Optical metasurfaces have emerged as promising candidates for multi-functional devices. Dynamically reconfigurable metasurfaces have been introduced by employing phase-change materials and/or by applying voltage, heat, or strain. While existing metasurfaces exhibit appealing properties, they don't express any significant nonlinear effects due to the negligible nonlinear responses from the typical materials used to build the metasurface. In this work, we propose and experimentally demonstrate one kind of Kerr metasurfaces that shows strong intensity-dependent responses. The Kerr metasurface is composed of a top layer of gold antennas, a dielectric spacer, and a ground layer of metallic quantum wells (MQWs) made by TiN/Al_2O_3multilayer stack. Due to the large Kerr nonlinearity supported by the MQWs, the effective optical properties of the MQWs can change gradually from metallic to dielectric with increasing of the input intensity, leading to dramatic modifications of the metasurface responses. This opens up new routes for tunable metasurface applications in the fields of nonlinear optics and extremely fast meta-optics.

Wave-Matter Interaction in Spatiotemporal Metastructures Nader Engheta; University of Pennsylvania, United States

Manipulation of waves is mostly achieved by materials with spatial inhomogeneities. However, exploiting the dimension of time, in addition to the three dimensions of space, for variation of material parameters can bring additional functionalities in such tailoring and sculpting the wave. The spatiotemporal metastructures in which the material parameters are engineered with spatial and/or temporal inhomogeneities exhibit special features that enrich the functionality of light-matter interaction. In my group, we are investigating a variety of scenarios in which such four-dimensional (4D) spatiotemporal material platforms can be exploited. These scenarios include 4D materials that provide us with temporal aiming, temporal anisotropy, anti-reflection temporal coatings, frozen waves, phase conjugation, asymmetric diffusion, temporal effective medium methods, etc. In this talk, I will give an overview of our most recent results in this area

Soft Metamaterials—From Isotropicity to Quantum Interaction Sui Yang and Xiang Zhang; University of California, Berkeley, United States

Metamaterials are artificially engineered structures designed to shape electromagnetic responses not found in nature

including superlensing, cloaking and communications. They traditionally comprise an array of fabricated subwavelength anisotropic structures on a planar geometry, which inevitably limit their responses in certain directions. We explore a novel type of soft metamaterial to overcome such limitations, in which building blocks and overall configurations that can be freely tailored, even after formation. In particular, we explored the complex soft metamaterial nanoarchitectures with tailored symmetries that achieved isotropic negative index at the optical frequency. Moreover, we expand such soft metamaterial design that created the first Casimir quantum trap in solution by manipulating electromagnetic waves from quantum fluctuations. These results provide new insights that facilitate and expand novel metamaterial design and applications.

Artificial Chirality Evolution in Micro-/Nano-Scale 3D Plasmonic Metamaterials Junsuk Rho[1,2]; [1]Pohang University of Science and Technology (POSTECH), Korea (the Republic of); [2]Pohang University of Science and Technology, Korea (the Republic of)

Plasmonic chiral metamaterials has attracted significant attention at it provides a new route to intriguing optical properties such as negative refractive index, light polarization filters, and phase modulation. However, the fabrication regarding with limited resolution in conventional synthesis and complexity of asymmetric synthesis pose a major hindrance for further development. In this study, a new class of three dimensional chiral plasmonic nanostructures was successfully fabricated using molecular shape modifiers and crystallographic control of nanoparticle. Previously, we developed three-dimensional chiral metamaterials based on photolithography overlay and electron-beam lithography overlay for terahertz and near-infrared, respectively. We found scaling down them further to visible frequency is extremely difficult. As an alternative solution, we discovered a novel system that characteristic of molecule is transformed into distinctive gold nanoparticle shape. On the basis of this system, chirality transfer between molecular modifier and gold surface allow us to achieve numerous chiral morphologies of gold nanoparticle, named plasmonic helicoids. Particularly, enantiospecific interaction of molecule and high index plane plays pivotal role to provide asymmetric structuring process on the gold surface, forming distinct chiral morphology in single nanoparticle level. One of the representative shapes of helicoid structure showed gammadion-like structure, consisting of four highly curved arms of increasing width, in all six faces of cubic geometry. The unprecedented chiral morphology of plasmonic helicoid has remarkable optical activity (dissymmetry factor ~ 0.2 at 622 nm) even in a randomly dispersed solution, substantiated by direct visualization of macroscopic color transformation. Changes in molecular recognition and growth parameter led to different morphological evolution, and structural alterations provided a straightforward means of tailoring optical response, such as optical activity, handedness, and resonance wavelength. Also, our aqueous phase synthesis is readily scalable without losing exquisite chiral structure at nanoscale. In these aspects, our approach, chirality evolution in single nanoparticle, provides a truly new paradigm and valuable insight for chiral metamaterial fabrication. Such unique fabrication technique will provide the opportunity to achieve the significant step making metamaterials from science to technology. References 1. S. Zhang et al., Phys. Rev. 8:30 PM *F.NM02.04.09
Metamaterials Defined by Connectivity C.T. Chan; The Hong Kong University of Science and Technology, Hong Kong

We report on the study of some metamaterials whose properties, including dispersions and topological characteristics, are determined by the connectivity of a network rather than the resonance of individual resonators.

Metamaterials are described using effective medium theories in the long-wavelength limit in the sense that their optical properties can be described using local permittivity and permeability tensors. We will see that some metallic structures cannot be described using such a language. Their properties depends on the network connectivity, where braiding can create effective sythetic gauge fields that induce shift in momentum space. The consequence is that such materials can have their index ellipsoids centered not at k=0, and they can possess multiple index ellipsoids centered at arbitrary nonzero k-points. The number of modes that are allowed at zero frequency can be described by Betti numbers. Such systems differ from conventional metamaterials because the functionality does not come from the resonances of individual resonators and as such, their functionalities tend to be broadband.

We will also discuss network structures that have non-trivial topology in momentum space and these materials can couple orbital angular momenta with the wave vector. The topological character originates from the connectivity of the network and goes beyond typical space group descriptions. Such systems can exhibit angular momentum-dependent one-way edge states,

and their properties can be described using local Chern numbers. Such systems can also be used to realize other interesting topological systems such as high order topological insulators and topological Anderson insulators, and topological systems in which the topological order cannot be described by integers.

Electrically Reconfigurable Metasurface for Spatial Light Modulation Junghyun Park, Byung Gil Jeong, Sun Il Kim, Duhyun Lee, Kyoungho Ha and Hyuck Choo; Samsung Advanced Institute of Technology, Korea (the Republic of)

We have demonstrated an ultrafast, ultra-compact, and all-solid-state metaphotonic spatial light modulator (M-SLM) which can dynamically shape light in reflection. The M-SLM is an array of electrically controlled plasmonic nanostrip cavities, and it can continuously adjust the phase of reflected light from 0 to 360 degrees and, at the same time, independently modulate the amplitude over its full range. The fabricated M-SLM contains 50 active pixels and measures 250×250 ?m2 in dimensions. By tuning the voltages applied to the M-SLM, we have demonstrated beam steering and beam splitting with a steering angle up to 8°, the side mode suppression ratio of +2.7 dB (the highest value reported in the field), and the deflection efficiency up to 48%. The experimentally measured modulation speed marks 5.6 MHz while the energy consumption per pixel is calculated to be as low as 354 pJ per switching. Accomplishing arbitrary light manipulation using active metaphotonics has remained challenging, especially due to coupling between the phase and amplitude during modulation which resulted in unwanted background noises. To overcome this limitation, we have delved into the fundamental modeling of the light wave and observed that it would require minimum two variables, for example, the real and imaginary coefficients, to properly express the phase and amplitude of the light wave. Based on this observation, we developed the two-control-parameter algorithm and translated the concept into the hardware design. In the array of the designed M-SLM, each plasmonic nanostrip cavity is a stacked double-gated structure with an indium-tin-oxide layer as an active intermediate channel, which allows an application of two independent control voltages to the top and bottom gate metals. We have also performed extensive numerical investigation and confirmed that the highly versatile light-manipulating capability of the designed M-SLM, including arbitrary phase and amplitude modulation, originates from the superposition of the effects generated by the voltages applied independently to the top and bottom metals. To our knowledge, the M-SLM is the first all-solid-state, electrically controlled metasurface that accomplishes the 360-dgree full phase sweep and independent amplitude modulation. Unlike previously reported work, our M-SLM does not involve the use of slow, temperature-sensitive liquid crystals, stiction-and-vibration-prone micro-electromechanical systems (MEMS), or an array of pre-fabricated size-varying structures to achieve phase changes. The M-SLMs extremely low power consumption, ultrafast modulation speed, ultra-compact form factor, outstanding predicted reliability, and the use of standard IC-fabrication processes promises wide adaptation and proliferation of the ultrafast and extremely power-efficient SLMs for 3-dimensional real-time holographic display, light detection and ranging (LiDAR), and wearable display for virtual reality. We look forward to sharing and discussing the details of our M-SLM design philosophy, hardware design & fabrication, and testing results with the audience at the MRS 2020 Spring.

Metasurfaces for Holography and Light Harvesting—New Approaches with Orbital Angular Moment Modes and Tailored Disorder Stefan A. Maier[1,2], Haoran Ren[1] and Changxu Liu[1]; [1]LMU Munich, Germany; [2]Imperial College London, United Kingdom

Metasurfaces significantly widen the parameter space for control over light, mainly via the many ways phase control can be achieved and varied within the plane of the surface. Here, we take a closer look on how to further widen these possibilities via introducing elements such as control over amplitude and phase simultaneously, i.e. the complex amplitude of the impinging light field, and secondly via disorder.
As a first application, we examine the use of beams of higher orbital angular momentum coupled to metasurfaces in a context of holography. We demonstrate the design and implementation of metasurface phase holograms with strong orbital angular momentum selectivity, based on nanostructured gallium nitride. This opens up a new degree of multiplexing, allowing

lensless reconstruction of distinct holographic images in each orbital angular momentum channel. We further show how metasurfaces with additional variation in the height of the underpinning nanostructures allow for complete control over the complex amplitude of the impinging wave. We demonstrate that this significantly reduces cross talk between different orbital angular momentum coding channels, enabling up to 200 independent orthogonal image frames for realistic parameters.
The second application is in a context of energy harvesting. Based on a disordered array of plasmonic nanoresonators, we show how deterministic coupling of this effective photonic layer to an external cavity can lead to two different regimes of operation — broadband absorption and narrow-band reflection. As an example, we demonstrate the use of such coupled disordered-layer / cavity systems for colour generation.

Coherent Coupling of a Quantum Emitter and a Plasmonic Nanoantenna Vahid Sandoghdar; Max Planck Institute for the Science of Light, Germany

Plasmonic antennas are capable of enhancing the coupling of light and matter due to their strong electric field confinement. At room temperature, where dephasing is the dominant contribution to the linewidth of a solid-state emitter, studies of plasmonic coupling have usually concerned incoherent interactions, e.g. a Purcell enhancement [1]. At low temperatures, however, the resonant coherent scattering from the emitter becomes significant and another regime of plasmonic interactions can be observed: here, not only the plasmonic particle changes the interaction of the emitter with light, but the emitter can influence the scattering properties of the plasmonic particle. In an extreme case, a single molecule can fully suppress scattering from a (much larger) plasmonic particle, rendering it effectively transparent [2]. In this presentation, I discuss an experiment, where a single organic molecule partially cloaks a large gold nanoparticle [3].

It has recently been reported that a nanogap antenna formed by a gold nanoparticle separated from a metallic substrate by a thin dielectric gap can achieve ultra-strong enhancement, even at room temperature [4]. When the enhanced emission rate is fast enough to compete with the room temperature dephasing and the plasmon losses rates, the emitter starts to interact coherently with the plasmon mode, bringing the system into the strong coupling regime. In this presentation, we also demonstrate a significant enhancement of a single quantum dot coupled to a plasmonic nanogap antenna. We observe an ultrashort fluorescence lifetime less than 38 ps limited by the instrumental response function. Moreover, by controlling the position of the quantum dot with respect to the nanogap antenna, we can tune the system from the weak coupling to the strong coupling regime leading to spectral splitting in the fluorescence spectra [5].

