α-ferrite precipitates grow during in-service exposure at grain boundaries with a Kurdjumov-Sachs orientation relationship to at least one neighbouring austenite matrix grain. The creep cavities were observed to initiate at the intergranular $M_{23}C_6$ and α ferrite precipitates. Based on the orientation relationship of the ferrite precipitates with the austenite matrix, some creep cavities are initiated after the ferrite precipitates have formed. The influence of microstructure changes on creep cavitation of materials during in-service aging and the implications for more reliable predictions of lifetime for components operating at high temperature are discussed.

From High Entropy Alloys to Complex Concentrated Alloys—How to Tune Multiple Properties Mathilde Laurent-Brocq[1], D. Mereib[1], T. Rieger[1], Loic Perriere[1], J. Monnier[1], Y. Danard[1], C. Vary[1], H. Ben Kahla[1], B. Villeroy[1], Jean-Marc Joubert[1], I. Guillot[1], D. Mercier[2], X.A. Wang[2], P. Marcus[2], M. Roussel[3] and A. Facco[3]; [1]Université Paris Est Créteil, CNRS, ICMPE, UMR 7182, France; [2]Chimie ParisTech, PSL University, CNRS, Institut de Recherche de Chimie Paris, Physical Chemistry of Surfaces Group, France; [3]Manoir Industries, France

Since the discovery of the face-centered-cubic (fcc) single-phased CoCrFeMnNi and the proposal of the concept of high entropy alloys (HEA) in 2004, the understanding of the thermodynamic and mechanical behavior of those alloys has greatly increased. Indeed, it is now possible to reliably map the stable phases in the Co-Cr-Fe-Mn-Ni system using the CALPHAD method [1] and to calculate the solid-solution strengthening [2]. So today, modelling tools are available to "investigate the unexplored central region of multi-component space" [3]. It is time to go pass single-phase materials and/or equimolar quinary compositions and look for complex concentrated alloys. To do so, two different approaches will be presented.
First, the objective is to identify compositions of solid-solution to resist to severe environment (like high temperature and corrosive environment). The strategy consists in: (i) identifying criteria which are relevant for the targeted properties (like the yield strength, the Cr content or the cost) ; (ii) mapping those criteria for the entire composition space ; (iii) selecting compositions ; (iv) performing an experimental validation by processing, microstructural characterization and properties measurements. This will be presented for the Co-Cr-Fe-Mn-Ni and Co-Cr-Fe-Mo-Ni systems.
Second, the objective is to create a chemical architecturation within the CoCrFeMnNi alloy in order to strengthen it while preserving its ductility. More specifically, a mixture of pure Ni and CoCrFeMnNi powders is sintered in order to create chemical gradients at the interfaces of both phases [4]. The microstructure of these innovative chemically architectured alloys will be characterized in detail. Then it will be shown how the width of the gradient can be controlled by varying the processing parameters and how it influences the mechanical properties. Finally, the different strengthening contributions will be sorted out and analyzed.

5:15 AM *F.SF06.01.02
Corrosion of Single Phase Compositionally Complex NiFeCrMnCo Alloys Gerald S. Frankel[1], Tianshu Li[1], Sarita Sahu[1], John Scully[2] and Angela Gerard[2]; [1]The Ohio State University, United States; [2]University of Virginia, United States

The corrosion resistance of several single phase, non-equiatomic, NiFeCrMnCo compositionally complex alloys (CCAs) containing a range of Cr content from 6-22% was investigated in chloride solutions. Comparison was made to NiCr and FeCr binary alloys with similar Cr contents as the CCAs. The oxide film character and the localized corrosion performance, including susceptibility to crevice and pitting corrosion, were studied utilizing in-situ electrochemical and ex-situ surface-sensitive techniques. An NiFeCrMnCo CCA with only 6% Cr was found to exhibit passivity and breakdown by pitting corrosion. Crystallographic pit morphology was observed in most of these CCAs, suggesting a difficulty in precipitation of a salt film, which would result in polished pit surfaces. The crystallographic pit morphology indicates that the pit growth was under charge-transfer/ohmic control. The passive film composition, thickness, and elemental valence states, and fate of each element were studied for the CCA with 22% Cr by in-situ atomic emission spectro-electrochemistry, ex-situ X-ray photoelectron spectroscopy, and atom probe tomography. It demonstrated slightly better corrosion resistance than the binary Ni-24Cr alloy. Passive films on the HEA contained primarily Cr, and small amounts of Ni, Fe and Mn, while dissolution of Ni, Fe, Co was observed. Metallic Ni was enriched at the passive film-metal interface. Enrichment of Cr in the passive film occurred to a greater extent in the HEA than for the Ni-Cr binary alloy. Enrichment factors were determined and the origins of enrichment were assessed.

5:30 AM F.SF06.01.03
Hydrogen Storage by Ti-V-Cr Based Multi Component Alloys Etsuo Akiba, Rika Hayashi and Shota Itano; Kyushu University, Japan

Ti-V-Cr based hydrogen absorbing alloys these have BCC structure absorb hydrogen up to 3 wt% that is the highest among materials working under ambient conditions [1]. However, they have a potential to store hydrogen around 4 wt% because more than 1wt% of hydrogen in the hydrogenated alloys cannot be released at room temperature. To improve hydrogen capacity, the number of constituent elements is increased to make multi component alloys. Equimolar multi component alloys are called as high entropy alloys or multi principal element alloys. It has been reported a five-element equimolar high entropy alloy TiZrNbHfTa absorbed hydrogen at 300°C [2]. We tried to prepare four or five element Ti-V-Cr based alloys with equimolar or near-equimolar compositions because they are lighter than the reported high entropy alloys consisted of heavy elements and expected to absorb hydrogen under ambient conditions. Hydrogen absorbing performance was measured at room temperature. Some of four and five element alloys with BCC structure prepared in this study reversibly absorb and desorb hydrogen at room temperature.

5:40 AM F.SF06.01.04
Synthesis, Mechanical Properties, and High Temperature Stability of the Spinel High Entropy Oxide $(Mg_{0.2}Ni_{0.2}Co_{0.2}Cu_{0.2}Zn_{0.2})Al_2O_4$ Brianna Musico[1], Joshua Smith[1], Quinton Wright[1], Claudia Rawn[1], Kurt E. Sickafus[1], David Mandrus[1,2] and Veerle Keppens[1]; [1]The University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States

Reports on the unique properties achieved with HEAs, including improved mechanical properties, has motivated the application of the multi-component approach to oxide materials, expanding the available compositional space and providing greater flexibility to meet the demands of today's advanced materials. We have applied this methodology to an alumina based spinel oxide, resulting in the synthesis of polycrystalline $(Mg_{0.2}Ni_{0.2}Co_{0.2}Cu_{0.2}Zn_{0.2})Al_2O_4$. Samples were made by either the solid state reaction method or the polymeric steric entrapment (PSE) technique, and in-situ High Temperature X-Ray Diffraction (HTXRD) was used to compare the phase transformation behavior and investigate the high temperature phase stability. Resonant Ultrasound Spectroscopy (RUS) has been used to evaluate the elastic behavior of a dense polycrystalline pellet sample, allowing for a comparison of the mechanical properties of the multicomponent $(Mg_{0.2}Ni_{0.2}Co_{0.2}Cu_{0.2}Zn_{0.2})Al_2O_4$ to those of the traditional $MgAl_2O_4$ spinel.

5:50 AM F.SF06.01.05
Electrical Resistivity Change of CrMnFeCoNi High-Entropy Alloy by Electropulsing and Annealing Hisanori Tanimoto, Ryo Hozumi and Mari Kawamura; University of Tsukuba, Japan

High-entropy alloys (HEAs) are a new class of metallic materials because of their unique properties; high strength and ductility at low temperatures, texture stability due to sluggish diffusion of atoms at elevated temperatures, and so on. HEAs are solid solution and the constitute atoms form a lattice but the chemical atomic arrangement is totally disordered. It is pointed out that, however, some local inhomogeneity or structure are existed in HEAs to accommodate the large local strains and hence assist the stability of HEAs [1]. Amorphous alloys are another type of random system where the atom positions are chemically and topologically disordered. Existence of local structures in amorphous alloys and the characteristic dynamic response were suggested by several studies. We found that the resistivity of amorphous (a-) ZrCu alloys was decreased to less than 60% of the initial value after passing an electric pulse(electrpulsing). In the experiment, the current exponentially decayed with the time constant of ~3 ms from the initial current density of ~0.6 GA/m^2 [2]. Further, nanocrystallites of ZrCu, the high-temperature intermetallic compound phase, were revealed from the X-ray diffraction measurement and transmission electron microscopy. These observations suggested that that crystalline-like local structures in a-ZrCu are embedded in the amorphous alloys and transformed to nanocrystallites through collective motions of the local structures excited by electropulsing. The information on the local structure and its dynamical behavior can be surveyed from the electropulsing experiment.
In the present study, the electropulsing experiments were performed for CrMnFeCoNi HEA in the as-prepared state and annealed state. The phase separation of CrMnFeCoNi HEA was reported after annealing below 1073 K [3]. It is expected that the local structure is developed by annealing below 1073 K and the texture change or phase separation are accelerated by electropulisng. For CrMnFeCoNi HEA in the as-prepared state, no decrease in the resistivity and no secondary phase formation were observed after electropulsing up to 1.4 GA/m^2. By annealing at 1023 K for 1 hour, the resistivity of

CrMnFeCoNi HEA showed an increase by 10 % from that in the as-prepared state. The resistivity increased by annealing showed a slight recovery by electropulsing up to 1.2 GA/m^2; the resistivity became 8% larger than that in the as-prepared state. It is noted that no texture change and no new phase formation were detected by the XRD measurements after the present annealing and subsequent electropulsing. The increase in the resistivity by annealing indicates some local structure formation toward the phase separation, whereas the slight recovery of the increased resistivity by electropulsing disappearance of the local structure induced by annealing. These results suggest that in CrMnFeCoNi HEA, local structures which are dynamically unstable and easily transform to other states are not exited or considerably stable if existed.

Designing High Entropy Oxides as Effective Catalysts for Pollution Abatement Christopher Riley[1], James Park[1], Stephen Percival[1], Andrew De La Riva[2], Abhaya Datye[2] and Stan Chou[1]; [1]Sandia National Laboratories, United States; [2]The University of New Mexico, United States

High entropy oxides (HEOs) offer great potential to innovate fields involving applied materials. However, the development of HEOs for use as heterogeneous catalysts is still lacking, due in part to current HEO production methods. Common synthetic techniques involve physically mixing individual metal oxides and heating the mixture to high temperatures (>1000 °C), which allows for interdiffusion and achievement of phase pure structures. However, high temperature synthetic routes sinter HEOs into low surface area materials, rendering them inactive in catalyzed gas-phase reactions. Here, we explore a sol-gel synthesis of HEOs conducted at much lower temperatures (500 °C). The resulting HEOs contain primarily rare earth elements and are made with uniform structure, high surface area, and high catalytic activity for CO oxidation. Incorporation of multiple dopant elements into the fluorite phase HEOs facilitates the transfer of reactive lattice oxygen to CO reactant via a Mars van Krevelen mechanism. Further, the high surface area of these materials leads to a high number of active sites for CO oxidation. The sol-gel synthesis presented herein is broadly applicable and enables the design of HEOs as effective catalysts.

6:10 AM F.SF06.01.10
A Novel B2-Ordered $Fe_{30}Co_{40}Mn_{15}Al_{15}$ Medium-Entropy Alloy with Outstanding Soft Magnetic Properties and High Thermal Stability Youxiong Ye, Scott D. Lish, Markus W. Wittmann and Ian Baker; Dartmouth College, United States

Thus far, soft magnetic behavior in high-entropy alloys has only been observed in disordered single-phase microstructures (e.g., FCC or BCC) or a mixture of disordered and ordered structures (e.g., FCC/BCC + B2/$L2_1$/$L1_2$). Here, we have reported, for the first time, a novel single-phase B2-ordered $Fe_{30}Co_{40}Mn_{15}Al_{15}$ medium-entropy alloy with potential use as a soft magnet. The microstructure and deformation mechanisms were examined using transmission electron microscopy. The effects of annealing at 600, 800 and 1000 °C on phase stability, mechanical behavior and magnetic behavior were studied. Outstanding soft magnetic properties were obtained for the as-cast alloy, i.e., a high saturation magnetization of ~156 emu/g, a high Curie temperature of ~810 °C, and a very low coercivity of ~2.6 Oe, which are superior to values previously reported for medium- and high-entropy alloys. The alloy exhibited excellent microstructural, mechanical, and magnetic stability upon long time (> 3 days) annealing at up to 600 °C. Furthermore, high temperature magnetic measurements revealed a gentle decrease in the saturation magnetization and almost unchanged coercivity at temperatures up to 700 °C, suggesting its potential for high-temperature applications as a soft magnet. The work was supported by NIST grant 60NANB2D0120.

6:20 AM F.SF06.01.11
Multicomponent Pyrochlore Solid Solutions with Uranium Incorporation—New Perspective of Materials Design for Nuclear Applications Kun Yang and Jie Lian; Rensselaer Polytechnic Institute, United States

Compositionally complex pyrochlore oxide solid solutions with and without uranium incorporation were fabricated by solid state reaction and consolidated by sparking plasma sintering. The as-sintered compositionally complex pyrochlore oxide with distinct mixing entropy varies from medium to high were considered and their thermal and mechanical properties were

compared to baseline single component rare-earth titanate pyrochlore ($A_2Ti_2O_7$). The medium entropy pyrochlore oxides have lower thermal conductivity than its high entropy counterpart. The measured thermal conductivity increases by increasing the A-site mixing entropy and decreasing a modified size disorder parameter, and thus the size disorder and mixing entropy could be good indicators for predicting thermal conductivity of multicomponent pyrochlore solid solutions. Uranium incorporation in general reduces hardness and fracture toughness as compared with single component compositions due to the significant low hardness and fracture toughness for UO_2. High entropy pyrochlore with uranium displays the highest thermal conductivity among all of the multicomponent pyrochlore solid solutions with significantly better mechanical properties than UO_2. This work opens up the possibility of designing multicomponent oxide solid solutions by controlling their chemical disorder/mixing entropy to achieve acceptable thermal-mechanical properties and desired radiation and corrosion performance for potential nuclear waste form and inert matrix fuel applications.

Effect of Short Range Order on Physical Properties for Cr-Co-Ni Medium Entropy Alloy Katsushi Tanaka, Takeshi Teramoto, Yusuke Ito and Kentaro Kitasumi; Kobe University, Japan

Short range ordering (SRO) in Cr-Co-Ni medium entropy alloy is considered as an important phenomenon for understanding its physical properties. Recent works indicate that slowly cooled alloy from 1273 K exhibits relatively higher yield stresses and higher stacking fault energies. The knowledges of the thermodynamic condition and kinetics of the formation of SRO are required to understand the physical and mechanical properties of the alloy, but are still open question. In the present study, we have successfully confirmed that an atomic scale rearrengement occurs by annealings at the temperatures below 873 K, which may be attributed as the formation of SRO. The SRO disappears when the specimen is annealed at the temperatures of 973 K or higher. We will show experimental results indicating the developement of SRO in Cr-Co-Ni medium entropy alloy and variations of other physical properties such as lattice constant, elastic properties and yeild stress.

Local Structural Disorder Revealed by EXAFS Measurements in Medium-Entropy Alloy CrCoNi Noriaki Hanasaki[1], Masaharu Oda[1], Kodai Niitsu[2], Kazuki Ehara[2], Hiroaki Nitani[3], Hitoshi Abe[3] and Haruyuki Inui[2]; [1]Dept. of Physics, Osaka University, Japan; [2]Kyoto University, Japan; [3]KEK, Japan

High-entropy alloys are promising materials for the high strength and ductility. As the origin of these important properties, the lattice distortion, sluggish diffusion, and cocktail effect have been discussed. The previous studies suggested that the yield strength is proportional to the atomic displacement theoretically. Thus, it is essential to clarify the local structure in this class of alloys experimentally. We investigated the local structure in the medium-entropy alloy CrCoNi by the measurements of the EXAFS (extended x-ray absorption fine structure) for the Cr, Co, Ni-K edges, whose spectra were obtained accurately by recording the transmitted x-ray beam. We found that the Debye-Waller factor in the Cr atom is larger than those in the Co and Ni atoms, suggesting that the Cr atom has a guest-like character inducing the local structural disorder in CrCoNi. Our result is consistent with the previous studies suggesting that the atomic displacement tends to be larger in the atom having the lower atomic number. We will discuss the local structure and the annealing effect on the basis of the EXAFS results.

5:20 AM F.SF06.02.04
Local Structure and Carbon Vacancies in High Entropy Carbides Abinash Kumar[1], Mohammad Delower Hossain[2], Jon-Paul Maria[2] and James M. LeBeau[1]; [1]Massachusetts Institute of Technology, United States; [2]The Pennsylvania State University, United States

High entropy ceramics- a chemically disorder crystal with four or more metals randomly distributed in the cation sublattice and either carbon, oxygen or boron populates the anion sublattice. These new materials displayed remarkable properties such as high hardness, low thermal conductivity and reversible electrochemical energy storage behavior [1-3]. The local structure in the chemically disorder crystal affects the properties which demands a nanoscale probe to establish the structure property relationship. Scanning transmission electron microscopy (STEM) provides the opportunity to map the local structure in high entropy materials with variation in local chemistry or in presence of point, line and planar defects in the crystal.

High entropy carbide thin films were synthesized by using reactive radio frequency (RF) magnetron sputtering and carbon content in the samples were regulated by flowing 99.99% methane gas during deposition. Two thin films having a 10% C vacancy and a stoichiometric high entropy carbide were characterized by a combination of STEM imaging and spectroscopy techniques. The low magnification TEM and STEM images reveals formation of stacking faults in the carbon deficient sample. The clustering of carbon vacancies instigated the stacking faults in the materials which is substantiated by EELS mapping in STEM mode. Segregation of carbon vacancies are preferred due to the reduced energy penalty by the formation of stacking faults compared to the random distribution as explored by first principle calculation in binary transition metal carbides [4]. In comparison, the stoichiometric high entropy samples are free from any kind of point or line defects. We observed a broad distribution of the cation-cation bond distances in both samples which are corroborated by the pair distribution generated from density function theory calculation of the chemically disorder crystal. The atomic size mismatch among the constituents of the high entropy carbide cations contributed to the wider distribution. High-angle annular dark field (HAADF) STEM imaging of stoichiometric sample show variation in the intensity of the metal atomic columns with alternate plane of higher and lower intensity. Such variation can be associated with the presence of nanoscale cation ordering in the sample. We will further discuss using statistical tools how such variation in elemental distribution lead to change in local strain which may have profound effect on strengthening of the materials.

Characterizing the Extent of Short-Range Order in a Lightweight FeMnAlC Steel Alloy Using STEM Michael Xu, Hyun Seok Oh, Cem Tasan and James M. LeBeau; Massachusetts Institute of Technology, United States

Compared with many other steel alloys, highly alloyed FeMnAlC lightweight steels have been shown to have a unique combination of strength and ductility, which has gained interest for automotive applications [1-3]. One of the potential reasons for these enhanced properties has been attributed to the growth of ordered κ-carbides in the austenitic matrix upon aging [3-5]. A particularly important deformation mechanism for high strain-hardening rate alloys is short-range order (SRO)-linked planar glide [6]. Thus, in order to understand the role that local atomic structure may ultimately have on material properties, it becomes crucial to characterize and correlate short-range ordering with deformation mechanisms.

In this presentation, we will show the direct imaging of atomically ordered clusters within the austenite matrix with scanning transmission electron microscopy (STEM). Using Revolving STEM (RevSTEM) imaging, atom column indexing, intensity correlation, and analysis [7,8], we first show direct evidence for nanosized ordered clusters in FeMnAlC, suggesting $L1_2$-type ordering of the substitutional atoms in agreement with κ-carbide. We then map the extent of ordering with respect to the introduced plastic strain, and the evolution of crystallographic defects such as dislocations and twin boundaries, to provide insights on the behavior of defects in relation to short-range ordering. Finally, we will examine the effect of aging treatments on these phenomena [9].

Experimental Determination of the Effective Atomic Radius of the Constituent Elements in Cr-Mn-Fe-Co-Ni High Entropy Alloy Takeshi Teramoto, Momoko Narasaki and Katsushi Tanaka; Kobe University, Japan

Solid solution strengthening is the major strengthening mechanism for its yeild stress in high entropy alloys (HEA). In order

to understand the solid solution strengthening mechanism, lattice distortions caused by the difference in effective atomic radii of the constituent elements have recently been discussed theoretically such as first-principles calculations and Goldschmidt radius. However, no experimental study has been reported to determine the effective atomic radii of the constituent elements in HEA. In this study, the effective atomic radii of the constituent elements in the Cr-Mn-Fe-Co-Ni alloys have been experimentally determined. The effective atomic radii are estimated by applying a rigid sphere model to the effective atomic volumes of the constituent elements determined by an X-ray diffraction. As a result of comparing the derived effective atomic radii with the previously reported theoretical ones, the experimentally determined effective atomic radii show different trends in terms of the absolute values and the order. It has been reported that there is a correlation between the yield stress and the mean square atomic displacement (MSAD) parameter caused by the difference in the atomic radii. However the present study shows there is no correlation between the yield stress and the lattice strains estimated from the experimentally determined atomic radii. These results suggest that the difference in atomic radii is not directly related to the solution strengthening mechanism of HEAs.

5:50 AM F.SF06.02.07
Combinatorial Exploration of High Entropy Alloys Sebastian A. Kube[1], Pamela Banner[1], Sungwoo Sohn[1], David Uhl[2], Amit Datye[1], Suchismita Sarker[3], Apurva Mehta[3] and Jan Schroers[1]; [1]Yale University, United States; [2]Southern Connecticut State University, United States; [3]SLAC National Accelerator Laboratory, United States

High Entropy Alloys (HEAs) are inherently complex and span a vast composition space, across which single-phase solid solutions (SPSS) potentially form. Using combinatorial co-sputtering and high-throughput EDX and synchrotron XRD, we consistently fabricate and characterize large numbers of distinct quinary HEAs. By mining a first data set comprising ~2,500 quinary HEAs based on the elements Al, Cr, Mn, Fe, Co, Ni, and Cu, we show that resulting crystal structures are determined by the combination of the BCC/FCC element content and the atomic size difference. We further reveal a BCC preference effect: The BCC structure becomes increasingly favorable with increasing atomic size difference, because of its ability to accommodate atoms of various sizes more efficiently than FCC. Finally, we present our new expanded data set comprising 10,000 ternary and quinary compositions based on 20 different elements. We place special emphasis on the metastable character of these alloys: Given the high cooling rates involved (~10^{10} K/s), SPSS and glasses are obtained through polymorphic solidification and can be studied across exceptionally wide composition ranges.

6:00 AM F.SF06.02.08
Magnetically Driven Short-Range Order in the CrCoNi System Flynn Walsh[1,2], Robert Ritchie[1,2] and Mark Asta[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

The presence, nature, and impact of chemical short-range order in the CrCoNi multi-principal element alloy are all topics of current interest and debate, especially in the context of the system's role as a model for related high-entropy alloys. While the ordering of this material has been previously analyzed in terms of purely chemical relationships, first-principles calculations reveal that its origins are fundamentally magnetic. Specifically, the dominant interaction is found to be repulsion among like-spin Cr nearest neighbors, which is complemented by a preference to form a second-nearest neighbor sublattice of Cr with moments opposing those of ferromagnetic Co. Magnetically aligned pairs of Co and Cr atoms are additionally calculated to be unfavorable, emphasizing the need to analyze the ordering of this material in spin-polarized terms. Models of order following these principles are used to explain anomalous experimental measurements concerning both net magnetization and atomic volumes across a range of compositions, demonstrating the effects of both short-range order and magnetic interactions with implications for a broader class of high-entropy alloys containing multiple principal 3*d* elements.

6:10 AM F.SF06.02.09
Order-Disorder Transition Behaviors in Lightweight High-Entropy Alloys Rui Feng[1,2], Chuan Zhang[3], Michael Gao[4,5], Zongrui Pei[4,6], Fan Zhang[3], Yan Chen[2], Dong Ma[2], Ke An[2], Jonathan Poplawsky[2], Yang Ren[7], Michael Widom[8], Jeffery Hawk[4] and Peter Liaw[1]; [1]The University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States; [3]Computherm, LLC, United States; [4]National Energy Technology Laboratory, United States; [5]Leidos Research Support Team, United States; [6]ORISE, United States; [7]Argonne National Laboratory, United States; [8]Carnegie Mellon University, United States

The much larger compositional space afforded by high-entropy alloys (HEAs) compared to traditional alloys, opens new opportunities to develop high-performance materials. Here the CALculation of PHAse Diagrams (CALPHAD)-based high-throughput computational method (HTCM) is used to screen lightweight HEAs in the Al-Cr-Fe-Mn-Ti system that contain nanoscale $L2_1$ precipitates within the body-centered-cubic (BCC) matrix for cost-effective high-temperature applications. The order-disorder transition behaviors and their effects on the microstructures and mechanical properties of these newly-

designed lightweight high-entropy alloys (LWHEAs) are understood by *in-situ* neutron scattering and advanced microcopies, *ab-initio* molecular dynamics (AIMD), and Monte-Carlo (MC) simulations. The fundamental understanding of the order-disorder transition behaviors of these LWHEAs explains the different microstructural and mechanical responses among them, which provides in-depth insights into the discovery of advanced precipitation-strengthened structural materials by the HEA concept.

Asymmetry of Elecment-Specific Lattice Distortion in 3D Transition Metal Based Complex Concentrated Alloys Hyun Seok Oh[1], Khorgolkhuu Odbadrakh[2], Yuji Ikeda[3,4], Sai Mu[5], Fritz Koermann[3,6], Chengjun Sun[7], Hye Sang Ahn[8], Kook Noh Yoon[8], Duancheng Ma[9], Cem Tasan[1], Takeshi Egami[10] and Eun Soo Park[8]; [1]Massachusetts Institute of Technology, United States; [2]University of Tennessee and Oak Ridge National Laboratory, United States; [3]Max-Planck-Institut für Eisenforschung, Germany; [4]University of Stuttgart, Germany; [5]Oak Ridge National Laboratory, United States; [6]Delft University of Technology, Netherlands; [7]Argonne National Laboratory, United States; [8]Seoul National University, Korea (the Republic of); [9]Friedrich-Alexander-Universität, Germany; [10]The University of Tennessee, Knoxville, United States

Lattice distortion has been regarded as one of the four core effects of complex concentrated and high entropy alloys. Recently, it was shown that atomic-level pressure (or the misfit volume) in 3d transition metal element (V, Cr, Mn, Fe, Co, Ni)-based complex concentrated alloys (3d CCAs) with face-centered cubic structure originates from charge transfer between neighboring atoms, which suggests the electronic origin of lattice distortion, rather than a classical mechanical view mainly based on atomic size arguments. Here we show that the magnitude of the local lattice distortion of a specific element is strongly affected by its electronegativity. The trend is only little affected in the presence of short-range order . This study provides an important link between atomistic properties (electronegativity) and physical properties in 3d CCA, and rationalizes the proposed relation between lattice distortion and complexity-induced properties in 3d CCAs.

Role of Local Chemical Order in Orientation Relationship Determination in an $Al_{0.3}CoCrFeNi$ High Entropy Alloy Elaf A. Anber[1], Daniel Foley[1], Diana Farkas[2], Peter Liaw[3] and Mitra L. Taheri[1]; [1]Johns Hopkins University, United States; [2]Virginia Tech, United States; [3]The University of Tennessee, United States

High entropy alloys (HEAs) have attracted the major interest due to their novel mechanical and structural properties. Local chemical ordering (LCO) plays an important role in determining thermal and electrical conductivity of solid solutions, diffusion, and passivity of alloys containing elements that are electrochemically active. Here, we describe that the change in LCO may promote formation of a distinct-uncommon crystal orientation relationship (OR) with the matrix. In this study, we examined the role of LCO on the OR of BCC precipitates in annealed Al0.3CoCrFeNi via using in-situ and ex-situ TEM heating techniques, where we report a new BCC-ORs due to local chemical fluctuations. These studies were coupled with Extended Electron Energy Loss Fine Structure (EXELFS) and Energy-dispersive X-ray spectroscopy (EDS). Overall, the LCO associated with ORs offers new opportunities to tune properties, enabling a more predictive view of phase transformation in this class of alloys.

Strength and Toughness in TRIP, TWIP and Dual-Phase CrMnFeCoNi High-Entropy Alloys Bernd Gludovatz[1], Hyun Seok Oh[2], Eun Soo Park[2] and Robert Ritchie[3,4]; [1]UNSW Sydney, Australia; [2]Seoul National University, Korea (the Republic of); [3]Lawrence Berkeley National Laboratory, United States; [4]University of California, Berkeley, United States

Compositionally complex alloys, often termed high-entropy alloys (HEAs), are alloy systems with at least five principal elements in (near-)equiatomic ratios that are promising candidates for the development of materials with enhanced damage tolerance, i.e., that is a good combination of strength and toughness, which is key for the increasing complexity of energy-efficient and safety-critical applications. Despite containing elements with different crystal structures, the most studied HEA to date, the Cantor alloy CrMnFeCoNi, is a single-phase face-centered cubic (FCC) material that has been shown to exhibit strength levels above 1 GPa and fracture toughness values well above 200 $MPa.m^{½}$ at room temperature. Interestingly, the alloy's strength, ductility and fracture toughness improve simultaneously with decreasing temperatures, a trend that is the opposite for most other materials. This is achieved through a combination of sequentially triggered deformation mechanisms including planar dislocation slip, rapid motion of partial dislocations, near-tip crack bridging and deformation-induced nano-twinning. Based on our work on this alloy we will examine compositionally modified variations of this material that were designed with the aim to gradually lower stacking-fault energy. We will show how their failure resistance develops in the same temperature range when compositionally triggered deformation mechanisms such as transformation induced plasticity (TRIP) or twinning induced plasticity (TWIP) are enabled and additionally compare their behavior to a similar alloy that contains a second phase. Using a combination of advanced electron microscopy imaging techniques, we will show how deformation modes such as planar dislocation slip, deformation-induced nano-twinning, and transformation-induced plasticity control mechanical properties and highlight the importance of controlled triggering of each individual mechanism.

Dynamic Amorphization, Inverse Hall Petch Behavior and the Tribological Properties of High Entropy Alloys Morgan R. Jones, Brendan Nation, Ping Lu, Andrew Kustas, Michael Chandross and Nicolas Argibay; Sandia National Laboratories, United States

We report on tribological investigations with an additively manufactured (AM) equiatomic CoCrFeMnNi high entropy alloy. As this work highlights, AM HEAs are a promising combination of advanced and processing techniques for next-generation structural and multi-functional devices, including applications where high-consequence and low volume drive design and qualification. The tribological, mechanical, and microstructural properties for this HEA in a range of environments are studied, including ultra-high vacuum (UHV), to highlight environment-dependent frictional and wear properties. We showed that low friction (mu< 0.4) and high wear resistance (K ~ 10^{-6} mm^3/Nm) are achievable with unlubricated high entropy alloys in inert environments and establish evidence of inverse Hall-Petch behavior by a recently proposed process of dynamic amorphization. We also discuss the origin of impressive wear resistance, linked to extreme grain refinement, that was achievable even in inert environments.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy?s National Nuclear Security Administration under contract DE-NA0003525. -or- if you have a character limit, you may use: SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

5:25 AM F.SF06.03.04
High Entropy Alloy Displays Unique Strengthening and Deformation Pathways Simon Tsianikas[1], Yujie Chen[1], Zonghan Xie[1], Jiwon Jeong[2] and Siyuan Zhang[2]; [1]The University of Adelaide, Australia; [2]Max Planck Institute for Eisenforschung, Germany

Most of high entropy alloys (HEAs) with body centered cubic (BCC) structure suffer from limited plasticity at room temperature, which hinders their practical applications. To tackle this challenge, a $Fe_{49.5}Mn_{30}Co_{10}Cr_{10}B_{0.5}$ high entropy alloy with body centered cubic (BCC) structure was prepared by closed field unbalanced magnetron sputtering. The coating exhibits an excellent combination of strength and ductility (~ 2.8 GPa yield strength and ~ 40% compressive strain), which can be attributed to the synergy of multiple strengthening mechanisms, including transformation induced plasticity (TRIP) and twinning induced plasticity (TWIP) effect, compositional fluctuations, grain boundary engineering, grain refinement, and nanolaminate strain partitioning. A two-step phase transformation; namely, BCC to hexagonal closed packed (HCP) and then to face centered cubic (FCC) structure, was identified under applied load. On one hand, the phase transformation from BCC

to HCP and then to FCC structure, along with the formation of heterogeneous, bi-modal microstructure, works to absorb the strain and mitigate the stress concentration in the alloy. On the other hand, the increased phase boundaries generated by phase transformation pose as additional barriers to dislocation movements, providing extra strain hardening. The results of this work demonstrates that the two-step phase transformation is an effective mechanism that imparts the new HEA with appreciable damage tolerance while maintaining high strength.

Influence of Creep Tests Temperature on Sluggish Diffusion of the Single Crystalline High and Medium Entropy Alloys CrMnFeCoNi and CrCoNi Christian Gadelmeier, Sebastian Haas and Uwe Glatzel; University of Bayreuth, Germany

The equiatomic, face centered cubic (fcc), single phase high and medium entropy alloys CrMnFeCoNi and CrCoNi are perfect candidates for the study of solid solution hardening in a statistically distributed crystal lattice. Both alloys show extraordinary properties compared to conventional alloys like nickel-based superalloys or steels, which is not expected for single face fcc materials. Previous investigations on CrMnFeCoNi and CrCoNi alloys have concentrated almost exclusively on polycrystalline structures.

This work focuses on the determination of the entropy effects of mechanical deformation on single crystalline (SX) single phase fcc alloys with 5, 3 and 1 component. Any influences such as grain size, grain boundary sliding and diffusion or effects due to precipitation can be isolated. Targeted creep tests under vacuum made it possible to eliminate the influence of oxidation at higher temperatures. These ideal conditions allow a dined comparison to study the solid solution strengthening effect towards to a higher configurational entropy depending on the temperature. Therefore, the alloys with different configurational entropy CrMnFeCoNi (Sconf = 1.61 J/(mol*K), CrCoNi (Sconf = 1.10 J/(mol*K), and pure nickel (Sconf = 0 J/(mol*K), were chosen.

All alloys were cast in single crystalline state by using induction casting under argon atmosphere for further characterization. For the mechanical testing the miniature specimens are manufactured by electrical discharge machining (EDM) and tested in a radiation-heated vacuum creep device with a maximum temperature tolerance less than ± 1 °C. A main part of this work concentrated on the investigation of the dislocations in the alloys. This was realized over a wider temperature range from 700 °C to 1200 °C.Using stress levels of 2 MPa, the results of the creep tests provide quite different behavior of sluggish diffusion in the three tested alloys. The reason for this discrepancy was examined in more detail by electron channelling contrast imaging (ECCI) and transmission electron microscopy (TEM). Especially for this purpose some creep tests were interrupted and cooled down to room temperature under load, to examine the dislocation structure in the samples.