Vortical Reflection and Spiraling Fermi Arcs with Weyl Metamaterials Shuang Zhang; Univ of Birmingham, United Kingdom

Weyl points are linear band crossings at discrete points in the momentum space, corresponding to three-dimensional (3D) extensions of the two-dimensional (2D) Dirac nodes, and functioning as monopoles of Berry flux with topological charges defined by the Chern numbers. In photonics, Weyl points have been realized in systems with broken inversion symmetry such as photonic crystals and metamaterials, with broken time reversal symmetry such as magnetized plasma and in synthetic dimensions. As a key signature of Weyl systems, Fermi arcs that connect between the projections of Weyl points of opposite topological charges have been observed. However, the manifestation of the topological nature of Weyl points in their interaction with free space radiations remain obscure in both quantum and classical systems.
Scatterings and transport in Weyl semimetals have caught growing attention in both condensed matter and classical physics. In condensed matter systems, the chiral zero modes and the associated magnetoresistance and chiral magnetic effects underlie some highly unusual scattering and transport properties of Weyl semimetals. It has also been proposed that Weyl semimetals may have handedness dependent Imbert–Fedorov shift within the bulk Weyl material. Electrical conductance is usually measured in the experiments, which has contribution from both the bulk Weyl nodes and the fermi arcs. However, it is generally difficult to perform momentum resolved scattering and transport studies, since the leads that transport the electrons to the Weyl semimetals, by their nature, cannot control the momentum of the input electrons. Therefore, previous attempts to associate the topology to scattering matrix mostly remain theoretical.

In this work, vortical phase profile in the momentum space is demonstrated for elliptically polarized electromagnetic waves reflected by a photonic Weyl system, which represents a key signature of the topological nature of the Weyl points and could lead to alignment-free phase plates for vortex beams generation. The nontrivial topology of Chern insulator can not only be revealed by the number of surface states, but also by the scattering matrix S, i.e. the total winding number in 2π of the phase of the eigenvalues of the scattering matrix. It has been rigorously proven that the topological classification of the Hamiltonian and the scattering matrix are equivalent. The scattering matrix method however, are more accessible for investigation in photonics with the readily available optical components from visible to microwave wavelengths to perform the angle resolved measurements.
We further discover a novel type of spiraling guided mode in a hybrid waveguide system formed by the Weyl metamaterial and a metal plate, enabled by the vortical phase profile in the momentum space. we demonstrate that the fermi arcs possessing arbitrary number of windings around the projected Weyl points can be realized in a photonic Weyl semimetal-waveguide hybrid system, revealing a new intriguing physical properties of photonic Weyl systems. The metamaterial-waveguide hybrid system is formed by an air layer sandwiched between a metallic ground plane and an ideal Weyl metamaterial. In such a system, the surface arc states exponentially decay into the Weyl metamaterial, while forming waveguide modes in the thin air layer between the Weyl metamaterial and the confining metallic plate. By measuring the electromagnetic field distribution inside the waveguide, we are able to visualize the Fermi arc's iso-frequency contour in the momentum space through Fourier transformation, and demonstrate the windings of the Fermi arcs in the vicinity of the Weyl frequency.

Dielectric Nano-Structures Functionalized Optical Fibers—A Novel Pathway Towards Single-Fiber Optical Trapping and Boosting In-Coupling Efficiencies Markus Schmidt[1,2,3], Malte Plidschun[1,3], Henrik Schneidewind[1], Uwe Huebner[1], Matthias Zeisberger[1], Torsten Wieduwilt[1], Jisoo Kim[1,3], Ronny Foerster[1], Oleh Yermakov[4], Yuri Kivshar[4,5], Andrey Bogdanov[4], Haoran Ren[6] and Stefan A. Maier[6]; [1]Leibniz Institute of Photonic Technology, Germany; [2]Otto Schott Institute of Materials Research, Germany; [3]Abbe Center of Photonics and Faculty of Physics, Germany; [4]ITMO University, Russian Federation; [5]The Australian National University, Australia; [6]Ludwig Maximilian University of Munich, Germany

The interfacing of nano-structures or meta-surfaces with optical fibers represents a promising approach to unlock novel types of functionalities within a multitude of fields including biophotonics, quantum technologies or optical sensing. Here commonly used top-down implementation strategies are hard to employ in case fiber end-faces are considered due to the intrinsic mismatch of the fiber geometry with wafer-based fabrication technology.
Within this presentation, we would like to report on two implementation pathways to circumvent the mentioned bottleneck, namely (i) 3D nano-printing and (ii) modified electron-beam lithography. Both approaches allow for the implementation of sophisticated nano-structures on the end-face of optical fibers leading to significant performance improvements compared to fibers with unstructured end faces. These improvements are shown here on the examples of (i) optical trapping using only one single-mode fiber via the integration of dielectric meta-surfaces and (ii) boosting in-coupling efficiencies into fibers at almost grazing incidence via dielectric ring-type nano-structures .

(i) A tight focus of light plays an essential role in a vast number of applications including optical imaging, optical manipulation, material processing, biophotonics, microscopy and quantum technology. Here optical fibers show fundamental limitations due to the divergence of light emerging from the fiber facet which for instance has limited the use of single fibers within optical trapping, demanding numerical apertures >0.8. In this presentation we show that 3D nano-printing via direct laser writing allows for the integration of ultra-high numerical aperture meta-lenses on the facet of single-mode fibers that include beam expansion sections. Record-high numerical apertures of up to 0.9 and diffraction-limited spots have been reached. The capabilities of this device have been demonstrated by optically trapping microbeads and biologically relevant bacteria (E. coli) for the first time with one single-mode fiber, solving a serious limiting factor within fiber optics research.

(ii) Optical fibers are particularly difficult to use within the context of wafer-based implementation technologies due to the large aspect ratios of fibers, being complementary to wafers. Using an additional planarization step prior to nano-fabrication we open up a novel pathway to implement dielectric nano-structures onto the end-face of optical fibers via electron-beam based technology. Here, we show that by integrating dielectric gratings consisting of concentric rings located on the core of single-mode fibers, in-coupling efficiencies can be increased by more than four orders of magnitude at almost grazing incidence compared to fibers with unstructured end faces. Specifically, application relevant in-coupling efficiencies of several percent at angles of more than 75° have been reached, suggesting a clear pathway to solve one serious bottleneck of optical fibers which has imposed limitations on applications of optical fibers.

Remote Structuring of Near-Field Landscapes Federico Capasso[1], Vincent Ginis[1,2], Marco Piccardo[1,3] and Michele Tamagnone[1]; [1]Harvard University, United States; [2]Vrije Universiteit Brussel, Belgium; [3]Istituto Italiano di Tecnologia, Italy

The electromagnetic near-field enables subwavelength applications such as near-field microscopy and nanoparticle manipulation. Present methods to structure the near-field rely on optical antenna theory, involving nanostructures that locally convert propagating waves into confined near-field patterns. We develop a theory of remote rather than local near-field shaping, based on cascaded mode conversion and interference of counterpropagating guided waves with different propagation constants. We demonstrate how to structure at will the longitudinal and transverse variation of the near-field, allowing for distributions beyond the conventional monotonic decay of the evanescent field. We provide an experimental realization that confirms our theory. Our method applies to fields with arbitrary polarization states and mode profiles, providing a new path towards unprecedented three-dimensional control of the near-field.

4:30 PM *F.NM02.04.21
High Quality Factor Phase-Gradient Metasurfaces Jennifer A. Dionne, Mark Lawrence, David R. Barton, Dixon Jefferson, Elissa Klopfer and Sahil Dagli; Stanford University, United States

High quality factor ("High Q") cavities have revolutionized information processing, communications, sensing, and nonlinear optics by increasing photon storage times and significantly enhancing light-matter interactions. However, when the size of dielectric cavities is reduced to the nanoscale, resonant modes start to resemble point sources, scattering an incident wave in many different directions. While this scattering has been leveraged to create remarkable metasurfaces that precisely control the phase, amplitude, and polarization of light in an ultrathin footprint, metasurfaces generally exhibit high radiative loss rates and thus low Q-factors. Indeed, to date, resonant features in the far-field transmission of metasurfaces have Q-factors on the order of ten.

Here, we describe a general strategy for generating high quality factor resonances in a phase gradient metasurface. Resonances are created by including subtle structural changes in individual resonators to weakly couple free-space light into otherwise bound modes. We experimentally demonstrate control over the quality factor and resonant wavelengths in this scheme, achieving record metasurface Q's greater than 2500. We also show via simulations that Q-factors can exceed millions. We highlight this scheme's general applicability by designing and fabricating metasurfaces that act as beamsteerers to different angles, beam splitters, and lenses. We also show how this platform can be integrated with electro-optic materials for low-power metasurface modulation. Finally, we describe applications of high-Q metasurfaces spanning i) free-space optical sensors of COVID-19 antigens and antibodies; ii) all-optical magnetic switching; and iii) an all-optical self-isolating laser.

5:00 PM *F.NM02.01.10
Plasmonic Nanoantennas and Their Applications Pierre Berini; University of Ottawa, Canada

Nanometallic structures, such as resonant plasmonic nanoantennas, are useful for the conversion of light to surface plasmon-polaritons (SPPs) localized to ultra-small volumes [1]. Such structures can provide highly enhanced fields, strong confinement, high surface sensitivity, and can double as a device electrode for applying voltages or passing currents to active regions in optoelectronic devices. Here we review some of their many applications, in the areas of plasmon-enhanced nonlinear optics [2-5] and optoelectronics [6-9].
In nonlinear optics, plasmon enhancement can be applied to the pump [2], or to the nonlinear emission [3-5], through spectral alignment. An advantage of the former is that all nonlinear processes involving the pump are enhanced, but a disadvantage is that the pump, typically of high intensity, can damage the nanostructures. Nonetheless, such enhancement was exploited in high-harmonic generation via re-collision radiation in Si [2], where a 10x enhancement was observed for all harmonics emitted up to the 9th. Alternatively, exploiting the latter is advantageous because the structures are resonant with the nonlinear emission which is typically weak, and non-resonant with the pump so are less susceptible to damage. Such enhancement was

exploited in Raman scattering experiments [3-5], where the nanoantennas were spectrally-aligned with the Stokes wavelengths of graphene. Under this scenario, single-antenna scattering cross-section enhancements of over 500× were observed [5].
In optoelectronics, plasmon enhancement can be exploited to improve the performance of, *e.g.*, electro-optic modulators [6], photodetectors [7,8], and beam-steering devices [9]. A key requirement is for the plasmonic enhancement to overlap strongly with the active region of the device, which requires that the nanostructure also operate as a device electrode. Such a structure consists of an array of Au nanoantennas contacted perpendicularly by electrical contact lines. The contact lines may be aligned on the nanoantennas such that they are minimally invasive optically. Structures such as these are very promising for beam steering, as each row can be routed to an individual contact such that a 1D phase gradient is applied over the array [9]. Nanostructures that consist of holes in a metal film are also of significant interest [10], especially arrangements of nanoholes (*e.g.*, heptamers), which can be fabricated via focussed ion beam milling because they exhibit interesting and useful Fano resonances [11].

Scalable Light-Matter Interactions in Nanoparticle Lattices Teri W. Odom; Northwestern University, United States

Rationally assembled nanostructures exhibit distinct physical and chemical properties beyond their individual units. This talk will describe fundamentals and applications of metal nanoparticle lattices that show long-range diffractive interactions when the lattice spacing is close to the wavelength of incident light. These collective excitations are known as surface lattice resonances (SLRs) or lattice plasmons. We will discuss advances in nanofabrication techniques that have enabled the patterning of a wide range nanoparticle materials over macroscale (> in^2) areas and with units that are highly uniform in size, shape, and crystallinity. Such patterned substrates support SLRs with wavelengths that approach the theoretical limit. We will also describe how different lattice symmetries can result in band-edge modes at high symmetry points in reciprocal space. The confined electromagnetic fields of SLRs can manipulate processes such as exciton-plasmon coupling, nanolasing, and imaging via tunable, flat optics.