5:45 AM F.SF06.03.09
Discovery and Design of Fatigue-Resistant High-Entropy Alloys Weidong Li, Peter Liaw and Shuying Chen; The University of Tennessee, Knoxville, United States

Fatigue resistance is a crucial requirement to the novel high-entropy alloys when they come to engineering applications, as many metal structures used in practice are failed by cyclic loading. Here, a thorough analysis of the information on the low-cycle fatigue, high-cycle fatigue, crack-growth rates, and fatigue mechanisms in the high-entropy alloy literature unveils a guideline through which the discovery and design of fatigue-resistant high-entropy alloys can be facilitated. Overall, multi-phase alloys, particularly the metastable ones, are favorable to fatigue resistance over single-phase alloys. Suggestions are proposed in the end to accelerate the discovery and design of candidates for fatigue-resistant applications.

5:55 AM F.SF06.03.10
Microstructure Evolution and Mechanical Properties at Intermediate to Elevated Temperatures of Refractory Mo-V-Nb-W-Ti High-Entropy Alloys Maximilian Regenberg, Georg Hasemann, Markus Wilke, Thorsten Halle and Manja Krueger; Institute for Materials and Joining Technology, Germany

High-entropy alloys (HEAs) can either be defined as solid solution alloys containing at least 5 elements in equiatomic or near-equiatomic composition, or as alloys with high configurational entropies (larger than 1,5R), regardless of the number of elements involved [1]. In the present study we report on an alloy design route for refractory high-entropy alloys (RHEAs) based on equimolar Mo-V-Nb alloys with additions of W and Ti. In general, our work was motivated by Senkov et al. [2, 3] who investigated refractory HEAs based on Mo-Nb-W-Ta and Mo-V-Nb-W-Ta. Also to be noted is the US Patent published by Bei [4] in which a multi-component solid solution alloy with high entropy of mixing, namely Mo-V-Nb-W-Ti, has been mentioned. Senkov et al. investigated their alloys experimentally and showed that they have a single-phase body-centered

cubic (bcc) structure. It is assumed that the patented alloy Mo-V-Nb-W-Ti also consists of a single-phase bcc structure. The aim of our present experimental work was to produce and analyze a refractory high-entropy alloy of aforesaid composition with a single-phase structure and a reduced density, compared to Senkov's alloys, by replacing one and/or both of the heavy elements W and Ta with Ti. For this purpose, a systematic alloy design involving four- and five-element compositions was used. SEM (scanning electron microscopy) analysis have shown that Mo-V-Nb-xW-yTi (x=0, 20; y=5, 10, 15, 20, 25) is in fact a RHEA with a bcc dendritic structure. Furthermore, the Ti-concentration of the experimental alloys was varied within the composition interval between 5 at.% and 35 at.% as it is defined by Yeh [5], for each principle elements in HEAs, to obtain the influence of Titanium on the microstructure evolution. Additionally, compressive tests at elevated temperatures (in a range of 400-1100 °C) will be carried out to evaluate the influence of the different alloying elements and the Ti-fraction, on the mechanical properties. The observations of the present work are then compared to the published results on similar alloys from the group of K. F. Yao et al. and critically discussed [6, 7].

6:05 AM F.SF06.03.12
Dynamic Behavior of CrMnFeCoNi High-Entropy Alloy Zezhou Li[1,2], Shiteng Zhao[3], Carlos J. Ruestes[4], Wen Yang[1], Bingfeng Wang[5], Yong Liu[5], Nathan Mara[2], Robert Ritchie[3] and Marc A. Meyers[1]; [1]University of California, San Diego, United States; [2]University of Minnesota, Twin Cities, United States; [3]Lawrence Berkeley National Laboratory, United States; [4]Universidad Nacional de Cuyo, Argentina; [5]Central South University, China

High impact resistance of the annealed and pre-deformed equiatomic CrMnFeCoNi high-entropy alloys (HEAs) is expected from their excellent high-strain-rate plasticity. Its underlying deformation mechanisms under dynamic loading have been identified by both experiments and simulation. The microstructures of alloys after dynamic loading have been revealed by (high-resolution) transmission electron microscopy. The high strain-hardening ability of the CrMnFeCoNi HEA (enabled by solid-solution hardening, forest dislocation hardening, twinning hardening, and phase transformation), a marked strain-rate sensitivity and modest thermal softening, result in an excellent resistance to shear localization. For the annealed CrMnFeCoNi alloy, a shear strain of ~7 has been discovered as required for the shear-band propagation (using a hat-shaped specimen that enables one single shear band to initiate and grow). Additionally, the pre-deformed CrMnFeCoNi alloy obtains an even higher absorbed impact strain energy (under similar loading conditions). The remarkable high-strain-rate plasticity is significant for its structural applications.

6:15 AM F.SF06.03.13
Deformation by "Faulting" in Complex Concentrated Alloys? Shaolou Wei and Cem Tasan; Massachusetts Institute of Technology, United States

Crystalline defects are of fundamental importance in understanding and thereby tailoring the macroscopic mechanical responses of complex concentrated alloys (CCAs). Particularly in the context of microstructural metastability engineering, appreciable interest has aggregated in transformation-induced plasticity or twinning effect. However, the inherent operative unit for the foregoing deformation mechanism, stacking faults, has not yet drawn abundant attention. By investigating a CoCrNiW CCA, we will reveal in this presentation a lesser-explored deformation "faulting" response. Through coupled in-situ synchrotron and electron channeling contrast imaging (ECCI) experiments, we will show that it is the nucleation of extensive stacking faults that is acting as the major plasticity carrier within this CCA, providing macroscopic strain hardenability, and thereby suppressing the formation of the blocky HCP-martensite. We will demonstrate through

computational thermodynamic approach that this sort of faulting mechanism is largely ascribed to a negative intrinsic stacking fault energy, for which our in-situ ECCI deformation experiment will reveal a direct validation. Broader insights into the role of multi-layer generalized stacking fault energy landscape will also be discussed in a sense to complement the current thermodynamic-guided design strategy of metastable CCAs or high-entropy alloys.

Late News: High-Temperature Tensile Creep Properties and Microstructure of a CrMnFeCoNi High Entropy Alloy Mingwei Zhang[1], Easo P. George[2,3] and Jeffrey C. Gibeling[1]; [1]University of California, Davis, United States; [2]Oak Ridge National Laboratory, United States; [3]The University of Tennessee, Knoxville, United States

High entropy alloys (HEAs) can exhibit good combinations of mechanical properties, thermal stability, and corrosion resistance that are critical for high-temperature applications. However, their suitability for service at elevated temperatures under creep conditions has not been explored in detail. In addition to understanding how the special attributes of the concentrated solid solution matrix influence creep, knowledge of the creep properties and deformation mechanisms of the HEA is a prerequisite for further consideration of engineering the material for creep resistance through precipitation or dispersion strengthening. In the present study, constant stress creep tests on an FCC single-phase CrMnFeCoNi were conducted under vacuum between 1023 K and 1173 K. The stress exponent was found to be 3.7±0.1 over all temperatures and stresses. The apparent activation energy of creep was determined to be lower than that for lattice self-diffusion. No significant change in grain size and texture was observed during creep deformation. The steady-state creep microstructure is characterized by highly entangled dislocations networks without subgrain boundary formation. This structure resembles that of low and room temperature deformation at high plastic strain for CrMnFeCoNi and is unlike the creep microstructure of conventional alloys. This observation suggests that the dislocations in CrMnFeCoNi feature more rapid multiplication than in Class A alloys and more sluggish recovery than in Class M alloys.

Late News: A High Entropy Alloy for High Temperature Applications Kevin Garber and Bhaskar S. Majumdar; New Mexico Tech, United States

We report our investigation of high entropy alloys (HEA) for use in the range 600 – 900C, for turbine engine applications. The goal was to evaluate whether the high configurational entropy of HEAs would permit high temperature strengths that were competitive with superalloys while offering a lower density. CALPHAD based alloy design relied on forming a high volume fraction of $L1_2$ precipitates in an fcc matrix for high temperature strength and creep resistance, while minimizing brittle phases and reducing density. Samples of screened alloys were prepared by arc melting and suction cast into 3 mm diameter rods. Compression tests of the final alloy (ΔS_{config}=1.62) up to 871 C revealed that it had a 0.2% offset yield strength of 950 MPa at 750 C, which is not only competitive with most superalloys ($\Delta S_{config} \leq 1.3$) but bettered the best high temperature HEA to date. The density was approximately 7.9 gm/cc, giving the alloy specific strength advantage over existing superalloys. TEM revealed important composition trends in the precipitate phase, and possibly a result of high alloy content influencing atomic partitioning. The microstructure and mechanical properties will be discussed.

Effect of Phase Stability on Nanograin Formation and in Fcc High-Entropy Alloys Koichi Tsuchiya[1,2] and Jein Lee[3]; [1]National Institute for Materials Science, Japan; [2]University of Tsukuba, Japan; [3]Pusan National University, Korea (the Republic of)

FCrMnFeCoNi high-entropy alloy, known as Cantor alloy, exhibits enhanced ductility and high fracture toughness at cryogenic temperatures. This anomalous damage tolerance was attributed to the formation of nanotwins at lower temperatures. Such study motivated the extensive investigations on fcc high/medium entropy alloys, but major effort has been on the search for new compositions and mechanical properties, while the effect of phase transformation on mechanical properties or microstructure formation is not well-understood.

In the present study, a series of high-entropy alloys with different fcc/hcp phase stability was designed and the deformation behavior and microstructures were investigated. They were also subjected to severe plastic deformation (SPD) by high-pressure torsion (HPT). The process of grain refinement was compared for different alloys.
Ingots of Cr20Mn20Fe20Co40-xNix (x=0~20) was prepared by high-frequency melting. They were then hot forged and rolled into bars. They are heat treated at 1473 K for 48 hrs followed by water quench. In as-quenched condition, the samples with 0~10mol%Ni were composed of hcp phase and fcc phase, while others are in a fcc single phase state.
Room temperature tensile tests revealed that yield stress does not depend on Ni content while tensile strength and total elongation depends strongly on Ni content. The best strength-elongation balance was obtained in the 10Ni and 15Ni samples. X-ray diffraction and EBSD revealed deformation induced fcc-hcp transformation (5Ni) and pronounced twinning (10Ni), both of them led to pronounced work hardening. Sample with hcp phase exhibited higher strength but lower ductility than those of fcc single phase samples.
The 10 mmΦ disks of 0~20Ni alloys were deformed by HPT under an applied compressive stress of 5 GPa up to 10 rotations of the anvils. For the samples with 15~20Ni, HPT led to a drastic increase in the value of micro Vickers hardness (Hv). Hv was about 125 in an as-quenched sample; it increased to about 320Hv in the center of the disk and to about 420Hv at peripheral positions even after 0.25 rotation. This can be attributed to rapid progress of grain refinement. BSD-SEM observations revealed that pronounced formation of lamellar structures with about 100 nm width separated by nanotwins. The formation of lamellar limits the mean-free path of dislocations and accelerate dislocation density increase which leads to formation of equiaxed nanograins (~50 nm) by continuous dynamic recrystallization. The observed behavior was similar to low stacking fault materials such as SUS316 or Cu-Al alloys. It was found the with decreasing Ni content and volume fraction of fcc phase resulted in less pronounced hardening and grain refinement by HPT deformation, which may be due to limited number of slip systems in hcp. <gdiv></gdiv>

5:15 AM *F.SF06.04.03
Microstructural Formation and Thermal Stability in Refractory Metal High Entropy Superalloy Systems Nicholas Jones; University of Cambridge, United Kingdom

In just ten years, research that evolved from equiatomic combinations of refractory metal elements has led to the discovery of a new class of materials that has great potential for high temperature service. The so called refractory metal high entropy superalloys (RMHES) exhibit fine-scale two-phase microstructures comprising small coherent cuboidal precipitates of one phase within a matrix of the other. Visually, these microstructures are similar to those of Ni-based superalloys, and the similarities continue in that both phases have cubic structures with similar lattice parameters and one phase is a superlattice structure of the other. However, there are two key differences between RMHES and conventional superalloys. First, RMHES are based on a body centred unit cell and not the face centred form, which may have implications for a range of material properties. Second, in current RMHES, the matrix phase has the ordered CsCl (B2) structure whilst the precipitates are a disordered *bcc* solid solution phase, the inverse configuration to that found in Ni-based systems. The presence of an ordered matrix leads to concerns with respect to ductility and toughness, both of which are key parameters for many industrial applications. Despite this, initial mechanical property data from these alloys is extremely promising with the state-of-the-art material, $AlMo_{0.5}NbTa_{0.5}TiZr$, exhibiting a 0.2% proof stress of 2 GPa at room temperature and ~1.6 GPa at 800°C. In addition, the incorporation of a significant quantity of Al, Ti and Zr means that the density of this alloy is 7.4 $g.cm^{-3}$, well below that of Ni-base superalloys. As such, RMHES show great potential as an alternative or complementary option to conventional Ni-base superalloys for elevated temperature service.

However, there is still a huge amount to learn about these new materials and several aspects of their metallurgy require further investigation. In particular, work is required to understand the microstructural formation pathway, to elucidate the mechanism by which the two phases form and evaluate whether their configuration can be inverted. Similarly, it is critical to assess the stability of the fine-scale two-phase microstructure during prolonged exposure to likely service temperatures, particularly given the detrimental effect that topologically close packed phases are known to have on the properties of other high temperature alloys.

One of the challenges in studying the microstructural formation and stability of these materials is their inherent compositional complexity, which makes it difficult to identify the effects of individual alloying elements. As such, our approach has been to elucidate the critical mechanisms through the characterisation of key compositionally simpler constituent systems. Consequently, this talk will present data from a number of systematically varying alloy series, that build in complexity from ternary to senary systems. The results of these studies will be used to discuss how the fine-scale microstructure observed in these alloys arises, identify the role of specific key elements and determine the phase equilibria, and hence stability, of the microstructure following long duration thermal exposures. Such information will be critical in the continued development of RMHES and the determination of a commercially viable high temperature alloy.

5:30 AM F.SF06.04.06
Visualizing Phase Stability in High Entropy Alloys Daniel Evans, Jiadong Chen and Wenhao Sun; University of Michigan–Ann Arbor, United States

The identification of promising solid-solution regions in High Entropy Alloy composition space is hindered by the lack of suitable tools to visualize stability relationships in high-component systems. Traditional phase diagrams use barycentric coordinates to represent composition axes, requiring $D = (N-1)$ spatial dimensions to visualize an N component system. This means that systems with ≥4 components cannot be visualized on traditional phase diagram axes. We propose forgoing barycentric composition axes in favor of two energy axes: a formation-energy axis and a 'reaction energy' axis. These two dimensional visualizations are successful in capturing complex stability relationships in $N \geq 5$ component systems. By constructing temperature-dependent phase stability graphs, we show that these visual tools can both rationalize high-level qualitative statements regarding the quench-ability of metastable HEA solid-solutions as well as illuminate details about compositional phase-separation.

5:40 AM F.SF06.04.07
Is My Alloy Single Phase? A Simulated X-Ray Diffraction Study of the Detection Limit of Secondary Phases in High-Entropy Alloys Howie Joress, Brian L. DeCost and Jason R. Hattrick-Simpers; National Institute of Standards and Technology, United States

In the high-entropy alloy (HEA) community, it is often a goal to find compositions that are stable as single phases. This single-phase label is often applied based on interpretation of powder x-ray diffraction (XRD), specifically the lack of a detectable peak not indexable to the HEA phase. While scientifically important in general, accuracy of these labels is particularly crucial for accurate machine learning based models in these systems. Depending on many factors, including background levels, signal-to-noise ratio (SNR), grain size and other peak broadening effects, and peak overlap, detection of these secondary phase peaks can be quite difficult. For instance, we show that in a compositionally varying NbTiTa film, the portion of the film in which we can identify the presence of a secondary phase varies considerably based on XRD collection time (and thereby SNR). To quantify this effect in a broad way, we simulated XRD patterns from a common HEA phase with a distinct secondary phase, varying sample and measurment factors including SNR, phase fraction, peak spacing, peak widths, and background level. Each pattern is fit with two models, an HEA specific model and a two phase model having at least one extra peak compared to the HEA model. We then use a Bayesian information criterion based on these fits to apply a single-phase and dual-phase label to the simulated data, so that we can clarify the role of each nuisance factor on the detection limit for secondary phases. We demonstrate that under realistic sample and diffraction conditions, even with idealized simulated data, a secondary phase can remain obscured even at the several percent phase fraction level. We hope this data set can act as a guide for understanding a reasonable lower limit for phase detection and will facilitate a conversation leading to improved standards for data quality when applying phase labels in the HEA space and beyond.

5:50 AM F.SF06.04.09
A High-Throughput Investigation of the Compositional Effects on Phase Stability and Mechanical Properties in Nb-Ti-V-Zr Mu Li, Zhaohan Zhang, Arashdeep S. Thind, Guodong Ren, Rohan Mishra and Katharine Flores; Washington University in St. Louis, United States

Refractory complex concentrated alloys (RCCAs) open new opportunities for high-temperature structural applications that require a combination of high strength, high melting point, good ductility, low density etc. Despite the vast compositional space due to the presence of multiple principal elements, current design of RCCAs is mostly focused on equiatomic compositions to increase stability of single solid solution BCC phase, and to avoid formation of brittle intermetallic phases. Nevertheless, the knowledge of what competing phases are and their stability dependence on each element is yet to be broadened to optimize the development of RCCAs. In this work, we start with an equiatomic NbVZr alloy, which is one of the two multi-phase-forming ternary compositions in the Nb-Ti-V-Zr system. Besides a BCC majority phase, we identified two Laves phases, cubic C15 and hexagonal C14 phases, of which C14 was previously reported to be unstable. With first principles calculations, we determine the stable composition for each phase, and a good consistency is found with the experimental results. The Laves phases are more compliant than BCC, but they strengthen the material, as measured by nanoindentation. Ongoing work expands the scope to non-equiatomic compositions to better understand elemental effects on the alloy's phase selection and properties. We apply combinatorial methods to synthesize Nb-Ti-V-Zr compositional libraries via direct laser deposition, which facilitates the high-throughput identification of different phases, microstructures and mechanical properties as a function of composition. This work also provides guidelines for exploration of compositional effects in all RCCA systems; a complete knowledge of the role each element plays will significantly expedite the design of

RCCA candidates for high-temperature applications.

6:00 AM F.SF06.04.10
Late News: High Temperature Crystal Structure and Microsturcture Evolution in High-Entropy Alloys CoCrFeNiX (X = Al, Ti, Cu, Mn) Produced by Mechanical Alloying Alexander S. Rogachev[1,2], Dmitrii Y. Kovalev[1], Sergei G. Vadchenko[1], Nikolai A. Kochetov[1], Natalia Shkodich[1], Alexander S. Shchukin[1], Kirill V. Kuskov[2], Anna V. Panteleeva[2] and Alex Mukasyan[3]; [1]Russian Academy of Sciences, Russian Federation; [2]National University of Science and Technology "MISIS", Russian Federation; [3]University of Notre Dame, United States

High-entropy alloys (HEA) were initially regarded as stable single-phase disordered solid solutions with fcc or bcc structures stabilized by increased configurational entropy [1,2]. Later, a question about possible metastability of these phases arose [3], and currently the most of the known HEAs recognized as metastable materials [4]. Decomposition of the metastable HEA phases results in (i) precipitation of new phases (intermetallic, σ-, η-, etc.) and (ii) crystal structure changes in the initial major multicomponent phase. Both these effects are equally important for understanding stability and metastability of HEAs. However, most of the known up-to-now works derive metastability of HEAs from the experimentally observed precipitation of secondary phases after annealing, and less attention was paid to evolution of the matrix phase, which commonly remains multicomponent. Thus, a question arises concerning "final destination" of major fcc and bcc high-entropy phases after long-term annealing: will they finally transform into stable HEA or decay down to simple ordered phases, such as intermetallic and binary (ternary) solid solutions?
A task of this work is to reveal *in situ* fine crystal structure transformations in the major fcc and bcc phases of the 3d-transition metals high-entropy alloys CoCrFeNiX, where X = Al, Ti, Cu, or Mn.
A uniform high entropy alloys were produced in a powdered form by fast (90-120 min) mechanical alloying in the planetary mill. The powders were annealed at different temperatures, up to 1473 K in vacuum, with simultaneous X-ray diffraction analysis. Compacted bulk samples were obtained using Spark Plasma Sintering (SPS) method. Structure and properties of the powders and bulk samples were studied with XRD, SEM, EDS, TEM and other methods.
Several specific transformations of crystal structure and microstructure were detected for different studied HEAs. They involve shrinking and expansion of crystal lattice, co-existence of two FCC phases, transformations of BCC into FCC phase, and, possibly, martensitic-like transformation of cubic into tetragonal phase. Shrinking of the atomic structures were detected for all phases after annealing in the temperature range 873 – 1273 K for 5 – 6 h. A drift of the (111) peak regarding to (200) peak of the fcc phase CoCrFeNiAl at 1273 K allow assumption of weak martensitic transformations: high-temperature cubic phase turns into slightly tetragonal (c/a = 1.00123) phase at room temperature. Despite of the structural transformations, the alloys remains multi-principal elemental (high-entropy) after annealing.
This research was done at the expense of grant from Russian Science Foundation (Project No. 20-13-00277). Use of the Spark Plasma Sintering set-up was possible due to support from the Ministry of Education and Science of the Russian Federation under the Competitiveness Enhancement Program of NUST MISiS (Grant no. K2-2020-015).

SESSION F.SF06.05: Theory, Simulation and Modeling
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020
F-SF06

5:00 AM *F.SF06.05.01
Machine Learning-Assisted *Ab Initio* Exploration of High-Entropy Alloys Alexander Shapeev; Skoltech, Russian Federation

High-entropy alloys possess unique properties such as long decomposition time of their metastable random solution phase. Being favorable from the point of view of applications, this property also manifests a challenge to their experimental study: it requires long annealing times to observe alloy decomposition. This opens avenues for application of ab initio methods which, in their turn, encounter the problem of large supercells and long simulation times which are beyond the capabilities of

modern supercomputers. Machine learning hence comes to the stage as a tool to accelerate ab initio calculations through learning from a limited number or relatively small-scale calculations and using the efficient machine-learned model in full-scale simulations.

Application of machine learning, in its turn, faces difficulties originating from the vast configurational space of high-entropy alloys. Indeed, there are about 300 different nearest-neighbor atomic environments in an fcc-based binary alloy (after applying symmetries), while this number for a five-component alloy is about 25 million. Such a large configurational space is harder to cover in interatomic interaction models, which typically manifests in degradation of their accuracy. For instance, when using cluster expansion - a data-driven model used to model confrontational lattice entropy - it gets harder to maintain the meV accuracy of the model with adding more and more elements into the model. Also, the accuracy of interatomic potentials that are used to model alloys at vibrational time scales, degrade with increasing chemical complexity.

In my talk I will present some of the latest developments in machine learning-assisted ab initio modeling of entropic effects in high-entropy alloys. Namely, I will show how one can use machine-learning interatomic potentials to accurately study elastic properties, thermal expansion, short-range order, and stability of phases of prototypical medium-entropy and high-entropy alloys.

5:15 AM *F.SF06.05.02
Estimation of Material Parameters in High-Entropy Alloy by Adjoint Method Derived from Phase-Field Method Toshiyuki Koyama; Nagoya University, Japan

Recently, high-entropy alloys (HEAs) have attracted attention as a new category of advanced metal materials, and large amount of effort are concentrated to explore the solid solution single phase of HEAs because of their excellent mechanical properties. Latest development of HEAs extends not only to structural materials but also high-performance functional materials. Although attention is often paid on the single phase HEAs, the most important contribution of HEAs to physical metallurgy and alloy engineering must be its application to the matrix phase of multi-phase microstructures, i.e. the HEAs are utilized as a matrix phase of structural materials with multi-phase microstructures. High strength and good ductility of HEAs provide ideal properties as a matrix phase of microstructure, and there is a great choice because of a large variety of HEAs, the element combination in HEAs with considering the composition variation is almost infinite. Up until now, alloy systems have been categorized into Fe-based alloys, Ni-based alloys and so on, focusing on the principle element in the matrix phase. Therefore, so to speak, "HEA-based alloys" must be the ultimate alloy system in the history of metallurgy.
In order to carry forward the development of "HEA-based alloys", it is convenient that we are able to utilize the conventional approaches for alloy design based on phase diagrams and phase transformations. However, we always encounter the difficulty because the phase diagram of multi-component alloy systems, in particular high composition region in the phase diagram, is unknown in many cases, and the most of phase transformations observed in multi-component alloy systems is quite complicated. Therefore, the fundamental issues to boost up materials design in the field of HEAs are (1) the effective and accurate assessment of phase diagrams and Gibbs energies in the wide composition range of multi-component alloy systems, and (2) the rapid optimization of materials properties and microstructures within the diverse space of materials parameters and process conditions. In order to overcome these issues, we focused on the following three targets in this study: (i) First-principals calculation on the phase diagram of HEAs and re-assessment of the Gibbs energy database with Calphad approach, (ii) Comprehensive evaluation of materials parameters in Gibbs energy functions and diffusion mobility functions based on the phase-field method with data assimilation techniques by using the kinetic data of microstructures, and (iii) Effective optimization of materials properties and microstructures accelerated by several machine learning techniques. The objective of this study is to provide the efficient strategy in materials science and engineering to handle HEAs on a daily basis.
In particular, as the phase-field method coupled with data science technique is an interesting topic in this approach, the recent results obtained from this study are demonstrated in the presentation. We applied one of the data assimilation techniques "Adjoint method" to the phase-field theory, which derives the adjoint equations in conjunction with phase-field method, and the thermodynamic parameters in Gibbs energy function and the atom diffusivities in HEAs are estimated from the experimental data of composition profiles of HEAs, which is obtained by the conventional diffusion couple investigation on HEAs. As a result, materials parameters are reasonably and efficiently determined in this methodology. It should be emphasized that the inverse problem implemented with phase-field method is quite useful because there are a lot of materials parameters and process conditions utilized in phase-field simulations, and the large amount of experimental microstructure data required for data assimilation process is now available due to the recent development of material characterization devices and techniques.

5:30 AM *F.SF06.05.03

Atomic Scale Computational Investigations of Dislocations in bcc High Entropy Alloys Sheng Yin[1,2], Yunxing Zuo[3], Jun Ding[4], Robert Ritchie[1,2], Shyue Ping Ong[3] and Mark Asta[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]University of California, San Diego, United States; [4]Xi'an Jiaotong University, China

In traditional body-centered cubic (bcc) metals, the core properties of screw dislocations play a critical role in plastic deformation at low temperatures. Recently, much attention has been focused on refractory high-entropy alloys (RHEAs), which also possess bcc crystal structures. In this presentation we present results on dislocation core structures and their mobilities in bcc HEAs, including effects of chemical short-range order (SRO) in these multiple principal element alloys. Specifically, using density functional theory (DFT), we investigate the distribution of dislocation core structures and energies in MoNbTaW RHEAs alloys, and how they are influenced by SRO. The average values of the core energies in the RHEA are found to be larger than those in the corresponding pure constituent bcc metals, and are relatively insensitive to the degree of SRO. However, the presence of SRO is shown to have an effect on narrowing the distribution of dislocation core energies and decreasing the spatial heterogeneity of these energies in the RHEA. It is argued that the consequences for the mechanical behavior of HEAs is a change in the energy landscape of the dislocations which would likely heterogeneously inhibit their motion. We also present results of molecular dynamics simulations using a machine-learning potential for MoNbTaW RHEAs, that is shown to reproduce well the DFT results for distribution of core energies. The simulations investigate dislocation motion for both screw and edge dislocations, and are analyzed in terms of the nature of the mechanisms of motion and pinning induced by spatial heterogeneities in the RHEA. This research was supported by the US Department of Energy, Office of Science, Office of Basic Energy Sciences, Materials Sciences and Engineering Division, under contract no. DE-AC02-05-CH11231 within the Damage-Tolerance in Structural Materials (KC 13) program.

5:45 AM F.SF06.05.07
Continuous Modeling of Dislocations in Random fcc Alloys Ali Rida[1], David Rodney[2], Enrique Martinez[3] and Pierre-Antoine Geslin[1]; [1]INSA LYON, France; [2]Université Claude Bernard Lyon 1, France; [3]Los Alamos National Laboratory, United States

The motion of dislocations and their interactions with obstacles control the mechanical behavior of metals and alloys. In disordered random alloys such as binary solid solutions or high entropy alloys, the random distribution of atoms generates internal stresses that impede the motion of dislocations, leading to improved mechanical properties. Understanding the interactions between dislocations and this structural environment is crucial to better predict the mechanical properties of the alloys.

In this context, we investigated the behavior of a dislocation evolving in a random solid solution by means of a continuous elastic model based on previous work [1]. In a first step, using micro-elasticity theory, we derived general expressions for the spatial correlations of the stress and displacement fields emerging from elastic interactions of different atoms in random alloys. This approach is based on the definition of eigenstrains associated with each atomic lattice site in a linear elastic medium. In particular, we show that in the case of isotropic elasticity the spatial correlations of the displacement and stress fields follow $1/d$ and $1/d^3$ behaviors respectively.

In a second step, the influence of the random solid solution is assessed by relaxing a dislocation line in a noisy stress environment. The nature of the noise (amplitude and spatial correlations) is carefully implemented using the developed analytic expressions to mimic the stress environment of atomistic random solid solutions. This approach allows us to characterize the shape of the dislocation represented as a power spectrum, as well as model quantitatively the dislocation behavior in a random structural environment without integrating the dynamics of individual atoms. Finally, the results obtained from the continuous model are compared with atomistic simulations performed in Al_{50}-Mg_{50} random alloys, and the assumptions used in previous models in the literature [2] are discussed in light of the present findings.

Machine Learning Formation Enthalpy of Compositionally Complex Intermetallics Zhaohan Zhang, Mu Li, Katharine Flores and Rohan Mishra; Washington University in St. Louis, United States

Strengthening high entropy alloys (HEAs) via secondary intermetallic phases has been proven to be an effective approach experimentally. However, the design of intermetallic phases in HEAs for property enhancement is challenging due to the limited understanding of intermetallics in compositionally complex space. While density-functional-theory (DFT)-based methods have promoted design of binary and ternary intermetallics, they are not amenable for rapidly screening the vast combinatorial space of HEAs. In this work, we have developed a machine learning model to accelerate the discovery of intermetallics by predicting their formation enthalpy given only the composition. The model uses easily accessible elemental properties as descriptors and has a mean absolute error (MAE) of ~ 0.044 eV/atom for a testing set of binary alloys. We use the ML model to successfully identify new binary intermetallics that are subsequently confirmed using DFT. The model trained with binary intermetallics can predict ternary intermetallics with a MAE of ~0.057 eV/atom without further training. We further extend this model to multi-element systems and guide the prediction of compositionally complex intermetallics that may form in HEAs.

Late News: Theory and Simulation of Interdiffusion in Multicomponent Systems—A Challenge Andrei V. Nazarov[1,2]; [1]National Research Nuclear University MEPhI, Russian Federation; [2]Institute for Theoretical and Experimental Physics named by A.I. Alikhanov of National Research Center "Kurchatov Institute", Russian Federation

Multi- principal-element alloys (high-entropy alloys) have attracted worldwide attention because they open up a vast compositional space in which different kinds of materials may be discovered [1] and the understanding of the diffusion kinetics in HEAs is of fundamental significance [2]. Weexamine the interdiffusion in multicomponent systems using the approach analogically to one developed earlier for description of interdiffusion in binary alloys [3-5]. In opposite to traditional theory this approach takes into consideration an active role of vacancies, equilibrium distribution of which is not supposed, therefore there are contributions in equations for component fluxes, conditioned by vacancy concentration gradient. We have developed the system of diffusion equations for components and vacancies after substituting the expressions for fluxes in the equations of a continuity. Solutions of the equations show that the vacancy concentration's deviation from the equilibrium one equalize the fluxes of components [3] and component profiles are determined by interdiffusion coefficient. This coefficient [3-5] differs from traditional one (Darken's approach).
A direct generalization of the theory to the case of multicomponent systems meets with serious mathematical complexities. Therefore, we developed a new version of the equations linearization of the original system. The system of linearized equations is solved and we have found a relation between the interdiffusion coefficients and the corresponding tracer diffusion coefficients. Interdiffusion coefficient equations significantly differ from traditional one (Darken's approach). Then we numerically simulate interdiffusion in some alloys and analyze interdiffusion in high-entropy alloys, a possibility of sluggish diffusion in these alloys and the reasons of this effect. Using results the applicability of the quasi-binary approximation is analyzed in calculating the diffusion coefficients in multicomponent alloys.

The Effects of Ti and Si on Mechanical Properties of CoCrFeMnNi-Based Face-Centered Cubic Single-Phase Alloy Syuki Yamanaka, Ken-ichi Ikeda and Seiji Miura; Hokkaido University, Japan

Cantor alloy, which is a face-centered cubic (fcc) high entropy alloy composed of the equiatomic ratio of Co, Cr, Fe, Mn, and Ni, has been attracting attentions as structural materials because of its good strength–ductility balance. By introducing a

secondary strengthening phase to the Cantor-based fcc matrix, the development of materials with an excellent balance of strength and ductility is expected. We selected Ti and Si as additive elements. We investigated the phase equilibrium of Ti or Si added Cantor alloy and found that these elements introduce some secondary phases such as Laves phase, αMn structure phase, and βMn structure phase. However, as the basis of alloy designing with these phases as precipitates, it is quite important to reveal the effect of additive elements on the mechanical properties of the matrix phase. In the present study, the effect of Ti or Si addition on mechanical properties of Cantor-based fcc single-phase alloys were investigated.
Several (Co, Cr, Fe, Mn, Ni) -Si and (Co, Cr, Fe, Mn, Ni) -Ti alloys were prepared by arc melting or induction melting. The ratio of Co, Cr, Fe, Mn, and Ni was selected and kept to be equiatomic. Each alloy sealed in evacuated silica tubes was annealed at 1000 ˚C for 168 hours. After homogenization, all the alloys were identified as fcc single-phase alloys by using XRD and FE-EPMA. The Vickers hardness was investigated with a load of 4.9 N. After machining from the cold-rolled sheets, the dog-bone-shaped specimens for tensile tests were annealed at 1000 ˚C for 15 minutes, and fully recrystallized fcc single-phase specimens with a grain size of ~40 μm were obtained, regardless of the composition. The tensile test was performed with an engineering strain rate of 1.0×10^{-3} s^{-1} at room temperature.
It was found that the Vickers hardness increased with either element addition. The increase in hardness of the Ti-added alloy was greater than that of the Si-added alloy. Furthermore, the ductility was improved by Si addition, while Ti addition does not show significant improvement. It was suggested that Ti is an alloying element that improves strength, while Si improves both strength and elongation of the matrix phase.

F.SF06.06.03
Plastic Deformation of Single Crystals of a Cr-Fe-Co-Ni Equiatomic Medium Entropy Alloy Ashif Equbal and Kazuki Ehara; Kyoto University, Japan

Medium/high entropy alloys are a class of complex compositional solid solution alloys with equiatomic or nearly equiatomic compositions, which prefers to form single-phase solid solution. Some of these alloys exhibit exceptional mechanical properties. For example, their strength, ductility and fracture toughness increase with decreasing temperature. Cr-Fe-Co-Ni equiatomic solid solution alloy is one such alloy with face-centered cubic (FCC) structure, which has been reported to exhibit exceptional strength in polycrystalline materials. However, the detailed mechanisms behind the exceptional mechanical properties of Cr-Fe-Co-Ni equiatomic alloy remain unclear in many aspects, primarily because of the lack of fundamental studies using single crystals. In this study, we prepared single crystals of the Cr-Fe-Co-Ni equiatomic solid solution alloy by directional solidification in an optical floating zone furnace, and investigated the deformation behavior of the [-123]-oriented single crystals under uniaxial tensile and compressive loading over a wide temperature range (13K to 1073K). Temperature dependence of the activation volume were investigated by strain rate change compression tests (1×10^{-5} to 5×10^{-3} s^{-1}). Stress-strain curves obtained from tensile tests at low temperatures indicate the presence of twinning deformation, also found in Cr-Mn-Fe-Co-Ni and Cr-Co-Ni equiatomic solid solution alloys. This is considered to reflect a relatively low stacking fault energy for the Cr-Fe-Co-Ni equiatomic alloy. We also compared the critical resolved shear stress (CRSS) of the Cr-Fe-Co-Ni equiatomic alloy with Cr-Mn-Fe-Co-Ni and Cr-Co-Ni equiatomic alloys. The CRSS value increases significantly with decreasing temperature down to 0 K, and with increasing temperature above 873 K. Activation volume of the Fe-Cr-Co-Ni equiatomic alloy is found to be much lower than those of binary FCC solid solution alloys, which is consistent with quinary HEA and ternary MEA.

F.SF06.06.04
Solute Concentration Effect on Stacking Fault Energy in $CoFeCrNi_xMn_y$ HEAs Eryo Wada[1], Tatsuya Fukushi[1] and Naoyuki Hashimoto[2]; [1]Graduate School of Engineering, Hokkaido University, Japan; [2]Faculty of Engineering, Hokkaido University, Japan

The high entropy alloys (HEAs) have unique properties such as a high radiation resistance and corrosion resistance at elevated temperatures compared with conventional nuclear component materials. This attractive property could make HEAs candidates for high temperature nuclear reactor components. However, the studies on their microstructural evolution and mechanical property change under irradiation, especially at elevated temperatures, is very limited. FCC-type nuclear fission and/or fusion materials have lower stacking fault energies (SFE), and these materials would form stacking fault-type defects, such as stacking fault tetrahedron (SFT) especially in Cu alloy and Ni base alloys and Frank loops in matrix, when irradiated in a wide temperature range. Those stacking fault-type defects, especially Frank loops, would increase the yield strength and decrease the elongation of materials. Therefore, the control of SFE would be a key of less degradation of FCC-type materials under irradiation.In this study, we investigated the effect of Mn and Ni concentration on the stacking fault energy (SFE) in $CoFeCrNi_xMn_y$ high entropy alloys. The TEM observation of the deformed alloys indicated that the SFE of $CoFeCrNi_xMn_y$ seemed to be increased with increasing Mn and Ni concentration. Furthermore, the tensile properties of the alloys appeared to have a relationship with SFE, especially in the yield strength and total elongation. From these results, it is

suggested that $CoFeCrNi_xMn_y$ could be well-designed by controlling the stacking fault energy with optimized Mn and Ni concentration.

F.SF06.06.06
Plastic Deformation Behavior of a Ti-Zr-Nb-Hf-Ta Equiatomic Solid Solution Alloy Shutaro Matsuura, Kyosuke Kishida, Kodai Niitsu and Haruyuki Inui; Kyoto University, Japan

Recently, high-entropy alloys (HEAs) with the body-centered cubic (BCC) structure have received considerable attentions as new structural materials because of their attractive mechanical properties, such as superior strength retention at elevated temperatures of V-Nb-Mo-Ta-W equiatomic alloy and its derivatives and good low-temperature ductility observed for Ti-Zr-Nb-Hf-Ta equiatomic alloy. However, the underlying mechanisms endowing these BCC-HEAs with attractive mechanical properties are largely unknown mostly because of the lack of experimental results for these BCC-HEAs. It is thus quite important to investigate fundamental deformation behavior of these BCC-HEAs. In the present study, we have prepared polycrystalline ingots of the Ti-Zr-Nb-Hf-Ta equiatomic alloy by arc-melting, cold-rolling and subsequent heat-treatment. Compression tests of polycrystalline specimens were carried out at room temperature and 77 K and orientation dependence of slip plane was investigated through trace analysis of apparent slip planes appeared on the surfaces of compressed polycrystalline specimens. In addition, micropillar compression tests of single crystals fabricated from the polycrystalline ingots were carried out as a function of specimen size and loading axis orientations in order to clarify the size and orientation dependence of critical resolved shear stress.

F.SF06.06.07
Research and Development of FeCrNiMn-Based HEAs for Nuclear Reactor Tatsuya Fukushi[1], Eryo Wada[1] and Naoyuki Hashimoto[2]; [1]Graduate school of Engineering, Hokkaido University, Japan; [2]Faculty of Engineering, Hokkaido University, Japan

In order to operate advanced nuclear power reactors safely and efficiently, it is essential to develop new structural materials with high irradiation resistance, especially at higher temperatures. The development of structural materials for nuclear reactors has been mainly focused on highly reliable steel materials such as austenitic stainless steels and low alloy steels. While, in recent years, high entropy alloys (HEAs) have attracted attention as a high radiation resistance material at high temperatures. In this study, we investigated the effects of Mn and Ni composition on the change of mechanical property and microstructure development in FeCrNiMn-based alloys under irradiation.
The results of the present study indicate that the stacking fault energy of FeCrNiMn-based alloys seemed to be increased with increasing Mn and Ni concentration. Furthermore, the ion-irradiation to the alloys resulted in the formation of plane defects such as stacking fault tetrahedra and frank loops. The number density and the average size of these defects appeared to have a strong relationship with stacking fault energy of each alloy. From these results, it is suggested that FeCrNiMn-based alloys could be improved to a higher irradiation resistant alloys with an appropriate stacking fault energy by controlling Mn and Ni concentration.

F.SF06.06.08
Understanding and Tuning Lattice Distortion in an Entropy Stabilized Oxide, $(MgCoNiCuZn)O_5$ Jonathan Kaufman and Keivan Esfarjani; University of Virginia, United States

Lattice distortion in high entropy alloys is postulated to have major effects on these alloys and their properties. There are limited studies that look at the effect of lattice distortion on entropy stabilized oxides. In this study, the entropy stabilized oxide, $MgCoNiCuZnO_5$ is explored to understand the lattice distortion in this system. This work uses molecular dynamics to identify the explicit distances that each atom and atom type distorts from its parent rocksalt crystal structure. Through manipulation of the Buckingham interatomic potentials used to define the structure, effectively changing the alloy composition, changes in the lattice distortion are understood. This entropy stabilized oxide can be optimized to either increase or decrease the total lattice distortion in the system by changing the atomic composition or by replacing certain elements with alternative elements. The effective bond length between metal and oxygen as opposed to bond strength, charge, or mass, is the main factor that causes the distortion of this system.

F.SF06.06.14
Late News: New High-Entropy Alloys: Preliminary Study of Their Properties for a Possible Use as Material for Medical Instruments Pedro Pablo Socorro Perdomo[1], Ionelia Voiculescu[2], Viviana Lucero Baldevenites[1], Nestor Florido Suarez[1] and Julia C. Mirza Rosca[1]; [1]Universidad de Las Palmas de Gran Canaria, Spain; [2]University Politehnica of Bucharest, Romania

The alloys have been traditionally held using a base metal and others in lesser proportion in order to improve the properties of the former. However, at the end of the 20th century a new concept of alloys emerged totally revolutionary based on the mixing of multiple components in fractions identical or similar molars and it was not until 1996 when the concepts of "high-entropy alloys" (HEAs) and "multi-principal-element alloys" (MPEAs), which were perfected and extended in 2004 in publications by Jien-Wei Yeh (Taiwan) and Brian Cantor (UK) (Yeh *et al.*, 2004)(Zhang, 2019)
The behavior of two new high entropy alloys named BioHEA 1 (FeMoTaTiZr) and BioHEA 2 (NbMoTaTiZr) containing chemical elements that exhibit relatively low bio-toxicity for the human body has been obtained and characterized in order to use them for medical instruments, such as surgical blades, saws or cutters.
Vacuum arc remelting (VAR) process was used for the manufacture of the high-entropy alloys by using the MRF ABJ 900 VAR at ERAMET Laboratory (Romania). Highly pure powders of Mo, Ta, Ti, Zr, Nb and Fe (99.9%) were used and classified according to ASTM B214-16 . Eventual losses of material by vaporization are to be heed, so as the theoretical chemical elements assimilations degree into the melt. Both conditions are taken into account for the charge. The alloys obtained were melted in VAR unit up to seven times making use of Argon as inert atmosphere, so that an adequate homogeneity could be achieved.
The experimental alloys were microstructurally characterized to highlight the phase's types and the distribution of chemical elements in the dendritic formations.
The corrosion properties of the HEAs were evaluated using a potentiodynamic polarization method, open circuit potential, pitting potential and repassivation potential. Also the electrochemical impedance spectroscopy (EIS) technique was used. The alloys were immersed in SBS (Simulated Body Fluid) during one week and the corrosion parameters were registered. Analysis of the impedance spectra was carried out by fitting different equivalent circuits to the experimental data. Two equivalent circuits, with one time constant and two time constants respectively, can be satisfactory used for fitting the spectra: one time constant represents the characteristics of the passive film and the second one is for the charge transfer reactions.
We concluded that the low corrosion rates, low corrosion currents and high polarization resistance attest the good stability of these high entropy alloys in simulated biological environment.

Microstructural Heterogeneity and Post Processing Effects on Mechanical Properties of Ti-48Al-2Cr-2Nb Additively Manufactured by Electron Beam Melting (EBM) John Lewandowski[1], Ayman Salem[2], Dan Satko[2], Mohsen Seifi[1,3] and S.L. Semiatin[3]; [1]Case Western Reserve University, United States; [2]Materials Resources LLC, United States; [3]Air Force Research Laboratory, United States

Both cast and wrought titanium aluminide alloys have been studied for more than two decades because of attractive properties that include low density, high specific strength, high specific stiffness and oxidation resistance up to about 700°C. Electron beam melting provides another processing approach to produce net shape components, although little work has been conducted to examine processing-microstructure-property relationships. This work examines as-deposited γ-TiAl (Ti-48Al-2Cr-2Nb) specimens made by Arcam AB and post-processed materials. Mechanical behavior studies on as-deposited, HIPed, and HIPed + Vacuum heat treaded conditions included Vickers micro-hardness, compression, fracture toughness and fatigue crack growth testing. In addition, microstructural details were investigated over a range of scales using various microscopy tools. The presentation will summarize this evolving work on the characterization of AM γ TiAl and provide some comparison to other conventional (e.g. as-cast, wrought) γ-TiAl alloys.

12:00 PM *F.SF07.01.02
TiAl Blades Produced by EBM—Industrialization Challenges Michele Coppola, Gianfranco Vallillo, Veronica Malerba and Silvia Sabbadini; GE AVIO, Italy

Electron Beam Melting has proven to be a technology capable of producing high quality Titanium Aluminide blades and is currently being applied to additively manufacture Low Pressure Turbine airfoils for the GE9x: the largest, most powerful and fuel-efficient commercial aircraft engine in its class, which incorporates GE's most advanced technologies developed over the last decade.
While providing several benefits such as being capable to process a highly reactive alloy such as TiAl, producing sound parts and reducing development time, this additive manufacturing technology has also posed many challenges related to its industrialization and scale-up.
This article is aimed at giving an overview of the main technical areas that had to be addressed to advance EBM from a lab scale to a mass production environment and to guarantee material and process control when it comes to part certification.
One of the main areas of attention was to identify Key Process Variables, determine the associate tolerance band and their impact on desired characteristics of finished parts, such as mechanical (e.g., static strength, fatigue, fracture), metallurgical, physical, or chemical properties.
A significant part of this effort was focused on gaining a good understanding of the defects that can be generated by the additive process and that are different from traditional manufacturing routes such as casting and forging. Additionally, the impact of such defects on material properties, their detectability and acceptance limits are key items to be considered.
Process quality control is another crucial focus area, including part-to-part, build-to-build, machine-to-machine variations, machine qualification, powder handling and correlation between batch coupons and parts. Destructive and non-destructive tests and statistical process control are also part of this effort.
As of now more than 10000 blades have been produced and most certification engine tests have been completed, which makes a great contribution to pushing further the additive technology development and usage.

12:25 PM BREAK

12:40 PM *F.SF07.02.02
Insights into TiAl Processing by *In Situ* Characterisation Florian Pyczak[1,2], Katja Hauschildt[1], Marcus W. Rackel[1] and

Andreas Stark[1]; [1]Helmholtz-Zentrum Geesthacht, Germany; [2]Brandenburg University of Technology Cottbus-Senftenberg, Germany

TiAl-alloys are a typical example that advanced modern lightweight materials have an increasingly complex chemical composition and phase constitution. Accordingly, a sophisticated and complete characterisation of the material is necessary to fully comprehend their behaviour and properties for knowledge-based alloy and process development. Unfortunately, many processing methods for TiAl as well as their operation itself take place at high temperature making their direct monitoring and characterisation difficult. In addition, it is also of interest to investigate the material behaviour if other external loads as for example an applied stress are present in parallel.
In the contribution examples for the direct monitoring and characterisation of the processing of TiAl alloys using *in situ* specimen environments and high energy X-ray diffraction at synchrotron sources are shown. The processes can be rather simple as for example a heat treatment at a certain annealing temperature where the phase composition and its development are monitored (e.g. [1]). But, also complex processing scenarios like hot forming [1,2] or a transient liquid phase bonding process [3] can be directly investigated by those methods. In the former case the texture development during the hot forming is observed while in the latter case the solidification of the joining zone and the subsequent phase transformations are investigated to understand the microstructure formation.
Simple heat treatment, hot forming, transient liquid phase bonding and many other processes for TiAl alloys have in common that phase constitution, texture or microstructure react very sensitively to changes of applied temperature and/or stress. They normally change significantly when the stress is removed or the specimen is cooled down at the end of the processing step. Due to these reasons it is not possible to unambiguously reconstruct the situation at processing temperature and/or under stress based on subsequent material characterisation at room temperature or in absence of the mechanical load. In situ characterisation as presented here is the only means to aquire the full picture and get insight into crucial process details under processing conditions.

Intermetallic Titanium Aluminides Helmut Clemens and Svea Mayer; Montanuniversitaet Leoben, Austria

Intermetallic TiAl alloys based on the γ-TiAl phase are already used as engineering lightweight high-temperature materials in aircraft and automotive engines. Thereby, they partly substitute the twice as heavy Ni-base superalloys. Present applications are, for example, blades in the low-pressure turbine of advanced aero-engines, turbine wheels for turbocharger systems of car diesel engines and engine parts used in racing sport applications. All the applications mentioned above require balanced mechanical properties, i.e. certain ductility at room temperature as well as defined creep strength at elevated temperatures. In the framework of this presentation the alloy design strategies, which have been applied for the development of so-called process adapted TiAl alloys will be explained. Besides the considerations which have led to the selected alloying elements, the heat treatments conducted subsequent to conventional hot-forging and additive manufacturing are discussed. In this context it will be shown that a combination of computer-aided alloy design and novel characterization techniques, e.g. in-situ high-energy X-ray and neutron diffraction, has accelerated both alloy and process development as well as the understanding of this class of alloys sustainably.

SESSION F.SF07.08: Live Keynote II: Processing Structure-Property Relationship of Advanced Intermetallic-Based Alloys for Structural and Functional Applications

A Hexagonal Close Packed Multi-Principal-Element Alloy Identified Computationally Mark Asta[1,2], Daryl Chrzan[1], Qijun Hong[3], Lu Jiang[1], Andrew Minor[1,2], Velimir Radmilovic[4], Julian E. Sabisch[5], Ruoshi Sun[3] and Axel van de Walle[3]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Brown University, United States; [4]University of Belgrade, Serbia; [5]Sandia National Laboratories, United States

In this work we consider the design of alloys that can mimic the excellent combination of room temperature and high-temperature mechanical properties displayed by the refractory elemental metal rhenium, but with reduced cost. Experimental investigations of the deformation mechanisms and microstructures in this material highlight the important role of {11-21} deformation twinning, and high-resolution electron microscopy combined with first-principles calculations offer insights into the origin of the dominance of this twin system. These considerations lead to a design principle that trades off average valence electron count and cost considerations, identifying a promising pool of candidate substitute alloys in the Mo-Ru-Ta-W quaternary system. We demonstrate how this design principles is combined with a computational thermodynamics model of phase stability, based on high-throughput ab initio calculations, to further narrow down the search and lead to the identification of alloys that maintain rhenium's desirable hcp crystal structure. The predictions of this modeling are validated through comparisons to known binary phase diagram sections and corroborated by experimental synthesis and structural characterization demonstrating multi-principle-element hcp solid-solution samples selected from a promising composition range. Additional theoretical calculations and initial mechanical properties measurements will be presented to assess the potential performance of these alloys for high temperature applications.

3:25 PM *F.SF07.05.01
Exploding, Weeping and Reversible Phase Transformations on the Way to a Shape Memory Ceramic Hanlin Gu[1], Justin Jetter[2], Jascha Rohmer[2], Eckhard Quandt[2] and Richard D. James[1]; [1]University of Minnesota, United States; [2]University of Kiel, Germany

The systematic tuning of the lattice parameters to achieve improved kinematic compatibility between phases is an effective strategy for improving the reversibility, and lowering the hysteresis, of solid-solid phase transformations. We present an apparently paradoxical example in which tuning to near perfect compatibility leads to a high degree of irreversibility in oxides of ZrHfYNb, as manifested by violently explosive behavior. Tuning lattice parameters slightly away from near perfect compatibility gives an intermediate "weeping" behavior, in which the polycrystal slowly and steadily falls apart at the grain boundaries. Finally, tuning to satisfy a condition we term the equidistance condition results in reversible behavior with the lowest hysteresis in this system. We give evidence that these observations are explained by a more careful analysis of compatibility of the polycrystal. These results show an extreme diversity of behavior, from reversible to explosive, is possible in a chemically homogeneous system by manipulating conditions of compatibility.

3:50 PM *F.SF07.05.06
Intermetallic Compounds—A Versatile Class of Materials Meets Interesting Catalytic Challenges Marc Armbrüster; Chemnitz University of Technology, Germany

Heterogeneous catalysis is dominated by two material properties, i.e. the electronic structure (ligand effect) and the arrangement of the atoms (geometric effect). A priori, any material offering altered electronic or structural properties is of interest for heterogeneous catalysis. While intermetallic compounds fulfil these criteria, they offer three advantages compared to substitutional alloys: i) stability, caused by the chemical bonding, which can prevent segregation or decomposition in reactive atmosphere, ii) a wide range of chemical potential of the involved (transition)metals and iii) peculiar combinations of electronic and crystal structure. Since intermetallic compounds are thermodynamically stable and available in a wide range of materials, covering nanoparticles, polycrystalline materials as well as large single crystals, they can serve as platform materials to address catalytic challenges.
The stability allows studying their intrinsic properties in many environments, while the different available chemical potentials can be used to adjust the redox properties to the needs of the reaction in question. Systematic study of the geometric effects in reactions is possible by exploiting the large variety of available crystal structures. The use of isostructural substitutional series or compounds with different valence electron concentration allows addressing the electronic effect (ligand effect) on a reaction. Since only the filling degree of the electronic structure is changes, while the crystal structure and thus the electronic scaffold is kept, the electronic effect can be studied with only minor influence of the geometric effect. Like the metallic elements and the substitutional alloys, intermetallic compounds possess electrical conductivity, allowing electrochemical

studies. The versatility of intermetallic compounds created a vivid and active community and in the contribution, several examples will be presented to elaborate the possibilities - and the requirements - for catalytic studies on this class of materials.

Current Activities on Powder Processed TiAl Alloys for Jet Engine Applications in Japan Masao Takeyama; Tokyo Institute of Technology, Japan

A five-year National project of "*Structural Materials for Innovation* (SM^4I)" in *Cross-ministerial Strategic Innovation Promotion Program* (SIP) starting from 2014 in Japan ended in 2018, and the following another 5-year project of "Materials Integration for Revolutionary Design System of Structural Materials" in the SIP II Program has started in 2018. For both programs I have been committed to as the technical leader and take responsibility for the alloy design and development of TiAl alloys, in collaboration with universities and industries. In the first program, the focus was placed on the design/process principles of innovative wrought and cast TiAl alloys to be used for LPT blades, based on the thermodynamics and kinetics of multi-components titanium aluminide systems, and we have successfully proposed and developed new alloys. In the second program, however, we have focused on construction of inverse design principle for innovative TiAl alloys with required properties available for both MIM (metal injection molding) and AM (additive manufacturing) processes, in collaboration with Kobe Steel, Ltd., Osaka Yakin Kogyo Co., Ltd, Mitsubishi Heavy Industries Aero Engine and Osaka University. The degree of freedom of the microstructure design in MIM and AM processes is much wider than that in wrought and cast processes, but attention has to be paid to impurity levels of oxygen and carbon picked up by processing routes of powdering, injection molding and sintering in case of MIM. In this talk, we first show you how oxygen affects the phase equilibria among β-Ti, α-Ti (α_2-Ti_3Al) and γ-TiAl phases, and eventually affects the microstructures created through the phase transformations, based on our phase diagram studies. You have to be careful for alloy development under powder processes if you use currently existing thermodynamic databases. None of them works. The microstructure can significantly be changed from the fully α_2/γ lamellae to the β/γ grained, depending on oxygen level, even the major alloy elements as well as the heat treatment routes are the same. Current progress on this project, especially how important the b phase plays in role in improving mechanical properties for both MIM and AM, based on our novel customized powders, will be presented. A part of this study has been carried under the research of SIP II in JST (Japan Science and Technology Agency).

8:50 AM BREAK

9:05 AM *F.SF07.03.01
High Temperature Creep Behavior of MoSiBTiC Alloy Kyosuke Yoshimi, Ryuta Yanagiya, Shiho Kamata, Shuntaro Ida and Nobuaki Sekido; Tohoku University, Japan

High temperature creep behavior of TiC-added Mo-Si-B alloy was studied in the temperature range of 1400 - 1600°C and the stress range of 75 – 300 MPa. Creep strain under constant applied stress control was measured by directly reading the change in specimen gage length using CMOS image sensors. 4 stages were observed on the creep curves. That is, I. instantaneous strain, II. primary creep, III. secondary creep with the minimum creep rate and IV. tertial creep with acceleration. The minimum creep rates showed a good linear relationship with applied stress in the Norton plot, and the obtained stress exponent, n, was about 3.5, indicating power-law creep. The minimum creep rates also showed a good linear relationship with inverse temperature in the Arrhenius plot, and the obtained apparent creep activation energy, Q_c, was about 497 kJ/mol. The value is in good agreement with the activation energy of Mo self-diffusion (488 kJ/mol), strongly suggesting that Mo self-diffusion is the rate-controlling process of creep deformation of the MoSiBTiC alloy under the conditions. Instantaneous strain varied from 10^{-4} to 10^{-2} depending on stress and temperature. To reach a 10^{-2} instantaneous strain, some mechanisms in addition to an elastic strain should be considered to operate. Careful SEM observations indicated that micro-cracking in

coarse T_2 phase and interfacial separation appeared to occur during the increase in instantaneous strain. Those weakening mechanisms would cause the large instantaneous strain. From the perspective of high temperature applications, the time for creep strain to reach 1% is one of the guidelines for development. Therefore, suppressing the occurrence of those weakening mechanisms through microstructure control as well as the increase in strain-hardening coefficient of Mo solid solution is important for improving the high temperature creep strength of the MoSiBTiC alloy especially in a small creep strain.

9:30 AM *F.SF07.05.09
Relationship Between Thermoelectric Properties and Phase Interfaces Formed on a Multiscale by Phase Separation in the Same Ordered Structure Phases Yoshisato Kimura[1], Yaw Wang Chai[1] and Yonghoon Lee[2]; [1]Tokyo Institute of Technology, Japan; [2]KELK Ltd., Japan

Thermoelectric power generation is an appealing approach for conserving energy and preserving the global environment. Thermoelectric properties are sensitively affected by microstructure of materials which changes during high temperature fabrication processing and practical long term operations. Improvement of thermoelectric performance can be achieved by microstructure control. We focus on the formation of interfaces on a multi-scale according to the phase separation between the same ordered structure phases in two alloy systems. One is phase separation between half-Heusler structure TiNiSn–(Zr,Hf)NiSn according to the miscibility gap, and the other is that between anti-fluorite structure Mg_2Si–Mg_2Sn during coring microstructure formation. Objective of the present work is to understand the formation mechanism of interfaces by the phase separation, and evaluate the effects of interfaces on thermoelectric properties focusing on the electrical and thermal conduction.
Half-Heusler MNiSn (M = Hf, Zr, Ti) are excellent n-type thermoelectric materials. The present author's group reported the phase separation between TiNiSn and ZrNiSn, and TiNiSn and HfNiSn from a random solid solution MNiSn phase. The existence of a miscibility gap was suggested at temperatures higher than 1273 K. The relaxed lattice misfit, evaluated using XRD measurement, is about 3.2% between TiNiSn and ZrNiSn, and 2.5% between TiNiSn and HfNiSn, respectively. These values are quite large compared with 0.6% between ZrNiSn and HfNiSn. Considering the elastically constrained phase interface, a quite large elastic energy can be the driving force of the phase separation. Sharp grain boundaries between Ti-rich and Zr-rich half-Heusler phases can be observed in solidified microstructure of (Ti,Zr)NiSn alloys using SEM. On the other hand, it is very hard to observe a constrained interface. Diffuse interface can be barely observed using TEM in a (Ti,Zr)NiSn alloy after the heat treatment, annealed in the two-phase field for phase separation. Excellent electrical power factor exceeding 5 $mWm^{-1}K^{-2}$ can be achieved while the lattice thermal conductivity is effectively reduced around 3 $Wm^{-1}K^{-1}$ in Ti-rich (Ti,Zr)NiSn alloy according to the effect of solid solution together with the effect of interfaces introduced by phase separation.
Microstructure development in the Mg_2Si–Mg_2Sn pseudo-binary system is characterized by the peritectic reaction. The Mg–Si–Sn ternary phase diagram was evaluated experimentally focusing on the reaction scheme and solidification sequence. It has been found that the gradient composition layered structure is formed in $Mg_2(Si_x,Sn_{1-x})$ alloys on a micro-scale during the solidification process. Dominant mechanism is the phase separation of $Mg_2(Si,Sn)$ solid solution phase into Si-rich $Mg_2Si(Si,Sn)$ and Sn-rich $Mg_2(Sn,Si)$ phases during the coring structure development. Phase separation is occurred leaving phase interfaces to release the large elastic energy stored due to quite large lattice misfit. The constrained lattice misfit between Si-rich $Mg_2Si(Si,Sn)$ and Sn-rich $Mg_2(Sn,Si)$ phases has been evaluated about 5% based on the powder XRD measurements, and the semi-coherent interfaces with interfacial dislocation networks can be observed using TEM. Each layer of the gradient composition layered microstructure is consisting of nano- to micro-scale poly-crystal grains having a compositional gradient of Si/Sn composition ratio. The lattice thermal conductivity can effectively be reduced lower than 2 $Wm^{-1}K^{-1}$ in a $Mg_2(Si_{0.75},Sn_{0.25})$ alloy which contains high density of phase interfaces of gradient composition layered microstructure. Note that the dominant mechanism for the reduction of thermal conductivity is attributed to the phono scattering based on the solid solution effect in $Mg_2(Si_x,Sn_{1-x})$ phase grains and layers.

SESSION F.SF07.01: Titanium Aluminides, Novel Processing

Microstructural Heterogeneity and Post Processing Effects on Mechanical Properties of Ti-48Al-2Cr-2Nb Additively Manufactured by Electron Beam Melting (EBM) John Lewandowski[1], Ayman Salem[2], Dan Satko[2], Mohsen Seifi[1,3] and S.L. Semiatin[3]; [1]Case Western Reserve University, United States; [2]Materials Resources LLC, United States; [3]Air Force

Research Laboratory, United States

Both cast and wrought titanium aluminide alloys have been studied for more than two decades because of attractive properties that include low density, high specific strength, high specific stiffness and oxidation resistance up to about 700°C. Electron beam melting provides another processing approach to produce net shape components, although little work has been conducted to examine processing-microstructure-property relationships. This work examines as-deposited γ-TiAl (Ti-48Al-2Cr-2Nb) specimens made by Arcam AB and post-processed materials. Mechanical behavior studies on as-deposited, HIPed, and HIPed + Vacuum heat treaded conditions included Vickers micro-hardness, compression, fracture toughness and fatigue crack growth testing. In addition, microstructural details were investigated over a range of scales using various microscopy tools. The presentation will summarize this evolving work on the characterization of AM γ TiAl and provide some comparison to other conventional (e.g. as-cast, wrought) γ-TiAl alloys.

5:15 AM *F.SF07.01.02
TiAl Blades Produced by EBM—Industrialization Challenges Michele Coppola, Gianfranco Vallillo, Veronica Malerba and Silvia Sabbadini; GE AVIO, Italy

Electron Beam Melting has proven to be a technology capable of producing high quality Titanium Aluminide blades and is currently being applied to additively manufacture Low Pressure Turbine airfoils for the GE9x: the largest, most powerful and fuel-efficient commercial aircraft engine in its class, which incorporates GE's most advanced technologies developed over the last decade.
While providing several benefits such as being capable to process a highly reactive alloy such as TiAl, producing sound parts and reducing development time, this additive manufacturing technology has also posed many challenges related to its industrialization and scale-up.
This article is aimed at giving an overview of the main technical areas that had to be addressed to advance EBM from a lab scale to a mass production environment and to guarantee material and process control when it comes to part certification. One of the main areas of attention was to identify Key Process Variables, determine the associate tolerance band and their impact on desired characteristics of finished parts, such as mechanical (e.g., static strength, fatigue, fracture), metallurgical, physical, or chemical properties.
A significant part of this effort was focused on gaining a good understanding of the defects that can be generated by the additive process and that are different from traditional manufacturing routes such as casting and forging. Additionally, the impact of such defects on material properties, their detectability and acceptance limits are key items to be considered. Process quality control is another crucial focus area, including part-to-part, build-to-build, machine-to-machine variations, machine qualification, powder handling and correlation between batch coupons and parts. Destructive and non-destructive tests and statistical process control are also part of this effort.
As of now more than 10000 blades have been produced and most certification engine tests have been completed, which makes a great contribution to pushing further the additive technology development and usage.

5:30 AM F.SF07.01.03
Microstructure and Tensile Properties of β-Containing TiAl Alloy Additively Manufactured by Electron Beam Melting Ken Cho[1], Hajime Kawabata[1], Hirotaka Odo[1], Tatsuhiro Hayashi[1], Hiroyuki Y. Yasuda[1], Masao Takeyama[2] and Takayoshi Nakano[1]; [1]Osaka University, Japan; [2]Tokyo Institute of Technology, Japan

Intermetallic TiAl alloys that exhibit low density, high strength at high temperatures and excellent oxidation resistance are used for low pressure turbine (LPT) blades of an aero engine. In recent years, the alloys containing the β phase have attracted much attention due to their good mechanical properties at operation temperature of LPT blades. In this study, rectangular rods of β-containing Ti-Al-Cr alloy were fabricated by electron beam melting (EBM) which is one of the suitable manufacturing processes for the TiAl alloys. Surface morphology, internal defect, microstructure and mechanical properties of these rods were investigated focusing on input energy density of the EBM process. We found that the microstructure of the samples is strongly influenced by the input energy density. The rods fabricated at low energy densities contain fine α_2/γ lamellar structure with the β/γ cells discontinuously precipitated at the lamellar colony boundary. On the other hand, the $\alpha_2/\beta/\gamma$ mixed structure composed of the α_2/γ lamellar and (β+γ) structures can be obtained at high energy densities. The variation in microstructure is caused by the difference in solidification process and temperature distribution in the vicinity of the melt pool during the EBM process. We also found that the tensile properties of the alloys depend strongly on the volume fraction of the α_2/γ lamellar structure, the β/γ cells and the b phase. The strength of the alloys prepared under the optimum condition demonstrate at room temperature and 1023 K is higher than that of Ti-48Al-2Cr-2Nb alloy and comparable to that of Ti-Al-Nb-Mo-B (TNM) alloy.

This work was supported by Council for Science, Technology and Innovation(CSTI), Cross-ministerial Strategic Innovation Promotion Program (SIP), “Materials integration” for revolutionary design system of structural materials” (Funding agency: JST).

5:40 AM F.SF07.01.04
Microstructure Evolution and Mechanical Properties of TiAl/TiAlNb Gradient Alloys Produced by Laser Direct Metal Deposition Yu Zou; University of Toronto, Canada

TiAl/Ti2AlNb dual alloys exhibit potential applications on aerocraftengines, but manufacturing of such alloys needs to achieve an appropriate gradient transition between these two alloys. Here, we deposited -TiAl alloy on a AlNb substrate using the direct metal deposition (DMD) technique and analyzed their graded zone near the interface. Our results show that the transition zone mainly consists of three characteristic layers: the first layer possesses a small amount of and phases dispreading in the matrix. In the the second layer, directional dendrites (phases as dendrite core and phases as dendrite arms) are developed in matrix. The third layer exhibits equiaxial (+) colony with fully lamellar microstructure, which is similar to the microstructure of the -TiAl alloy. We also preformed nanoindentation tests on different phases and layers to revel their mechanical properties. The relationship between nanoindentation results and characteristic microstructure has been identified.

Key words: intermetallics; direct metal deposition; microstrcture; nanoindentation; mechanical properties.

5:50 AM *F.SF07.01.05
Current Activities on Powder Processed TiAl Alloys for Jet Engine Applications in Japan Masao Takeyama; Tokyo Institute of Technology, Japan

A five-year National project of “*Structural Materials for Innovation* (SM^4I)” in *Cross-ministerial Strategic Innovation Promotion Program* (SIP) starting from 2014 in Japan ended in 2018, and the following another 5-year project of “Materials Integration for Revolutionary Design System of Structural Materials” in the SIP II Program has started in 2018. For both programs I have been committed to as the technical leader and take responsibility for the alloy design and development of TiAl alloys, in collaboration with universities and industries. In the first program, the focus was placed on the design/process principles of innovative wrought and cast TiAl alloys to be used for LPT blades, based on the thermodynamics and kinetics of multi-components titanium aluminide systems, and we have successfully proposed and developed new alloys. In the second program, however, we have focused on construction of inverse design principle for innovative TiAl alloys with required properties available for both MIM (metal injection molding) and AM (additive manufacturing) processes, in collaboration with Kobe Steel, Ltd., Osaka Yakin Kogyo Co., Ltd, Mitsubishi Heavy Industries Aero Engine and Osaka University. The degree of freedom of the microstructure design in MIM and AM processes is much wider than that in wrought and cast processes, but attention has to be paid to impurity levels of oxygen and carbon picked up by processing routes of powdering, injection molding and sintering in case of MIM. In this talk, we first show you how oxygen affects the phase equilibria among β-Ti, α-Ti (α_2-Ti_3Al) and γ-TiAl phases, and eventually affects the microstructures created through the phase transformations, based on our phase diagram studies. You have to be careful for alloy development under powder processes if you use currently existing thermodynamic databases. None of them works. The microstructure can significantly be changed from the fully α_2/γ lamellae to the β/γ grained, depending on oxygen level, even the major alloy elements as well as the heat treatment routes are the same. Current progress on this project, especially how important the b phase plays in role in improving mechanical properties for both MIM and AM, based on our novel customized powders, will be presented. A part of this study has been carried under the research of SIP II in JST (Japan Science and Technology Agency).