Perovskite-Based Plasmonic Nanolasers Yu-Jung Lu[1,2,3]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan; [3]California Institute of Technology, United States

Nanolasers with plasmonic mode confinement represent a critical area of photonics, as new scientific phenomena such as low power consumption and fast switching are accessible because of the accompanying very small mode volumes and laser thresholds. That will be beneficial for its application in future on-chip ultracompact integrated circuits for imaging, data storage, quantum information technology, and optical communication. While plasmonic nanolasers are well established, with demonstrations in several gain materials and cavity geometries, notably missing among this important family of photonic

devices is an upconverting nanolaser.
In this study, we demonstrate the first known example of a subwavelength plasmonic upconverting nanolaser. This organo-lead trihalide perovskite based plasmonic upconverting nanolaser, realized via a two-photon nonlinear optical pumping process, features a record-small mode volume (~0.06 λ^3) and an ultralow lasing threshold (10 μJcm^{-2}). In addition, we observed temporal coherence of the emission, which is an important feature of lasing. This result was made possible by replacing the conventional noble metal plasmonic cavity structure with one composed of titanium nitride, whose material properties can be tailored during the fabrication processes to co-optimize the pump photon absorption and the upconverted photon emission rate. Moreover, the results show a very close agreement between the experiment and modeling, which provides detailed insight into the novel working mechanism of a plasmonic upconverting nanolaser. In addition, we demonstrate a continuous wave lasing from single lead halide perovskite ($CsPbBr_3$) quantum dot integrated with plasmonic nanocaviy with undetectable threshold (power density lower than 90 $mWcm^{-2}$) and ultra-sharp single mode lasing (linewidth of 1.4 nm) under a cryogenic temperature at 4 K. We will discuss the outlook for perovskite-based plasmonic nanolasers as well as quantum-dot based plasmonic nanolasers as robust on-chip light sources for bio-imaging, optical communication applications.

5:15 AM *F.NM02.01.02
Ultralow-Threshold Lasing from Single Quantum Dot in a Gap Plasmon Nanocavity Yu-Jung Lu; Academia Sinica, Taiwan

One of the main obstacles limiting potential applications of semiconductor nanolasers is the high threshold carrier density required for lasing, which makes them difficult to realize electrically driven lasing and integrate into optoelectronic devices. Organo-lead halide perovskite materials have recently received considerable attention for achieving an economic and tunable diode laser, owing to the use of solution-processable materials and the exceptional optical attributes of long carrier lifetimes and diffusion lengths, high fluorescence quantum yields, wavelength tunability and high optical gain coefficients1 (>104 cm?1). However, reducing the volume of such lasers to the nanoscale is the challenge nanophotonics, with potential applications in arrays of ultra-compact lasers on a chip. In this work, we demonstrate a continuous wave lasing from single lead halide perovskite (CsPbBr3) quantum dot integrated with plasmonic nanocaviy with undetectable threshold (power density lower than 90 mWcm-2) and ultra-sharp single mode lasing (linewidth of 1.4 nm) under a cryogenic temperature at 4 K. In our design, a silver nano-cube was placed on a gold substrate, with a single CsPbBr3 quantum dot placed in between. By finite-difference time-domain simulation method to calculate the electric field distribution of the designed structure, we theoretically observed a strong localized optical confinement, plasmonic gap mode, formed between the silver nanocube and the gold substrate acts as plasmonic nanocavity and contributes a large Purcell enhancement (Purcell factor ~200) which can be determined via time-resolved photoluminescence measurement. In order to avoid quenching effect, a 6 nm Al2O3 spacer was used to separate the quantum dot and the gold substrate, and the silver nano-cube was covered by 1 nm Polyvinylpyrrolidone to isolate the emitter. In order to measure the lasing threshold, the temperature dependent light-in-light-out curve was performed and we observed a very small lasing threshold (power density lower than 188 mWcm-2) at 80 K. We will also discuss the outlook for lead halide perovskite plasmonic nanolasers in applications including, on-chip coherent light sources for of bio-imaging, optical communication applications.

Excited States at Metal-Semiconductor Interfaces—Carrier Transport and Selective Photoelectrocatalysis Harry Atwater; California Institute of Technology, United States

Harvesting non-equilibrium carriers at semiconductor-metal interfaces offers an opportunity to modify the rates and pathways for photochemical reactions at the nanoscale. The carrier generation, transport and interface dynamics can be addressed with a combination of first-principles theory for carrier excitation and relaxation, observation of carrier dynamics via hot-carrier photocurrent spectroscopy, ultrafast transient absorption spectroscopy, and photoelectrochemical measurements that assess current transport, product yield and selectivity. We use as an example the gold/gallium nitride interface and compare results of theory to excited carrier transport, transient absorption and photocatalysis measurements. We also report the first known example of photoexcited hot hole injection at a metal-p-type wide bandgap semiconductor interface. Despite the presence of an interfacial Schottky barrier to hot-hole injection of more than 1 eV across the Au/p-GaN heterojunction, plasmonic Au/p-GaN photocathodes exhibit photoelectrochemical properties consistent with the injection of hot holes from Au nanoparticles into p-GaN upon plasmon excitation. The incident photon-electron conversion efficiency spectrum for the plasmonic photocathodes faithfully follows the surface plasmon resonance absorption spectrum of the Au nanoparticles, and a sustained photovoltage during plasmon excitation of plasmon-induced hot-hole capture and conversion, using a gold/p-type gallium nitride (Au/p-GaN) interface conditions tailored for studying photoelectrochemical CO2 reduction. Whereas the Au/p-GaN structure has an interfacial Schottky barrier to hot-hole injection of more than 1 eV, the Au/p-NiO has an approximately zero

Schottky barrier height. Taken together, our results offer experimental validation of photoexcited hot holes in high-barrier Au/p-GaN structures and also in low-barrier structures, such as Au/NiO. These results, together with other recent advances, form an outlook for the use of photoexcited carriers as a tool for enhancing chemical product selectivity in photon-driven catalytic processes.

Coherent Coupling of a Quantum Emitter and a Plasmonic Nanoantenna Vahid Sandoghdar; Max Planck Institute for the Science of Light, Germany

Plasmonic antennas are capable of enhancing the coupling of light and matter due to their strong electric field confinement. At room temperature, where dephasing is the dominant contribution to the linewidth of a solid-state emitter, studies of plasmonic coupling have usually concerned incoherent interactions, e.g. a Purcell enhancement [1]. At low temperatures, however, the resonant coherent scattering from the emitter becomes significant and another regime of plasmonic interactions can be observed: here, not only the plasmonic particle changes the interaction of the emitter with light, but the emitter can influence the scattering properties of the plasmonic particle. In an extreme case, a single molecule can fully suppress scattering from a (much larger) plasmonic particle, rendering it effectively transparent [2]. In this presentation, I discuss an experiment, where a single organic molecule partially cloaks a large gold nanoparticle [3].

It has recently been reported that a nanogap antenna formed by a gold nanoparticle separated from a metallic substrate by a thin dielectric gap can achieve ultra-strong enhancement, even at room temperature [4]. When the enhanced emission rate is fast enough to compete with the room temperature dephasing and the plasmon losses rates, the emitter starts to interact coherently with the plasmon mode, bringing the system into the strong coupling regime. In this presentation, we also demonstrate a significant enhancement of a single quantum dot coupled to a plasmonic nanogap antenna. We observe an ultrashort fluorescence lifetime less than 38 ps limited by the instrumental response function. Moreover, by controlling the position of the quantum dot with respect to the nanogap antenna, we can tune the system from the weak coupling to the strong coupling regime leading to spectral splitting in the fluorescence spectra [5].

Nonlinear Optics with Hot Carriers Wenshan Cai; Georgia Institute of Technology, United States

In nanostructured metals, the coherent coupling of electromagnetic radiations to plasmons creates a nonequilibrium distribution of electrons at an elevated temperature, which is termed hot electrons. The dynamics of such hot carriers has been wide employed for various applications, ranging from the detection of sub-bandgap photons in semiconductors to the production of hydrogen gas via photocatalytic processes.

The generation, transfer, and relaxation of hot carriers also provide a novel route to nonlinear optical effects. For example, the optical Kerr nonlinearity of plasmonic metals provides enticing prospects for developing reconfigurable and ultracompact all-optical modulators. Although enhanced nonlinear responses of metals are known to enable the optical control of light, the intrinsically slow relaxation dynamics of photoexcited carriers, primarily governed by electron-phonon interactions, impedes sub-picosecond modulation speeds. In this talk, we present femtosecond all-optical modulation in plasmonic systems via the activation of relaxation pathways for hot-electrons at the interface of metals and electron acceptor materials. We show that the relaxation kinetics and the optical nonlinearity can be tuned by leveraging the spectral response of the plasmonic system in the linear regime. Our findings introduce a generic scheme for achieving sub-picosecond modulation speeds in plasmonic

systems, suitable for the ultrafast control of the intensity, polarization, and phase of light upon exchange of energetic hot carriers.

The dynamics of hot carriers in hybrid plasmonic system is further exploited for the creation of optically induced second-order nonlinear materials. Second-order optical processes are pivotal to the active modulation and wave mixing of light waves. The inversion symmetry in most materials, however, prevents achieving a bulk chi-2 effect, thereby limiting the portfolio of second-order nonlinear materials. We propose and demonstrate ultrafast conversion of a statically-passive dielectric to a transient second-order nonlinear medium upon the generation and transfer of plasmonically induced hot electrons. Triggered by an optical switching signal, the amorphous dielectric with vanishing intrinsic chi-2 develops dynamically tunable second-order nonlinear responses, which can be leveraged to address the critical need for all-optical control of second-order nonlinearities in nanophotonic systems. The methodology developed here can be readily extended to any electron reservoir/acceptor pairs, enabling a new class of "material-by-design" for second-order nonlinear optical effects.

Plasmonic Nanoantennas and Their Applications Pierre Berini; University of Ottawa, Canada

Nanometallic structures, such as resonant plasmonic nanoantennas, are useful for the conversion of light to surface plasmon-polaritons (SPPs) localized to ultra-small volumes [1]. Such structures can provide highly enhanced fields, strong confinement, high surface sensitivity, and can double as a device electrode for applying voltages or passing currents to active regions in optoelectronic devices. Here we review some of their many applications, in the areas of plasmon-enhanced nonlinear optics [2-5] and optoelectronics [6-9].
In nonlinear optics, plasmon enhancement can be applied to the pump [2], or to the nonlinear emission [3-5], through spectral alignment. An advantage of the former is that all nonlinear processes involving the pump are enhanced, but a disadvantage is that the pump, typically of high intensity, can damage the nanostructures. Nonetheless, such enhancement was exploited in high-harmonic generation via re-collision radiation in Si [2], where a 10x enhancement was observed for all harmonics emitted up to the 9^{th}. Alternatively, exploiting the latter is advantageous because the structures are resonant with the nonlinear emission which is typically weak, and non-resonant with the pump so are less susceptible to damage. Such enhancement was exploited in Raman scattering experiments [3-5], where the nanoantennas were spectrally-aligned with the Stokes wavelengths of graphene. Under this scenario, single-antenna scattering cross-section enhancements of over 500× were observed [5].
In optoelectronics, plasmon enhancement can be exploited to improve the performance of, *e.g.*, electro-optic modulators [6], photodetectors [7,8], and beam-steering devices [9]. A key requirement is for the plasmonic enhancement to overlap strongly with the active region of the device, which requires that the nanostructure also operate as a device electrode. Such a structure consists of an array of Au nanoantennas contacted perpendicularly by electrical contact lines. The contact lines may be aligned on the nanoantennas such that they are minimally invasive optically. Structures such as these are very promising for beam steering, as each row can be routed to an individual contact such that a 1D phase gradient is applied over the array [9]. Nanostructures that consist of holes in a metal film are also of significant interest [10], especially arrangements of nanoholes (*e.g.*, heptamers), which can be fabricated via focussed ion beam milling because they exhibit interesting and useful Fano resonances [11].