6:05 AM *F.SF07.01.06
Intermetallic Titanium Aluminides Helmut Clemens and Svea Mayer; Montanuniversitaet Leoben, Austria

Intermetallic TiAl alloys based on the γ-TiAl phase are already used as engineering lightweight high-temperature materials in aircraft and automotive engines. Thereby, they partly substitute the twice as heavy Ni-base superalloys. Present applications are, for example, blades in the low-pressure turbine of advanced aero-engines, turbine wheels for turbocharger systems of car diesel engines and engine parts used in racing sport applications. All the applications mentioned above require balanced mechanical properties, i.e. certain ductility at room temperature as well as defined creep strength at elevated temperatures. In the framework of this presentation the alloy design strategies, which have been applied for the development of so-called process adapted TiAl alloys will be explained. Besides the considerations which have led to the selected alloying elements, the heat treatments conducted subsequent to conventional hot-forging and additive manufacturing are discussed. In this context it will be shown that a combination of computer-aided alloy design and novel characterization techniques, e.g. in-situ

high-energy X-ray and neutron diffraction, has accelerated both alloy and process development as well as the understanding of this class of alloys sustainably.

6:20 AM F.SF07.01.08
Applying a Softening Adapted Acceleration to the Hot Deformation of TNM-B1 Mark Eisentraut, Johan A. Stendal, Sebastian Bolz, Marcus Bambach and Sabine Weiß; Brandenburg University of Technology Cottbus-Senftenberg, Germany

Hot isostatically forged TiAl turbine blades made of TNM-B1 are commercially used in aircraft engines, as they offer significantly lower weight than the traditional nickel-based blades while exhibiting similar strength. Like other TiAl alloys, TNM-B1 displays high peak stress followed by a strong softening behavior (i.e. stress reduction) during hot deformation. This softening can be used to accelerate the deformation process by reducing the processing time and in turn the costs for TNM-B1 parts. In order to avoid increased damage during the accelerated process, a pre-heat treatment (HT) for the hot isostatically pressed material (HIP) is required. To simulate the accelerated forming process, hot compression tests were performed with a DIL805A/D/T dilatometer from TA Instruments (New Castle, Delaware, USA) with different strain rates (0.0013, 0.005, 0.01 and 0.05) and temperatures (T=1150, 1175 and 1200°C). Deformation of the heat-treated state revealed lower flow stress (in both, peak stresses and steady state stresses) and fewer voids compared to the HIP state. The compression test data were used to develop material and temperature specific strain rate profiles based on a material model presented in [Stendal, J.A et al., Applying machine learning to the phenomenological flow stress modeling of TNM-B1. Metals 9 (2019) 220]. Subsequently, hot compression tests were performed with different strain rate profiles (starting strain rates 0.0013 and 0.0052) for the HIP and the HT state. The results were evaluated with regard to their microstructure, deformation, and damage behavior. A reduction of the processing time for all tested strain rate profiles by factors 2-3 could be achieved compared to constant strain rates. Furthermore, the results indicated that the deformation with strain rate profiles (compared to constant strain rates) did not significantly change the resulting microstructure or damage tolerance of the HT state.
Maybe also HEXRD results of the strain rate profiles can be presented to show in detail that the accelerated forming process can lead to the same results as the constant forming process.

6:30 AM F.SF07.01.09
Diffusion Bonding of γ-TiAl Parts Marcus W. Rackel, Dirk Matthiessen, Jonathan D. Paul, Andreas Stark and Florian Pyczak; Helmholtz-Zentrum Geesthacht, Germany

In modern aero engines, γ-TiAl alloys can be used as a replacement for Ni-base super alloys for certain components such as low-pressure turbine blades, due to γ-TiAl alloys having about half the density of superalloys. Nevertheless, due to the relative novelty of γ-TiAl, not the whole variety of processes available for established materials has been fully investigated. One possibility for a joining or repair process is diffusion bonding. Diffusion bonding can be used to repair components by replacing damaged or worn sections without significantly modifying the microstructure. For Ni-base super alloys, diffusion bonding and brazing are well-established repair processes that are used to extend the life cycle of turbine blades. For γ-TiAl alloys, such repair processes are not commercially available.
In the current work diffusion bonding of two commercially used γ-TiAl alloys, Ti-48Al-2Nb-2Cr (4822) alloy and Ti-43.5Al-4Nb-1Mo-0.2B (TNM) alloy, (all compositions in at.%), was as a possible repair technique. The microstructure developed during diffusion bonding and the corresponding mechanical properties after bonding have been determined at room and elevated temperatures. Furthermore, the use of different surface treatments before bonding, such as wire cutting, grinding, drilling and turning as well as various geometric arrangements were examined.
For successful diffusion bonding temperatures above 1000°C had to be appliedto produce sound jointsracke in both alloys. The TNM alloy showed changes in the substrate microstructure (e.g. lamellar coarsening) after bonding at high temperatures close to the γ-solvus temperature. In contrast, there seemed to be no significant microstructural changes in the substrate of the cast 4822 alloy, except for some grain growth at and across the bonded joint.
By optimising the diffusion bonding parameters, it was possible to reach tensile strengths and ductilities in diffusion bonded samples that were comparable to those of the base material. Through optimisation of the surface treatment, it was also possible to produce solid joints for various geometric arrangements and improve the overall quality of the joint.

5:00 AM *F.SF07.02.02
Insights into TiAl Processing by *In Situ* Characterisation Florian Pyczak[1,2], Katja Hauschildt[1], Marcus W. Rackel[1] and Andreas Stark[1]; [1]Helmholtz-Zentrum Geesthacht, Germany; [2]Brandenburg University of Technology Cottbus-Senftenberg, Germany

TiAl-alloys are a typical example that advanced modern lightweight materials have an increasingly complex chemical composition and phase constitution. Accordingly, a sophisticated and complete characterisation of the material is necessary to fully comprehend their behaviour and properties for knowledge-based alloy and process development. Unfortunately, many processing methods for TiAl as well as their operation itself take place at high temperature making their direct monitoring and characterisation difficult. In addition, it is also of interest to investigate the material behaviour if other external loads as for example an applied stress are present in parallel.
In the contribution examples for the direct monitoring and characterisation of the processing of TiAl alloys using *in situ* specimen environments and high energy X-ray diffraction at synchrotron sources are shown. The processes can be rather simple as for example a heat treatment at a certain annealing temperature where the phase composition and its development are monitored (e.g. [1]). But, also complex processing scenarios like hot forming [1,2] or a transient liquid phase bonding process [3] can be directly investigated by those methods. In the former case the texture development during the hot forming is observed while in the latter case the solidification of the joining zone and the subsequent phase transformations are investigated to understand the microstructure formation.
Simple heat treatment, hot forming, transient liquid phase bonding and many other processes for TiAl alloys have in common that phase constitution, texture or microstructure react very sensitively to changes of applied temperature and/or stress. They normally change significantly when the stress is removed or the specimen is cooled down at the end of the processing step. Due to these reasons it is not possible to unambiguously reconstruct the situation at processing temperature and/or under stress based on subsequent material characterisation at room temperature or in absence of the mechanical load. In situ characterisation as presented here is the only means to aquire the full picture and get insight into crucial process details under processing conditions.

Effect of Microstructure Factor on Room-Temperature Fracture Toughness of β-Ti Phase Containing γ-TiAl Based Alloys Ryosuke Yamagata, Hirotoyo Nakashima and Masao Takeyama; Tokyo Institute of Technology, Japan

In order to clarify the effect of microstructure factor on the fracture toughness in β phase containing γ-TiAl based alloys, the room-temperature fracture toughness of these alloys have been investigated, because the room-temperature fracture toughness is a quite important material property for jet engine application materials. In addition, it is essentially important to understand the relationship between microstructure factor and alloy properties for not only predicting alloy properties from microstructure feature but also solving the inverse problem which means to propose the optimal microstructure feature from the required properties.
The microstructure of alloys studied were intentionally controlled from the nearly α_2-Ti_3Al/γ lamellae to β-Ti/γ grained, through the β/γ lamellae using the cellular reaction of $\alpha_2+\gamma \rightarrow \beta+\gamma$ in Ti-Al-Cr ternary system alloys. The fracture toughness was evaluated by an instrumented three-point bend test using a chevron-notched square-bar specimen with 30 mm in a span length under the cross-head speed of 0.05 mm/min. The K_{IC} was calculated using a maximum force in the load-displacement curve on the bend tests and the shape factor of chevron-notched specimen. Some of the specimens were also tested under the higher test speed. The results were compared with the ΔK_{th} and Paris slope those obtained by compact tension (CT) test.
We found that the existence of the β-Ti phase is effective in increasing the fracture toughness. Based on these results, methodology to predict the fracture toughness is discussed.
This work was supported by Council for Science, Technology and Innovation (CSTI), Cross-ministerial Strategic Innovation

Promotion Program (SIP), “Material Integration” for revolutionary design system of structural materials.

5:25 AM F.SF07.02.04
A New Method for Determining the Brittle-Ductile Transition Temperature of a TiAl Intermetallic Sarper Nizamoglu, Karl-Heinz Lang and Martin Heilmaier; Karlsruhe Institute of Technology–Institute for Applied Materials, Germany

Intermetallic materials typically change their deformation behavior from brittle to ductile at a certain temperature called the brittle-ductile transition temperature (BDTT). This specific temperature can be determined by tensile or bending test results conducted at different temperature steps. In order to find the effect of strain rate on the BDTT, these experiments should be repeated at different strain rates. In order to reduce the amount of specimens for finding the BDTT a new methodology is studied. Experiments with particular loading strategies were performed on a fully lamellar Ti-48Al-2Nb-0.7Cr-0.3Si alloy in order to find the BDTT by using a single specimen. For this methodology cyclic loading is applied isothermally under strain control. The same loading block is then repeated on the specimen at different temperatures. The change in plastic strain with increasing temperature is then used for determining the BDTT of the specimen. In the next step a study is conducted to find the effect of strain rate on the BDTT also by using a single specimen. The same methodology as for finding the BDTT is used, but the cyclic loading was applied at different strain rates in a temperature step. Additional dwell times at constant total strains were introduced to identify the BDTT at very low plastic strain rates. The BDTT’s of the TiAl alloy at different strain rates determined by this new methodology are compared in an Arrhenius plot from which the activation energy for brittle-ductile transition can be found.

5:35 AM F.SF07.02.05
Nano-Indentation Modulus and Hardness of β-Ti/α_2-Ti_3Al/γ-TiAl in Ti-Al-Cr System Yotaro Okada, Sota Taniguchi, Ryosuke Yamagata, Hirotoyo Nakashima and Masao Takeyama; Tokyo Institute of Technology, Japan

Microstructures of β-solidifying TiAl alloys typically consists of β-Ti, α_2-Ti_3Al, and γ-TiAl three phases. We have revealed that fatigue crack growth resistance and ductility could improve by introduction of β phase. However, in order to evaluate and estimate the properties of a bulk material more quantitatively, it is essential to measure the properties of each phase. Nano-indentation method is appropriate to evaluate properties of individual phase in multi-phase material. In this study, Young’s modulus and hardness of β, α_2, and γ phases have been investigated using nano-indentation in Ti-Al-Cr system. The alloys were heat-treated based on our phase diagram study. Young’s modulus and hardness were measured by nano-indentation tests with continuous stiffness measurement mode. Crystallographic orientation analysis was performed before measurements with electron backscatter diffraction technique in order to identify the effect of orientation on the properties. In Ti-44Al-4Cr (at.%) equilibrated at 1373 K, the Young’s modulus and hardness of all phases vary depending on the crystallographic orientation. In β and γ phases with (001) orientation, the Young’s modulus is 136 and 146 GPa respectively, and the hardness is 7.0 and 3.0 GPa at room temperature. The hardness of β phase is more than twice as much as that of γ phase. β phase is harder than γ phase even at 1073 K although β phase is often considered to be soft at high temperature.
This work was supported by Council for Science, Technology and Innovation (CSTI), Cross-ministerial Strategic Innovation Promotion Program (SIP), “Material Integration” for revolutionary design system of structural materials.

5:45 AM F.SF07.02.06
Effect of Interstitial Carbon and Oxygen in Solution on the Phase Equilibria Among β/α/α_2/γ Phases in TiAl Alloys Hirotoyo Nakashima and Masao Takeyama; Tokyo Institute of Technology, Japan

Phase equilibria among β-Ti, α-Ti, α_2-Ti_3Al and γ-TiAl phases has been examined experimentally in order to reveal the effect of interstitial carbon and oxygen in Ti-Al binary and Ti-Al-M (M: β stabilizing elements) ternary systems. Alloys with carbon/oxygen content from 0.13 (base) to 1.5 at. % were prepared by vacuum arc melting into button ingots. Those ingots were homogenized at the β or α single-phase region, and then equilibrated at temperature range from 1573 K to 1073 K for up to 2 months. Chemical compositions of the metal elements in the phases present in equilibrated samples were analyzed by conventional wavelength dispersive spectroscopy (WDS). Carbon and oxygen contents in phases were analyzed by Soft X-ray Emission Spectroscopy (SXES).
In Ti-Al binary system, both carbon and oxygen partition into the α (or α_2) against γ phase, and the α+γ two-phase region expands toward both lower and higher Al content side. Oxygen content in γ phase in equilibrium with a is clearly smaller than that of carbon, and thus the partition coefficient of oxygen between α/γ is almost twice higher. In Ti-Al-M ternary systems, interstitial elements also partition into the a (or α_2) against γ and β phases. By adding interstitials into the ternary alloys, the β+α+γ three-phase coexisting region shift towards the higher M content side. At the same time, the terminal composition of the β phase increases with increasing interstitial content in the alloy, especially in case of oxygen. Detailed difference between the effect of carbon and oxygen will be discussed.

This work was supported by Council for Science, Technology and Innovation (CSTI), Cross-ministerial Strategic Innovation Promotion Program (SIP), “Material Integration” for revolutionary design system of structural materials.

5:55 AM F.SF07.02.07
Phase Equilibria in Ternary Ti–Al–Nb Alloys Benedikt Distl, Martin Palm and Frank Stein; Max-Planck-Institute für Eisenforschung GmbH, Germany

Development of next-generation TiAl-based alloys for high-temperature, high-strength applications such as turbine blades relies on computational methods like CALPHAD modelling for alloy and microstructure design. To achieve the goal of further increased service temperatures, an exact knowledge of phase equilibria and microstructures is essential and plays an important role in determining the high-temperature mechanical properties of respective alloys. Therefore, a dataset of reliable experimental results is needed to improve the accuracy of the modelling. The Ti–Al–Nb system is the essential system for alloys such as TNM, TNB or 4822 which are currently used for low pressure turbine blades. However, there are only few results in the literature about the Ti–Al–Nb system regarding phase equilibria below 1000°C, and there is a variety of different and contradicting experimental results for temperatures of 1000°C and above. Based on these data, reliable predictions from CALPHAD modelling is difficult. For further development of TiAl-based alloys the existing CALPHAD database should therefore be improved. Another factor complicating the matter is the not fully understood formation of ternary O- (Ti_2NbAl) and ω- phase (Ti_4NbAl_3) from (βTi) and α_2 (Ti_3Al), respectively, which depend on a variety of factors. Since these phases are important for the mechanical properties of these alloys, research presented here aims to clarify the uncertainties in phase equilibria in Ti-Al-Nb alloys. The research is carried out within the scope of the EU-funded project ADVANCE which is part of the Clean Sky 2 research initiative. The aim of the project is to improve an existing database for TiAl-based alloys for speeding up the development of next-generation alloys based on titanium aluminides. The project is carried out in collaboration with Helmholtz-Zentrum-Geesthacht (Germany), Montanuniversität Leoben (Austria), and Thermo-Calc Software (Sweden).

6:05 AM F.SF07.02.08
The Effect of Zr Addition on High Temperature Phase Transformation and Microstructure of TiAl Alloys Fabian Kathöfer and Florian Pyczak; Helmholtz-Zentrum Geesthacht, Germany

Titanium aluminide alloys (TiAl) are widely recognized for their potential as aero engine components due to their combination of similar service temperature and lower density than conventional metallic systems as for example Ni-base superalloys. However, an improved understanding of the microstructure formation and phase transformation during the production of TiAl parts is necessary to adapt the process parameters for hot forming. Fortunately, an appropriate tuning of the alloy composition can provide good deformation capabilities. For instance, the addition of Zirconium (Zr), a β-stabilizing element, lowers the phase transformation temperatures of the ‘softer’ disordered α and β phases and has other additional beneficial effects e.g. solution strengthening of TiAl alloys. In order to determine appropriate TiAl-Zr compositions thermodynamic calculations were performed using Thermo-Calc Software (‘TCTI1 v1’ database). Based on these, samples with selected compositions were produced by arc melting and afterwards heat treated for chemical homogenization. The thermodynamic behavior during heating was investigated by differential scanning calorimetry (DSC) using a NETZSCH DSC 404 F3 Pegasus. Additionally, high-energy synchrotron X-Ray diffraction (HEXRD) was performed in-situ to observe the phase changes during heating. Both measurement methods reveal that thermodynamic calculations based on currently available databases for TiAl-Zr alloys can only show tendencies how phase transitions change with increasing or decreasing Zr content, but do not allow accurate predictions of transition temperatures.

6:15 AM F.SF07.02.09
Influence of Oxidation Protective Coatings on the Fatigue Behaviour of Ti-48Al-2Cr-2Nb Christoph Breuner[1], Stefan Guth[1], Karl-Heinz Lang[1], Peter-Philipp Bauer[2] and Martin Heilmaier[1]; [1]Karlsruhe Institute of Technology, Germany; [2]German Aerospace Center, Germany

Due to their good oxidation resistance and excellent specific mechanical properties at elevated temperatures, intermetallic Titanium Aluminides are candidate materials to replace Ni-base alloys in high temperature turbine applications. One promising example of Titanium Aluminides is Ti-48Al-2Cr-2Nb (at-%) which is already used for low-pressure turbine blades. Although its duplex microstructure is stable up to a temperature of 850 °C, the alloy is limited to temperatures below 700 °C since oxidation rates increase dramatically at higher temperatures. One possibility to reduce oxidation and increase the operation temperature are oxidation protective coatings. However, these coatings are typically very brittle and therefore unfavourable for fatigue loading. In this study, the influence of oxide layers and oxidation protective coatings on the fatigue lifetime of Ti-48Al-2Cr-2Nb at 750 °C are investigated. Stress-controlled fatigue tests were conducted on coated and

uncoated samples that were pre-oxidised for 300 h at 850 °C as well as on untreated samples. The results indicate that for low stress amplitudes the lifetimes for coated, uncoated pre-oxidised and untreated samples are comparable. Above a certain stress amplitude the S-N-curves for coated and uncoated-pre-oxidised samples are much flatter than for untreated material. I. e. lifetimes of coated and uncoated pre-oxidised materials decrease much more with increasing stress amplitude than lifetimes of untreated samples. The behaviour is discussed based on cyclic deformation analysis and damage observations and explanations are proposed.

High Temperature Creep Behavior of MoSiBTiC Alloy Kyosuke Yoshimi, Ryuta Yanagiya, Shiho Kamata, Shuntaro Ida and Nobuaki Sekido; Tohoku University, Japan

High temperature creep behavior of TiC-added Mo-Si-B alloy was studied in the temperature range of 1400 - 1600°C and the stress range of 75 – 300 MPa. Creep strain under constant applied stress control was measured by directly reading the change in specimen gage length using CMOS image sensors. 4 stages were observed on the creep curves. That is, I. instantaneous strain, II. primary creep, III. secondary creep with the minimum creep rate and IV. tertial creep with acceleration. The minimum creep rates showed a good linear relationship with applied stress in the Norton plot, and the obtained stress exponent, n, was about 3.5, indicating power-law creep. The minimum creep rates also showed a good linear relationship with inverse temperature in the Arrhenius plot, and the obtained apparent creep activation energy, Q_c, was about 497 kJ/mol. The value is in good agreement with the activation energy of Mo self-diffusion (488 kJ/mol), strongly suggesting that Mo self-diffusion is the rate-controlling process of creep deformation of the MoSiBTiC alloy under the conditions. Instantaneous strain varied from 10^{-4} to 10^{-2} depending on stress and temperature. To reach a 10^{-2} instantaneous strain, some mechanisms in addition to an elastic strain should be considered to operate. Careful SEM observations indicated that micro-cracking in coarse T_2 phase and interfacial separation appeared to occur during the increase in instantaneous strain. Those weakening mechanisms would cause the large instantaneous strain. From the perspective of high temperature applications, the time for creep strain to reach 1% is one of the guidelines for development. Therefore, suppressing the occurrence of those weakening mechanisms through microstructure control as well as the increase in strain-hardening coefficient of Mo solid solution is important for improving the high temperature creep strength of the MoSiBTiC alloy especially in a small creep strain.

Creep Performance of Pesting-Resistant Mo-Si-Ti Alloys Alexander Kauffmann, Martin Heilmaier and Susanne Obert; Karlsruhe Institute of Technology–Institute for Applied Materials, Germany

High-temperature structural materials require not only high solidus temperatures and acceptable densities, but especially good creep and oxidation resistance. The improvement in efficiency of high-temperature applications requires the development of alternates to Ni-based superalloys with operating temperatures higher than 1100 °C and densities lower than 8.5 g/cm^3. Ti macro-alloyed Mo-Si-based alloys have shown great potential due to their high solidus temperatures in the range of 1800 °C and considerably reduced densities down to 6 to 7 g/cm^3, while possessing a competitive creep resistance compared to state-of-the-art single crystalline Ni-based superalloys [1]. However, the oxidation behaviour is typically characterised by catastrophic mass loss at temperatures below 1000 °C caused by volatilisation of MoO_3, known as '*pesting*' [1]. In order to achieve pesting-stability in Mo-Si-Ti alloys, a threshold of Ti content of 43 at% needs to be exceeded [2]. The attained fine-scaled microstructures are either fully eutectic (alloy Mo-20Si-52.8Ti (at%) comprising Mo solid solution Mo_{SS} and $(Ti,Mo)_5Si_3$ [1]) or eutectic-eutectoid (alloy Mo-21Si-43.4Ti, comprising Mo_{SS}, $(Ti,Mo)_5Si_3$ and $(Mo,Ti)_5Si_3$ [2]) and possess a solidus temperature-dependent creep resistance. Thus, the creep behaviour is determined by the Ti to Mo ratio, while the Ti content is pre-defined in order to ensure pesting-stability. With the aim of improving the creep resistance of those alloys, several alloy design approaches are pursued: (i) adjustment of the Mo content accordingly to the required Ti threshold, (ii) variation of the microstructural length scale including artificially coarsened microstructures and (iii) potential strengthening phases like Mo_{SS} and $(Mo,Ti)_5Si_3$. It is found that both targets, pesting-stability and creep resistance are met by an intermediate alloy Mo-21.6Si-44.2Ti comprising a eutectic-eutectoid matrix with a small volume fraction of primary solidified $(Mo,Ti)_5Si_3$ (< 5 vol%). Moreover, the alloy Mo-26Si-40Ti with almost 30 vol% primary solidified $(Mo,Ti)_5Si_3$ was created, which reveals a further improved creep resistance at 1200 °C and still provides pesting-stability.

Oxidation Resistance of Additively Manufactured Mo-Si-B Alloys Julia Becker[1], Janett Schmelzer[1], Manja Krueger[1], Georg Hasemann[1], David Fichtner[2], Christoph Heinze[2] and Sven Schmigalla[3]; [1]Otto von Guericke University, Germany; [2]Siemens AG, Germany; [3]Institute für Korrosions- und Schadensanalyse, Germany

Mo-Si-B alloys are high-performance materials that exhibit excellent mechanical properties at ultra-high temperatures (> 1200°C), thus enabling their use in demanding load scenarios. Especially ternary Mo-Si-B alloys, which consist of a Mo solid solution matrix with intermetallic phases (Mo_3Si and Mo_5SiB_2), offer the potential to replace the currently used nickel base superalloys, whose operating temperature is limited to a maximum of 1150°C.
However, the production of such Mo-Si-B alloys is difficult due to the very high melting temperatures of over 2000 °C and the complex solidification behavior. A possible way of production is a multi-stage powder metallurgical process. The development of a single-stage process for the production of Mo-Si-B alloys represents a new challenge.
Additive manufacturing processes such as the powder bed-based Laser Powder Bed Fusion (L-PBF) and the powder nozzle-based Directed Energy Deposition (DED) offer unique new possibilities for near-net-shape production with targeted adjustment of fine-grained microstructures or chemically graded materials.
Initial findings show that it is possible to produce near-eutectic Mo-Si-B alloys using the L-PBF process. These alloys show excellent creep properties and reduced brittle-ductile transition temperatures compared to other Mo-Si-B alloys with a silicide matrix.
Besides the mechanical properties at elevated temperatures, oxidation resistance is another decisive factor for the use of Mo-Si-B alloys. Current work is being carried out to investigate the behavior under cyclic oxidation conditions. The mass loss curves of the additively manufactured Mo-Si-B alloys show that, compared to nickel-based alloys, comparatively high mass losses occur, which can be explained by the microstructures formed by additive processing. However, the AM alloys show an improved oxidation resistance compared with powder metallurgically produced Mo-Si-B alloys having a solid solution matrix.

Off-Stoichiometric Effect on Elastic and Plastic Properties of TiC Phase in Mo-Ti-C Ternary System Shuntaro Ida, Nobuaki Sekido and Kyosuke Yoshimi; Tohoku University, Japan

TiC is a promising carbide for ultrahigh temperature applications not only as a dispersion-strengthening phase but also as structural components. One of the biggest problems with this phase is its poor fracture toughness at room temperature. Interestingly, TiC phase has a wide compositional range away from stoichiometry like intermetallics, which can influence its elastic and plastic properties. Therefore, it is important to understand changes in the elastic and plastic properties of TiC phase in relation to off-stoichiometry and structural point defects. In this work, the effects of off-stoichiometry and Mo substitution on the elastic and plastic properties of TiC phase at room temperature were investigated for Mo-Ti-C ternary alloys in the Mo/TiC two-phase region. Multiple alloys on the same tie lines at 2073 K were made based on the Mo-Ti-C ternary phase diagram. The elastic moduli of the TiC phases with different terminal compositions in the two-phase region were estimated from the elastic moduli of the alloys obtained experimentally based on the rule of mixture by the Voigt model. The Young's modulus and shear modulus of the TiC phase increase with Mo substitution, but decrease from off-stoichiometry toward the metal-rich side. The change in the elastic moduli of the TiC phase is more effective by the off-stoichiometry than by the Mo substitution. The increase in Young's modulus and the decrease in shear modulus may improve fracture toughness since the increase in yield stress and the improvement of plastic deformability increase the energy absorbed during crack propagation. The TiC phase in the Ti-C binary system, which has the lowest shear modulus and Young's modulus, exhibits better toughness at room temperature than other TiC phases. The decrease in shear modulus appears to be a more important factor in improving the toughness of the TiC phase at room temperature.

5:45 AM F.SF07.03.05
Additive Manufacturing of a Near-Eutectic V-9Si-5B Alloy for High-Temperature Application Janett Schmelzer[1], Silja-Katharina Rittinghaus[2] and Manja Krueger[1]; [1]Otto-von-Guericke-University Magdeburg, Germany; [2]Fraunhofer - Institute for Laser Technology, Germany

There nearly is no other industry placing such high demands on materials as aircraft construction. Due to the mature design of the aircraft engines, further competition will take place with innovative materials and manufacturing processes. In the

vicinity of the combustor, where engine parts are burden with temperatures higher than 500 °C, Ni-based superalloys have been state-of-the-art for many years. However, Ni-based superalloys come along with a high density (~ 8.5 g/cm^3). Weight reduction is an important issue to achieve the target of increased thermodynamic efficiency including less fuel consumption and a reduced amount of exhaust emissions. To this end, research activities focus on new light-weight materials with good high-temperature properties to increase the thrust-to-weight ratio in aircraft engines by replacing Ni-based superalloys. Vanadium points out as an interesting candidate, since it offers the lowest density (ρ = 6.11 g/cm^3) in comparison to other high-melting metals. Moreover, alloyed with Si and B a multi-phase microstructure, consisting of a vanadium solid solution (V_{ss}) phase next to the intermetallic phases V_3Si and V_5SiB_2 [1,2] forms, which offers a low ductile-brittle-transition as well as enhanced high-temperature strength and creep resistance next to an improved oxidation resistance [1]. However, conventional ingot metallurgical processing of V–Si–B material and subsequent machining is energy- and time-consuming due to the different behavior of the ductile solid solution phase and the brittle silicides. This work presents the first study on the feasibility of printing pre-alloyed near-eutectic V-9Si-5B powder material via directed energy deposition (DED) as a method for additive manufacturing. Tailored V-9Si-5B powder material was produced by means of a gas atomization process. A novel setup for the DED experiments was developed and an overview of the production parameters for manufacturing of crack-free specimens is given. The microstructural evolution of the three-phase V-9Si-5B alloy is described by means of SEM, EBSD and STEM analyses during the entire process chain, i.e. the gas atomization of the powder material, the consolidation via DED and the heat treatment of the compacts. First mechanical tests demonstrate the high hardness and the competitive creep resistance of the AM V-9Si-5B material in comparison to other three-phase V-based alloys.

5:55 AM F.SF07.03.06
Properties of Laser-Based Additively Manufactured Mo-Si-B Alloys Manja Krueger; Otto von Guericke University, Germany

Additive manufacturing (AM) of Mo-Si-B alloys is very challenging due to their high melting temperatures above 2000 °C and their possible oxide formation reactions during processing. Additionally, multi-phase Mo-Si-B alloys are brittle up to ~ 950 °C, which is critical in terms of possible crack formation during fast cooling in AM processes.
In this presentation we will demonstrate that laser-based AM can be applied to produce dense Mo-Si-B bodies using tailored gas atomized powders. Therefore, the alloys Mo-9Si-8B, Mo-13.5Si-7.5B and Mo-16.5Si-7.5B were selected, which have different concentrations of silicide phases. We show how the modified processes Laser Powder Bed Fusion (LPBF) and Direct Energy Deposition (DED) lead to homogeneous and crack-free bulk materials with a low porosity of < 1%. The microstructure of these materials will be compared to microstructures derived from powder metallurgical (PM) processes and the properties of the AM and PM materials will be comparatively assessed. It will be demonstrated that the hardness, the brittle-ductile-transition-temperature (BDTT) and the creep response of AM Mo-Si-B materials are quite competitive with PM Mo-Si-B materials.

6:05 AM F.SF07.03.07
Micropillar Compression Deformation of Transition-Metal Disilicides with the C40 Structure Kyosuke Kishida and Haruyuki Inui; Kyoto University, Japan

Transition-metal disilicides, $TMSi_2$ (TM = Nb, Cr, Ta and V) with the hexagonal C40 structure have received considerable attention as base materials of a new-class of ultra-high temperature structural materials for more than three decades because of their high melting points, attractive mechanical properties at high temperatures and relatively low density. In these hexagonal C40 silicides, only basal slip has been confirmed to be operative at high temperatures above 400 °C in pristine single crystalline specimens. Among these four C40 silicides, $CrSi_2$ exhibits quite peculiar slip behavior of synchroshear-type, while the other three silicides deforms with normal slip. Recently, we have investigated room-temperature plastic deformation behavior of various hard and brittle intermetallics, such as TM_5Si_3 type silicides, laves phase, sigma phase, by micropillar compression methodology and have confirmed the dislocation activations in most of these hard and brittle intermetallics even at room temperature in the micropillar form. In the present study, room-temperature deformation behavior of single crystals of various transition-metal disilicides $TMSi_2$ (TM = V, Cr, Nb and Ta) with the C40 structure was investigated by the micropillar compression method as a function of the loading axis orientation and specimen size in order to clarify the details of operative slip systems and to evaluate their CRSS values at room temperature. Dissociation schemes of the identified dislocations were investigated by transmission electron microscopy imaging of dislocation microstructures and atomic-resolution scanning transmission electron microscopy imaging of their core structure. Although plastic flow is

observed only at high temperatures for most $TMSi_2$ in the bulk form, basal slip was confirmed to be operative at room temperature in the four C40-$TMSi_2$ in the micropillar form. The CRSS value for each slip system exhibits 'smaller is stronger' behavior following an inverse power-law relationship with the power-law exponents depending on slip systems and materials. Deformation mechanisms of these $TMSi_2$ at room temperature will be discussed based on the comparison with those previously obtained for bulk-sized single crystals at elevated temperatures.

V_{SS}-V_3B_2 Eutectic Alloys—Microstructure and Compression Properties Christopher Müller, Georg Hasemann, Maximilian Regenberg and Manja Krueger; Otto-von-Guericke-University, Germany

Due to their low density in combination with a high melting point, vanadium-based alloys provide great potential as a new type of structural lightweight material for high temperature applications. Based on the promising V-Si-B system, the microstructural evolution and room temperature deformability in different binary eutectic V_{SS} (V solid solution)-V_3B_2 alloys were determined. In particular, it was investigated how the binary eutectic trough (V_{SS}-V_3B_2) is affected by alloying with silicon and how the resulting phase fractions affect the compression properties at room temperature. These aspects where systematically investigated for the first time.
Different binary V-B and ternary V-Si-B alloys were produced by conventional arc-melting. Scanning Electron Microscopy (SEM) and X-ray Diffraction (XRD) methods were used to examine the as-cast microstructures as well as to identify phases and to determine phase fractions. Microhardness measurements and room temperature compression tests were carried out to determine the mechanical properties in dependence of the respective phase fractions.
The results were compared with the current literature in order to estimate the contributions of the various phases to the resulting compressive strengths and to re-evaluate the information available on solidification processes in the V-Si-B system. The results indicate that the V_{SS} phase controls the plastic deformability in the V_{SS}-V_3B_2 eutectic microstructure whereas the intermetallic V_3B_2 phase acts as second phase strengthener. With increasing silicon addition, the eutectic composition is shifted to lower boron concentrations. Compared to the calculated liquidus projection of the V-Si-B system, the present experimental results also suggest a much larger binary eutectic trough than recently reported in the literature.

6:25 AM F.SF07.03.09
Microstructure Evolution and Mechanical Properties of Eutectic V-Si-B Alloys Georg Hasemann[1], Christopher Müller[1], Weiguang Yang[2], Maximilian Regenberg[1] and Manja Krueger[1]; [1]Otto-von-Guericke University Magdeburg, Germany; [2]Forschungszentrum Jülich GmbH, Germany

The solidification behavior of arc-melted alloys in the V-rich portion of the ternary V-Si-B alloy system has been experimentally investigated. A detailed microstructure analysis of several as-cast alloys based on SEM observations, EDS/WDS and EBSD measurements was carried out. As a result, different solidification reactions in the V-rich V-Si-B system were identified. On the two binary boundary systems V-Si and V-B those reactions were attributed to primary V_{SS}, V_3Si, V_5Si_3, V_3B_2 and VB. Furthermore, a primary solidification reaction within the ternary system was attributed to V_5SiB_2. As a result, the new data allows a reconstruction of the liquidus surface of the V-Si-B phase diagram. Furthermore, a V_{SS}-V_3Si-V_5SiB_2 ternary eutectic reaction was identified and its composition was investigated experimentally. The V-based ternary eutectic is isomorph to the well-known Mo-Si-B system and the Mo_{SS}-Mo_3Si-Mo_5SiB_2 ternary eutectic. However, the V-based ternary eutectic has a solid solution character since V_{SS} forms the major phase as compared to the intermetallic character of the Mo-base eutectic with the Mo_3Si phase as the major phase. This will have advantages considering low temperature deformability and fracture toughness.
By carrying out this work special attention had been paid to the eutectic reactions in the binary V-Si and V-B systems as well as in the ternary V-Si-B system. Thus, the binary eutectic compositions of V_{SS}-V_3Si and V_{SS}-V_3B_2 had been re-investigated carefully, since they represent important anchor points for the liquidus projection in the ternary system.
Besides the microstructure evolution, room temperature compression tests were carried out to get first insights in the alloys compressive yield stress and deformability. Silicon was found to act as a strong solid solution strengthener without embrittling the V_{SS} phase, even at its maximum Si solubility of about 7 at.%.

A Hexagonal Close Packed Multi-Principal-Element Alloy Identified Computationally Mark Asta[1,2], Daryl Chrzan[1], Qijun Hong[3], Lu Jiang[1], Andrew Minor[1,2], Velimir Radmilovic[4], Julian E. Sabisch[5], Ruoshi Sun[3] and Axel van de Walle[3]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Brown University, United States; [4]University of Belgrade, Serbia; [5]Sandia National Laboratories, United States

In this work we consider the design of alloys that can mimic the excellent combination of room temperature and high-temperature mechanical properties displayed by the refractory elemental metal rhenium, but with reduced cost. Experimental investigations of the deformation mechanisms and microstructures in this material highlight the important role of {11-21} deformation twinning, and high-resolution electron microscopy combined with first-principles calculations offer insights into the origin of the dominance of this twin system. These considerations lead to a design principle that trades off average valence electron count and cost considerations, identifying a promising pool of candidate substitute alloys in the Mo-Ru-Ta-W quaternary system. We demonstrate how this design principles is combined with a computational thermodynamics model of phase stability, based on high-throughput ab initio calculations, to further narrow down the search and lead to the identification of alloys that maintain rhenium's desirable hcp crystal structure. The predictions of this modeling are validated through comparisons to known binary phase diagram sections and corroborated by experimental synthesis and structural characterization demonstrating multi-principle-element hcp solid-solution samples selected from a promising composition range. Additional theoretical calculations and initial mechanical properties measurements will be presented to assess the potential performance of these alloys for high temperature applications.

Deformation Microstructure of an $L1_2$ Intermetallic High Entropy Alloy Rachel D. Osmundsen and Ian Baker; Thayer School of Engineering at Dartmouth College, United States

In the search for single-phase high entropy alloys (HEAs), intermetallic HEAs have been largely neglected. Intermetallic HEAs are often components of multi-phase HEAs that have good structural properties, so, it is critical to understand their deformation microstructures. This work shows that the HEA $Al_{8.8}Co_{18.1}Cr_{21.7}Fe_{20.2}Ni_{31.1}$, which is the $L1_2$ phase of the $AlCoCrFeNi_{2.1}$ eutectic system, can be cast as a single ordered phase. The deformation microstructure was examined in the transmission electron microcope using weak-beam dark-field imaging on samples compressed to ~3% plastic strain. Deformation occurred on the {111}<110> slip system and stacking faults, dipole nets, and large macrokinks were observed. The stacking fault energy was estimated and dissociated dislocations identified through careful tilting experiments. Tensile tests were performed on the alloy in both the disordered and strongly ordered states. The difference in tensile properties between the two is thus due to features unique to the ordered state, such as antiphase boundary (APB) tubes. Additionally, magnetization curves were taken with a vibrating sample magnetometer to measure the the change in magnetization with APB tube formation. The formation of APB tubes changes the local chemical environmnt, including where ferromagnetic elements sit in realtion to one another. The formation of APB tubes in ordered $Al_{8.8}Co_{18.1}Cr_{21.7}Fe_{20.2}Ni_{31.1}$ is compared to other binary alloys, with a focus on Ni_3Fe. This work was supported by the U.S. Department of Energy, Basic Energy Sciences, under award #DE-SC0018962.

5:25 AM F.SF07.04.03
Development of Fe–Al–Nb(–B) Alloys for High-Temperature Structural Applications Angelika Gedsun and Martin Palm; Max-Planck-Institut für Eisenforschung GmbH, Germany

For high-temperature structural applications, e.g. compressor blades in steam turbines, novel sustainable and heat resistant materials are required. Fe–Al based alloys show significant longevity due to their outstanding corrosion and wear resistance additionally to their low density and good mechanical properties.
Fe–Al based alloys are becoming more interesting for industrial applications, not at least because they are an economically efficient alternative to replace Cr-steels and Ni-based superalloys in specific applications. Moreover, standard processing techniques can be applied for their large-scale production [1, 2].

Through recent developments, especially the creep resistance could be improved by different alloying concepts [2]. E.g., incoherent precipitates such as borides or Laves phase or coherent precipitates can significantly enhance the mechanical properties.

In Fe–Al–Ta the formation of the stable hexagonal C14 Laves phase is preceded by the formation of the coherent metastable $L2_1$ Heusler phase, which improves strength and creep resistance up to 750°C. Through thermomechanical processing, heat treatment or doping, microstructures with fine scaled and homogeneously distributed Laves phase precipitates inside the Fe–Al matrix and at grain boundaries were obtained [3].

For further optimization, Ta was replaced by Nb in the present research.
In the Fe–Al–Nb system, the controlled distribution of the stable Laves phase within the Fe–Al matrix and at grain boundaries could also be achieved when the formation of the incoherent Laves phase is preceded by the formation of the coherent metastable Heusler phase.
Further investigations focus on the morphology of Laves phase precipitates at grain boundaries and their coarsening.

Predict Homogeneous Crystal Nucleation Rate from Melts with a Steep Composition Gradient—A Computational Study of NiAl Intermetallic Formation Peng Yi, Tim Weihs and Michael L. Falk; Johns Hopkins University, United States

Reactions at interfaces between different solid (crystalline or amorphous) materials are critical processing steps for a variety of applications including microelectronics, superconducting magnet wires, coatings on turbine blades, and reactive materials.[1] Due to the highly non-equilibrium nature of interfaces, phase formation at these interfaces is complicated and difficult to predict. It is well established experimentally that the first phase to form through an interfacial reaction need not be the most stable phase predicted by the phase diagram. As an example, DSC and TEM experiments in the Ni/Al multilayer system have suggested that the formation of intermetallic phases can be suppressed by a high heating rate, [2, 3] or by reducing the interspacing between the layers.[4, 5] Different heating rate or interspacing lead to different composition gradient across the interface, which strongly affects the thermodynamics and kinetics of the nucleation process.

We studied homogeneous nucleation of the non-stoichiometric NiAl-B2 intermetallic compound from deeply undercooled amorphous melts with an imposed composition gradient.[6] Data from MD simulations permits quantification of the nucleation rate of the intermetallic phase and indicates that nucleation proceeds in a polymorphous mode. The nucleation rate decreases with increasing gradient, and nucleation is completely suppressed above a critical gradient, as suggested by Desré and co-workers[7]. Based on an argument of crystal nucleus stability, a simple estimate provides good prediction of the critical gradient. A modified classical nucleation model parameterized with thermodynamic and kinetic quantities calculated independently predicts the nucleation rates and their variation with the imposed gradient, matching the MD results very well. This model can be used to compute the nucleation rates for different intermetallic compounds at an interface for the prediction of the phase formation sequence.

Study of the Initial Stages of Precipitation of Alloy 718 During Conventional versus Direct Ageing Vitor V. Rielli[1], Felix Theska[1], Flora Godor[2], Aleksandar Stanojevic[2], Bernd Oberwinkler[2] and Sophie Primig[1]; [1]UNSW Sydney,

Australia; [2]voestalpine BÖHLER Aerospace GmbH & Co KG, Austria

Recent global events have been negatively affecting the air transport market exposing the great need for operational excellence and efficiency due to optimal utilization of materials [1]. Better aircrafts with more efficient engines will push materials to the limit, and as a vital alloy for turbine discs, Alloy 718, a Ni-based superalloy, must have its properties improved in order to withstand higher temperatures and workloads. Direct ageing is a common processing route where solution annealing between forging and ageing is omitted, producing yield strength increases up to 10% in comparison to conventional ageing [2]. Several mechanisms are responsible for this behaviour, such as changes in γ-matrix grain size, δ phase fraction, dislocation density, and mainly the configuration of γ' and γ" precipitates [3]. An investigation regarding the nucleation and growth of these precipitates during the early stages of precipitation during direct ageing was published recently [4] and it has found that the presence of dislocations enabled the formation of γ" precipitates during air cooling from forging and an accelerated growth during direct ageing. A comparison between the evolution of the nanoscale precipitates during direct ageing of materials water quenched after forging and conventionally aged materials is still lacking. In this study through the use of atom probe microscopy and TEM in-situ heating, a holistic analysis of the precipitation of γ' and γ" is given and the effects on the mechanical properties are investigated.

Experimental and Calculation Approach for Phase Equilibria Among γ/TCP/GCP *oP*6 Phases at Elevated Temperatures Ryota Nagashima, Hirotoyo Nakashima and Masao Takeyama; Tokyo Institute of Technology, Japan

Strengthening of Ni-base superalloys are in principle designed using GCP (Geometrically Closed- packed) phase of Ni_3Al-γ' ($L1_2$), however game-changing microstructural design principle without relying on γ' phase will be needed for further development of the alloys. We are currently constructing a novel microstructure design principle, using thermodynamically stable TCP (Topologically Close-packed phase) or α-W for grain boundaries, together with GCP (Geometrically Close-packed phase) other than γ' phase for grain interiors, based on grain boundary precipitation strengthening mechanism.
One of the promising systems is Ni-Cr-Mo ternary system, where TCP phases of NiMo, μ and P together with GCP phases of Ni_3Mo, Ni_4Mo and Ni_2Cr (*oP*6) exist. We have clarified that *oP*6 phase becomes extremely stable by Mo in solution at over 1073 K which is stable at 873 K in Ni-Cr binary system. Thus, there exist three-phase regions of γ/NiMo/*oP*6 and γ/P/*oP*6, unlike the phase diagram calculated based on commercially available thermodynamic databases. Moreover, *oP*6 phase precipitates coherently with tweed-like morphology and possess an orientation relationship of $\{110\}_{\gamma}//(100)_{oP6}$, $<001>_{\gamma}//[010]_{oP6}$, just like precipitation behavior of γ' particles in ordinary Ni-based superalloys. In contrast, the TCP phases preferentially precipitate at the g grain boundaries. On the other hand, in Ni-Cr-W ternary system, g phase equilibrates with α-W phase. By partially replaced Mo by W, there arises another possibility of γ/α-W/*oP*6 three-phase region. Since W is the same transition metals of VIb group with Cr and Mo, *oP*6 phase stability is expected to increase by W.
In order to evaluate the possibility for utilizing a novel microstructure design principle for Ni-based alloys having TCP phase at grain boundaries and GCP phase other than γ' phase within grain interiors, in this study phase equilibria among γ/TCP or α-W/GCP *oP*6 phases in Ni-Cr-M (M: Mo, W) ternary and Ni-Cr-Mo-W quaternary systems, have been experimentally examined at elevated temperatures. Since it is not easy to clarify the phase diagram based on only experimental, we assess the thermodynamic model for each phase and optimize the interaction parameters to calculate the phase diagram in good agreement with experimentally determined phase diagram. Novel microstructure design using TCP or α-W and *oP*6 phases has been suggested based on the phase equilibria.

The Effects of RE-RE Substitution on the Phase Stability of LPSO Phase in Mg Alloys Seiji Miura[1], Futoshi Miyakawa[1], Ken-ichi Ikeda[1], Satoshi Takizawa[1], Toshiaki Horiuchi[2], Satoshi Minamoto[3] and Takaomi Itoi[4]; [1]Hokkaido University, Japan; [2]Hokkaido University of Science, Japan; [3]National Institute for Materials Science, Japan; [4]Chiba University, Japan

An LPSO (long period stacking ordered) phase appearing in Mg alloys has been attracting attention as a strengthening phase. The phase is composed of transition elements (TM) such as Zn, Ni, Cu and Al, together with rare-earth elements (RE) such as Y, Dy and Gd. Many investigations have been dedicated to understand the stability of LPSO phases, however, still the reason of the formation type of Mg alloys with LPSO phases are not well understood. In a previous study, the effect of substitution of TM elements in a Mg-Al-Zn-Gd quaternary system from Mg85Al6Gd9 to Mg85Zn6Gd9 was investigated and found that

the formation type of Mg alloys changes from Type II -> Type I -> Type II [(1)]. For a further discussion, it is needed to investigate the substitution behavior of rare-earth elements. Especially there are several rare-earth elements which do not form LPSO phases. In the present study it is attempted to confirm the existence of stable phases around the LPSO to understand the substitution behavior of Mg-Zn-RE LPSO phase.
Quaternary alloys, the total weight of each sample is approximately 30 g, were prepared by melting Mg blocks (99.95 wt.% purity), Zn blocks (99.5 wt.% purity) and several RE metal blocks (99.9 wt.% purity) in a graphite crucible placed in a high-frequency furnace under argon atmosphere, and casting into a mild steel mold. All the alloys sealed in glass tubes under argon atmosphere were annealed for up to 1000 h at 673 K or 723 K and then quenched into water. Phases in the samples were identified by X-ray diffraction (XRD, PHILIPS, X'Pert-MPD), and by wavelength dispersive X-ray spectrometer (WDS) equipped with field emission electron probe microanalyzer (FE-EPMA, JEOL, JXA-8530F).
It was found that almost no Ce substitutes for Y in Mg-Zn-Y-Ce based LPSO, while almost no Y substitutes for Ce in the $Mg_{12}Ce$ phase. These phases co-exist in Mg85Zn6Y4.5Ce4.5 alloy, suggesting that the stable $Mg_{12}Ce$ is one of the reasons why the limited amount of Ce can be solved into the LPSO phase.

Tribomechanical Investigation of TiC-Reinforced Tribaloy T400 Suspension-Powder Plasma-Sprayed Composite Biocompatible Coating Moumita Mistri[1], Shrikant Joshi[2], Kantesh Balani[1] and Kamal Kar[1,1]; [1]Indian Institute of Technology Kanpur, India; [2]University West, Sweden

Tribaloy T400 (CoCrMoSi) alloy is considered as a potential candidate in impeding the wear-assisted surface material loss from engineering modules operating at a temperature as high as 800 °C. In this report, a hybrid suspension-powder plasma spray technique has been employed to deposit TiC (d_{50}= 2.2 μm)-reinforced T400 (average powder size = ~10-45 μm) composite coating for such application. A uniform and adherent T400-TiC coating of thickness ~100 μm revealed in microstructural analysis infers favorable higher densification (ImageJ Pro analysis) characteristic to suspension plasma spray. Dendritic Laves CoMoSi/Co_3Mo_2Si and hard intermetallic Co_7Mo_6/Co_2Mo_7 phases of T400, along with the corresponding TiC phases, are confirmed in phase analysis. Synergistic reinforcement of TiC has further elicited an enhancement in elastic modulus (of ~184.5 GPa) by ~36%, and Vickers hardness (of ~11.5 GPa) by ~82% in comparison to that of T400 (~135.2 GPa, and ~6.3 GPa respectively); which unambiguously elucidates the consequent increase in plasticity index by ~26.7% and a drop in maximum displacement amplitude (h_{max}) by ~19.8% in T400-TiC. A subsequent deceased fretting wear contact diameter, hence an improved damage tolerance, in T400-TiC compared to T400 alone is noted from a contact area-based wear model postulated herein. Further, with synergistic cell viability in L929 fibroblast, TiC reinforcement in T400 is ascertained to accommodate heavy-duty in-situ load-bearing application with substantially improved micro-hardness via retaining the smaller grain size, and a subsequent fretting wear augmentation through carbide phase strengthening.

Exploding, Weeping and Reversible Phase Transformations on the Way to a Shape Memory Ceramic Hanlin Gu[1], Justin Jetter[2], Jascha Rohmer[2], Eckhard Quandt[2] and Richard D. James[1]; [1]University of Minnesota, United States; [2]University of Kiel, Germany

The systematic tuning of the lattice parameters to achieve improved kinematic compatibility between phases is an effective strategy for improving the reversibility, and lowering the hysteresis, of solid-solid phase transformations. We present an

apparently paradoxical example in which tuning to near perfect compatibility leads to a high degree of irreversibility in oxides of ZrHfYNb, as manifested by violently explosive behavior. Tuning lattice parameters slightly away from near perfect compatibility gives an intermediate "weeping" behavior, in which the polycrystal slowly and steadily falls apart at the grain boundaries. Finally, tuning to satisfy a condition we term the equidistance condition results in reversible behavior with the lowest hysteresis in this system. We give evidence that these observations are explained by a more careful analysis of compatibility of the polycrystal. These results show an extreme diversity of behavior, from reversible to explosive, is possible in a chemically homogeneous system by manipulating conditions of compatibility.

Giant Compressive Superelastic Deformation of a [001]-Oriented $SrNi_2P_2$ Micropillar via Double Lattice Collapse and Expansion Shuyang Xiao; University of Connecticut, United States

Shape memory materials or superelastic crystalline solids have the capability to recover their original shape even after the large amount of deformation is applied. The shape recovery of these materials usually occurs through a reversible phase transformation between martensitic and austenitic phase, which is a shear process. However, their elastic performance is limited by the energetics and geometry of the phase transformation, limiting their application range. Therefore, it is desirable to seek out a new material that can overcome this limit through a completely different superelasticity mechanism. In this presentation, we report our first discovery of the giant superelasticity in a novel intermetallic compound $SrNi_2P_2$ via the double lattice collapse and expansion, which correspond to making and breaking P-P bonds in two different co-existing crystal structures.
In-situ uni-axial compression on [001]-oriented $SrNi_2P_2$ micropillars revealed superelasticity with a remarkably huge elastic limit over 17%, which is one of the highest elastic limits ever reported for crystalline solids, via sudden lattice collapse and expansion. This sudden structural collapse corresponds to the first order phase transition. The collapsed tetragonal phase transition, which results from making P-P bonds during the uni-axial compression, is the main mechanism of superelasticity and differs entirely from the shear process of martensitic-austenitic transition of conventional crystalline superelastic materials. Density Functional Theory (DFT) simulation, X-ray diffraction measurement, and High-Resolution Transmission Electron Microscopy analysis have confirmed that $SrNi_2P_2$ consists of two different crystal structures. DFT calculations of uniaxial deformation of each crystal structure showed that these structures are collapsed at different stresses, leading to double lattice collapse and expansion, which are also shown as double-steps in both loading and unloading curves in stress-strain data. No fatigue damage was observed after 10,000 cycles of superelastic deformation because a simple making and breaking bond mechanism is not associated with any shear-based plastic deformation process such as dislocation plasticity or deformation twinning. Therefore, $SrNi_2P_2$ is expected to be strongly fatigue-resistant. Up to our knowledge, this is the first report that shows the co-existence of two different superelastic $ThCr_2Si_2$-type structures in a single material and their unique double lattice collapse and expansion. By considering that $ThCr_2Si_2$-type structure is one of the most populous crystal structures (over 2500 compounds), therefore, our results are believed to make a significant impact in fundamental understanding of superelasticity of $ThCr_2Si_2$-structured intermetallic compounds.

5:25 AM F.SF07.05.03
Heterogeneity of Multiscale Deformation in Notched Martensitic Shape Memory Alloys Partha P. Paul[1,2], Harshad Paranjape[3], Darren Pagan[4], Nobumichi Tamura[5] and L. Catherine Brinson[6]; [1]Stanford Synchrotron Radiation Lightsource, United States; [2]Northwestern University, United States; [3]Confluent Medical Technologies, United States; [4]Cornell University, United States; [5]Lawrence Berkeley National Laboratory, United States; [6]Duke University, United States

The low symmetry martensite phase in Nickel-Titanium (NiTi) shape memory alloy (SMA) has a hierarchical microstructure with micro-scale crystallites, which themselves consist of nano-laminates with an internal twin structure. The martensite phase deforms inelastically though reorientation of the twin structure. Furthermore, structural features in the specimens such as cracks or notches interact with the microstructure, influencing the deformation of martensite. We explore this complex interaction between structure and microstructure during tensile loading in martensitic NiTi specimens, with machined notches [1, 2].

In this work, using multi-scale experiments and macro-scale modeling, we demonstrate that the deformation of martensite in NiTi at the macro scale in a notched specimen is largely determined by the structural features, and the hierarchical nature of the microstructure plays a smaller role. Digital image correlation is used to obtain macro (specimen)-scale strain fields while macro-scale modeling is used to isolate the effect of notch geometry from the inherent microstructural anistropy in the heterogeneous deformation field. At the micro-scale, in-situ, high-energy x-ray diffraction measurements at two spatial resolutions (3D x-ray diffraction microscopy and microdiffraction) indicate that the martensite microstructure continuously evolves during tensile loading and unloading. This spatial evolution of the martensitic microstructure is also spatially

heterogeneous, with respect to the notch. This observation is counter to the intuition of martensite twins reorienting to large domains of the most favored crystallographic variant at larger loads. Finally, the nano-laminate twin structure persists despite the large imposed deformation and the presence of stress concentrating features such as a notch, primarily due to the non-uniaxial stress field induced by the notch in its vicinity. Nanoscale characterization (using TEM) reveals nanocrystallization of martensite close to the notch on the fracture surface, and a persistence of twins away from the notch on the fracture surface.
These results can guide modeling of fracture-related deformation phenomena in NiTi martensite phase. This persistence of a nano-laminate structure rather than coarsening into large domains of individual variants indicates that the deformation field around cracks/notches in martensite may be modeled for fracture-related phenomena with adequate accuracy using coarse-grained models, without a compelling need for computationally expensive martensite single-variant-scale models.

Supercooled Austenite-Martensite Transformations in CuZr-Based Thin-Film Shape Memory Alloys Yucong Miao and Joost Vlassak; Harvard University, United States

CuZr-based alloys are being investigated as potential shape memory alloys for use in high-temperature applications. Previous studies on bulk samples of these alloys have reported typical athermal martensitic transformations where the degree of transformation to martensite is independent of time, and is a function of temperature and strain only. Here we report that in sputter-deposited CuZr, CuZrNi and CuZrCo thin-film samples, the austenitic phase can be supercooled below the martensite finish temperature M_f and then transforms to martensite in an explosive process that converts the entire sample in microseconds. This explosive transformation behavior is characterized by the following observations: 1) The transformation takes place at a critical temperature below M_f, causing a sudden temperature spike. 2) The critical temperature has a narrow distribution and decreases slightly with cooling rate. 3) Whether the transformation occurs explosively depends on the temperature history of the sample above the austenite finish temperature A_f. If the sample is quenched immediately on heating above A_f, the martensite forms gradually on cooling below the martensite start temperature M_s; if the sample is allowed to dwell above A_f for a few seconds, the martensite forms explosively. We suggest that austenite supercooling in thin-film samples is due to a lack of heterogeneous nucleation sites, while the gradual transformation is facilitated by the presence of defects. Transmission electron microscopy of CuZrCo samples suggests that the defects may be residual martensite above the austenite finish temperature. Kinetics measurements using nanocalorimetry reveals that the reverse transformation of this residual martensite can be described by an interface mobility model that takes into account the free energy difference between the two phases.

Intermetallic Compounds—A Versatile Class of Materials Meets Interesting Catalytic Challenges Marc Armbrüster; Chemnitz University of Technology, Germany

Heterogeneous catalysis is dominated by two material properties, i.e. the electronic structure (ligand effect) and the arrangement of the atoms (geometric effect). A priori, any material offering altered electronic or structural properties is of interest for heterogeneous catalysis. While intermetallic compounds fulfil these criteria, they offer three advantages compared to substitutional alloys: i) stability, caused by the chemical bonding, which can prevent segregation or decomposition in reactive atmosphere, ii) a wide range of chemical potential of the involved (transition)metals and iii) peculiar combinations of electronic and crystal structure. Since intermetallic compounds are thermodynamically stable and available in a wide range of materials, covering nanoparticles, polycrystalline materials as well as large single crystals, they can serve as platform materials to address catalytic challenges.
The stability allows studying their intrinsic properties in many environments, while the different available chemical potentials can be used to adjust the redox properties to the needs of the reaction in question. Systematic study of the geometric effects in reactions is possible by exploiting the large variety of available crystal structures. The use of isostructural substitutional series or compounds with different valence electron concentration allows addressing the electronic effect (ligand effect) on a reaction. Since only the filling degree of the electronic structure is changes, while the crystal structure and thus the electronic scaffold is kept, the electronic effect can be studied with only minor influence of the geometric effect. Like the metallic elements and the substitutional alloys, intermetallic compounds possess electrical conductivity, allowing electrochemical

studies. The versatility of intermetallic compounds created a vivid and active community and in the contribution, several examples will be presented to elaborate the possibilities - and the requirements - for catalytic studies on this class of materials.

High Performance NiFe Permanent Magnets Ian Baker[1], Nour Hayek[1], Ty P. Teodori[1], Xiaobin Guo[1], Rachel D. Osmundsen[1], Cynthia Bundi[1], Elisa Giraso[1], Jonathan D. Bonilla Toledo[1], Damien Fabrègue[2], Patrice Chantrenne[2], Si Chen[3], Yang Ren[3], Liang Wang[4], Gheorghe Gurau[5], Heung Nam Han[6], Ju-Won Park[6], Gerard Ludtka[7] and Bart Murphy[7]; [1]Dartmouth College, United States; [2]INSA Lyon, France; [3]Argonne National Laboratory, United States; [4]Beijing Institute of Technology, China; [5]Universitatea "Dunarea de Jos" Galati, Romania; [6]Seoul National University, Korea (the Republic of); [7]Oak Ridge National Laboratory, United States

Demand for high-performance permanent magnets for motors is increasing rapidly for applications such as wind turbine generators and motors in electric and hybrid cars. Sm-Co and Nd-Fe-B magnets are generally used for such challenging applications. While these rare earth (RE) magnets have the highest energy product $(BH)_{max}$ of any material, they are not without problems such as corrosion and brittle fracture. Other important issues are that over 95% of REs are produced in China, and that there are no US-owned manufacturers of RE magnets. There has also been substantial price volatility with the RE elements. Finally, RE mining has been associated with severe environmental degradation. In this project we aimed to establish a low-cost method to produce bulk $L1_o$-structured NiFe, which has magnetic properties comparable to the best RE magnets. Replacing the latter in electric motors in electric/hybrid cars and wind turbines will not only lead to large cost reductions, and hence greater adoption of these technologies with associated energy reductions, but the reduction in RE metal production will also lead to substantial environmental benefits and reduction in energy usage in their production. The key issue is that the transformation from the high temperature f.c.c. phase to the L1o-structured phase occurs at around 600 K and, thus, is exceedingly slow. We attempted several paths to produce the transformation to the equilibrium room-temperature $L1_o$ - structured, i.e. the incorporation of a large supersaturation of vacancies followed by annealing; cold rolling (including at 77 K) followed by conventional annealing, electro-pulse annealing or high magnetic field processing; and high pressure torsion processing followed by annealing. We also looked at carbon doping, which can lead to the formation of a martensitic phase upon quenching. It is quite difficult to determine if the $L1_o$ phase has formed since the superlattice reflections are weak and the lattice parameters of the $L1_o$ and f.c.c phases are both 0.3585 nm. Thus, both synchrotron XRD and neutron diffraction were used to identify the phases, while EBSPs/orientation imaging in a SEM was used to determine the extent of recrystallization. The results of these different processing methods will be outlined. Funding at Dartmouth was provided by the Irving Institute for Energy and Society, the Women in Science Program, the First-Year Research in Engineering program, and the Presidential Scholars program.

6:10 AM *F.SF07.05.09
Relationship Between Thermoelectric Properties and Phase Interfaces Formed on a Multiscale by Phase Separation in the Same Ordered Structure Phases Yoshisato Kimura[1], Yaw Wang Chai[1] and Yonghoon Lee[2]; [1]Tokyo Institute of Technology, Japan; [2]KELK Ltd., Japan

Thermoelectric power generation is an appealing approach for conserving energy and preserving the global environment. Thermoelectric properties are sensitively affected by microstructure of materials which changes during high temperature fabrication processing and practical long term operations. Improvement of thermoelectric performance can be achieved by microstructure control. We focus on the formation of interfaces on a multi-scale according to the phase separation between the same ordered structure phases in two alloy systems. One is phase separation between half-Heusler structure TiNiSn–(Zr,Hf)NiSn according to the miscibility gap, and the other is that between anti-fluorite structure Mg_2Si–Mg_2Sn during coring microstructure formation. Objective of the present work is to understand the formation mechanism of interfaces by the phase separation, and evaluate the effects of interfaces on thermoelectric properties focusing on the electrical and thermal conduction.
Half-Heusler MNiSn (M = Hf, Zr, Ti) are excellent n-type thermoelectric materials. The present author's group reported the phase separation between TiNiSn and ZrNiSn, and TiNiSn and HfNiSn from a random solid solution MNiSn phase. The existence of a miscibility gap was suggested at temperatures higher than 1273 K. The relaxed lattice misfit, evaluated using XRD measurement, is about 3.2% between TiNiSn and ZrNiSn, and 2.5% between TiNiSn and HfNiSn, respectively. These values are quite large compared with 0.6% between ZrNiSn and HfNiSn. Considering the elastically constrained phase interface, a quite large elastic energy can be the driving force of the phase separation. Sharp grain boundaries between Ti-rich and Zr-rich half-Heusler phases can be observed in solidified microstructure of (Ti,Zr)NiSn alloys using SEM. On the other hand, it is very hard to observe a constrained interface. Diffuse interface can be barely observed using TEM in a (Ti,Zr)NiSn

alloy after the heat treatment, annealed in the two-phase field for phase separation. Excellent electrical power factor exceeding 5 $mWm^{-1}K^{-2}$ can be achieved while the lattice thermal conductivity is effectively reduced around 3 $Wm^{-1}K^{-1}$ in Ti-rich (Ti,Zr)NiSn alloy according to the effect of solid solution together with the effect of interfaces introduced by phase separation.
Microstructure development in the Mg_2Si–Mg_2Sn pseudo-binary system is characterized by the peritectic reaction. The Mg–Si–Sn ternary phase diagram was evaluated experimentally focusing on the reaction scheme and solidification sequence. It has been found that the gradient composition layered structure is formed in $Mg_2(Si_x,Sn_{1-x})$ alloys on a micro-scale during the solidification process. Dominant mechanism is the phase separation of $Mg_2(Si,Sn)$ solid solution phase into Si-rich $Mg_2Si(Si,Sn)$ and Sn-rich $Mg_2(Sn,Si)$ phases during the coring structure development. Phase separation is occurred leaving phase interfaces to release the large elastic energy stored due to quite large lattice misfit. The constrained lattice misfit between Si-rich $Mg_2Si(Si,Sn)$ and Sn-rich $Mg_2(Sn,Si)$ phases has been evaluated about 5% based on the powder XRD measurements, and the semi-coherent interfaces with interfacial dislocation networks can be observed using TEM. Each layer of the gradient composition layered microstructure is consisting of nano- to micro-scale poly-crystal grains having a compositional gradient of Si/Sn composition ratio. The lattice thermal conductivity can effectively be reduced lower than 2 $Wm^{-1}K^{-1}$ in a $Mg_2(Si_{0.75},Sn_{0.25})$ alloy which contains high density of phase interfaces of gradient composition layered microstructure. Note that the dominant mechanism for the reduction of thermal conductivity is attributed to the phono scattering based on the solid solution effect in $Mg_2(Si_x,Sn_{1-x})$ phase grains and layers.

6:25 AM F.SF07.05.10
Effect of Different Inclusion Species on the Thermoelectric Transport and Mechanical Properties of the Zintl Phase $Yb_{14}MnSb_{11}$ Giacomo Cerretti, Sabah Bux and Jean-Pierre Fleurial; NASA Jet Propulsion Laboratory, United States

Composite materials are conceptualized with the intent of obtaining a final material with improved characteristics. In thermoelectrics this has been achieved for organic-inorganic composites where conducting materials embedded in polymeric matrixes improved the thermoelectric properties. A completely different situation is the combination of two inorganic compounds. Although according to some studies a thermoelectric composite cannot have better properties than its constituents, a study from Bergman and Fel (1999) proved that the enhancement of the figure of merit of a composite material is possible under specific conditions. The purpose of this work is to show the effect of different kind of metal inclusions on the electronic and thermal property of $Yb_{14}MnSb_{11}$. $Yb_{14}MnSb_{11}$, with a zT of about 1.2 at 1200 K, is already the most performing p-type material for high temperature thermoelectric applications. Our intent is to further increase its thermoelectric performance by decoupling the electronic transport properties (σ, S). Transition metals are characterized by a metallic electrical conductivity, but some of them still show a relatively high Seebeck coefficient. Therefore, the selected metal inclusions are expected to provide a boost to the electrical conductivity, while affecting only marginally S. Another important aspect of compositing with metal inclusions is the improvement of mechanical properties and fracture toughness, a fundamental aspect in terms of device fabrication. To verify the validity of our assumptions, we synthesized samples with different inclusion density, always remaining largely below percolation limit. The samples have been chemically, electrically, thermally, and mechanically characterized and the obtained results will be shown and compared with the baseline of the Jet Propulsion Laboratory for the $Yb_{14}MnSb_{11}$ ATEC (Advanced ThermoElectric Converter).

6:35 AM F.SF07.05.11
Synthesis of P-Type BaCuSi Clathrate for Thermoelectric Materials Chiho Inoue, Shinji Munetoh, Masahide Yasuda, Yuichiro Magami and Zilong Zhang; The Kyushu University, Japan

BaCuSi clathrate samples for p-type thermoelectric materials were synthesized with various initial composition of Cu ratio. Cu ratio in the samples increased with initial composition Cu ratio. However, volume of BaCuSi clathrate phases in their samples decreased with the increase of initial composition of Cu ratio. Those phases cannot be detected their accurate electrical properties because of their small grain size. In this study, we synthesized the sample by using CZ method to obtain the larger phase. It was found that the Cu ratio in the CZ sample was smaller than the sample without CZ method. The CZ sample with a large grain size can be obtained with heavy Cu doping sample. The CZ sample successfully showed p-type properties.

6:45 AM F.SF07.05.12
Processing and Defects Responsible for Embrittlement in P-Type PbTe Thermoelectric Materials James P. Male[1], Riley Hanus[2,1], Naomi Pieczulewski[1], Raphael P. Hermann[3] and G. Snyder[1]; [1]Northwestern University, United States; [2]Georgia Institute of Technology, United States; [3]Oak Ridge National Laboratory, United States

Heavily-doped, p-type PbTe thermoelectric materials reach the heat-to-electricity conversion efficiency necessary for

improved space power generation or waste heat recovery. However, unexplained brittle behavior at high electronic doping levels occurs in p-type PbTe, but not in n-type PbTe. This distinctively asymmetric trend restricts the thermoelectric community's best-performing materials for practical use. Our mechanical and elastic property measurements on single crystal and polycrystalline PbTe contradict previously suggested explanations for embrittlement, such as bond stiffening from PbTe's Σ band. We also show certain dopants break the previously established mechanical trend. Strain measurements through neutron powder diffraction show that ball milling can double the amount of strain in undoped PbTe beyond unstrained samples. Introducing extrinsic p-type dopants increases the strain by another factor of two and better maintains strain at high temperatures. We propose that increased dislocation strain from typical processing methods is linked to embrittlement. Further, by analyzing extrinsic doping efficiency, we note a link between strain and both extrinsic dopant defects and intrinsic compensating defects. Introducing dislocation strain, as is often done to reduce thermal conductivity and increase thermoelectric efficiency, thus appears to also be detrimental for mechanical properties in p-type PbTe. This study seeks to explore the link between these properties and offers routes to tune them through phase boundary mapping, choice of dopant, and intrinsic defect engineering.