Plasmonics in Coupled Topological Insulator Heterostructures Zhengtianye Wang, Vishnuvardhan Mambakkam, Theresa

Ginley, Yuying Zhang, Greeshma Chandan, Chaoying Ni and Stephanie Law; University of Delaware, United States

Topological insulators (TI) are a class of quantum materials that exhibit metallic surface states and bulk insulating states. Electrons occupying these surface states are 2D massless, linear dispersed, and spin-momentum locked Dirac Fermions. The optical transitions among these surface states, for example Dirac plasmon polariton, are in the hardly accessed far-IR and THz spectral ranges by tradtional semiconductors. In TI thin film, Dirac plasmons are excited simultaneously on the top and bottom surfaces. They are electrostatically coupled and generate an optical mode and an acoustic mode. Only the former can be observed in optical measurements because of a non-zero dipole. In addition, for the 3D TI Bi_2Se_3, the continuum plasmon state interacts with discrete bulk phonon states, namely the α phonon at 2THz and the β phonon at 4THz, giving rise to plasmon-phonon polariton modes. These unique properties enable TI a promising platform for far-IR sensing, security screening, and other optoelectronic devices that function in the THz.
Similar to the two surfaces coupling in a single layer TI film, the multiple surfaces introduced by stacking alternating TI and band insulator (BI) layers will also couple and produce additional plasmon modes. The optical responses are expected to be dependent on the structural parameters and bulk properties of both the TI and BI material. To create multiple topological edge states, we stack Bi_2Se_3 with $(Bi_{0.5}In_{0.5})_2Se_3$ (BIS), which is topologically trivial band insulator. It has the same van der Waals strucutre and close lattice constant to Bi_2Se_3. We build a five layer structure comprising BIS /Bi_2Se_3/BIS/Bi_2Se_3/BIS on a c-plane sapphire substrate via molecular beam epitaxy (MBE) and explored the plasmonic polariton coupling of such layered TI heterostructures by varying the structural parameters: spacer BIS thickness and Bi_2Se_3 thickness. To excite localized surface plasmons polariton, the films were patterned into periodic microribbon arrays. The wavevector of the polariton is defined by $q=\pi/a$, a is the width of a microribbon, so we can map out the dispersion by measuring polariton frequencies in films with different microribbon widths.
An asymmetric Fano lineshape extinction curve is observed in the FTIR measurement due to the plasmon hybridization with both α phonon and β phonon. Three plasmon-phonon polariton modes are generated: two of them (ω_l for lower frequency, ω_h for higher frequency) show visible peaks in the range of 2-8THz where detector is sensitive and the sapphire substrate is transparent; the other one is pushed below 2THz due to the Fano-resonance. With increasing wavevector, ω_l and ω_h both blue shift, in accordance with the dispersion predicted by transfer matrix (T-matrix) modelling. Fixing the wavevector, when the BIS spacer thickness d_s<50nm, ω_l blueshifts and ω_h redshifts, which is not captured by T-matrix modelling; when d_s>50nm, they both stay nearly constant, agree well with modelling. With increasing Bi_2Se_3 thickness d_{TI}, ω_l always blueshifts while ω_h shows a redshift. All the modes shifts can be explained within the frame of plasmon-phonon hybridization except the behavior for thin d_s. These changes can only be explained by the quantum correlation of the surface states across the band insulator layer, or in other words, coupling of two Bi_2Se_3 layer. This has revealed that the Dirac surface states can also couple across a topologically trivial band insulator even though the spin-orbit coupling strength is weak inside the bulk. A thorough understanding of how these surface states in multilayer TIs are coupled will provide a deep insight to the many-body interaction in low-dimensional strong spin-orbit coupling systems.

All-Optical Manipulation of Magnetization Enhanced by Surface Plasmons Feng Cheng, Chuangtang Wang, Zhaoxian Su, Xinjun Wang, Ziqiang Cai, Nian Sun and Yongmin Liu; Northeastern University, United States

Plasmonic nanostructures enable to confine light into deep subwavelength scales and at the same time significantly increase the local field intensity. They have been utilized to increase the device performances in a variety of applications, such as plasmon-enhanced energy harvesting, magneto-plasmonics and heat-assisted magnetic recording (HAMR). In the HAMR technique, the plasmonic nanoantenna first locally heat up the recording media within a data bit. Then an external magnetic field (generated by electric currents) is applied to write data within that heated area. This technique can boost the recording areal density to the petabyte per meter square level[1,2]. On the other hand, recent research work has demonstrated the control of magnetization by femtosecond (10^{-15} s) lasers, paving the way towards all-optical recording with the writing speed three orders of magnitude higher than that of the current magnetic data storage technologies. In all-optical recording, laser is utilized to directly record data on the magnetic media, and the external magnetic field is no longer needed. The phenomenon was firstly found in rare-earth transition-metal (RE-TM) ferrimagnetic alloys, and later demonstrated in frromagnetic thin films[3-5].

Combining plasmonics with all-optical recording is of great research interest, which can potentially be developed into a magnetic recording technique with low power, high intensity and ultrafast speed. Such plasmonic-enhancement effect in all-optical recording has been demonstrated in the RE-TM materials[6]. People have been pursuing similar enhancement effects in ferromagnet thin films, but no experimental demonstrations were reported so far. In this talk, we will present the experimental observation of the plasmon-enhanced all-optical magnetic manipulation in ferromagnet thin films[7]. We have integrated the gold nanoislands on top of the Co/Pt thin films (with a SiO_2 separation layer). The gold nanoislands were

fabricated by annealing a thin film of gold layer under appropriate temperature and time. We have measured the minimum laser power required for magnetic manipulation under the on- and off-resonance conditions, and have observed an 18.5% decrease in the threshold power. The full-wave simulations indicated an averaged 14.6% field enhancement of the electric field intensity in the Co/Pt thin films, which quantitatively explains the observed reduction in the threshold. Our research findings demonstrate the possibility to achieve all-optical magnetic recording with low energy consumption, low cost, and high areal density by integrating plasmonic nanostructures with magnetic media.

Dynamics of Strongly Coupled Singlet Fission Molecules in Optical Microcavity Bin Liu[1], Vinod Menon[1,2] and Matthew Sfeir[2,2]; [1]The City College of New York, United States; [2]The City University of New York, United States

We use transient optical spectroscopy to study a molecular singlet fission system that is strongly coupled to an optical microcavity to probe the interconversion of exciton-polaritons, singlet excitons, and triplet excitons. We find that transient spectra in the optical microcavity are influenced by modifications of the exciton-photon coupling conditions in addition to the population dynamics of “reservoir” or uncoupled molecular excited states. For example, though our exciton-polaritons themselves are short-lived (< 1ps), weak interactions with long-lived molecular excited states give rise to exciton-polariton emission signatures that persist for the lifetime of the singlet exciton (~ 50 ps). Similarly, we observe long-lived transient signals corresponding to optical transitions of the exciton-polariton, even in the absence of a real polariton population. Following singlet fission, polariton transient features persist for > 10us, consistent with the excited state lifetimes of dark triplet excitons. We conclude that in addition to the usual singlet fission population dynamics, microcavity transient spectra reveal information pertaining to the dynamics of (1) exciton-polaritons populated via direct excitation, (2) exciton-polaritons populated via scattering from “reservoir” states, and (3) transient modification of the exciton-polariton transition energies due to changes in the population of molecular excited states.

Evanescent Field Polarization for Giant Chiroptical Modulation from Achiral Gold Half-Rings—Theoretical Insight from Simulations Luca Bursi; Department of Physics, University of North Texas, United States

Metal nanoantennas have been under intense investigation due to their strong light-matter interactions and significant polarization sensitivities determined by their nano-structure. For applications seeking to realize on-chip polarization-discriminating nanoantennas, efficient energy conversion from surface waves to far-field radiation is desirable. However, the response of individual nanoantennas to the particular polarization states achievable in surface waves, such as evanescent fields, has not yet been thoroughly studied. Here, we report the giant modulation of the visible light scattering predicted from gold half-ring, pinwheel, and other nanoantennas excited through total internal reflection of left- and right-handed circularly polarized light, by exploiting the distinct polarization properties of surface evanescent waves1. This result provides a fundamentally different mechanism for chiroptical responses requiring a phase delay between transverse and longitudinal electric field oscillations, not found in free-space light2. Specifically, we focus on the insight provided by theory, and in particular by the electromagnetic simulations, performed with COMSOL Multiphysics software, of the systems of interest and aspects of their chiroptical response. Dynamic Organic Plasmonics from Conductive Polymer Nanoantennas Shangzhi Chen and Magnus Jonsson; Linkoping University, Sweden

Metal nanostructures are key elements in nanooptics due to their strong resonant interaction with light through plasmonic charge oscillations1. Their ability to shape light at the nanoscale have made them critical in a multitude of areas, including biosensing, energy conversion and ultrathin flat metaoptics. Yet another dimension of avenues is foreseen for dynamic nanoantennas2, ranging from tuneable metalenses for miniaturized medical devices to adaptable windows that control radiation flows in and out of buildings. However, enabling nano-optical antennas to be dynamically controllable remains highly challenging and particularly so for traditional metals with fixed permittivity1. Here, I will present our recent work that introduces conductive polymers as a new class of redox-tuneable plasmonic materials3. We show that nanodisks of highly conductive polymers can provide clear optical extinction peaks via excitation of dipolar localised surface plasmon resonances. The resonances redshift with increasing nanodisk aspect ratio, in agreement with simulations and calculations based on dipolar polarizability theory. We furthermore demonstrate complete and reversible switching of the optical response of the organic nanoantennas by chemical tuning of their redox state, which modulates the permittivity between plasmonic and dielectric regimes. Our results show that conductive polymer nanostructures can act as redox-tuneable plasmonic nanoantennas, based on polaronic charge carriers rather than electrons or holes as in conventional metals. Future research may investigate different polymers and geometries and explore their use in various applications. References 1 Maier, S. A. Plasmonics: Fundamentals and Applications. Understanding the Physics of Interaction Between Surface Plasmons and Dielectric Matters in Ag/ZnO Nanorod System Using STEM-EELS Jaeyeon Jo and Miyoung Kim; Seoul National University, Korea (the Republic of)

Localized Surface Plasmons (LSPs) of metal nanoparticles have a distinguished characteristic, confining the electromagnetic fields on the nanometer length scale. This feature fascinates many researchers who are interested in surface-enhance Raman spectroscopy, biosensing, and nano- optics. Recently, the interaction between LSPs and dielectric matter as well as the LSPs themselves have drawn attentions from many people due to its unique energy dispersion and potential applications. However, the fundamental process in plasmon-matter interaction is not well understood. The clear understanding the physics of the phenomena is essential for tailoring them to specific applications, which can be achieved by correlating measurements with theoretical simulations. In this study, a silver nanoparticle on a ZnO nanorod is used as a model system, in which the plasmon-exciton strong coupling was reported [1]. For characterization, Scanning Transmission Electron Microscopy (STEM) – monochromated Electron Energy Loss Spectroscopy (EELS) approach is chosen to investigate the spatial distributions of plasmonic or plasmon-matter coupled modes. In addition, Cathodoluminescence (CL) measurement in a STEM mode was also employed for complementary information on electronic structures. We discuss the differences in EEL spectra in the Ag/ZnO nanorod system compared to the spectrum of a single silver nanoparticle. Boundary Element Method (BEM) simulations are performed for more correct theoretical interpretation of EEL spectra with MNPBEM developed by Hohenester, Ulrich [2]. Various factors such as distorted shape of a silver nanoparticle, symmetry breaking of dielectric environment, and plasmon-exciton coupling are considered to find the origin of the differences. The work will help to figure out the fundamental principle for light-matter interaction. It also highlights the power of STEM-EELS and STEM-CL for studying plasmonics. [1] Wei, Jiake, et al. Nano letters 15.9 (2015): 5926-5931. [2] Hohenester, Ulrich. Computer Physics Communications 185.3 (2014): 1177-1187.