6:55 AM F.SF07.05.13
Modeling Atomic Displacement and Ionic Charges in Filled Skutterudite via Resonant X-Ray Dynamical Diffraction Rafaela F. Penacchio[1], Maurício B. Estradiote[1], Adriana Valerio[1], Marli R. Cantarino[1], Fernando A. Garcia[1], Sergio L. Morelhao[1], Stefan W. Kycia[2], Guilherme A. Calligaris[3] and Claudio M. Remédios[4]; [1]University of Sao Paulo, Brazil; [2]University of Guelph, Canada; [3]Brazilian Synchrotron Light Laboratory, Brazil; [4]Universidade Federal do Pará, Brazil

Thermoelectric properties of the materials originate from thermal conduction by free charge carriers instead of by collective lattice vibrations (phonons). Understanding the scattering mechanism, or dissipation, of phonons allows the engineering of materials with higher coefficient of Seebeck [1], i.e. higher difference of electric potential created for a given thermal gradient. In skutterudite type of thermoelectric materials, dissipation of phonons are attributed to localized, low frequency and anharmonic vibrations of heavy ions of the lanthanide family introduced into the large voids of the crystalline structure. Since most of these materials can be synthesized in the form of high quality single crystals, we have the possibility of revisiting the phonon scattering mechanism through x-ray phase measurements via dynamic diffraction effects [2]. Structure factor phases are susceptible to the differences between the vibration amplitudes of the atoms (root mean square atomic displacements), or in other words, phase values are invariants with temperature only when all occupied sites of the unit cell have the same Debye-Waller factor.

Structure factor calculation in model structures revealed suitable Bragg reflections and x-ray energies to resolve the difference in atomic vibrations as a functions of temperature. It also revealed a giant resonante phase shift for the whole familiy of filled skutterudites RFe4P12 (R=Ce, La, Nd, Pr, Sm). By exploiting this resonant phase shift with synchrotron x-rays at different temperatures in CeFe4P12, we were able to demonstrated that rattling of Ce alone inside the icosahedral cage is not enough to explain phonon scattering and that the whole cage of 12 P is taking part of scattering mechanism.

F.SF07.06.01
Construction of an EAM Type Inter-Atomic Potential Model for Describing Metallic Polytype Structures Shinya Ogane[1], Taku Miyakawa[2,1] and Koji Moriguchi[1,2]; [1]Graduate School of Environmental Studies, Tohoku University, Japan; [2]R&D Laboratories, Nippon Steel Corporation, Japan

Polytypism is a special case of polymorphism when the two polymorphs differ only in the stacking of identical two-dimensional sheets or layers. The polytypes are characterized by a stacking sequence with a given repeating unit along a directional axis (c-axis) and are theoretically possible to have endless permutations of the sequences. Among these polytypes, the crystalline systems composed of close-packed (CP) layers have especially attracted attention on their fundamental and technological properties for many years. While these polytypes are often experimentally observed in wide-bandgap semiconductors, SiC systems are particularly known to show several hundred polytypes [1]. Since some SiC polytypes located around the ground state are energetically degenerated with about $\Delta T = 2K$ [1], it is difficult to control the phase stability during the growth of single crystals with the desired stacking polymorphism. For this reason, a variety of physical perspectives are being investigated in order to establish better single crystal growing techniques [2, 3]. In addition, the long period stacking ordered (LPSO) Mg alloys with light weight, high specific strength, and high heat resistance are also recently drawing attention as a metallic system with similar polytypism to that in SiC [4, 5].

We have proposed a computational method coupled with three theoretical tools (PGA: polytype generation algorithm; FPC-DFT: first-principles calculations based on the density functional theory; and ANNNI: axial next-nearest-neighbor Ising model), which can make us possible to efficiently investigate the structural energetics for diverse nonequivalent polytypes [1]. In our recent study [5], we have systematically evaluated the static energetics of metallic polytypes for a wide variety of elements based on the same computational method proposed by the authors [1]. For all these elemental systems, the atomistic geometry, energetics, and electronic structure for all polytypes with up to the periodic stacking length of L=13 (165 kinds of polytypes in total) have been carefully calculated based on the DFT within the GGA [5]. Using the ANNNI model extracted from the GGA calculations, we have shown from the perspective of static structural energetics that the interlayer interaction among CP layers is one of the important factors for the polytype formation [5].

Not only the static energetics but also the dynamical aspect generally affects the polytype selection during the crystal growth processes [2, 3]. It is, therefore, important to elucidate the polytype formation mechanism from the viewpoint of dynamics associated. Since the molecular dynamics (MD) simulations have become a powerful computational tool to understand and predict the structural, thermodynamic and dynamic properties of materials, the direct MD observation of dynamical aspects for the polytype growth is expected to greatly advance our understanding on the polytype selection. While the state-of-the-art potentials are often fitted to many databases including a large set of atomic configurations calculated by FPC-DFT [6], we have found that the potential models proposed so far cannot describe the accurate polytypes energetics. In the present study, we are, therefore, developing an Embedded Atom Method (EAM) type potential [6] which can be used for the dynamical simulations of metallic polytype structures focusing on the lanthanum (La) system. The basic properties and transferability of the EAM type potential model constructed in the present work will be discussed.

Phase Equilibria and Crystal Structures of Highly Ordered Intermetallic Compounds of Fe_2Al_5 Phases with the Framework Structure of η-Fe_2Al_5 Phase Tetsuya Hamada, Ryutaro Sakai, Kodai Niitsu and Haruyuki Inui; Kyoto University, Japan

Hot dipped Zn-Al alloy coated steel is widely used in the field of automobile. It is well known that the coated layer is mainly composed of the Fe_2Al_5 intermetallic compound. This compound has been considered to be the orthorhombic η phase (space group *Cmcm*). On the other hand, our group has recently found that the layer phase often crystallizes into highly ordered atomic arrangement most likely termed as the η''' phase even during short-term dipping. Besides, recent researches address there exists several ordered phases similar to the η''' phase with the framework structure of η phase[1]. According to Burkhardt's study[2], the η phase is composed of a full occupied framework structure (4 Fe and 8 Al atoms) and partially occupied chains along the *c*-axis (6 Al sites). The *c*-axis chain is considered to allow chemical tenability and various kinds of atomic orderings; the formation of various kinds of ordered phases is considered to be responsible for how Fe and Al atoms order in the *c*-axis chain sites. However, the crystal structures of some of these ordered phases are still controversial and phase equilibrium among them are not consolidated.
In this study, we have examined the phase equilibrium among these phases and refined their crystal structures. Experiments are carried out with scanning electron microscope, energy dispersive spectroscopy, X-ray diffraction, transmission electron

microscope, scanning transmission electron microscope and synchrotron X-ray diffraction. There are some invariant reactions : the η phase is found to dissolve into the η''' and η^m phases at around 350 °C while the η phase has been thought to be stable at low temperature. Some of the other phases are found to have highly ordered long-period structures with periodic antiphase boundaries.

ANNNI Model Descriptions on Structural Energetics for a Wide Variety of Metallic Polytypes Composed of Close-Packed Layers Koji Moriguchi[1,2], Taku Miyakawa[2,1], Shinya Ogane[1], Kazumasa Tsutsui[2] and Yuta Tanaka[2]; [1]Tohoku University, Japan; [2]Nippon Steel Corporation, Japan

The local inhomogeneity such as defect, surface, interface, and nanostructure often assumes an important role for developing sophisticated materials since the functionalities of materials usually originate from the spatial inhomogeneity in the associated systems. In this work, among the many phenomena related to inhomogeneity in materials, we will report our computational research on the phenomenon called "Polytypism". Polytypism is a special case of polymorphism where two polymorphs differ only in the stacking sequences of the same two-dimensional sheets or layers.

Many crystalline compounds can be considered to be composed of one or more structural units. When these units can be stacked in different ways to form stable or metastable phases, the resulting phases are known as polytypes. Among the polytypes for these compounds, the silicon carbide (SiC) systems have been the most attractive and motivated tremendous amounts of theoretical and experimental investigations on their fundamental and technological properties for many years. Many SiC polytypes located around the ground state have been found to be energetically degenerated with energy of about $\Delta T = 2K$ [1]. It is, therefore, very difficult to control the phase stability during the growth of a single crystal in order to obtain the desired stacking polytype in SiC systems. For this reason, a variety of physical perspectives are being investigated in order to establish better single crystal growing techniques [2]. In addition, the long period stacking ordered (LPSO) Mg alloys with light weight, high specific strength, and high heat resistance are also recently drawing attention as a metallic system with similar polytypism to that in SiC [3]. For both systems, the physical mechanism behind polytype selection is not yet fully understood and remains challenging issues to be solved.

In this situation, we have proposed a computational method coupled with three theoretical tools (PGA: polytype generation algorithm; FPC-DFT: first-principles calculations based on the density functional theory; and ANNNI: axial next-nearest-neighbor Ising model), which can make us possible to efficiently investigate the structural energetics for diverse nonequivalent close-packed(CP) polytypes [1, 4]. In the present work, the static energetics of a wide variety polytypes for 17 kinds of metallic elements (M=Be, Mg, Sc, Y, Co, Zn, Cu, Ag, Au, Ni, Pd, Pt, Al, Ca, Sr, Ba, and La) is systematically evaluated based on the same computational method proposed by the authors [1, 4]. For all these elemental systems, the atomistic geometry, energetics, and electronic structure for all polytypes with up to the periodic stacking length of L=13 (165 kinds of polytypes in total) have been carefully calculated based on the DFT within the GGA. The equilibrium theories based on the ANNNI model that is well known in the field of statistical mechanics have played an efficient role in the study of the origins of polytypism [5, 6]. In this work, the ANNNI model including interactions up to the third-nearest neighbor layer with the four-spin term [6] is adopted for the systems considered. Using the ANNNI model extracted from the GGA calculations, we will describe the inter-layer interactions, the phase diagrams of ANNNI model with interactions up to third-nearest neighbor, and the stability of stacking faults for each element. The relation to polytypism in the metallic systems considered will be also discussed.

Microstructure Characterization of As-Cast and Directionally Solidified Near-Eutectic Mo–Si–B Alloys Linye Zhu[1], Shuntaro Ida[1], Georg Hasemann[2], Manja Krueger[2] and Kyosuke Yoshimi[1]; [1]Tohoku University, Japan; [2]Otto-von-Guericke

University Magdeburg, Germany

Mo–Si–B-based alloys have been developed as ultrahigh temperature material candidates for high-pressure turbine blades. Recently, Hasemann et al. reported that a Mo–Si–B alloy with Mo_{ss} + T_2 + Mo_3Si eutectic prepared by directional solidification (DS) has substantially improved creep resistance compared with a powder metallurgy (PM) processed alloy. It was found that a homogenous microstructure with preferentially orientated grains through DS can ameliorate mechanical performance, however, the effect of DS on the microstructure evolution of Mo–Si–B alloy is still not clear. In this study, phase constitution and microstructure of as-cast and directionally solidified near-eutectic Mo–Si–B alloys are investigated to clarify the microstructure evolution caused by DS.
Alloys with the nominal composition of Mo–17Si–7B (at.%) corresponding to the Mo_{ss} + T_2 + Mo_3Si eutectic point were prepared by arc-melting (as-cast alloy) and crucible-free zone melting (directionally solidified alloy) in an Ar atmosphere. The microstructure of the as-cast alloy consisted of primary Mo_{ss} dendrites and two eutectics of Mo_3Si + T_2 and Mo_{ss} + Mo_3Si + T_2 in cellular or dendritic growth, while the directionally solidified alloy was almost composed of a uniform and well-aligned Mo_{ss} + Mo_3Si + T_2 eutectic phase in cellular growth. The electron backscatter diffraction (EBSD) results showed that in the as-cast alloy only <100> orientation of the T_2 phase preferentially grew along the solidification direction while the other Mo_{ss} and Mo_3Si phases had no apparent orientation. However, the <001> growth direction of Mo_3Si phase parallel to the solidification direction became much stronger by the directional solidification. The coupled growth of <001>Mo_{ss}//<100>T_2//<001>Mo_3Si in the directionally solidified alloy presumably had an effect on the mechanical properties because of the texture. No habit relationship between the phases was found in both alloys possibly because the lattice parameters of constituent phases are greatly different and the system cannot minimize interfacial energy by atomic arrangement.

Energy Barrier of the Initial Stage Microstructure Formation in Martensitic Transformation of TiNi Shape Memory Alloy Kazuya Nagahira, Takeshi Teramoto and Katsushi Tanaka; Kobe University, Japan

The self-accommodation microstructure, which is the martensitic microstructure of the shape memory alloy, is constructed by a plate-like martensite variant. Recently, formation process of the self-accommodation microstructure during the martensitic transformation have been reported in the several shape memory alloy systems. In TiNi shape memory alloy, specific variant pairs including {11−1} type-I twinning interface are frequently observed in the initial stage of martensitic transformation. In this study, we refer the variant pair that formed in the initial stage of martensitic transformation as initial stage microstructure (ISM). This result suggests that there is a selection rule for the self-accommodation microstructure in the initial stage of martensitic transformation. The selection rule of ISM is important for understanding self-accommodation microstructure because it represents a mechanism of variant selection in the absence of the influence of other variants. In the present study, we have performed evaluations of energy barrier of the formation of ISM in order to elucidate the factors that determine the selection rule of ISM in TiNi shape memory alloy.
The energy barrier of the formation of ISM is the sum of the interfacial energy of the twin interface included in ISM and the elastic strain energy for the ISM formation. In the TiNi shape memory alloy, 8 types of twin orientation relations and corresponding variant pairs exist. It is considered that the variant pair with the smallest energy barrier is selectively formed as ISM. The interfacial energy of twin interface was evaluated by the first-principles calculation using VASP (Vienna Ab initio Simulation Package) code. The elastic interaction energy to form a variant pair was evaluated by a micro-mechanics proposed by Eshelby.
Since interfacial energy of {11−1} type-I twin and elastic interaction energy of the variant pair including {11−1} type-I twin are relatively small among the twin interfaces considered, it is supposed that the energy barrier of the variant pair including {11−1} type-I twin is smaller than others. These results indicate suggests that the variant pair with a small energy barrier is selectively formed as the initial stage of martensitic transformation.

Transient Liquid Phase Bonding of Bi-Ni Intermetallics for High-Temperature Electronics Hamid Fallahdoost and Junghyun Cho; State University of New York at Binghamton, United States

Transient liquid phase bonding (TLPB) has been used as a bonding process that joins dissimilar materials by employing an interlayer that provides a lower melting process. It shows the potential to be used in high temperature electronics (operated or exposed over 200°C), where there are no clear lead (Pb)-free solder options available. During the reflow process for electronics components, the interlayer melts and the constituents of the interlayer and its joining materials diffuse each other, subsequently making a homogenous intermetallic bond via isothermal solidification. Once formed, it results in a higher melting point than the bonding temperature. This research investigates such a TLPB system made of a nickel (Ni) bonding

surface and a bismuth (Bi) interlayer, which can serve as a Pb-free solder alternative for high-temperature electronics. Upon melting of Bi on Ni, intermetallic phases (Bi_3Ni, BiNi) nucleate and grow by consuming a Ni layer on the substrate or the die side. Intermetallic reactions and microstructure developments were studied under various reflow conditions including temperature and time on three sets of the sandwiched assemblies: 1) Si die Sputtered Ni (1 μm-thick)/Bi/Si die; 2) Si die/Bi/Ni foil (0.5 mm-thick); 3) Ni foil/Bi/Ni foil. As such bonds constitute the structural joints in electronic packaging, mechanical properties of the intermetallic bonds and their long-term microstructural developments under high temperature aging and thermal cycling (-55°C to 200°C) were investigated by shear testing and cross-sectional microstructure analyses of the sandwiched samples. It was shown that temporal evolution of two intermetallic phases composed of faster Bi_3Ni and slower BiNi, along with the remaining Bi, are responsible for mechanical performances of TLPB. This presentation will also discuss about optimal microstructure development for the TLPB, which is critical to offset the defects and brittleness of the intermetallic phases.

Microstructure and Crystallographic Orientation Relationships in Directionally Solidified $NbSi_2/Nb_5Si_3$ Eutectic Composites with Mo Addition Haruka Uemura, Kosei Takeda, Kyosuke Kishida and Haruyuki Inui; Kyoto University, Japan

Eutectic composites composed of intermetallics and/or ceramics with very high eutectic temperatures have been considered as attractive materials for ultra-high temperature structural applications because of their high melting temperature, high structural stability and good mechanical properties. Recently, we have systematically investigated microstructure-property relationship of $MoSi_2/Mo_5Si_3$ eutectic composites with very high eutectic temperature of 1900 °C and have revealed that their high-temperature strength and room-temperature fracture toughness can be improved simultaneously by optimization of microstructure and interface properties through controlling growth condition and ternary/quaternary alloying. These previous results open a new possibility to develop novel structural materials endowed with excellent high-temperature strength and good room-temperature fracture toughness by utilizing interphase boundaries. In the present study, we focused on $NbSi_2/Nb_5Si_3$ eutectic composites (eutectic temperature ~1900 °C for binary) as a new target system and investigated microstructure variation of directionally solidified (DS) ingots of the eutectic composites as a function of ternary Mo addition. When Mo is alloyed more than 2 at. %, DS ingots are conformed to composed of C40-$(Nb,Mo)Si_2$ and $D8_m$-$(Nb,Mo)_5Si_3$, which indicates that the $D8_m$ (high temperature) to $D8_l$ (low temperature) phase transformation that occurs in binary Nb_5Si_3, is suppressed by the Mo addition. A fine eutectic microstructure of the so-called script-lamellar type, which is similar to those observed in $MoSi_2/Mo_5Si_3$ DS eutectic composites, is confirmed to develop for the Mo-alloyed $NbSi_2/Nb_5Si_3$ DS eutectic composites. Crystallographic orientation relationships between C40 and $D8_m$ phases as well as their preferential growth directions are identified by electron backscattered diffraction (EBSD) in scanning electron microscopy and transmission electron microscopy (TEM).

Evaluation of Mechanical Properties for Constituent Phases by Nano-indentation Method in γ-TiAl Alloys Sota Taniguchi, Yotaro Okada, Ryosuke Yamagata, Hirotoyo Nakashima and Masao Takeyama; Tokyo Institute of Technology, Japan

Nano-indentation method is a powerful tool to evaluate the mechanical properties of each phase in materials consisting of multi-phase microstructures. If the mechanical properties of each phase can be evaluated correctly, then we can predict the mechanical properties of bulk materials having different amounts of the phases, which would allow us to construct the design principle for materials integration (MI) to solve invers problems. However, there are a number of factors affecting the properties by this method, since the machine is so sensitive to the specimen itself such as surface conditions, as well as the machine itself such as specimen set-ups and tip of the indenters. In this study, titanium aluminide alloys were selected to evaluate the mechanical properties of the constituent phases since the alloys consists of three phases of b-Ti (bcc), a_2-Ti_3Al ($D0_{19}$ with hcp based) and g-TiAl ($L1_0$ with fcc based). In addition, we recently revealed that the introduction of an appropriate amount of the b phase is effective in improving the fracture toughness as well as tensile properties. Thus, it is very important to build up the mechanical property database for each phase in equilibrium each other in order to construct the construction of MI platform for inverse problems. The alloy studies are Ti-Al-Cr ternary alloys. These alloys were homogenized first in the b single phase region, and then heat treated in the three-phase region at 1173 K to reach the equilibrium state, based on our phase diagram study. The specimens were mechanically polished, followed by electro-polishing. Before and after the indentation test, the microstructure and orientation analysis of each phase were performed by FE-SEM and EBSD. Nano-indentation tests were performed to evaluate the Young's modulus and hardness using a continuous stiffness measurement (CSM) method with a frequency of 110 Hz using a Berkovich type indenter made of diamond. The advantage of the CSM method allows us to evaluate the properties continuously as a function of indentation

depth. The results were compared with those obtained from the Oliver-Pharr method. Both properties are found to be sensitive to the indentation depth and sampling distance, depending on the phases as well as orientation. The details of the appropriate conditions will be discussed, in conjunction with the O-P method. This work was supported by Council for Science, Technology and Innovation (CSTI), Cross-ministerial Strategic Innovation Promotion Program (SIP), "Material Integration" for revolutionary design system of structural materials.

F.SF07.06.09
Effect of Si in Solution on the Crystal Structure of σ Phase (*tP*30) in Fe-Cr Binary Alloys Eitaro Maeda and Masao Takeyama; Tokyo Institute of Technology, Japan

FeCr-σ with a crystal structure of *tP*30 (ordered tetragonal phase) is one of the TCP phases and often observed in heat resistant materials. This phase is considered as a harmful phase to deteriorate mechanical properties of the materials. However this phase could be a strengthening phase, just like Laves phase, if the phase stability can be increased by alloying. In the previous study, we have found that the lattice parameters of both *a* and *c* become either larger or smaller by the addition of M in solution, depending on the size of atomic radius of M relative to those of Fe (r_{Fe}=1.274 Å) and Cr (r_{Cr}=1.282 Å) as usual, except Fe addition. In case of the excess addition of Fe in solution, the *a* axis becomes smaller whereas the *c* axis becomes larger. We attributed the unusual anisotropic lattice parameter change to the site occupancy change in five sub-lattice sites (M1, M2, M3, M4, M5) of the σ phase, based on the Rietveld analysis; the occupancy of Cr atom in M5 sub-lattice site increase with increasing excess Fe atoms. In this study, we picked up non-transition element Si as the third element since it has larger atomic radius (r_{Si}=1.322 Å) and is known as strong σ stabilizer, and investigated the lattice parameter change with Si in solution.
The alloys studies are Fe-(50-x/2)Cr-xSi (at. %) where x=5, 10. They were prepared by arc melting to 30g button ingot, and homogenized in the σ single-phase region. Phase identification was conducted by powder XRD techniques and the lattice parameters were calculated from obtained XRD profiles. The obtained XRD profiles were further analyzed by means of Rietveld method to determine the structural change of σ phase as well as site occupation of the elements. Microstructures were examined by SEM and hardness was measured by micro Vickers hardness machine. We confirmed that both alloys with 5 and 10 at.% Si exhibit σ single phase with almost the same hardness of 12 GPa. It is interesting to note that, just like Fe addition, the anisotropic behavior of the lattice parameters was obtained; the *a* axis decreases whereas the *c* axis increases with increasing in Si content. However, Rietveld analysis suggested that this anisotropic behavior is different from that in Fe case related to the site occupancy change of M5 sub-lattice site. The detailed mechanism of this anisotropic behavior and the crystal structure change will be discussed in conjunction with the *c*/*a* ratio and unit cell volume of the σ phase.

F.SF07.06.10
Towards High-Throughput First-Principles High-Temperature Thermodynamic Modeling Siya Zhu and Axel van de Walle; Brown University, United States

We demonstrate how widely used high-throughput first-principles calculation frameworks for novel phase discovery can be augmented to enable phase stability predictions above absolute zero and yield informative phase diagrams at a fraction of the computational cost of traditional methods. The approach is based on a combination of (i) the special quasirandom structures formalism, extended to account for possible short-range order, (ii) carefully selected lattice dynamics calculations (iii) efficient molecular dynamics modeling of liquid phases that leverage high-quality experimental thermodynamic for elemental liquids and (iv) the CALPHAD approach for free energy modeling. As an example, we investigate the Ni-Re system, where earlier calculations predicted the presence of novel $D0_{19}$ and $D1_a$ phases. We find that, in spite of their stability at 0K, these intermetallic compounds become unstable at high temperature. These findings also prove helpful in guiding the search for alloys that provide cost effective substitutes for rhenium as a structural material.

F.SF07.06.11
Development of a Thermodynamic Database for CALPHAD Simulations of CoNiCrAlY Metallic Coatings Marlena Ostrowska[1], Yao Wang[1,2] and Gabriele Cacciamani[1]; [1]University of Genoa, Italy; [2]Centre of Excellence for Advanced Materials, China

High temperature materials, such as superalloys, are often covered with metallic coatings in order to protect the substrate from oxidation and to extend its working life. The phases present in the coatings, partly determined by the alloy composition, play an important role in the material properties. Among them, several are beneficial for the properties while some phases are detrimental during service. Co and Ni are the major elements in the metallic coatings. The appropriate amounts of Al, Cr and Y are added to improve their overall performance and to meet the demanding industrial requirements. In general Al-Co-Cr-Ni alloys are adopted as the main coatings for superalloys and small amounts of Y are added to improve oxide scale adherence.

However, it is very difficult to predict how phase stabilities are affected by the addition of each element in multi-component alloys, without performing computational simulations.
A reliable thermodynamic database containing Al, Co, Cr, Ni and Y has been developed to support the design of CoNiCrAlY coatings, following the CALPHAD approach. All binary and ternary subsystems are included in the database. Most of the ternary subsystems, due to the lack of consistent thermodynamic description in the literature, were assessed by our group, namely Al-Co-Ni [1], Al-Cr-Ni [2], Co-Cr-Ni [3] and several ternary systems containing yttrium, such as Al-Co-Y, Al-Cr-Y, Al-Ni-Y and Co-Ni-Y (paper in preparation).
The new database was used to simulate a few commercial alloys used as metallic coatings protecting gas turbine blades. The calculated phase compositions were then confronted with the available experimental data from the literature for the following coatings: PWA270 (Ni-21%Co-18%Cr-12.7%Al-0.17%Y), PWA286 (Ni-21.1%Co-17.1%Cr-12.7%Al-0.61%Y) at 1000°C [4] and the Co-based coating Co-28.6Ni-21.2Cr-15.6Al-0.4Y at 1150°C [5] (in at%). The good agreement between calculated and experimental data was evident, therefore, the present database can be reliably used to predict phase equilibria in alloy coatings already in use or to support the design of new alloys with improved performance. In particular, to find the temperature range in which undesired phases (e.g. σ) are stable and investigate the influence of each element on the phase stability.

Influences of Loading Axis Orientation and Specimen Shape on Kink-Band Formation in Single Crystals of Mg-Zn-Y LPSO Phase Investigated by Micropillar Compression Tests Kohei Okage, Kyosuke Kishida and Haruyuki Inui; Kyoto University, Japan

Mg-TM(transition metal)-RE(rare earth) ternary alloys containing a precipitation phase with a long-period stacking-ordered (LPSO) structure have received considerable attentions as a new light-weight structural material endowed with high strength and good ductility simultaneously. Such attractive mechanical properties are believed to be caused by heavily kinked structure of platelet precipitates of Mg-LPSO phase developed during hot extrusion process. Formation of the kinked structure in HCP metals with a relatively high c/a ratio has been interpreted generally with the dislocation-based kink band formation mechanisms such as the Hess and Barrett model, Frank-Stroh model, and Gilman model, which considered different trigger mechanisms for the activation of basal slip when the loading axis is (nearly) parallel to the basal planes, i.e., elastic buckling, stress concentration caused by pre-existing or pre-introduced defects, and a slight tilt of basal plane, respectively. However, the actual controlling factors for the kink-band formation in Mg-LPSO phases have not been fully clarified yet. In the present study, we investigated compression deformation behavior of Mg-LPSO single crystals as a function of loading axis orientation, specimen shape and stacking sequence of the LPSO structure (18*R* and 14*H*-type) by utilizing micropillar compression methodology in order to clarify the dominant controlling factors for the kink-band formation in Mg-LPSO phases.

F.SF07.06.13
The Effect of Forming Internal Electric Field in Seebeck Effect Momoka Sakamoto[1], Rikuto Sasaoka[2], Chiho Inoue[2] and Shinji Munetoh[2]; [1]Chikushigaoka High School, Japan; [2]Kyushu University, Japan

In the Seebeck effect in p-type semiconductor, the voltage can be generated by the diffusion of excited career in high temperature side to low temperature side in impurity level. However, careers in a valence band rediffuse to high temperature side because of electric potential difference, and the value of voltage drop at equilibrium. On the other hand, the block of rediffusing career can generate larger the value of voltage. In this study, we combined two different fermi level of p-type semiconductors, the light boron doped silicon and the heavy boron doped silicon, in order to form internal electric field in the

interface with Spark Plasma Sintering. This process has formed the barrier of energy for prevention of career rediffusion. We found that the synthesized sample's voltage increased in comparison with the light boron doped silicon and the heavy boron doped silicon. It is indicated that voltage can increase by forming internal electric field, with the sample combined different fermi level p-type semiconductors.

Late News: The Influence of the Powder Metallurgy Precursor on the Microstructure and Mechanical Properties of a Porous Cu-Al-Ni Alloy Maria T. Malachevsky[1,2], Alberto Baruj[1,2], Graciela Bertolino[1,2] and Ignacio Papuccio[3]; [1]Centro Atomico Bariloche - CNEA, Argentina; [2]CONICET, Argentina; [3]Facultad de Ciencias Exactas -UNCPBA, Argentina

Shape memory alloys are able to stand large deformations and to recover their shape afterwards. Depending on the temperature, the shape recovery could take place after heating or by the so-called pseudoelastic behavior. These particular properties make these smart materials good candidates for applications such as damping or actuation. Cu-based shape memory alloys are commercially attractive due to their relatively low cost compared to Ni-Ti alloys. Multiple research efforts have focused on expanding their potential applications by adding features that can improve the material. Porous shape memory alloys were developed in an effort to combine the shape recovery and energy dissipation properties with reduced density and weight. However, most polycrystalline Cu-based shape memory alloys are prone to intergranular fracture both in compact and porous samples. Reducing the material grain size could decrease the stress concentration at grain boundaries and help to avoid fracture. This can be achieved by alloying with other elements or by selecting an appropriate manufacturing method. As a possible fabrication route, we used powder metallurgy starting from a small particle size.
Among Cu-based shape memory alloys, Cu-Al-Ni alloys are an alternative with good properties and low cost. In this work, we explored the fabrication of porous Cu-14Al-3Ni by conventional powder metallurgy, starting from mechanically pre-alloyed powder and a mixture of the elemental metal powders. For preparing the pre-alloyed powder, we employed a high-energy Fristsch Pulverissette 7 planetary mill, processing under Argon at 700 rpm for 3 hours. The resulting powder was analyzed by means of X-Ray Diffraction (XRD). The XRD pattern showed no presence of Al or Ni while the Cu peaks were shifted to lower angles indicating the solid solution of both Al and Ni in the structure. The Cu peaks were also significantly widened due to the strain resulting from the high-energy milling. Some peaks of γ-Cu_9Al_4 were detected, as well as small CW peaks resulting from the milling media contamination. The other precursor was prepared by hand mixing the elementary powders in an agate mortar. Both precursors were mixed with 1 wt.% mixture of PVA and PVB as a binder and, after drying, 30 vol.% ammonium bicarbonate was added as space holder. Cylindrical samples were prepared by uniaxial cold pressing at 700 MPa. After sintering at 1000 °C, the samples were solution-treated for 24 h at 900 °C under Ar. After the treatment, they were water-quenched to obtain the martensitic phase.
The samples prepared with the milled powder were investigated by XRD. After sintering, the phases detected were α, γ-Cu_9Al_4 and AlNi. The heat treated samples consisted of the shape memory phase 18R accompanied by α and AlNi. The presence of AlNi in the sintered sample suggests that the alloy resulted short of both elements and consequently the solution treatment was performed in the α-β two-phase field. After quenching, α remained as a secondary phase. Meanwhile, the samples prepared with the hand mixed precursor consisted of the 18R and 2H shape memory phases.
X-ray microtomography images of the porous samples were acquired with an Xradia Micro XCT-200 microscope. The samples prepared with the pre-alloyed precursor presented internal cracks indicating that the presence of the brittle γ-Cu_9Al_4 phase reduced the powder compressibility. The lower density prevented their mechanical characterization. On the other hand, samples prepared with the hand mixed precursor were well sintered allowing their complete characterization. Compression uniaxial tests were performed and the shape memory behavior was corroborated. Samples recovered 100% from a 7% strain and 98.56% from 11.5% strain when heated to 140 °C. The obtained grain size is about 30 µm.

Structural and Chemical Atomic Complexity of Lattice Defects—From Defect Phase Diagrams to Material Properties Sandra Korte-Kerzel[1], Tilmann Hickel[2], Liam Huber[2], Jorg Neugebauer[2], Dierk R. Raabe[2], Stefanie Sandlöbes[1] and Mira Todorova[2]; [1]RWTH Aachen University, Germany; [2]Max Planck Institut für Eisenforschung, Germany

The design of new metallic materials is essential in fulfilling the promise of emerging and improving key technologies from efficient energy conversion over lightweight transport to safe medical devices. Over the last decades, two approaches in materials physics have proven immensely successful in the design of new metallic materials: Firstly, thermodynamic descriptions of crystalline phases have enabled materials scientists and engineers to tailor and process alloys to obtain a desired internal structure at the microscale. Secondly, better understanding and manipulation of the crystal defects, which govern the material's strength, formability and corrosion resistance, has led to the development of new alloying and processing concepts that provide some of the most advanced high-performance alloys in operation today. However, to date, these two concepts remain essentially decoupled.
Our vision is to bridge the gap between these existing and powerful approaches by bringing them together in one new conceptual framework, which will consider defects and their thermodynamic stability in a holistic manner. Consequently, a new material design concept originating from the atomic scale will be accessible to materials physicists and engineers which jointly considers the local crystalline structure of defects (structural complexity), the atomic distribution of each element among the different types of phases and defects (chemical complexity) and the stability of defects under the given conditions, such as bulk composition, temperature and applied stress or electrode potential. We will show here, how these can be linked by defect phase diagrams, which will describe the transition between and the coexistence of defect phases. This structural and chemical complexity at the atomic scale naturally exists in all materials. On this basis, we believe that a new physical description of metallic materials will possible and will provide a powerful toolbox for future design of engineering materials with tailored properties regarding concurrent mechanisms and properties, such as mechanical and corrosion performance of engineering materials.

7:00 PM *F.SF08.06.01
Grain Boundary Migration—Coupling Modes and Disconnections Nicolas Combe[1,2]; [1]CEMES - UPR 8011, France; [2]University Toulouse III, France

In specific conditions, grain boundary (GB) migration occurs in poly-crystalline materials as an alternative vector of plasticity compared to the usual dislocation activity. The shear-coupled GB migration, the expected most efficient GB based mechanism, couples the GB motion to an applied shear stress. For a given GB, several migration mechanisms referred as coupling modes can occur.
Both experimental and theoretical studies have evidenced that the migration of the GB occurs through the nucleation and motion of disconnections [1-3]. Disconnections are GB defects that have both a step and a dislocation (Burgers Vector) character. They can homogeneously or heterogeneously nucleates [4-6].
We use atomistic simulations (especially the Nudge Elastic Band method) on symmetric tilt grain boundary in FCC materials to evidence these disconnections and to characterize both their structural and energetic properties. In this study, we focus on homogeneous disconnections nucleation. Investigating the <100> and <110> coupling modes, we evidence the disconnections characteristics dependence on the grain boundary disorientation. Besides, we evidence the operation of specific disconnections involving coupling modes different from the usually observed <100> and <110> coupling modes.

The Coupling of Plasticity and Mass Transfer in Al Alloys Christopher Hutchinson; Monash University, Australia

High strength Al alloys exploit solid state precipitation to tailor their mechanical response. This precipitation requires two ingredients: a thermodynamic driving force and atomic mobility. For a given alloy chemistry, the heat treatment (precipitation) temperature is chosen as a compromise between having sufficient driving force for precipitation and sufficient atomic mobility so that the precipitation reaction occurs in a reasonable time and results in a 'not too coarse' precipitate distribution. It is this compromise that frames the competition between nucleation, growth and coarsening that constrains the possible precipitate distributions and hence mechanical responses.

This talk demonstrates a new approach that uses small amplitude cyclic plasticity at room temperature as a means of continually pumping vacancies into the system to achieve atomic mobility under conditions of high thermodynamic driving force. The approach is self-regulating (in both space and particle size) and results in extremely fine-scale inhomogeneous solid solutions. Such structures lead to combinations of strength and elongation that exceed those of conventionally precipitate strengthened alloys, without the presence of precipitate free zones.

Since the approach does not use thermal treatments, it somewhat decouples control of the thermodynamic driving force and atomic mobility. This provides a means to fully alter the competition between precipitate nucleation, growth and coarsening and new microstructures, with new combinations of properties are obtained. Examples of both monotonic and cyclic properties are demonstrated.

Cryo Atom Probe—Measuring Hydrogen in Steels via Deuterium Charging Julie Cairney, Yi-Sheng Chen and Ingrid McCarroll; University of Sydney, Australia

Hydrogen in steel is associated with a catastrophic failure mode, known as hydrogen embrittlement. This phenomenon is abrupt and is initiated at the atomic level. Although the exact mechanisms are still subject to debate [1], some mitigation strategies are available, including minimizing hydrogen ingress with surface coatings, or controlling hydrogen diffusion within via the introduction of microstructural 'traps', e.g. second phase precipitates such as niobium carbide [2]. It is believed that the incorporation of fine, distributed traps can reduce the mobility of detrimental hydrogen atoms and mitigate the macroscale embrittlement. However, as hydrogen is difficult to examine at fine scale, the experimental evidence is lacking for further optimization of the microstructural design.

Atom probe tomography is a powerful technique that can provide accurate 3D maps showing the position and identity of atoms. H is easily detected but, because it is so mobile, researchers are never sure whether it arises from the sample or the chamber itself. It has recently been demonstrated [3] that this issue can be tackled by charging samples with deuterium (D), the less common stable isotope of H, and cooling the specimen to cryogenic temperatures immediately after charging to slow diffusion. This approach allows the D to serve as a marker for H, so that the location of the H atoms can be determined unambiguously.

The University of Sydney has recently installed a suite of tools that allow the preparation and transfer of samples into and between instruments via ultra-high vacuum cryogenic transfer. These facilities include a purpose-built controlled-atmosphere glovebox (Microscopy Solutions), a Zeiss Auriga scanning electron microscope-focused ion beam (SEM-FIB) equipped with a custom-designed cryogenic stage (also Microscopy Solutions), and a CAMECA laser-assisted local electrode atom probe (LEAP) equipped with a Vacuum and Cryo Transfer Module (VCTM) on the load lock, all which are connected by a Ferrovac UHV suitcase. This new specimen treatment chamber allows specimens to be charged with D in a gaseous environment, at various temperatures, quenched to cryogenic conditions and then transferred to the atom probe for analysis. This talk will include an overview of this system as well as atom probe data from deuterated steel samples, including direct observation of deuterium at trapping sites, such as dislocations, grain boundaries and precipitates in martensitic steels [4].

Controlling the Structure of Interfaces and Dislocations to Directly Alter Mechanical Response Timothy J. Rupert; University of California, Irvine, United States

Both grain boundaries and dislocations have been recently shown to experience structural transitions between defect states known as complexions. In this talk, we discuss how one can manipulate the natural variations in stress, chemistry, and atomic structure near grain boundaries and dislocations to stabilize these defects and use them as tailorable features. We also demonstrate how different complexions can alter the mechanical properties of materials on the nanoscale. For grain boundary complexions, we focus on nanocrystalline metals, where such features have the largest effect due to the high grain boundary density. We isolate the materials and processing conditions which can cause the strength and ductility of these materials to be simultaneously augmented, as well as report on small-scale mechanical testing and atomistic modeling techniques to study grain boundary mechanics. For linear complexions, our work uncovers how nanoscale phases restricted to the region along a dislocation line direction can affect plasticity, encompassing both initial yield and subsequent flow. Alloy choice is shown to be very important, as various responses ranging from softening to strong hardening are predicted. As a whole, this work demonstrates that our field is on the precipice of a new age, where defects can be manipulated and designed rather than simply tolerated.

2D and 3D EBSD Studies of Alpha Variant Selection During Electron Powder Bed Fusion of Ti-6Al-4V Sophie Primig, Ryan W. Demott and Nima Haghdadi; UNSW Sydney, Australia

Ti-6Al-4V is one of the most commonly used alloys for additive manufacturing (AM) due to its applications as orthopaedic implants and aerospace components which can uniquely benefit from the advantages of AM. However, the inherent inhomogeneity and cyclic thermal loading in additive manufacturing processes significantly complicate the microstructural evolution of this alloy. The current understanding of the microstructural evolution in Ti-6Al-4V is based on traditional processing and cannot adequately predict its behaviour during AM.

Analysis of different interfaces (prior beta grain boundaries, alpha inter-variant boundaries) formed during AM of Ti-6Al-4V can clarify the competition between different modes of alpha variant selection in determining the final microstructure. Here,

traditional 2D characterization methods are often insufficient for uncovering complex, interconnected microstructural features that arise from solid-solid phase transformations during AM.

In this work, Ti-6Al-4V blocks were produced using different scanning strategies during electron beam powder bed fusion and characterized using 2D and 3D electron backscatter diffraction. This revealed that the microstructure is more complex, and that alpha laths are more interconnected than previously believed. For example, inter-variant boundary character distributions showed significant evidence of different variant selection mechanisms as a function of the position in the build and the scanning strategy. Some of these variant selection mechanisms are more desirable than others. Understanding the complexity of the microstructure in 3D provides new insights into the fundamental phenomena behind the microstructural evolution of titanium alloys in AM, and will help to give recommendations for optimising process design.

A Novel Technique to Synthesize Metallic Films with Controlled Heterogeneous Microstructures and Its Tensile Deformation Behavior Rohit Berlia and Jagannathan Rajagopalan; Arizona State University, United States

Materials with heterogeneous microstructures have been shown to exhibit a superior combination of strength and toughness compared to homogeneous nanostructured or coarse-grained materials.However, only a limited progress has been made in producing heterogeneous microstructures with good repeatability and robust control of key microstructural parameters such as grain size dispersion, texture or spatial distribution of grains. In this work, we report a novel technique to synthesize metallic films with highly tailored heterogeneous microstructures using magnetron sputtering. The technique is capable of precisely controlling the volume fraction, in-plane texture, spatial arrangement, morphology and connectivity of two or more sets of grains. Using this technique, we synthesized bimodal films of pure metals like aluminum, copper, iron and nickel where the mean size of smaller grains is around 30-300 nm while the coarser grains have a mean size exceeding 5 μm. The microstructure of these films was characterized by a combination of X-ray diffraction, electron backscattered diffraction and transmission electron microscopy to reveal the grain size dispersion, texture and orientation distribution. Mechanical characterization via uniaxial tensile loading-unloading was performed on bimodal Fe films with varying volume fraction and spatial arrangement of nanocrystalline and coarse grains using MEMS stages. Films with higher volume fraction of coarse grains showed enhanced strain hardening capability and a better combination of strength, ductility and toughness. This method enables the optimization of microstructural parameters (volume fraction of fine and coarse grains, texture, morphology, etc.), to obtain films with superior mechanical properties.

Slip-Twin Transfer Across Phase Boundaries—An *In Situ* Investigation of a Ti-Al-V-Fe (α+β) Alloy Shaolou Wei, Gaoming Zhu and Cem Tasan; Massachusetts Institute of Technology, United States

Microstructural plastic strain distribution evolution is highly heterogeneous even in single-phase alloys. One of the important factors that govern this heterogeneity is slip/twin transfer across grain/phase boundaries. In this regard, the fundamentals of transfer across grain boundaries have drawn significant attention in the literature, while the understanding of phase boundaries remains comparatively limited. (α+β) titanium alloys provide a profound platform to explore these phenomena, since: (i) both of the present phases can exhibit plastic deformation at similar microscopic strain levels; (ii) both slip and mechanically-induced twinning can be triggered to accommodate plastic strain. By integrating in-situ EBSD/SEM testing, crystallographic calculations, and microstructure-based strain mapping approach, we aim to address the following three propositions in this presentation: (1) could deformation transfer take place in the form between mechanical twinning in the α-phase and dislocation glide in the β-phase? (2) What parameters would be rational indicators to quantify the propensity for the incipience of this event? (3) What micro-mechanical consequences are associated with the slip-twin transfer activity? Broader indications for mechanistically-guided microstructural design concept will also be discussed.

5:00 AM *F.SF08.02.01
Integrating Computational Modeling and *In Situ* Experiment to Decipher Microscopic Deformation Mechanisms Ting Zhu; Georgia Institute of Technology, United States

With recent advances in computational modeling and in situ experimental technologies, there have been increased efforts to combine these approaches to understand microscopic deformation mechanisms in metals and alloys. In this talk, I will present our recent studies that integrate in situ electron microscopy and diffraction experiments with crystal plasticity and atomistic simulations for gaining a deep understanding of microscopic deformation processes. For example, we have combined in situ synchrotron X-ray diffraction experiments with crystal plasticity simulations to investigate the microscale residual stresses in additively manufactured stainless steel. We have also combined in situ transmission electron microscopy experiments and atomistic simulations to study the effects of atomic structures and elemental distributions on the exceptional mechanical properties of high-entropy alloys. In addition, we have used this strategy to reveal the grain boundary deformation atom by atom, step by step, thus uncovering the unexpected grain boundary sliding mechanisms in real time.

5:15 AM F.SF08.02.02
Plastic Deformation of Cr Single Crystals in Triple-Q State Compressed at 77 K Jakub Holzer[1,2], Zdeněk Chlup[1], Tomáš Kruml[1] and Roman Gröger[1,2]; [1]The Czech Academy of Sciences, Czechia; [2]Central European Institute of Technology, Czechia

A series of compression tests on chromium single crystals at 77 K was carried out in order to investigate the slip activity in the first 2-4% of plastic strain. Macroscopic samples of about 3×3×10 mm were polished mechanically and electrolytically and their orientations prior to and after deformation were determined by electron backscatter diffraction to assess the magnitudes and directions of crystal rotations. The crystals compressed in the direction close to [001] deformed primarily by slip on the most highly stressed (-101)[111] and (101)[-111] systems. Loading the crystals in the directions close to the [011]-[-111] edge of the stereographic triangle resulted in preferential twinning on {112}<111> systems. For loading in the center-triangle direction, the slip morphology was dominated by anomalous slip on the low-stressed (0-11) plane in contrast to the prediction of the Schmid law. Diffraction contrast imaging in TEM reveals the presence of [100] screw junctions between intersecting 1/2[111] and 1/2[-111] screw dislocations. Using molecular statics simulations, we show that this junction is not removed under the applied stress. Instead, the three dislocations move on the (0-11) plane, which results in the anomalous slip.

5:25 AM F.SF08.02.03
Dislocation Interactions During Shear Deformation of a Colloidal Crystal Seongsoo Kim, Ilya Svetlizky, David Weitz and Frans Spaepen; Harvard University, United States

Understanding dislocation interactions at different length scales, from atomistic to macroscopic, is important in the study of work hardening, fatigue and crack formation. Colloidal systems, in which particles can be tracked by confocal microscopy in 3D-space and time during deformation, provide the opportunity to study dislocations and their interactions over a wide size scale, from the particle to the sample level. The colloidal crystals in this work consist of micrometer-size hard spheres dispersed in a liquid, which have been sedimented onto a template to form a face-centered cubic single crystal. When the crystal is sheared, dislocations nucleate, glide, react and often form Lomer-Cottrell locks. We supplement these observations with measurements of the local stress and strain fields and identify the zipping-unzipping mechanism of the locks.

5:35 AM F.SF08.02.04
Multi-Scale Visualization with Machine Learning of Dislocation Networks in Colloidal Single Crystals Ilya Svetlizky, Seongsoo Kim, Seong Ho Pahng, Agnese Curatolo, Michael P. Brenner, David Weitz and Frans Spaepen; Harvard University, United States

Understanding the formation and evolution of dislocation networks and their effect on the mechanical properties of solids is challenging, as it spans a vast hierarchy of length and time scales. Hard-sphere colloidal suspensions provide a unique model system to address this difficulty: the micrometer size of the suspended particles both slows down their motion and allows them to be visualized by optical microscopy. At high density. these colloidal particles form face-centered cubic crystals with non-zero stiffness, which allows us to use them to study the principles of crystalline plasticity.
Here we present simultaneous multi-scale visualization of dislocation networks. At the single particle level the structure of the dislocations and their interactions are visualized by laser confocal microscopy. To visualize the large-scale collective

dislocation dynamics we developed a laser diffraction imaging technique inspired by the classical TEM imaging methods in atomic systems. The flexibility in manipulating visible light, in contrast to electrons, allows us to image under multiple diffraction conditions almost instantaneously. We designed a deep convolutional neural network to address the inverse problem of inferring the structure of the dislocation network from the multiple complex diffraction images. We will show that the neural network reliably reconstructs the spatial positions of the dislocations and their Burgers vectors by testing the results with in-situ confocal microscopy data on a smaller portion of the sample. We demonstrate the success of our method by applying it to the network of misfit dislocations formed via during particle sedimentation on a strained substrate.

5:45 AM F.SF08.02.05
***In Situ* Nanomechanics of Crystalline Metallic Nanowires** Guangming Cheng[1], Sheng Yin[2], Gunther Richter[3], Huajian Gao[4,2] and Yong Zhu[1]; [1]North Carolina State University, United States; [2]Brown University, United States; [3]Max Planck Institute for Intelligent Systems, Germany; [4]Nanyang Technological University, Singapore

Metallic nanowires have been widely used in a variety of nanoengineering applications, including nanoelectromechanical systems, nanosensors, transparent electrodes, optoelectronics, and flexible and stretchable electronics. Mechanical behaviors of metallic NWs play a crucial role in reliability of the nanowire-based devices. Here I will present our recent work on in-situ nanomechanics of crystalline metallic nanowires inside transmission electron microscope (TEM) in three case studies. First, we report competition of deformation mechanisms (twinning and slip) in single-crystalline metallic nanowires. We found that the competition depends on the cross-sectional shape of the nanowire, which affects the change of surface energy associated with each deformation mechanism. Second, we found unexpectedly, through careful cross-sectional TEM study, that most of the synthesized single-crystalline nanowires include a central twin boundary along the entire length of the nanowire, so we call them bi-twinned nanowires. We also found two competing deformation mechanisms – localized dislocation slip and delocalized plasticity via an anomalous tensile detwinning mechanism – depending on the volume ratio between the two twin variants and the cross-sectional aspect ratio. The mechanism of the observed tensile detwinning was investigated. Finally, we found that the twin boundary can cause interesting recoverable plasticity and Bauschinger effect.

Effect of Stacking Fault Energy and Solute Atoms on Microstructural Evolutions of Cu, Ag and Cu-Al Alloys Processed by Equal Channel Angular Pressing Mayu Asano, Motohiro Yuasa and Hiroyuki Miyamoto; Doshisha University, Japan

The stacking fault energy (SFE) changes with an addition of solute atoms for FCC metals. Tendency to form deformation twins and stacking faults increases with decreasing SFEs and affects the mechanical properties. In severe plastic deformation (SPD), alloying elements generally enhance grain refinement by inhibiting dynamic recovery and accumulating dislocations leading to smaller grain size than that in pure FCC metals. The role of alloying elements on grain refinement has two possibilities. The first is the formation of extended dislocations on decreasing SFE with the addition of solute atoms. The second is the segregation of solute atoms at dislocations and stacking faults. Both the two effects can suppress the dynamic recovery and retard the formation of grain boundaries until the significant dislocation densities is accumulated. Previous studies have focused only on the effect of SFEs on grain refinement and do not take the effect of segregation of solute atoms into consideration. In these cases, it is not obvious which one is the major effect. The purpose of this study is to investigate the relative importance of the effect of SFEs and solute atoms on microstructural evolutions for ultrafine grained (UFG) materials. Pure copper, pure silver, Cu-4.6at%Al and Cu-6.8at%Al were selected (SFEs are about 41, 22, 37 and 23 mJ/m^2, respectively). UFG structures were formed by ECAP at the same homologous temperature so that the effect of temperature on thermal activation can be eliminated. Samples processed from one to eight passes through Route Bc at 5mm/min for pure metals and 1mm/min for alloys. Microstructural evolutions were observed by EBSD, TEM and XRD. The microstructural investigation is focused on variation of the subgrain or grain size, the distribution of grain boundary misorientations and the dislocation density. The results show that grain size significantly decreases at initial stage of pressing while it saturates at the final stage of pressing. The final grain size after eight passes for Cu, Ag, Cu-4.6at%Al and Cu-6.8at%Al were 325, 268, and 251 and 76 nm. It is found by comparing Ag and Cu-6.8at%Al, that grain size of the Cu-6.8at%Al was smaller than that of Ag despite the same SFE. It seems that the final grain size is determined by the ultimate cell size because cell boundaries lose

mobility once they transformed to sharper grain boundaries by dynamic recovery. It is assumed the solute effect is greater to inhibit the transformation of cell boundaries than the effect of stacking faults, which result in smaller effect of SFE than solute atoms om grain refinement.

5:10 AM F.SF08.03.04
Connecting Short Range Order into Mechanical Response in High Entropy Alloys Daniel Foley[1], James Hart[1], Elaf A. Anber[1], Robert Ritchie[2], Andrew Minor[2], Mark Asta[2], Flynn Walsh[2], Douglas E. Spearot[3] and Mitra L. Taheri[1]; [1]Johns Hopkins University, United States; [2]UC Berkeley/Lawrence Berkeley National Laboratory, Berkeley, United States; [3]University of Florida, United States

This talk reviews recent work complex systems local structure evolution in high entropy alloys (HEAs). Despite their nominal chemical disorder, several studies have reported short range order (SRO) in HEAs – i.e. preferential bonding, local elemental enrichment and/or clustering – and such SRO may have broad implications for HEA performance. To tackle this problem, a suite of spatially resolved, electron imaging, diffraction, and spectroscopy techniques is leveraged to correlate local order with microstructural evolution and related dislocation phenomena. Microstructures of HEAs subjected to a variety of deformation regimes and quantified using diffraction-based techniques. In these samples, the extent to which SRO controls localized dislocation-based phenomena during microstructural evolution is discussed. The techniques presented allow for the direct observation of the interplay between chemistry and microstructure, and thus, provides us with key tuning knobs for future HEA development.

Cryo Atom Probe—Measuring Hydrogen in Steels via Deuterium Charging Julie Cairney, Yi-Sheng Chen and Ingrid McCarroll; University of Sydney, Australia

Hydrogen in steel is associated with a catastrophic failure mode, known as hydrogen embrittlement. This phenomenon is abrupt and is initiated at the atomic level. Although the exact mechanisms are still subject to debate [1], some mitigation strategies are available, including minimizing hydrogen ingress with surface coatings, or controlling hydrogen diffusion within via the introduction of microstructural ‘traps’, e.g. second phase precipitates such as niobium carbide [2]. It is believed that the incorporation of fine, distributed traps can reduce the mobility of detrimental hydrogen atoms and mitigate the macroscale embrittlement. However, as hydrogen is difficult to examine at fine scale, the experimental evidence is lacking for further optimization of the microstructural design.

Atom probe tomography is a powerful technique that can provide accurate 3D maps showing the position and identity of atoms. H is easily detected but, because it is so mobile, researchers are never sure whether it arises from the sample or the chamber itself. It has recently been demonstrated [3] that this issue can be tackled by charging samples with deuterium (D), the less common stable isotope of H, and cooling the specimen to cryogenic temperatures immediately after charging to slow diffusion. This approach allows the D to serve as a marker for H, so that the location of the H atoms can be determined unambiguously.

The University of Sydney has recently installed a suite of tools that allow the preparation and transfer of samples into and between instruments via ultra-high vacuum cryogenic transfer. These facilities include a purpose-built controlled-atmosphere glovebox (Microscopy Solutions), a Zeiss Auriga scanning electron microscope-focused ion beam (SEM-FIB) equipped with a custom-designed cryogenic stage (also Microscopy Solutions), and a CAMECA laser-assisted local electrode atom probe (LEAP) equipped with a Vacuum and Cryo Transfer Module (VCTM) on the load lock, all which are connected by a Ferrovac UHV suitcase. This new specimen treatment chamber allows specimens to be charged with D in a gaseous environment, at various temperatures, quenched to cryogenic conditions and then transferred to the atom probe for analysis. This talk will include an overview of this system as well as atom probe data from deuterated steel samples, including direct observation of deuterium at trapping sites, such as dislocations, grain boundaries and precipitates in martensitic steels [4].

5:15 AM F.SF08.04.04
Atomistic and Mesoscopic Modeling of Plasticity in Carbon Steels Arnaud Allera[1,2], Fabienne Ribeiro[1], Michel Perez[3], Jaime Marian[4] and David Rodney[2]; [1]Institut de Radioprotection et de Sûreté Nucléaire, France; [2]Univ Lyon, Université Claude Bernard Lyon 1, CNRS, France; [3]Univ Lyon, INSA-Lyon, France; [4]University of California, Los Angeles, United States

The vessel of pressurized water reactors operated in nuclear plants consists mainly of ferritic steels (Fe-C alloys). During operation, these components are subjected to extreme conditions (600 K, 155 bar, irradiation, ...) that affect their microstructural evolution and induce hardening and embrittlement, which can significantly impact the safety of the plant. In particular, the carbon atoms tend to diffuse and segregate over time, forming Cottrell atmospheres around dislocations and modifying their core structure [1].

The aim of this work is to establish a link between microstructural evolution and plastic properties. This requires to refine our understanding of the glide of screw dislocations in ferritic steels, in the presence of carbon solute atoms and at different scales. A number of state-of-the-art Fe-C interatomic potentials from the literature were tested on different alloy and dislocation properties, including carbon-carbon and carbon-dislocation binding energies, the screw dislocation core structure and Peierls potential. While none of the potentials fully agrees with *ab initio* reference data, we propose a combination of the two that perform best [2] [3].
This new potential is used in molecular dynamics (MD) simulations to study the glide of screw dislocations pinned by random solute atoms. It is evidenced that (1) short range interactions between solute and dislocation core atoms prevail compared to mid-range elastic interactions, (2) that the dislocation adopts a 3D structure due to its interaction with carbon atoms in different neighboring octahedral positions and (3) that the dislocation is very strongly pinned when the distance between carbon atoms decreases below a few tens of Burgers vectors. The simulated time scale is then extended to model static and dynamic strain ageing with a kinetic Monte Carlo approach parameterized on the DFT and EAM calculations. This work paves the way for the development of a general mobility law for dislocations in aged steels.

Thermomechanical Conversion in Metals—Constraints from a Two-Temperature Dislocation Plasticity Model Charles Lieou[1] and Curt Bronkhorst[2]; [1]Los Alamos National Laboratory, United States; [2]University of Wisconsin–Madison, United States

Using two-temperature thermodynamics, we derive an important constraint on the Taylor-Quinney coefficient, which quantifies the fraction of plastic work that is converted into heat during plastic deformation. We show that the Taylor-Quinney coefficient is a function of a thermodynamically defined effective temperature that measures the configurational disorder in the material, and increases as deformation progresses. Finite-element analysis of a recent experiment on the AA6016-T4 aluminum alloy, using the thermodynamic dislocation theory (TDT) of Langer et al., shows good agreement between theory and experiment for both stress-strain behavior and temporal evolution of the temperature.

5:10 AM F.SF08.05.02
TiAl Embrittlement at High Temperatures Camille Thenot[1], Jean-Philippe Monchoux[1], Damien Connetable[2] and Pierre

Sallot[3]; [1]CEMES CNRS UPR 8011, France; [2]CIRIMAT CNRS UMR 5085, INP UPS, ENSIACET, France; [3]SAFRAN Tech, France

Titanium-Aluminum alloys (TiAl) are very interesting for applications in turbomachines because of their low density (3,8 - 4,2 g.cm^{-3}) and of their high mechanical strength at high temperatures. However, when exposing TiAl alloys to high temperatures, a catastrophic loss of ductility is observed. Here, we study the role of oxygen in this phenomenon. For this purpose, we investigate the nature of the TiAl-oxygen solid solution (diluted O atoms, or forming clusters), we determine the oxygen diffusion mechanisms and study the interactions between the dislocations and the oxygen atoms. The nature of the solute solution and the diffusion mechanisms have been investigated theoretically using atomistic calculations (DFT), and the dislocation-oxygen interactions have been studied experimentally by characterizations at the microscopic scale (TEM).
In the experimental part, tensile test on $Ti_{48}Al_{48}W_2B_{0.08}$ alloys have been carried out on samples exposed in air at 800°C for 500h, to characterize the embrittlement phenomenon. It was shown that the embrittlement comes from oxygen penetration in a surface layer 10 µm to 100 µm thick. Then, to evaluate the influence of oxygen on the bulk mechanical properties, tensile tests on alloys with low and high oxygen concentrations have been performed. Results showed that the alloy with high bulk oxygen concentration has a lower ductility than the alloy with lower oxygen content, as classically observed in TiAl alloys. TEM observations showed the presence of pinning points on the dislocations, which may have an impact on the alloy ductility. Based on these results, our hypothesis is that TiAl embrittlement at high temperature occurs by a loss of ductility of the superficial diffusion layer.
In the numerical part, DFT simulations were used to study the interactions between clusters of one to 6 oxygen atoms with lattice defects such as vacancies and antisites at the atomic scale. We identified which type of complex defect (defect + oxygen cluster) would be the most probable and in which concentration, depending on the temperature. However, these clusters of 1 to 6 oxygen atoms are much smaller than the clusters pinning the dislocations, which should be composed of about 10^9 oxygen atoms, according to the first evaluations based on the TEM images. Nevertheless, both the two clusters may have an impact on the mechanical properties. The small clusters are likely to decrease the diffusivity of oxygen in TiAl by acting as traps, which would lead to decrease oxygen penetration, and thus to diminish embrittlement. On the contrary, the big clusters, which pin the dislocations, probably contribute to increase the strength and to lower the ductility in the surface layer, which increase embrittlement.

Dislocation Motion and Cross-Slip in f.c.c. Metals—Atomistic Simulations Eyal Oren, Ohad Grinbaum, Eyal Yahel and Guy Makov; Ben-Gurion University of the Negev, Israel

Dynamic properties of dislocations are both of fundamental importance in understanding and modelling plasticity and mechanical deformation of solids and are required for constructing mesoscale dislocation dynamics simulations. However, these properties are not easily accessible by experimental means due to the short time-scales. Molecular dynamics provides a tool for studying the dynamics of dislocations at the short time and length scales, which are difficult to access by experimental means, but requires careful convergence for physical meaning. We have studied the dynamics of dislocation glide and of dislocation cross-slip in FCC crystals of Al, Cu, Ni and Ag to elucidate the effect of chemical species on the dislocation properties. Highly converged simulations were performed on long dislocations in large FCC crystal supercells with full periodic boundary conditions, incorporating a dislocation dipole with zero net Burgers vector. Kinematics were studied by accelerating dislocations at constant stress and temperature. The relation between stress and terminal velocity at cryogenic and room temperatures for both screw and edge dislocations was obtained. A transition from viscous behaviour to near sonic asymptotic behaviour was identified and the velocity dependence of the drag force was characterised. At higher stresses a shift into the transonic regime occurs and the mechanism and stability of this transition is examined. The thermally activated process of cross-slip was simulated multiple times creating statistical data from which the kinematics and kinetics were deduced and from which the activation parameters were calculated. The effects of stresses in the cross-slip and glide planes on the activation volumes were determined. Finally, the rate-controlling step of the cross-slip process was identified producing insight into the cross-slip mechanism.

5:30 AM F.SF08.05.04
Plasticity in Small-Sized Crystals Through Diffusion-Mediated Surface Defects Xiang Wang, Sixue Zheng and Scott X. Mao; University of Pittsburgh, United States

Due to the small scale and high surface-to-volume ratio of nanometer-sized metallic crystals, it is generally believed that surface surface-related deformation mechanisms govern the plasticity of nanocrystals at atomic scale. As the sample size of the nanocrystals goes further went down to sub-ten nanometer, strong surface diffusion activities took place and mediated plastic deformation. However, thus far, much less is known about the yielding and plastic flow mechanisms at atomic scale in small-sized nanocrystals where surface atomic diffusion is activated. Here, by performing in- situ transmission electron microscope tensile tests of Ag NWs and Pt NWs, it was revealed that the yield strength-size relationship changed from ''smaller is stronger'' to ''smaller is weaker'' with decreasing the sample diameters of Ag NWs, while Pt NWs showed traditional "Hall-Petch" size-dependent behavior. This difference arose from surface atomic diffusion activities in Ag NWs, which may increase dislocation nucleation sites and the probability of surface defect interaction, thereby lowering critical surface dislocation nucleation stress. The coupled displacive-diffusive plasticity was quantitatively investigated by analyzing the lattice stress-applied strain evolution in nanowires at atomic scale. This work provides new insights into the atomic-scale mechanisms of diffusion-assisted dislocation nucleation and diffusion-mediated plastic deformation process with displacive plasticity in small-sized materials.

5:40 AM F.SF08.05.05
Probing the Small-Scale Plasticity of an Icosahedral Quasicrystal, i-Al-Pd-Mn, at Moderate Temperatures Yu Zou; University of Toronto, Canada

Quasicrystalline materials possess a remarkable structure that does not exhibit crystallographically legitimate periodicity in certain crystallographic directions. Despite their special configuration and many related useful properties, the major drawback of these quasiperiodic structures is extreme brittleness of the materials at temperatures below about 0.75 T/Tm(Tm-the melting point) which hugely handicaps their practical implementation in the moderate temperature region. Here, we study the mechanical behavior of a typical icosahedral quasicrystal (i-Al-Pd-Mn) using a micro-thermomechanical technique over the temperature range of 25-500 °C, which has never been explored before. A couple of interesting phenomena have been observed, including micro-pillar shrinkage, phase transformations, grain refinement, and thermally induced transition from brittle fracture to serrated and homogeneous plastic flows. Furthermore, we discuss the multiple underlying mechanisms on the deformation behavior of the quasicrystal in this temperature regime, including surface evaporation/diffusion, diffusion-enhanced plasticity, dislocation activities, and grain boundary rotation/sliding.
Our study bridges the gap between room temperature and high temperature plasticity in quasicrystals and also demonstrates a new opportunity to study complex intermetallic phases in broad size and temperature regimes.

5:50 AM F.SF08.05.06
High-Temperature Bulk Dislocation Dynamics in Aluminum Leora Dresselhaus-Marais[1], Grethe Winther[2], Marylesa Howard[3], Arnulfo Gonzalez[3], Sean R. Breckling[3], Can Yildirim[4], Philip Cook[5], Mustafacan Kutsal[2,6], Luis Zepeda-Ruiz[1], Amit Samanta[1], Carsten Detlefs[6], Jon Eggert[1], Hugh Simons[2] and Henning F. Poulsen[2]; [1]Lawrence Livermore National Laboratory, United States; [2]Technical University of Denmark, Denmark; [3]Nevada National Security Site, United States; [4]CEA Grenoble, France; [5]Universität für Bodenkultur Wien, Austria; [6]European Synchrontron Radiation Facility, France

Establishing the appropriate thermal pathways to tune a metal's microstructure and generate the appropriate continuum response requires a quantitative view of high-temperature annealing. The dislocation motion and interactions that are known to dictate microstructural changes in metals depend strongly on temperature, however, the necessary time-resolved measurements have been elusive, especially near the melt. We use time-resolved dark-field X-ray microscopy to directly image dislocation motion at temperatures spanning the final 7% to T_m. Our real-time movies resolve the creep-dominated dislocation motion and interactions deep beneath any surface in single-crystal, showing dynamics that has previously been limited to theory. Quantitative analysis of the temperature-dependent dislocation mobility in these findings present opportunities to test and refine dislocation models that have previously relied on indirect measurements and multi-scale models for validation.
This work was performed in part under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

5:00 AM *F.SF08.06.01
Grain Boundary Migration—Coupling Modes and Disconnections Nicolas Combe[1,2]; [1]CEMES - UPR 8011, France; [2]University Toulouse III, France

In specific conditions, grain boundary (GB) migration occurs in poly-crystalline materials as an alternative vector of plasticity compared to the usual dislocation activity. The shear-coupled GB migration, the expected most efficient GB based mechanism, couples the GB motion to an applied shear stress. For a given GB, several migration mechanisms referred as coupling modes can occur.
Both experimental and theoretical studies have evidenced that the migration of the GB occurs through the nucleation and motion of disconnections [1-3]. Disconnections are GB defects that have both a step and a dislocation (Burgers Vector) character. They can homogeneously or heterogeneously nucleates [4-6].
We use atomistic simulations (especially the Nudge Elastic Band method) on symmetric tilt grain boundary in FCC materials to evidence these disconnections and to characterize both their structural and energetic properties. In this study, we focus on homogeneous disconnections nucleation. Investigating the <100> and <110> coupling modes, we evidence the disconnections characteristics dependence on the grain boundary disorientation. Besides, we evidence the operation of specific disconnections involving coupling modes different from the usually observed <100> and <110> coupling modes.

Atomistic Insight into the Deformation Map of Grain Boundary Qi Zhu and Jiangwei Wang; Zhejiang University, China

Grain boundary (GB) migration is a prevalent plastic deformation mode in nanocrystalline and polycrystalline materials, and a systematic insight of GB migration is vital to the development of novel materials through GB engineering. However, current understanding on the atomistic mechanism of GB-dominated plasticity remains largely elusive. Here, we combine state-of-the-art in situ TEM nanomechanical testing and atomistic simulations to investigate the atomistic dynamics of shear-induced GB migration in Au nanocrystals. Using the <110> tilt GBs as examples, we demonstrate that the shear-induced GB migration is fundamentally accommodated by GB defects, including disconnections (high angle GB) and geometrically necessary dislocations (low angle GB). In the high angle range (as exemplified by the Σ11(113) GB), we unambiguously reveal a disconnection-mediated GB migration mechanism under shear loading, where the nucleation, propagation and dynamic interactions of various disconnections dominate the GB migration. Moreover, the migrating Σ11(113) GB can readily accommodate intragranular lattice defects (including dislocation and stacking fault), where the pre-existing disconnections interact with the residual disconnections generated on the GB. This disconnection-mediated dynamic is further proved to be universal among different high angle GB structures, where triple junctions can serve as effective nucleation and annihilation sites of disconnections. In contrast, low angle GBs with dislocation characters typically migrate via conservative gliding of intrinsic GB dislocations. The fully reversible motion of such coherent GBs can be achieved under shear loading cycles in Au nanocrystals, due to the suppression of heterogeneous surface nucleation of lattice defects and robust structural stability throughout GB motion. Inspired by these scientific insights, we propose a GB engineering protocol to realize controllable plastic reversibility in metallic nanocrystals. This reversible deformation via conservative GB migration is retained in a broad class of face-centered cubic metals with low stacking fault energies when tuning the GB misorientation, external geometry and loading conditions over a wide range. Above results enable us to establish a full deformation map of <110> tilt GBs, providing novel insights into the GB-dominated plasticity in nanocrystalline materials.
This talk is based on our recent works: In situ atomistic observation of disconnection-mediated grain boundary migration. *Nat. Commun.* **10**, 156 (2019); Metallic nanocrystals with low-angle grain boundary for controllable plastic reversibility. *Nat. Commun.* (2020, accepted); In situ atomistic observation of grain boundary migration subjected to defect interaction. (under review).