Universal Metric for Plasmonicity of Excitations at the Nanoscale Luca Bursi[1,1,2], Runmin Zhang[1,1], Kyle D. Chapkin[1,1], Naomi Halas[1,1,1] and Peter J. Nordland[1,1,1]; [1]Rice University, United States; [2]University of North Texas, United States

A promising trend in plasmonics involves shrinking the size of plasmon-supporting structures down to a few nanometers, thus enabling control over light-matter interaction at extreme-subwavelength scales. In this limit, quantum mechanical effects, such as nonlocal screening and size quantization, strongly affect the plasmonic response, rendering it substantially different from classical predictions. For very small clusters and molecules, collective plasmonic modes are hard to distinguish from other excitations such as single-electron transitions or photonic modes. Using rigorous quantum mechanical computational techniques for a wide variety of physical systems, we describe how an optical resonance of a nanostructure can be quantitatively classified as either plasmonic or nonplasmonic. More precisely, we define a universal metric for such

classification, the generalized plasmonicity index1 (GPI), which can be straightforwardly implemented in any computational electronic-structure method or classical electromagnetic approach to discriminate plasmons from single-particle excitations and photonic modes. The GPI relates to experimentally accessible quantities and it is equivalent–at resonance–to the Q-factor of the corresponding harmonic oscillator. Using the GPI, we investigate the plasmonicity of optical resonances in a wide range of systems including: classification and characterization of features in single and hybrid classical systems; the emergence of plasmonic behavior in small jellium spheres as the size and the number of electrons increase; atomic-scale metallic clusters as a function of the number of atoms; and nanostructured graphene as a function of size and doping down to the molecular plasmons in polycyclic aromatic hydrocarbons (PAHs). Further, the GPI identifies molecular plasmonic excitations of selected charged PAHs, in the visible region of the spectrum, whose excited-state lifetime dynamics is then studied2. The GPI metric deepens our fundamental understanding of what is a plasmon down to the molecular limit of plasmon-supporting nanostructures and provides a rigorous foundation for their further development based on molecular plasmonics. Plasmonic Lattices Enable Engineering of Quantum Dot Lasing Jun Guan[1], Laxmi K. Sagar[2], Ran Li[1], Danqing Wang[1], Golam Bappi[2], Nicolas E. Watkins[1], Marc R. Bourgeois[1], Larissa Levina[2], Fengjia Fan[2], Sjoerd Hoogland[2], Oleksandr Voznyy[2], Joao Martins de Pina[2], Richard D. Schaller[1], George C. Schatz[1], Edward H. Sargent[2] and Teri W. Odom[1]; [1]Northwestern University, United States; [2]University of Toronto, Canada

Colloidal quantum dots (QDs) are attractive gain materials for coherent light sources because of their bright photoluminescence, size-controlled color tunability, and solution processability. Engineering directionality of QD lasing is important for applications in remote sensing, laser projection, and on-chip optical network. This talk describes how the emission angle of a QD nanolaser can be manipulated by leveraging the high-symmetry points in plasmonic nanoparticle lattices. We built nanolasers by conformally coating CdSe-CdS core-shell QDs on two-dimensional square arrays of Ag nanoparticles. With waveguide-surface lattice resonances (W-SLRs) near the Δ point in the Brillouin zone as optical feedback, we realized lasing emission at off-normal emission angles. Varying the periodicity of the plasmonic lattices enables other high-symmetry points (Γ or M) of the lattice to overlap with the QD gain, which facilitates controllable lasing direction. We also increased the thickness of the QD film to access higher order W-SLR modes with additional avoided crossings in the band structure, thereby expanding the selection of cavity modes for any desired lasing emission angle.

Extraordinarily Large Permittivity Modulation in Undoped Zinc Oxide for Ultrafast Dynamic Nanophotonics Soham Saha, Aveek Dutta, Clayton DeVault, Benjamin Diroll, Zhaxylyk Kudyshev, Xiaohui Xu, Richard D. Schaller, Vladimir Shalaev, Alexander Kildishev and Alexandra Boltasseva; Purdue University, United States

Active modulation of a material's permittivity makes it possible to control the phase, amplitude, and polarization of light interacting with the material. The ideal material for tunable nanophotonics would exhibit large optical changes and fast response times, in addition to being compatible with industrial fabrication techniques [1].

Extraordinary optical phenomena like ultrafast reflection modulation [2], extraordinary enhancements of nonlinearities [3], and broadband frequency shifts [4] have been demonstrated with doped conducting oxides. Thus, the ultrafast time-scales of optical modulation make it a promising avenue to study optical non-reciprocity [5], control topology protection [6], and implement photonic time-crystals [7]. Yet the effect of optical pumping on their permittivities tuning limits, optical losses, and their effective carrier masses remain largely unexplored.

In this work, we demonstrate unity-order permittivity changes in low, loss, undoped zinc oxide films, induced by optically generated free-carriers. Because of this permittivity modulation, metal-backed ZnO films demonstrate broadband reflectance modulation up to 70% at the telecommunication wavelengths, with picosecond-scale relaxation times. The epsilon near zero points can be dynamically tuned from 8.5 microns down to 1.6 microns with an optical pump, with picosecond-scale relaxation times. The modulation can be selectively enhanced at specific wavelengths by designing hybrid plasmonic resonators while maintaining the picosecond switching times. The modulation is limited by the increasing effective mass of the photoexcited carriers, saturable absorption of the material at the pump wavelength, and the increased Drude damping of the photoexcited electrons.

This work provides insights into the free-carrier-assisted permittivity modulation in zinc oxide, and demonstrates reflectivity modulation of both lithography-free and patterned nanostructures, with large modulation depth and picosecond response

times. The techniques employed in this work can be used to study doped conducting oxides employed in optically switched nanophotonic devices and will facilitate the realization of active devices for beam-steering, polarizers, and spatial light modulators.

Non-Fading Plasmonic Color Printing on Semicontinuous Metal Films Sarah N. Chowdhury[1], Piotr Nyga[1,2], Zhaxylyk Kudyshev[1], Alexander Kildishev[1], Vladimir Shalaev[1] and Alexandra Boltasseva[1]; [1]Purdue University, United States; [2]Military University of Technology, Poland

With sixteen million colors available in the realm of natural and artificial palette, we are still yearning for new shades of colors. Common approaches to achieve a wide color range involve synthetic dyes that expel toxic chemicals that are not only non-biodegradable and carcinogenic, but also are capable of altering the physical and chemical properties of soil, deteriorating water bodies and causing harm to the environment. With a growing demand for higher resolution and shrinking of the ink-jets, current color printing technologies generate ultrasmall particles that cause adverse health effects such as cardio-pulmonary ailments and complex disorders in cellular processes.
Recently, plasmonic colors have emerged as a no-fade, environmentally-friendly alternative for artificial dyes. Their color filtering effects are a consequence of the resonant coupling of light and free electrons in metal nanoparticles, known as surface plasmons that confine light at the nanoscale and lead to the enhancement of the local electromagnetic field. Semicontinuous metal films (SMF), which are randomly distributed metal nanoparticles at the near-percolation regime, can offer both plasmonic sub-wavelength color resolution and large-scale, low-cost fabrication. Random, fractal-type island SMFs are comprised of nanoparticles of diverse sizes and shapes resonating at different wavelengths. When illuminated with high-intensity laser light, thermal effects modify nanoparticles in SMFs, leading to variations in the optical response, and hence, generation of different colors.
In this work, we demonstrate a wide range of plasmonic colors generated by a silver SMF on a silver mirror with a dielectric spacer (SMF/M). This structure utilizes the so-called gap-plasmon modes and generates colors in the reflection mode. The thickness of Ag SMF layer is varied, and the dependence on a dielectric overcoating layer to increase the stability of Ag SMF is analyzed. An ultrafast Ti:Sapphire femtosecond laser (1 kHz, 80 fs, 800 nm, linear polarization) is used to structurally modify the Ag nanoparticles for respective color generation through varying the laser parameters. We obtain intricate artistic designs with the in-house built laser scanning setup.
The proposed approach offers the possibility of producing CMYK colors in an easy and less expensive manner compared to commonly used e-beam lithography. Potentially, SMF-based coloring can be applied to flexible substrates. In addition to color printing and arts, the demonstrated sub-micrometer resolution technique could pave the way to security and optical data storage applications while successfully addressing the challenges of scalability and toxicity across multiple technologies.

Highly Anisotropic Tungsten Bronze Nanocrystals for Tunable NIR-Plasmonic Absorption and Scattering Yannis Cheref[1], Louise Daugas[1], Capucine Cleret de Langavant[1], Florian Lochon[2], Axel Laborieux[1], Eric Larquet[1], Alexandre Baron[2], Thierry Gacoin[1] and Jongwook Kim[1]; [1]Ecole Polytechnique - CNRS, France; [2]Centre de Recherche Paul Pascal - CNRS, France

The study of doped semiconductor nanocrystals exhibiting localized surface plasmon resonances (LSPR) has been growing over the last decade, with the main interest being their intrinsic tunability through dopant concentration. Among these

materials, degenerately doped metal oxide nanocrystals are of particular interest because of their ability to absorb light in the near-infrared (NIR) range while remaining non-absorbing at visible frequencies. These properties open many opportunities for applications in the fields of solar shielding, laser optics, and biomedical treatments [1].

Hexagonal tungsten bronzes (HTB) have a unique NIR-LSPR property originating from their highly anisotropic crystal phase. It was shown that the crystalline anisotropy of HTB nanocrystals influences the LSPR 'band-splitting' in conjunction with the effect of shape anisotropy. This results in a double peak feature of isotropically shaped particles and a band overlap for elongated particles [2]. However, synthesis of HTB nanocrystals with a good control over both their crystalline structure and their morphology has been challenging. Specifically, high aspect ratio HTB rods have not been reported, however producing them could confirm the theorized 'bands-crossover' effect and the polarization selectivity of the absorbance.

We investigated the limitations of the previous chloride-salt-based synthetic process and found them to be linked to a competitive precipitation of alkaline chloride salt. Using alternative reactants, we achieved synthesis of highly anisotropic HTB nanorods, with aspect ratios up to 6.5 and lengths up to 100 nm. Extending the tunability of the particles' aspect ratio also extended the LSPR tunability further in the NIR range. We present a full LSPR band dynamics where particles grow from strongly colored HTB platelets to long HTB rods invisible to the eye. Furthermore, control of the particle size allowed us to measure LSPR light scattering for the first time in doped semiconductor nanoparticles, despite carrier densities in these materials being lower than in the well-studied noble metal nanoparticles. These experimental measurements are supported by numerical simulations based a finite-element model and using an anisotropic Drude-Lorentz dispersion for the dielectric constant of HTB. Our simulations are in good agreement with the experimental measurements. These findings extend our insight into LSPR phenomena, allowing for tunable dual-band NIR absorbers and scatterers.

Tin Oxide Nanowire Networks Decorated with Plasmonic Rhodium Nanopyramids and Thermochromic VO2 Particles for Enhanced Gas Detection David Graf, Sanjay Mathur and Michael Frank; University of Cologne, Germany

The high surface-to-volume ratio as well as the typically high crystallinity and directional charge carrier transport of metal oxide NWs are beneficial for the use in chemo-resistive gas sensors. Semiconducting n-type SnO_2 nanowire networks have been site-selective deposited on gas sensor platforms by chemical vapor deposition approach based on a gold catalyst-mediated vapor-liquid-solid (VLS) growth mechanism. The selective detection of target gas molecules in a complex gaseous composition is quite challenging. We improved the lack of selectivity toward gaseous species through surface decoration with metal oxides (VO_2) and noble metals (Rh) nanoparticles by a second CVD step. For this approach, we developed novel molecular precursors based on designed multidentate organic ligands in order to tailor the gas-phase conversion into targeted nanoobjects with defined size and shape. An enhanced gas detection capability towards reducing gases and oxidizing gases were demonstrated, due to electronic and chemical sensitization via spill-over effects. Moreover, optical reflectance spectroscopy revealed plasmonic resonance absorption in visible (465 nm) and UV (350) region resulted from the gold catalyst on the tip on the SnO_2 nanowire and distinctive rhodium nanopyramids. In addition, surface decoration with thermochromic VO_2 exhibits a plasmon resonance absorbance in the near-infrared region. The potential as a multimodal optical sensor towards adsorbed complex chemical species will be discussed.

Hybridization of Plasmonic Resonances in Nanorod Polygons Revealed by High-Resolution Electron Energy Loss Spectroscopy Grace Pakeltis[1], David Garfinkel[1], Siamak Khorasani[2], Robyn Collette[1], Juan C. Idrobo[3], David Masiello[2] and Philip D. Rack[1,3]; [1]The University of Tennessee, Knoxville, United States; [2]University of Washington, United States; [3]Oak Ridge National Laboratory, United States

The search for metamaterials that support negative permittivity and permeability towards the visible frequency has led to the exploration of various architectures that support coupled plasmonic responses. While standard split ring resonators (SRR) have been extensively studied and shown to be extendable to near infrared frequencies, pushing to higher frequencies is challenging. Thus ring-like structures of nanoparticles and nanorods have become a viable solution for higher frequency

applications. While coupled nanosphere assemblies have been more extensively studied for their unique optical and magnetic properties, rods have stronger polarizability and plasmon resonances. High-aspect-ratio nanorods, in particular, provide an additional route for engineering plasmonic responses, however, have not been studied as extensively as spherical nanoparticles. Although studies on individual nanoparticle/nanorod arrangements have been studied, a comprehensive investigation on the geometric effects on the hybridization of plasmonic nanorods is still lacking. In this study, the hybridization of the electric and magnetic dipoles for a series of polygons were lithographically patterned, where the number of edges (n=3-6), gap length, and edge length were studied. High-resolution EELS spectrum images were measured, and the combined spectra and spectrum images clearly reveal the nature of the various resonance modes that are active. Electron discrete dipole approximation simulations were performed to clarify the resultant consequent electric and magnetic field distributions. This work elucidates the hybridization trends of arranged polygons to provide the opportunity for negative permeability and permittivity.

Metal Optoelectronics—Hot Carrier Devices Using Novel Materials and Substrates Jeremy N. Munday; University of California, Davis, United States

High conductivity metals have long been the material of choice for traditional electronics, and over the past two decades low-loss metals have led to many novel optical devices and structures as a result of plasmonic confinement. As these fields merge, metal optoelectronics using hot carrier effects may pave the way for new device architectures with improved flexibility, frequency response, and ultrafast time-dynamics. In this presentation, we will discuss our recent work building hot electron photodetectors for NIR detection using Si and metal oxides [1], improved response using nanoscale metal alloys [2], and time-resolved ultrafast detection via pump-probe techniques exploiting surface plasmon excitation [3]. Further, we will show how the incorporation of index near zero (INZ) substrates can lead to nearly 100% absorption in thin metal films, providing a new platform for hot electron devices [4]. We will conclude with an outlook and discuss future possibilities with these novel material systems.

Optothermal Generation and Manipulation of Plasmons Eduardo Brioso Dias[1], Renwen Yu[1] and F. Javier Garcia de Abajo[1,2]; [1]ICFO–The Institute of Photonic Sciences, Spain; [2]ICREA - Institució Catalana de Recerca i Estudis Avançats, Spain

Nanoscale photothermal effects enable important applications in cancer therapy, imaging, and catalysis. They also induce substantial changes in the optical response experienced by probing light, thus suggesting their application in all-optical modulation. These important applications have been extensively investigated in conducting materials due to the substantial enhancement produced in the strength of nanoscale photothermal processes as a result of the excitation of their collective electron oscillations, known as plasmons. In this work [1], we theoretically investigate the thermal control of plasmons assisted by light absorption in graphene, thin metals and graphene/metal hybrid films.

Graphene displays stronger photothermal effects than noble metals. A small amount of heat deposited on graphene electrons causes large temperature variations and changes in its optical response because the electronic heat capacity of this material is remarkably small. On the other hand, because plasmon resonances are deep subwavelength excitations, extra momentum is required to couple external light into them. Recently, an alternative route to excite graphene plasmons has been proposed [2], where two interfering optical pump beams create a periodic spatial temperature profile in graphene to assist the coupling of a probe beam to plasmons. Here, we further demonstrate that not only graphene plasmons but also metal plasmons or even sub-wavelength acoustic plasmons can be excited using this approach. We assume a periodic pattern of electron temperature created by the optical grating pump only inside the graphene sheet with a modulated temperature range extending from 300 to 8000 K. Due to the strong temperature dependence of the graphene conductivity, this is spatially modulated and serves as an effective grating.

Lateral patterning of the structures considered above directly enables light coupling to their plasmons. We study the thermo-

optical properties of these types of structures by considering a thin metal grating placed underneath a graphene sheet. We first investigate metal-like plasmons occurring at a higher energy and supported primarily by the metal. Importantly, we consider graphene doped to some Fermi level E_F and choose a silver grating period such that the plasmon energy is slightly smaller than $2E_F$, so that a large modulation is expected by thermally activating interband transitions. At room temperature, $2\mu \approx 2E_F$ is above the plasmon energy, so we have well-defined modes observed in the reflection spectrum of the patterned 1-nm silver film. However, when graphene electrons are heated to a high temperature via ultrafast optical pumping, the chemical potential can be reduced, enabling Landau damping of the plasmon, whose quality factor strongly drops. The observed dip in peak reflectance is observed also for graphene acoustic plasmons and even for metal plasmons in the absence of graphene, although in these cases the effect is due to the increasing of the electronic inelastic damping. Depending on the material composition and thickness, this modulation effect can be as strong as >70%.

The remarkably small electronic heat capacity of atomically thin systems, such as graphene and few-atomic-layer noble metal films, allows us to elevate their electron temperature via ultrafast optical pumping in such a way that their optical responses are dramatically modified with moderate pump intensities below the damage threshold. We have shown that the addition of a noble metal film in close proximity to graphene enables similar levels of modulation >70% to be reached over a wider spectral range extending down to the visible domain.

9:15 AM F.NM02.01.35
Broad Infrared Spectrum Accessibility Through Plasmonic Coupling in In:CdO Thin Films Angela Cleri[1], Joshua Nolen[2], Joshua D. Caldwell[2], Evan Runnerstrom[3] and Jon-Paul Maria[1]; [1]The Pennsylvania State University, United States; [2]Vanderbilt University, United States; [3]U.S. Army Research Office—Materials Science Division, United States

Cadmium oxide (CdO) is one of the most promising material systems for low-loss infrared (IR) plasmonics. Through reactive co-sputtering using high power impulse magnetron sputtering (HiPIMS) and radio frequency (RF) sputtering, doped CdO demonstrates high mobility films with tunable carrier concentrations across a range corresponding to plasmonic light-matter interactions coupling to wavelengths spanning the mid-IR and reaching into the near-IR. Specifically, indium-doped CdO (In:CdO) yields carrier densities ranging between $2x10^{19}$ cm^{-3} and $5x10^{20}$ cm^{-3} while maintaining mobilities between 300-400 cm^2/Vs across this range, thus allowing for the widest accessibility of the IR spectrum (1650-5325 cm^{-1}) of a single plasmonic material grown by sputtering.

Fully accessing the spectrum of plasmonic applications, including surface plasmon oscillations, epsilon-near-zero (ENZ) modes, and strong coupling phenomena requires that one maintains these appealing transport properties over a film thickness range spanning a few tens to a few thousands of nanometers. Extensive CdO fabrication experiments using high-power impulse magnetron sputtering reveal a strong dependence of carrier density and mobility on film thickness when thickness drops below 100 nm, a particularly significant range for ENZ modes. We attribute this behavior to well-reported surface charge accumulation and depletion layers caused by Fermi level pinning. In this presentation, we demonstrate the reversal between surface charge accumulation and depletion in In:CdO. Further, we show how these surface effects can influence optical properties, i.e. perfect absorber ENZ modes, and how they can be controlled by suppressing acceptor defect formation and sandwiching ENZ layers between unintentionally doped CdO to eliminate interfacial defects.

9:25 AM F.NM02.01.36
Doped Conjugated Polymers for Infrared Plasmonics Hemanth Maddali and Deirdre O'Carroll; Rutgers, The State University of New Jersey, United States

Plasmonic materials have garnered a lot of interest due to their ability to confine light below the diffraction limit which enables applications in energy harvesting, light localization and detection, and for environmental sensing in the mid-infrared. The vast majority of plasmonic materials used at visible and infrared wavelengths are either metals or doped inorganic semiconductors. Most metals exhibit their plasma frequency in the UV or visible wavelength regions and both localized plasmon resonances and surface plasmon polaritons can be supported at wavelengths spanning from the UV to near infrared (IR). Inorganic semiconductor compounds cannot support visible-wavelength plasmonic modes; however, they can exhibit strong plasmonic behavior in the infrared if their conductivity is high enough. Many of these inorganic compounds are expensive and involve high processing and fabrication costs that make devices that include these materials very expensive. Doped organic semiconductors, such as conjugated polymers, could act as cheaper and more versatile IR plasmonic materials that enable advancement of IR localization and sensing. Numerous studies have shown that highly-doped conjugated polymer

materials such as polyacetylene, polypyrrole and polythiophene can exhibit conductivities ranging from ~100 S/cm to 10,000 S/cm. In that conductivity range, a plasmonic response could be observed at mid-IR wavelengths because highly-doped polymers can exhibit metal-like behavior. However, very few studies have demonstrated plasmonic responses in the IR region for highly-doped conjugated polymers.
In this study, we investigate the use of doped conjugated polymers as potential IR plasmonic materials. Drude model calculations were performed to estimate the theoretical conductivity that is required for a material to exhibit a plasma frequency in the mid-IR region. A correlation was established between plasma frequency and the conductivity of the thin films was established using the calculations. Poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) thin films were doped multiple times with para-toulenesulfonic acid (PTSA) in dimethyl sulfoxide (DMSO). These doped films were then treated with sulfuric acid to further increase the conductivity of the PEDOT:PSS films. IR reflectivity measurements will be performed across mid-IR wavelengths to check for a non-linear increase in reflectivity from the highly doped PEDOT:PSS films. This is expected to provide evidence for the occurrence of a plasma frequency in the IR region. Subsequently, the surface of the PEDOT:PSS will be imprinted with gratings using nano imprinting lithography. These gratings will then be excited at a range of incident angles to investigate if surface plasmon polaritons can be launched on the doped polymer films.

Phonon Sculpting—Infrared Functionality via Vibration Thomas Beechem[1], Eric Hoglund[2], Thomas Folland[3], Amun Jarzembski[1], Joshua Shank[1], Sean Smith[1], Elizabeth Paisley[1], Chris Saltonstall[1], James Howe[2], Joseph R. Matson[3], Roman Engel-Herbert[4], Jon Ihlefeld[2], Jason G. Valentine[3], Patrick Hopkins[2] and Joshua D. Caldwell[3]; [1]Sandia National Laboratories, United States; [2]University of Virginia, United States; [3]Vanderbilt University, United States; [4]The Pennsylvania State University, United States

The optical phonons of many oxides manifest through atomic oscillations at infrared frequencies. Often polar, these oscillations create electric fields that themselves have infrared frequencies. When exposed to IR-photons, the electromagnetic and vibration-induced fields can be of similar energy and momentum causing interactions that dominate the material's infrared properties within the Reststrahlen band bounded by the transverse- and longitudinal-optical phonon modes. Thus, by controlling, modifying, and even creating "designer" polar phonons, a route is opened to induce infrared phenomena. Here, the infrared properties of composite oxides composed of lamellar combinations of common dielectrics and ferroelectrics—MgO/CaO and SrTiO3/CaTiO3specifically—are examined to this end. Using a suite of vibrational spectroscopies in combination with materials modelling, the optical response of these "Reststrahlen laminates" extends beyond just a summation of the constituents. The resulting optical properties are examined in light of "synthetic" phonon dispersions that emerge with the variations in periodicity implicit in lamellar structures. Together, the work suggests a means of creating arbitrary infrared materials via composite phonon responses. This work was performed, in part, at the Center for Integrated Nanotechnologies, an Office of Science User Facility operated for the U.S. Department of Energy (DOE) Office of Science. Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International, Inc., for the U.S. DOE's National Nuclear Security Administration under contract DE-NA-0003525. Surface-Enhanced Raman Scattering on Colloidal Au Nanobipyramids Hui Wang; University of South Carolina, United States

Au nanobipyramids are anisotropic nanostructures with tunable plasmon resonance frequencies and well-defined electromagnetic hot spots, both of which are highly desired for quantitative surface-enhanced Raman spectroscopy (SERS). Here I will talk about how to fine-tune the plasmon resonance frequencies and fine-tailor the tip sharpness to achieve the optimal SERS enhancements on colloidal Au nanobipyramids. Taking full advantage of their wide plasmon tuning range and narrow plasmon bandwidths, we were able to systematically tune the longitudinal plasmon resonance frequency of Au nanobipyramids with respect to the excitation laser wavelength and the Raman scattering frequency of the molecular

adsorbates. We found that the highest SERS enhancements were achieved when the plasmon resonance energies of the nanobipyramids matched the energies of the inelastic scattering photons rather those of the excitation photons. We also discovered that the tip sharpness of Au nanobipyramids could be tailored in a highly controllable manner through plasmon hot electron-driven photocorrosion, which allowed us to establish a detailed correlation between the surface curvature at the nanobipyramid tips and the Raman enhancements.