A Comparative Study of Electromigration in Nanowires with Twin Boundaries Mohammad Waliullah and Rodrigo Bernal; The University of Texas at Dallas, United States

Electromigration is a critical failure mode of metallic interconnects in the semiconductor industry, and in the emerging fields of flexible and wearable electronics. This failure can be attributed to the diffusion of metallic atoms due to momentum transfer of electrons flowing through the interconnect when a high current density is applied. The diffusion eventually leads to formation of voids and hence a time-dependent increase of electrical resistance of the interconnect. Since it is a diffusion process, the microstructure of the interconnect is one of the controlling factors of electromigration. Twin boundaries, in contrast to grain boundaries, can have the potential to reduce diffusion of atoms and consequentially improve electromigration performance both in electronic chips and in flexible electronics. Note that in nanostructured flexible electronics, it is common to have nanowires with twin boundaries, acting as interconnects. Unfortunately, very few studies have been conducted about the diffusion performance of these interconnects. No literature is available about the collective effect of twin boundaries throughout the interconnect. Moreover, some of the studies said that twinning slows down the diffusion and hence void growth [1], [2] and some said that twinning does not necessarily hinders void growth [3]. Given these conflicting reports, there is clearly a need for a systematic study of diffusion through twinned interconnects.

In this work, we investigated electromigration failure of penta-twinned silver nanowires, with diameters ranging from 50 nm to 80 nm to understand the diffusion process during electromigration of twinned interconnects. Samples were prepared by random deposition of nanowires on a substrate containing gold electrodes fabricated by photolithography. The nanowires were connected with the electrodes by e-beam lithography. The electrodes were then connected to a printed circuit board (PCB) through a wirebonding package. Under a fixed current density and temperature, the resistance was measured using 4-point measurement method so that it can be measured continuously without the influence of contact resistances. The currents were applied in an automated fashion to test a large number of nanowires. The failure criterion was set as 10% increase in resistance which is widely used in the electronics industry. Resistance vs. time plots were obtained in different temperatures, which were fitted to a mathematical model combining the theory of electromigration diffusion flux and the theory of void growth. The fit produces a diffusivity product, independent of temperature, for twin boundaries and the activation energy required for atomic fluxes through twin boundaries. These parameters enable a comparison between the diffusion through twinned interconnects and the published data for diffusion through other microstructures of interconnects currently used in the electronics industry. The results of this study should also allow reliability calculations to be made for novel electronic devices that utilize twinned metallic interconnects, such as wearable electronics that use nanowires as flexible conductors.

Grain Boundary Solute Segregation Beyond the Dilute Limit Malik Wagih and Christopher Schuh; Massachusetts Institute of Technology, United States

Beyond the dilute limit, solute segregation to grain boundaries is known to be concentration dependent. The classic explanation for this effect comes from the Fowler-Guggenheim approach, which solely attributes this dependence to increasing solute-solute interactions at grain boundaries e.g. as solute concentration increases, a strong solute-solute repulsion at grain boundaries will reduce the segregation tendency of additional solute atoms. However, there is a second, less

understood, contribution to this concentration dependence: the gradual exhaustion of favorable segregation sites. Grain boundaries have a complex environment with a variety of site-types available for segregation, and a spectrum of solute binding "segregation" energies. Segregation will first occur at the most favorable sites, forcing the next round of solute atoms to compete for less favorable sites, which reduces their tendency to segregate. In this work, we outline a computational and analytical framework to delineate, for the first time, both contributions to the concentration dependence of solute segregation: 1) the spectrality of site energies in grain boundaries and 2) solute-solute interactions.

5:10 AM F.SF08.07.03
Exploring Grain Boundary Failure in Technically Pure and Micro-Doped Molybdenum via Bending Experiments S. Jakob[1], T. Weissenböck[1], A. Hohenwarter[1], A. Lorich[2], W. Knabl[2], R. Pippan[3], Helmut Clemens[1] and V. Maier-Kiener[1]; [1]Montanuniversitaet Leoben, Austria; [2]Plansee SE, Austria; [3]Austrian Academy of Sciences, Austria

Interfaces, such as grain boundaries, are crucial for the mechanical properties of metallic materials. Especially in refractory metals like tungsten and molybdenum, grain boundaries are often the weakest link regarding the materials' strength and ductility. These metals are inherently susceptible for intergranular failure and suffer from a limited deformation capability at low temperatures. An advanced approach for the improvement of the interfaces is segregation engineering, e.g. the addition of cohesion enhancing elements segregating to the grain boundaries.
In this work, three-point-bending tests are conducted on recrystallized commercially pure and microdoped molybdenum at temperatures between -40°C and room temperature. The early stages of intergranular crack formation are examined on the specimen surface which is under tension close to the final fracture plane. The occurring grain separations are investigated regarding their distinct features, for instance the crystallography of the adjacent grains or the frequency of open grain boundaries. Doping of molybdenum with elements such as carbon and/or boron is known to suppress intercrystalline failure. Therefore, the presented grain boundary characterization methods will be applied to extract mechanical changes caused by these segregations.

SESSION F.SF08.08: Grain Boundary and Dislocation

F-SF08

5:00 AM *F.SF08.08.01
Simulations of Grain Boundary-Dislocation Interactions in FCC Nickel Eric R. Homer[1], David Page[1], Devin Adams[1], Ricky Wyman[1], David Fullwood[1] and Robert Wagoner[2]; [1]Brigham Young University, United States; [2]The Ohio State University, United States

Grain boundary-dislocation interactions play a crucial role in the deformation behavior of polycrystalline materials. While it is well known that grain boundaries can respond in a variety of ways to imposed deformation, the criteria for each response is not well known. We present work focused on determining the criteria for nucleation of dislocations from a grain boundary as well as efforts to determine the criteria for transmission of dislocations through a grain boundary. The nucleation simulations of a single grain boundary find unique criteria for every slip system, which include non-Schmid effects. The transmission simulations sample a larger population of grain boundaries and find more variation in the observed geometric criteria and resolved shear stresses. We also detail current efforts to examine the evolving criteria as repeated dislocations impact a grain boundary.

5:15 AM F.SF08.08.03
Detwinning-Governed Size Effect in Zirconia Based Ceramics Haolu Zhang[1], Justin Jetter[2], Hanlin Gu[3], Richard D. James[3], Eckhard Quandt[2] and Julia R. Greer[1]; [1]California Institute of Technology, United States; [2]University of Kiel, Germany; [3]University of Minnesota, United States

Unlike dislocation-driven size-effect in single-crystalline materials at the nanoscale, the effect of sample dimensions on the strength of twin-containing materials, especially that of ceramics, still lacks universal understanding. Previous work has demonstrated >5% plastic strain in Zirconia-based ceramics via twinning. Using diffraction methods and *in-situ* nanomechanical experiments, we uncover the microstructure-strength relationship in these twin-containing ionic crystals and reveal contributing factors to the competition between twinning and slip as the major plasticity carrier. The prominent twinning-governed size-dependence was compared to that reported for metals, where the uncanny similarities between these

drastically different material systems shed light on an universal scaling relationship that can be tied back to the well-known "smaller-is-stronger" slip-governed size-effect.

5:25 AM F.SF08.08.04
Defect-Induced Hall-Petch Softening in Nanocrystalline-Nanotwinned Metals Frederic Sansoz[1], Morris Wang[2], Xing Ke[1], Jianchao Ye[2], Zhiliang Pan[1,3], Jaime Marian[4] and Ryan Ott[5]; [1]University of Vermont, United States; [2]Lawrence Livermore National Laboratory, United States; [3]Guilin University of Electronic Technology, China; [4]University of California, Los Angeles, United States; [5]Ames Laboratory, United States

Strengthening of metals through nanoscale grain boundaries and coherent twin boundaries is manifested by a maximum strength—a phenomenon known as Hall-Petch breakdown. Different softening mechanisms are generally considered to occur for nanocrystalline and nanotwinned materials. Here, we synthesized nanotwinned Ag metals with hardness 3.05 GPa, i.e. 42% higher than the previous record, by segregating trace concentrations of Cu impurity (<1.0 wt.%) to grain boundaries and twin boundary defects. The grain diameter and twin spacings were 45 nm and 3.6 nm, respectively, which is well below the current limits for pure Ag, making it possible to explore plasticity mechanisms in nanostructures that approach those only studied by atomistic simulation. In this presentation, hybrid Monte-Carlo and Molecular-Dynamics simulations reveal three distinct strength regions as twin spacing decreases, delineated by positive Hall-Petch strengthening to grain-boundary-dictated (near-zero Hall-Petch slope) mechanisms, and to softening (negative Hall-Petch slope) induced by twin-boundary defects. Both our experiments and simulations find that an ideal maximum strength is reached for a range of twin spacings below 7 nm in pure and Cu-segregated nanotwinned Ag. We present a continuum theory predicting the softening behavior from kink motion in twin boundaries applicable to pure metals and segregated alloys containing nanoscale twins.

5:35 AM F.SF08.08.05
Mechanistic Competition Between Grain Boundary and Dislocation Plasticity in Grain Boundary Doped Aluminum Alloys Wenbo Wang and Jason R. Trelewicz; Stony Brook University, United States

Grain boundary doping has been widely leveraged for the stabilization of nanocrystalline materials. Depending on the dopant species and concentrations, a range of mechanisms have been demonstrated for stabilizing the nanocrystalline grain structure that include thermodynamic contributions often driving alloy design criteria and kinetic pinning forces inhibiting grain boundary motion at elevated temperatures. The presence of deliberately designed solute heterogeneities has implications for the mechanical behavior with a number of studies reporting grain boundary segregated nanocrystalline alloys with significantly enhanced strength relative to their unalloyed counterparts. In this presentation, we use molecular dynamics simulations of nanocrystalline Al containing Mg doped grain boundaries to quantify the mechanisms responsible for this unexpected increase in strength in the context of fundamental changes in grain boundary properties upon alloying. We find that grain boundary microplasticity at low strains is suppressed by solute enrichment producing more stable interfacial configurations, which delays the onset of grain boundary-mediated dislocation slip and promotes an increase in strength. Following the yield point, the interaction of lattice dislocations with grain boundary solute atoms reduces the strain accommodated through dislocation plasticity, thus shifting plastic strain accommodation to the grain boundaries and augmenting flow behavior relative to pure nanocrystalline aluminum.

5:00 AM F.SF08.09.02
Multiscale Characterization of Cu/Nb Nanocomposites with Novel 3D Interfaces Zezhou Li[1], Justin Y. Cheng[1], Shuozhi Xu[2], Jonathan Poplawsky[3], Kevin Baldwin[4], Irene Beyerlein[2] and Nathan Mara[1]; [1]University of Minnesota, Twin Cities, United States; [2]University of California, Santa Barbara, United States; [3]Oak Ridge National Laboratory, United States; [4]Los Alamos National Laboratory, United States

We present our latest results mainly focusing on elevated temperature microstructural stability of Cu/Nb nanocomposites containing 3-D interfaces. Cu/Nb nanocomposites with atomically sharp 2-D interfaces that exhibit outstanding thermomechanical stability have been examined intensively for over two decades. Their strength is enhanced by defect-interface interactions such that dislocations are blocked from traversing Cu/Nb sharp interfaces. We have investigated the

relationship between atomic structure, mechanical behavior, and thermal stability in Cu/Nb nanocomposites with novel 3-D interfaces. We have shown that the mechanical properties (such as the strength) of Cu/Nb nanocomposites can be further improved by the introduction of chemical, crystallographic, and/or topological variations in all 3 dimensions at heterophase interfaces. Structural characterization employed a combined atom probe tomography (APT) and transmission electron microscopy (TEM) approach. These techniques complement each other very well. While it is possible to observe chemical inhomogeneities in 3-D interfaces with APT, it does not render atomic-resolution information and is prone to magnification artifacts caused by differences in atomic vaporization rates in multi-component samples. However, high-resolution TEM provides atomic-scale information to probe the existence of amorphous regions, metastable alloys, or third-crystal phase precipitates in the 3D interfaces, and help to identify the relevant structure and possible deformation mechanisms. Additionally, we carried out thermal stability studies, incorporating static annealing and differential scanning calorimetry (DSC) scans. Annealed samples were investigated by TEM to uncover the structural evolution associated with thermally perturbed 3D interfaces, while enthalpy changes by DSC analysis were used to identify the onset of thermally-induced structural changes. These correlated studies determined the thermal stability of 3-D interfaces, and how post-deposition annealing can be used to manipulate 3-D interface morphology and possibly enable optimal mechanical performance.

SESSION F.SF08.10: Phase Transformation
On Demand Abstracts Available for Viewing Starting Saturday Morning, November 21, 2020

5:00 AM *F.SF08.10.01
Structural and Chemical Atomic Complexity of Lattice Defects—From Defect Phase Diagrams to Material Properties Sandra Korte-Kerzel[1], Tilmann Hickel[2], Liam Huber[2], Jorg Neugebauer[2], Dierk R. Raabe[2], Stefanie Sandlöbes[1] and Mira Todorova[2]; [1]RWTH Aachen University, Germany; [2]Max Planck Institut für Eisenforschung, Germany

The design of new metallic materials is essential in fulfilling the promise of emerging and improving key technologies from efficient energy conversion over lightweight transport to safe medical devices. Over the last decades, two approaches in materials physics have proven immensely successful in the design of new metallic materials: Firstly, thermodynamic descriptions of crystalline phases have enabled materials scientists and engineers to tailor and process alloys to obtain a desired internal structure at the microscale. Secondly, better understanding and manipulation of the crystal defects, which govern the material's strength, formability and corrosion resistance, has led to the development of new alloying and processing concepts that provide some of the most advanced high-performance alloys in operation today. However, to date, these two concepts remain essentially decoupled.
Our vision is to bridge the gap between these existing and powerful approaches by bringing them together in one new conceptual framework, which will consider defects and their thermodynamic stability in a holistic manner. Consequently, a new material design concept originating from the atomic scale will be accessible to materials physicists and engineers which jointly considers the local crystalline structure of defects (structural complexity), the atomic distribution of each element among the different types of phases and defects (chemical complexity) and the stability of defects under the given conditions, such as bulk composition, temperature and applied stress or electrode potential. We will show here, how these can be linked by defect phase diagrams, which will describe the transition between and the coexistence of defect phases. This structural and chemical complexity at the atomic scale naturally exists in all materials. On this basis, we believe that a new physical description of metallic materials will possible and will provide a powerful toolbox for future design of engineering materials with tailored properties regarding concurrent mechanisms and properties, such as mechanical and corrosion performance of engineering materials.

5:15 AM *F.SF08.10.02
Controlling the Structure of Interfaces and Dislocations to Directly Alter Mechanical Response Timothy J. Rupert; University of California, Irvine, United States

Both grain boundaries and dislocations have been recently shown to experience structural transitions between defect states known as complexions. In this talk, we discuss how one can manipulate the natural variations in stress, chemistry, and atomic structure near grain boundaries and dislocations to stabilize these defects and use them as tailorable features. We also demonstrate how different complexions can alter the mechanical properties of materials on the nanoscale. For grain boundary complexions, we focus on nanocrystalline metals, where such features have the largest effect due to the high grain boundary density. We isolate the materials and processing conditions which can cause the strength and ductility of these materials to be

simultaneously augmented, as well as report on small-scale mechanical testing and atomistic modeling techniques to study grain boundary mechanics. For linear complexions, our work uncovers how nanoscale phases restricted to the region along a dislocation line direction can affect plasticity, encompassing both initial yield and subsequent flow. Alloy choice is shown to be very important, as various responses ranging from softening to strong hardening are predicted. As a whole, this work demonstrates that our field is on the precipice of a new age, where defects can be manipulated and designed rather than simply tolerated.

The Coupling of Plasticity and Mass Transfer in Al Alloys Christopher Hutchinson; Monash University, Australia

High strength Al alloys exploit solid state precipitation to tailor their mechanical response. This precipitation requires two ingredients: a thermodynamic driving force and atomic mobility. For a given alloy chemistry, the heat treatment (precipitation) temperature is chosen as a compromise between having sufficient driving force for precipitation and sufficient atomic mobility so that the precipitation reaction occurs in a reasonable time and results in a 'not too coarse' precipitate distribution. It is this compromise that frames the competition between nucleation, growth and coarsening that constrains the possible precipitate distributions and hence mechanical responses.

This talk demonstrates a new approach that uses small amplitude cyclic plasticity at room temperature as a means of continually pumping vacancies into the system to achieve atomic mobility under conditions of high thermodynamic driving force. The approach is self-regulating (in both space and particle size) and results in extremely fine-scale inhomogeneous solid solutions. Such structures lead to combinations of strength and elongation that exceed those of conventionally precipitate strengthened alloys, without the presence of precipitate free zones.

Since the approach does not use thermal treatments, it somewhat decouples control of the thermodynamic driving force and atomic mobility. This provides a means to fully alter the competition between precipitate nucleation, growth and coarsening and new microstructures, with new combinations of properties are obtained. Examples of both monotonic and cyclic properties are demonstrated.

Coupling Plasticity and Precipitation in Magnesium Alloys Using Hot Compression Suhas Eswarappa Prameela[1], Joey Chen[1], Yannick Hollenweger[2], Steven Lavenstein[1], Burigede Liu[3], Roshan Plamthottam[1], Peng Yi[1], Kaushik Bhattacharya[3], Jaafar El-Awady[1], Michael L. Falk[1], Dennis Kochmann[2] and Tim Weihs[1]; [1]Johns Hopkins University, United States; [2]ETH Zürich, Switzerland; [3]California Institute of Technology, United States

Simple aging of Magnesium alloys often yields inadequate precipitation hardening response compared to Aluminum alloys. Deformation induced precipitation is one viable strategy to overcome this problem. Using defects, one can severely alter the nucleation and growth of desired second phases and thereby tune their number density, size, shape, orientation, and spatial distribution. Through simple compression experiments on rolled, large-grained Magnesium-Aluminum alloys, we show how solid-solid phase transformations are altered in grain interiors and along grain boundaries after only 10% plastic strain and at four, relatively low temperatures (25C, 100C, 150C, and 200C). With ex situ TEM, we detail the nanoscale $Mg_{17}Al_{12}$ intermetallic precipitates that form with a fully solutionized Mg-9Al matrix after compression. With crystal plasticity simulations, we link the inhomogeneity of these nano precipitates to the heterogeneity of deformation gradients within the samples. Finally, we explore the underlying mechanisms behind this deformation induced precipitation.

Precipitate Nucleation Facilitated by Defects During Deformation in Magnesium Alloys Peng Yi and Michael L. Falk; Johns Hopkins University, United States

Magnesium has great potential as a lightweight material, and there are great interests in designing Mg alloys with enhanced mechanical properties. However, precipitate strengthening in the Mg alloys is much less effective as compared to Al alloys, due to the low number density of the precipitates in the Mg alloys and their highly anisotropic morphology. One promising method to overcome this limitation is dynamic processing, e.g. hot compression and ECAE, which could enhance nanoscale precipitation to achieve a higher precipitation strengthening effect.[1] This enhancement is achieved through precipitate nucleation facilitated by defects generated during deformation, including dislocations and vacancies.

We performed molecular dynamics (MD) simulations on nucleation of gamma-$Mg_{17}Al_{12}$ precipitates in Mg-Al solid solution. The critical nucleus size, and the Gibbs free energy calculated for solids under non-hydrostatic stress field, were used to

estimate the interfacial free energy using the classical nucleation theory (CNT). Dislocations and vacancy clusters significantly reduce the critical nucleus sizes and the nucleation barriers of the precipitates, mainly by reducing the precipitate-matrix interfacial free energies. A macroscopic strain hardening model to predict the dislocations multiplication for precipitate nucleation enhancement compared favorably with ECAE experiments.[2] Vacancy diffusion and clustering were also simulated using a continuum model parameterized using MD and kinetic Monte Carlo simulations. The temporal and spatial distributions of vacancy clusters are also consistent with the non-uniformity of the precipitate particles observed in dynamic processing experiments.

Computational Study of Radiation Damage in Bilayer Nanostructures Cameron Hopper[1], Raghuram Santhanpuram[1], Elton Chen[2], Remi Dingreville[2] and Arun K. Nair[1]; [1]University of Arkansas–Fayetteville, United States; [2]Sandia National Laboratories, United States

Neutron and ion radiation damage materials used in radioactive environments, such as nuclear reactors. This type of radiation can cause atoms to be moved around in the atomic structure or removed entirely, causing defects and damage to accumulate in the material, which leads to lower mechanical strength. Since these defects are on the atomic level, it can be hard to detect. We propose examining two different types of interfaces: bilayer interfaces, specifically Silicon-Aluminum and Silicon-Gold, as well as crystalline-amorphous interfaces to investigate whether these types of interfaces can help develop radiation-resistant materials. Using molecular dynamics, we will model these bilayer and amorphous structures as well introduce radiation in the form of Frenkel pairs to our system. To analyze the mechanical strength at different levels of radiation damage, yield surface calculations will be performed by subjecting the samples to biaxial and uniaxial tension and compression tests to determine the yield points. Different defect absorption mechanisms at the interface will also be discussed.

Late News: Understanding the Interaction Between Grain Boundary Precipitation and Creep Cavitation of Type 316H Stainless Steel During In-Service Aging Siqi He[1], Hao Shang[1], Antonio Fernandez-Caballero[2], Alexander Warren[1], David Knowles[1], Peter Flewitt[1] and Tomas Martin[1]; [1]University of Bristol, United Kingdom; [2]University of Oxford, United Kingdom

Creep cavitation is an important degradation mechanism for metallic components used at an elevated temperature. Stress, temperature and microstructure all play a role in the initiation of creep cavities, and the formation mechanism of cavities can depend heavily on local phase and chemistry. In this work, the relationship between microstructural evolution due to long term thermal ageing and creep cavitation is explored in an ex-service AISI type 316H stainless steel sample from an advanced gas-cooled nuclear reactor boiler header after 65,000 hours at 490 to 530°C. The microstructure of the ex-service specimen has been investigated by secondary electron microscopy, focused-ion beam cross sectioning, electron backscatter diffraction and transmission electron microscopy. $M_{23}C_6$ precipitates, α-ferrite precipitates and creep cavities are observed at grain boundaries, with increased precipitation and cavitation at random grain boundaries, and an absence of creep cavities at coincidence site lattice (CSL) 3 boundaries. The α-ferrite precipitates grow during in-service exposure at grain boundaries with a Kurdjumov-Sachs orientation relationship to at least one neighbouring austenite matrix grain. The creep cavities were observed to initiate at the intergranular $M_{23}C_6$ and α ferrite precipitates. Based on the orientation relationship of the ferrite precipitates with the austenite matrix, some creep cavities are initiated after the ferrite precipitates have formed. The influence of microstructure changes on creep cavitation of materials during in-service aging and the implications for more

reliable predictions of lifetime for components operating at high temperature are discussed.

Efficient Recycling and Regeneration of E-Mobility Components and Materials Anke Weidenkaff[1,2]; [1]Fraunhofer Research Institution for Materials Recycling and Resource Strategies IWKS, Germany; [2]Technical University of Darmstadt, Germany

A sustainable future e-mobility requires an efficient circularity of the energy converters with a programmable long lifetime. Electrochemical energy conversion processes in batteries, fuel cells and electrolysers require full reversibility of local effects, defect formations, phase segregations and redox reactions. Therefore, regenerative or self-repairing materials have to be developed to produce long-lasting devices.

The design of sustainable high performance materials is based on theoretical predictions, life cycle assessment and a profound knowledge on composition-structure-property relationships, defect chemistry, ion mobility assessment and the criticality analysis of applied elements to improve the cycle life of future batteries, fuel cells and electrolysers.

Biography:
Since October 1, 2018, Prof. Dr. Anke Weidenkaff has been head of Fraunhofer IWKS in Hanau and Alzenau. In addition, Anke Weidenkaff is professor at the Technical University of Darmstadt. Her principal areas of research and expertise are materials science and resource strategies, including the development, synthesis and characterization of sustainable materials for energy conversion and storage. Her current work focuses on regenerative, self-healing materials and the development of next-generation process technologies for fast and efficiently closed material cycles. Anke Weidenkaff completed her PhD degree in Chemistry at ETH Zürich in 2000, received the Venia Legendi for Solid State Chemistry and Materials Science from the University of Augsburg in 2006 and became section head at Empa as well as associated professor at the University of Bern, Switzerland. She was chair holder for Materials Chemistry and director of the Institute for Materials Science at the University of Stuttgart from 2013-2018, was president of the European Thermoelectric Society (ETS), elected member of the E-MRS Executive Committee and chair of the E-MRS spring meeting 2019. In 2011, she was awarded with the Kavli Foundation Lectureship prize. She also served on expert panels of the German Science Foundation DFG and on expert panels of the European Research Council (ERC) and is member of the German Advisory Council on Global Change (WBGU). Until present, Anke Weidenkaff published some 250 SCI rated publications on materials research in energy conversion technologies.

Intellectual Property Filing Strategy, Portfolio Management and Licensing of Material-Related Technologies Frederick Mau; Toyota Motor North America, Inc., United States

A key understanding of intellectual property strategies is essential to build meaningful intellectual property portfolios for material-related technologies. Intellectual property portfolios typically consist of a combination of both patents and trade secret/know-how information. Unlike other technologies, patent filings for material-related technologies such as batteries, catalysts and functionalized materials require additional data, description and documentation to ensure broad protection of the underlying technology. While patent application filings for mechanical, electrical and software technologies do require a detailed description of the structure and operation of the technology to enable recreation by one of skill in the art, material-related technologies additionally require demonstration of a strong understanding of the underlying mechanism behind the invention coupled with strong support of laboratory data. Any shortcoming in this area will result in narrow protection covering only the specific aspects of the invention supported by the data provided. This presentation will focus on best practices to ensure proper intellectual property protection for material-related technologies. Additionally, we will discuss how to build intellectual property portfolios around fundamental technologies with an eye toward protection of commercial interests and licensing.

Biography

Mau has the position of Intellectual Property Counsel with Toyota Motor North America, Inc. His job responsibilities include all patent filing, prosecution and patent portfolio management (domestic & foreign) for all Advanced Research, Vehicle Engineering and Manufacturing business units within North America. Furthermore, Mau handles and/or advises on many other Intellectual property-related matters, which may include patent disputes, patent clearance studies, open source software, intellectual property matters relating to contracts, business establishment and support of IP lobbying efforts for Toyota Government Affairs. In addition to his role as Intellectual Property Counsel for TMNA, Mau also oversees the licensing activity for Toyota IP Solutions as Director of Patent Licensing.

Extreme Wave Interactions in Metamaterials with Broken Symmetries Andrea Alù; The City University of New York, United States

In this talk, I discuss our recent discoveries in electromagnetics, nano-optics and acoustics showing how suitably tailored *meta-atoms* and their arrangements open exciting avenues to enable extreme phenomena and new technology based on light, radio-waves and sound. In particular, I discuss venues in which broken symmetries play a pivotal role in establishing emerging phenomena in metamaterials, from geometrical asymmetries and generalized forms of chirality, to time-reversal symmetry breaking and parity-time symmetry. Our work shows how symmetry concepts offer interesting tools to break Lorentz reciprocity and realize isolation without the need of magnetic bias, based on broken time-reversal symmetry induced by mechanical motion, spatio-temporal modulation and/or nonlinearities. Broken symmetries in space and space-time open

also the opportunity to induce topological order in metamaterials. The opportunities offered by hybrid metamaterials combining classical photonic material platforms with 2D and quantum materials characterized by exotic lattice symmetries will also be discussed. Finally, the role of parity-time symmetry and non-Hermitian physics in enabling broadband wave manipulations beyond the limits of passive systems will be outlined. In the talk, I will outline the impact of these concepts from basic science to practical technology, from classical waves to quantum phenomena.

Biography:
Andrea Alù is the founding director of the Photonics Initiative at the CUNY Advanced Science Research Center, Einstein Professor of Physics at the CUNY Graduate Center, and Professor of Electrical Engineering at The City College of New York. He is affiliated with the Wireless Networking and Communications Group and the Applied Research Laboratories, both based at the University of Texas at Austin, where he is a Senior Research Scientist and Adjunct Professor. His research interests span over a broad range of technical areas, including applied electromagnetics, nano-optics and nanophotonics, microwave, THz, infrared, optical and acoustic metamaterials and metasurfaces, plasmonics, nonlinearities and nonreciprocity, cloaking and scattering, acoustics, optical nanocircuits and nanoantennas. Since 2014, Dr. Alù has been also serving as Chief Technology Officer of Silicon Audio RF Circulator, a company that holds the exclusive license of a few inventions stemming from Alù's lab around magnetic-free technology for non-reciprocal devices.

High Open-Circuit Voltage (V_{OC}) in Dye-Sensitized Solar Cells (DSSC) by the Incorporation of ZnO/Au Nanoflowers into TiO_2 Photoanodes Susana Borbón; Universidad Autónoma de Nuevo León, UANL, Mexico

Dye-sensitized solar cells (DSSCs) are a promising alternative to the currently commercialized photovoltaic devices; they are semi-transparent, can be assembled on flexible substrates and have a good performance even under diffuse light. Furthermore, the fabrication process is simple, and the materials used are low-cost, making it a potentially economic technology. The most used semiconductor oxides in DSSCs are TiO_2 and ZnO. Both have a wide band-gap, are non-toxic, abundant and can be synthesized in varied morphologies; however, ZnO has a higher electron mobility. Despite its superior properties, ZnO DSSC does not surpass the efficiency of those composed of TiO_2. Therefore, it is desirable to fuse the properties of both semiconductors to obtain superior devices.
In this work we report on the enhancement of the open-circuit voltage (V_{OC}) of about 100 mV of a DSSC with an electrode composed of TiO_2 and ZnO nanoflowers. The proportion of ZnO nanoflowers was varied from 5, 10 to 15%, being the rest TiO_2. Moreover, to increase the short-circuit current (J_{SC}) we incorporated Au nanoparticles to the most efficient TiO_2/ZnO composition. The addition of the Au nanoparticles was achieved by decoration of the ZnO nanoflowers by a chemical reduction process in three different proportions. The ZnO/Au nanoflowers were characterized by field-emission scanning electron microscopy (FE-SEM), energy-dispersive spectroscopy (EDS) and inductively-coupled plasma optical emission spectroscopy (ICP-OES). The DSSCs were characterized by measuring the current-voltage (I-V) curves, electrochemical

impedance (EIS) and intensity modulated photovoltage and photocurrent spectroscopies (IMVS/IMPS). The results demonstrate that the coupling of TiO_2 and ZnO increases the recombination resistance (R_{CT}) and the electron lifetime ($t_{1/2}$) due to the improved charge carrier separation and electron-hole transfer, resulting in a larger V_{OC}. The incorporation of Au nanoparticles showed a beneficial effect on the J_{SC} due to its photocharging effect, especially for low Au loading. The most efficient DSSC consisted of a photoanode with 5% of ZnO nanoflowers decorated with 418 ppm of Au nanoparticles, and achieved an efficiency of 2.79% with a V_{OC} of 886 mV and a J_{SC} of 4.55 $mAcm^{-2}$.

F.IMRC.02
Evolution of Phase Transition H2ti3o7-Anatase and Its Effect on Physicochemical Adsorption and Photocatalytic Degradation Facundo Ruiz and Ana Laura Ruiz Castillo; Universidad Autónoma de San Luis Potosí, UASLP, Mexico

Titanate nanotubes (NTs) were synthesized by the hydrothermal method and later calcined at temperatures between 100 – 500 °C. The calcined NTs were characterized and evaluated for the physicochemical adsorption of safranin dye and photocatalytic degradation of caffeine. The materials calcined at low temperatures possess a tubular structure and H2Ti3O7 crystalline phase, which is transformed into anatase nanoparticles at 400°C. The NTs treated at 100 °C showed the highest adsorption capacity (94 %). Safranin is adsorbed through an ion-exchange mechanism, following a Langmuir isotherm model and a pseudo-second-order kinetic model. While NTs calcined at lower temperatures are better for adsorption, the photocatalytic degradation of caffeine increased in samples calcined at higher temperatures with a maximum removal of 72%. The photocatalytic behavior of the NT samples confirms that the crystalline anatase structure in conjunction with structural OH groups enhanced the photocatalytic activity. The addition of isopropanol as a scavenger demonstrated the important role of the ●OH radicals in the photocatalytic process. NTs calcined at 300 °C were efficient for both adsorption and photocatalytic processes. Due to its efficiency, this sample was reused after dye adsorption for the photocatalytic degradation of caffeine under visible light due to its enhanced absorbance in the visible region. This research work demonstrates the potential of NTs for wastewater purification.

F.IMRC.03
Change in the Rectification Ratio in Metal- ZnO:Ti Thin Structures at Low Magnetic Field Lucía Ivonne Juárez Amador[1], Miguel Galván Arellano[2], Karen Ailed Neri Espinoza[3], José Alberto Andraca Adame[4], Gabriel Romero Paredes[2] and Ramón Peña Sierra[2]; [1]Programa de Doctorado en Nanociencias y Nanotecnología Centro de Investigación y de Estudios Avanzados del IPN - CINVESTAV, Mexico; [2]CINVESTAV- IPN, Mexico; [3]Instituto Politécnico Nacional, IPN, Mexico; [4]Instituto Politécnico Nacional, UPIIH, Mexico

Magnetoresistance and rectification are two fundamentals physical properties in magneto- electronics devices (MED) fabricated with diluted magnetic oxide semiconductors (DMOs). The MED have great potential in the new generation magneto- optical devices based on DMOs as ZnO or SnO2. This study was directed to analyse the magnetoresistance effects in metal- DMOs structures. The DMOs films are titanium (Ti) doped Zinc oxide (TZO) grown by Magnetron Sputtering technique. TZO thin films were obtained at room temperature using co- sputtering process for both Ni and ZnO targets was performed using two separate power sources. The DC power of the Ti target material was 5, 10, 15 and 25 W, respectively while the radio frequency (RF) power of the Zinc Oxide (ZnO) target material was set to 150 W. The structural characteristics of the films can be further controlled with additional annealing stages at 250 and, 350 °C in N2 atmosphere by 30 min until the samples reach the usual electrical insulating character of separated ZnO films. The required annealing period to get insulating layers varies with the thickness of the Ti ion film and the film nanostructure. The ZnO:Ti ion films are formed by nanocrystallites of ~ 20 nm in size with (002) and (004) orientation and are stressed along the c- parameter according to X- ray diffraction measurements. The electrical resistivity of the films was varied from 7.69 to 392 ?- cm, the electron concentration from 1020 to 1016 cm- 3, for a range of carrier mobility from 1.57 to 14 cm2/V- s. The band gap energy of the films was of ~ 3.3 eV with transmittance of ~90% to ~95 % of in the visible region. The changes observed in the rectification ratio are attributed to the titanium doping by metal transition character. Change in the structure saturation current were also observed, this change can be explained by the dangling bonds at the metal- DMO interface. The I- V curves present the rectifying effect due to the intrinsic space- charge region in the junction Metal- TZO. For the zero- magnetic field I- V curve, the current is about 1.51 x 10- 9A at 4.38 V. On the other hand, when H=0.55T, at the same voltage bias 4.38 V the current is shifted down- ward to 3.06 x 10- 10 A.