5:15 AM *F.NM02.02.02
Towards Applications of Plasma-Synthesized Plasmonic TiN Nanoparticles as an Alternative to Gold and Silver Lorenzo Mangolini, Carla Berrospe Rodríguez, Alejandro Alvarez Barragan and Giorgio Nava; University of California, Riverside, United States

The great capacity of plasmonic nanoparticles to efficiently absorb, scatter and emit light has recently garnered attention for application of these materials in plasmon-based photocatalysts, solar cells and thermo emitters. Particularly, gold and silver have been used to successfully drive hydrogen dissociation and CO oxidation reactions by injecting hot electrons into molecules adsorbed to their surface. However, due to the low thermal stability and the high cost of both materials, the need of studying alternative plasmonic materials, that potentially will expand the field towards more cost-effective applications, has been growing in the last years. Titanium nitride (TiN) is a conductive ceramic with high hardness and bulk melting point (2930 °C). Its plasmon resonance located in the visible-NIR region, low cost (relative to gold and silver), and the well-understood properties as a thin film in the semiconductor industry, make it a strong alternative to plasmonic metals. The present work encompasses a comprehensive study of the plasma-based synthesis of TiN nanocrystals and highlights its potential as a high-temperature-resistant photothermal absorber. TiN particles were synthesized via a scalable, modular, non-thermal plasma method. Titanium and nitrogen precursors were transported into a RF frequency plasma where TiN particles nucleate and grow. Platinum nanoparticles were subsequently deposited on the TiN by photo-induced reduction of an aqueous solution of chlorplatinic acid (H2PtCl6). The reduction of the precursor metal was driven by electron hole pair generation via plasmon decay. The addition of methanol as a hole scavenger increased the electron lifetime, obtaining metallic platinum. This reaction occurred at temperatures below 40°C under visible light illumination. In addition, a novel TiN@SiOxNy core-shell structure was produced by taking advantage of the modular capabilities of the non-thermal plasma synthesis method. The synthesized core shell particles displayed a 60% higher plasmon peak in the extinction coefficient with respect to the uncoated TiN particles. To probe the potential of these heterostructures, core-shell and uncoated TiN particles were deposited on SiOx substrates by coupling the plasma reactor with a nozzle. This simple modification enables to deposit a thin film by jet impaction method. The absorptivity (1 - reflectivity) of both samples were measured under vacuum conditions, demonstrating the high temperature resistance of TiN@SiOxNy core-shell films, as their optical properties at 700 °C remained stable. This simple experiment demonstrates the stark promise of this material as an alternative to gold and silver nanoparticles.

5:30 AM F.NM02.02.05
Controlling Optical Properties of TiN Epitaxial Flims by Tuning Their Stoichiometry Ragini Mishra[1], Ching-Wen Chang[2], Zih-Ho Song[1], Chang-Wei Cheng[1], Khant Minn[3], Ho Wai (Howard) Lee[3] and Shangjr Gwo[1]; [1]National Tsing Hua University, Taiwan; [2]Academia Sinica, Taiwan; [3]Baylor University, United States

Recently developed plasmonic metasurface approach contributes an extraordinary way to manipulate the light-matter interaction at nanoscale, which plays a vital role in various fields such as biological and chemical sensors, surface enhanced Raman spectroscopy (SERS), nonlinear optics, and manipulation of quantum states. Titanium nitride is a promising material due to excellent plasmonic properties from visible to near-infrared. In this work, epitaxial TiN (111) thin films were grown on c-sapphire via plasma-assisted molecular beam epitaxy technique (PAMBE) under ultra-high vacuum conditions. By tuning stoichiometry of TiN via controlling nitrogen flux from lower nitrogen flux to nitrogen rich condition, the spotty reflection high-energy electron diffraction (RHEED) pattern became streakier, indicating a change in surface morphology. The smooth stoichiometric TiN provides excellent optical properties which can replace gold as a plasmonic material platform. The dielectric functions of TiN have been determined via Drude-Lorentz oscillator model fitting and ellipsometry measurement. It also reveals the plasmonic frequency has a blue shift from 2.6 eV (475 nm) to 2.7 eV (452 nm). Therefore, not only can replace TiN for gold in visible to near- infrared regions, but also TiN outperforms gold in the short wavelength region (<500 nm). XRD omega scan indicated the full width at half maximum is ~200 arcsec and the high-resolution atomic image revealed TiN crystalline arrangement. Furthermore, the epitaxial relationships of TiN and sapphire are determined to be TiN (111)|| sapphire (0001), TiN (1-10)|| sapphire (10-10) and TiN (11-2)|| sapphire (11-20). Reference: 1. W. P. Guo et al., Titanium Nitride Epitaxial Film as a Plasmonic Material Platform: Alternative to Gold, ACS Photonics 6, 1848-1854 (2019). 2. R. P. Sugavaneshwar et al., Fabrication of Highly Metallic TiN Films by Pulsed Laser Deposition Method for Plasmonic Applications, ACS Photonics 5, 814-819 (2018).

5:40 AM F.NM02.02.06
Bifunctional Nanocrystals for Catalyzing and Reporting on Chemical Reactions Shi Shi and Dong Qin; Georgia Institute of Technology, United States

Bifunctional nanocrystals with integrated plasmonic and catalytic activities embrace great promise for monitoring chemical reactions by in situ surface?enhanced Raman spectroscopy (SERS). In this talk, I first introduce two distinctive strategies to achieve dual functionality. The first strategy involves the fabrication of Ag-based bimetallic nanostructures with an integrated SERS activity from Ag and catalytic activity from the platinum group metals such as Pt or Pd. The second strategy relies on tuning the passivation of Ag surface with an isocyanide molecule for revitalizing the catalytic activity of Ag toward hydrogenation reaction. Next, I use the reduction of 4?nitrothiophenol as a model system to evaluate the capabilities of these two different types of bifunctional nanocrystals for monitoring catalytic reactions and elucidating reaction mechanisms.

5:50 AM F.NM02.02.07
Studying the Properties of Active Metamaterials Using Infrared Photoreflectance Thomas Folland[1], V. D. Wheeler[2] and Joshua D. Caldwell; [1]Vanderbilt University, United States; [2]U.S. Naval Research Laboratory, United States

Active meta-materials offer an appealing way to create high speed modulators in the mid- and far- infrared which cannot be realized with currently available technology. This kind of device typically relies on a material with optical properties which change upon application of an electric and/or optical field, resulting in changes to their refractive index and/or loss. Whilst conventional characterization techniques (such as FTIR) are capable of accurately characterizing large changes in the properties of an active metamaterial, measuring small absolute changes is often problematic. This is particularly important for understanding the properties of devices which are functioning off-resonance, or trying to determine changes to any weak resonances in the spectral response. In this paper, we describe how the use of photoreflectance implemented in a FTIR microscope acts as a powerful tool to understand the properties of active metamaterials in the infrared with high dynamic range. In particular, we study the modulated behaviour of VO2 films and coatings integrated onto SiC nano resonator arrays. Photoreflectance is a technique which was originally used to study semiconductor quantum wells in the visible to near infrared, capable of measuring optically dark transitions. It is based on using a modulated pump laser to modulate the optical constants of a material, and then using a lock-in amplifier to monitor the corresponding change in sample reflectance. Here, we extend this technique to FTIR microscopy using broadband cooled MCT detectors, providing modulated information across an extremely broad spectral range. Our approach is an expansion of earlier implementations in the mid-infrared, where we use a combination of amplitude modulated step-scan spectroscopy and visible pump lasers, in order to build a photoreflectance system. In order to characterize the properties of our photoreflectance system we study films of vanadium dioxide (VO2), a correlated oxide with a volatile metal-insulator phase transition near room temperature. VO2 acts as an exemplary material for such studies, as when fully switched it shows an extremely large change in its optical properties across the mid-infrared, and has been widely integrated into metamaterials. First, we consider thin (35nm) planar films of VO2 in order to determine the sensitivity of the photoreflectance technique. By fully undergoing the MIT in VO2 we can observe the change in optical properties using both conventional FTIR microscopy, as well as photoreflectance. However, with photoreflectance we are able to characterize much smaller changes in the optical properties, in particular close to the phonon energies of VO2. Furthermore, we are able to probe the spectral regions close to the optical phonons of the film. To implement these studies for studying metamaterial devices, we then study silicon carbide nanopillars which are conformally coated with a layer of VO2. We are able to quantify the change in device response across the full Reststrahlen band, and the modulation speed of the device, which would normally be extremely difficult without infrared lasers. We envision that this technique could act as a platform to understanding the coupling of metamaterials to active materials, including those with small changes in optical constants such as in piezoelectric materials.

All-Gas Phase Plasma Synthesis of Plasmonic Zirconium Nitride for Advanced Photochemistry Applications Chris Rudnicki, Stephen Exarhos, Alejandro Alvarez Barragan and Lorenzo Mangolini; University of California, Riverside, United States

Plasmonic nanomaterials absorb light extremely well due to a localized surface plasmon resonance (LSPR) that is correlated with the density of free charge carriers in nanomaterials. Plasmonic nanomaterials have received interest in a broad variety of fields, such as photocatalysis, photochemistry, photovoltaics, biophotonics, spectroscopy, sensing, and wave-guiding. We present a novel technique for the synthesis of plasmonic zirconium nitride (ZrN) nanoparticles using a scalable non-thermal plasma process.1 Cost, production concerns and most importantly high thermal stability motivate the search for plasmonic materials alternative to gold and silver, like Group IV transition metal-nitrides such as TiN2 the relatively unexplored ZrN.

Our ZrN nanoparticles display a plasmonic peak around 620 nm and from XRD and TEM we infer the crystallinity of the particles to be a cubic rock salt structure and a tunable size distribution below 10 nm. To prevent oxidation and the subsequent loss of plasmonic effect, we developed a modular non-thermal plasma system that coats the particles with amorphous silicon nitride in flight. This coating acts as an oxygen-sink when the material is exposed to atmosphere and yields blue-shifted and increased-intensity absorption. An attractive application of these plasmonic particles is the reduction of metals like platinum and chromium (VI) species in water which are extremely toxic.3 Here we have provided evidence of plasmon driven photo catalytic activity within visible wavelengths to reduce Platinum in solution.4 An aqueous solution of ZrN, methanol, and chloroplatinic acid (H2PtCl6) was illuminated using a monochromator set to various wavelengths in the visible regime. Energy dispersive X-ray spectroscopy (EDS) was then used to determine the ratio of reduced platinum to zirconium at a given wavelength. A similar method was used to reduce Chromium (VI) in water. Undoped Organic Semiconductor Films for Surface Enhanced Raman Spectroscopy Application Antonio Facchetti[1,2]; [1]Northwestern University, United States; [2]Flexterra Inc., United States

Organic small molecules comprising π-conjugated moieties and functional groups have been the subject of considerable applications in organic opto-electronics, however, π-conjugated small molecules have yet to play a significant role as substrate for Surface Enhanced Raman Spectroscopy (SERS) studies. Very recently we demonstrated that metal-free nanostructured semiconductor films based on a π-conjugated small molecule, (DFH-4T diperfulorohexyl-quaterthiophene), could be SERS-active with a remarkable enhancement factor (EF) surpassing 103.13 Prompted by this breakthrough, we questioned whether molecular engineering of the SERS-active organic semiconductors, and thus the corresponding optoelectronic properties and solid-state microstructure/morphology, can be tuned to further advance Raman enhancement performance. Here we report that a fluoroarene-modified oligothiophene, (DFP-4T, diperfluorophenyl-quaterthiophene) semiconductor, which includes an electron-rich quaterthiophene π-core similar to that of DFH-4T but end-capped with π-electron-deficient perfluorophenyl (-C6F5) units. Thus, this molecule employs a quite different design approach as compared with DFH-4T, wherein the π-insulating perfluoroalkyl substituents present in DFH-4T are removed and replaced with -C6F5 substituents leads to a fully π-conjugated backbone featuring small intramolecular torsions. Hydrophobic and nanostructured DFP-4T films prepared via PVD are found to exhibit unprecedented EF values of >105, indicating that the SERS performance of metal-free organic semiconductor films now approach those of the current plasmonic metal and inorganic semiconducting platforms. Furthermore, a very low detection limit of 10-9 M is demonstrated for methylene blue (MB) as the probe molecule.

Chirality, Complexity and Criticality in Inorganic Nanostructures Nicholas Kotov; University of Michigan, United States

The early observation of strong circular dichroism for individual nanoparticles (NPs) and their assemblies have developed into a rapidly expanding field of chiral inorganic nanostructures. They encompass a large family of mirror-asymmetric constructs from metals, semiconductors, ceramics, and nanocarbons with multiple chiral geometries with characteristic scales from Ångströms to microns. Versatility in dimensions and polarizability of the inorganic materials enables their multiscale engineering to attain a broad range of optical and chemical properties. These capabilities as chiral materials enabled their fast technological translation for biosensing and optoelectronics, which, in turn, opened new venues for scientific inquiry into the unifying role chirality at the interface of materials science, biology, chemistry, and physics. This talk will address (1) the origin of the uniquely high values of optical anisotropy; (2) mechanisms of chirality transfer in inorganic materials; and (3)

differences/similarities with chiral supramolecular, liquid crystal, and biological assemblies. Special attention will be given to the relationship between chirality and complexity traced over a large family of nano-, meso,- and microscale particles. Strict enumeration of complexity was accomplished by developing graph theory methods to describe NPs assemblies resulting in phase diagrams relating chirality and complexity. Non-uniform rise of complexity depending on temperature and enantiomeric excess in the system was examined in relationship with the phase transition between different hierarchical assemblies. The highest complexity was observed when high chirality coincided with the triple critical point in the phase diagram. If time permits, emerging venues for practical realizations of chiral inorganic nanoassemblies related to circular polarization spectroscopy in terahertz spectral window with chiroplasmonic kirigami composites will be introduced and discussed in relation to long-standing questions intermolecular interactions of chiral supramolecules.

A Nanoscale Plasmonic Reactor—Light-Driven Synthesis of Individual Core@Shell Nanoparticles Rifat Kamarudheen, Gayatri Kumari, Guillaume Baffou and Andrea Baldi; Dutch Institute for Fundamental Energy Research, Netherlands

Light is an efficient tool to activate and control a wide range of chemical reactions, from heterogeneous photocatalysis, to molecular switching, and pharmaceutical drug production. The advent of nanophotonics has further advanced these fields by allowing to focus, control and steer light at the nanoscale. In particular, the use of localised surface plasmon resonances, which are light-driven oscillations of free electrons in metal nanoparticles, is currently being explored to drive chemical processes such as nanoparticle syntheses, photocatalytic reactions, and nanolithograpic patterning. These plasmon resonances can activate chemical reactions thanks to non-equilibrium "hot" charge carriers, near-field enhancement of the electromagnetic fields, and nanoscale temperature gradients.1 The relative contribution of these different mechanisms is often quite difficult to disentangle due to the complex light propagation, poorly-understood quantum mechanical charge carrier generation and ejection, and complicated macroscopic and microscopic heat dissipation in irradiated reaction vessels.2 Single nanoparticle studies can be used to elucidate the mechanism at play, as parameters such as illumination intensity, light polarization, and sample and illumination geometry can be accurately controlled.3 So far, however, it has been challenging to control the synthesis of individual nanostructures with desired chemical compositions and controlled morphologies. Here, we show how we can selectively use plasmonic photothermal heating to activate and control the synthesis of individual Au@semiconductor core@shell nanoparticles.4 Under plasmon excitation of individual gold nanoparticles in a reactive flow cell, we activate the formation of conformal metal oxide and metal sulfide shells with growth rates that scale with the nanoparticle surface temperature. Given the large spectral sensitivity of plasmon resonances to the nanoparticle morphology, the shell growth reaction is self-limited in nature and can be monitored in-situ by tracking the photoluminescence spectra of the growing plasmonic nanostructure under laser irradiation. We demonstrate the versatility of plasmonic heating as a chemical activation mechanism by synthesizing CeO2, ZnO and ZnS shells on gold nanoparticles of different sizes and shapes. The use of light as a tool to activate and control chemical reactions at the nanoscale can lead to the synthesis of shape- and size-controlled hierarchical nanostructures which are inaccessible with classical colloidal synthetic methods, with potential applications in nanolithography, catalysis, energy conversion, and photonic devices. 1 M.L. Enabling Spatially-Selective Photochemical Transformations with Plasmonics Katherine Sytwu, Michal Vadal, Fariah Hayee, Alan Dai, Dixon Jefferson and Jennifer A. Dionne; Stanford University, United States

Plasmons have emerged as one solution to optically control chemistry at the nanoscale. Plasmonic photocatalysts have not only demonstrated increased reactivity, product selectivity, and new reaction pathways for heterogeneous catalysis, but also nanolocalized chemistry. However, in plasmonic photocatalytic systems, the overall reactivity is dictated by both the regions of localized enhanced electromagnetic fields (“hot spots”) and regions of high innate chemical reactivity (i.e. undercoordinated sites), which often coincide. To gain a systematic understanding of the influence of light on chemical reactions, one needs to be able to decouple the optical response from the surface chemistry preferred in the dark. Here, we spatially separate the electromagnetic hot spot from the catalytically favorable sites to demonstrate how plasmons can modify a reaction. As a proof of concept, we visualize the dehydrogenation of Pd nanorods coupled to Au nanobars in a cross-bar geometry. We use electron-beam lithography to pattern 75 nm wide Au nanobars onto a Si3N4 membrane, followed by the deposition of a 2.5 nm SiO2 spacer layer. Colloidally synthesized Pd nanorods of median length 450 nm are then dropcast on top. This geometry supports a strong gap plasmon mode between the Au nanobar and the Pd nanorod, creating an electromagnetic hot spot that is localized to the center of the Pd nanorod and well separated from the catalytically more favorable Pd tips. Using a light-coupled environmental transmission electron microscope, we track the plasmon-induced

dehydrogenation of individual Pd nanorods with sub-particle, nanometer-scale resolution. We map the nucleation site of the new phase as a function of hydrogen pressure, illumination power, and wavelength. Without illumination, the Pd nanorods dehydrogenate from their tips. In contrast, upon resonant illumination (around 640nm), the Pd nanorods nucleate their new phase in the middle of the nanorod near the plasmonic hot spot. We confirm this behavior across six Au-Pd antenna-reactor systems for H2 pressures spanning 49Pa-89Pa. By varying the illumination wavelength, we further confirm that this induced phase transition depends on exciting the gap plasmon resonance as no phase transition happens with off-resonance illumination. Our direct visualization of a plasmon-driven, spatially-selective reaction demonstrates optical control of reactive sites, an important result towards designing next-generation, multifunctional photocatalysts.

Lanthanide-Doped Nanophosphors for Multiplexed Spectral Imaging of Complex Biological Interactions Dayne F. Swearer, Stefan Fischer and Jennifer A. Dionne; Stanford University, United States

Immunogold staining is the current standard for characterizing cellular ultra-structures using the sub-nanometer resolution afforded within an electron microscope. However, despite nearly 50 years of use, immunogold staining only yields binary information based on image contrast between the heavy gold atoms and carbonaceous cellular structures and therefore cannot provide multiplexed imaging capabilities. This limit restricts the potential of immunogold staining when imaging critical biological phenomena such as protein-protein interactions or to map the extensive ensemble of transmembrane proteins across a cell's surface. Here, we report on the development of a library of small, electron-beam stable, and bright cathodoluminescent nanophosphors based on an alkaline-earth rare-earth fluoride host lattice. The base composition of each nanophosphor is BaYF5, where the Y3+ cations can be substituted with lanthanide cations (Ln3+) between 0 and 100% doping to act as optical emitters with distinct spectral emissions under electron beam excitation. The nanophosphors were colloidally synthesized using a strategy based on the thermal decomposition of mixed metal trifluoroacetate salts in a solvent system composed of oleic acid, octadecene, and oleylamine, which resulted in the nucleation of a narrow size distribution of 5 nm cores. Following a series of subsequent shelling steps, the nanophosphors were grown systematically until cubic nanoparticles with median edge lengths of 20 nm and 25 wt% loading of Ln3+ are incorporated into the nanophosphor where Ln3+ = Ce, Pr, Nd, Sm, Eu, Tb, Dy, Ho, Er, Tm, or Yb. These nanophosphors result in distinct and narrow spectral emissions that are characteristic of the atomic identity of the lanthanide dopant. Using an optically coupled scanning transmission electron microscope, ensemble cathodoluminescent spectra were obtained for eleven distinct nanophosphors using a focused electron beam at low currents (<100 pA) and short acquisition times (greater than or equal to 10 seconds). Focusing on the brightest nanophosphors, dozens of single nanoparticle cathodoluminescence spectra were obtained for three BaY0.75Ln0.25F5 species, where Ln3+ = Ho, Tb, Er. Each of these nanophosphors produce distinct cathodoluminescent spectra with maximum spectral emission at lEr= 675 nm, lHo= 635 nm, and lTb= 555 nm. The distinct emission of each nanophosphor allows for the realization of multiplexed spectrum imaging, and line scan analysis on samples containing both BaY0.75Tb0.25F5 and BaY0.75Ho0.25F5 opening the door to true nanoscale multiplexed imaging based on optical signatures from lanthanides. Through future work on surface modification, individual cathodoluminescent nanophosphors can be selectively attached to specific proteins of interest using similar chemistry pioneered through 50 years of immunogold staining research. This development opens the possibility for multiplexed imaging of biomolecules at the single-molecule level within the cellular ultra-structure, providing insight into the distribution and expression of proteins within cells at the high resolution afforded by electron microscopes.

Synthesis of Gold Nanostructures and Applications from Photonics to Photocatalysis Stephane Parola, Denis Chateau, Anthony Desert, Frederic Lerouge and Frederic Chaput; Chemistry Laboratory, Ecole Normale Superieure de Lyon, France

Among the various studied shapes of gold nanoparticles, nanobipyramids are one of the most interesting ones. Their anisotropic structure enables the tuning of their LSPR even further than gold nanorods, with higher local electric field enhancement, and their morphology (aspect-ratio, roughness, size, etc.) can be controlled with more freedom. We developed in our lab a high yield process to make such nanostructures, in the classic submillimolar concentration range. While this process was very efficient, its low concentration makes the production of concentrated solutions quite cumbersome and generates lots of waste. Therefore, we developed a new versatile process enabling the direct preparation of gold nanobipyramids and several other pentatwinned nanostructures at concentrations range between 15 and 30 mM (3 to 6g per liter). This novel synthesis has nearly quantitative yields, while allowing an easy tuning of LSPR wavelength. A specific influence of the nature of the reducing agent on the morphology has been observed, and this can be further controlled or enhanced by variating experimental conditions (surfactant, temperature, co-reagents). Those breakthroughs open further uses for gold pentatwinned nanostructrures by simplifying their preparation at gram scale and tuning their morphology for specific uses. In order to illustrate the potentialities of such gold nanostructures, we will show our recent investigations on their use

for optical applications. We developed an easy and general gold surface modification by a functional thiolated silicon polymer. In addition to be an alternative to the use of surfactants or long-chain polymers in order to provide efficient colloidal stabilization in a wide range of solvent, this surface modification allows us to prepare homogeneous hybrid materials like gold-doped sol-gel silica. Association with various photoactive compounds have been explored and enhancement for example of photocatalytic properties of TiO2 or non-linear optical absorption of dye-doped glasses. Finally, we will present our current efforts regarding core-shell AuBP@SiO2 NPs for enhanced photocatalysis based on singlet oxygen generation.

Hydrophobicity Modification of an Au Nanowire Substrate for the Collection and Detection of Low-Concentration Analytes via Surface-Enhanced Raman Spectroscopy Minjoon Kim and Yeon Sik Jung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Detection of trace amount molecules is crucial for analytical studies and inspection of environmental contaminants. Of many detection systems, surface-enhanced Raman spectroscopy (SERS) stands out as an outstanding option not only for its rapid process but also for its non-destructive properties and molecular-specific signals. Previous studies have reported up to attomolar concentration detection via SERS by utilizing “hot spots” produced from diverse nanostructures and fabrication methods. “Hot spots” are regions with localized surface plasmon resonance (LSPR) formed between nanostructured gaps that significantly enhance the Raman signal of analytes. Yet, despite advances in fabricating noble metal nanostructures with high-signal enhancement factors, trace-amount detection remains problematic as the delivery of adequate amounts of analytes to the proximity of “hot spots” is required for sufficient enhancement effects. Therefore, a platform to gather enough target molecules within the vicinity of “hot spots” is important for trace-amount molecule detection.
Here, we introduce a hydrophobic Au nanowire substrate with a hydrophilic center for the collection and detection of low-concentration analytes. The hydrophilic center acts as a concentrating point during the evaporation of highly-dilute analyte solutions and allows easy location of the measurement point during direct Raman spectroscopy. The SERS substrate is fabricated via solvent-assisted nanotransfer printing (S-nTP) to form the highly dense Au nanowire surface. The center is then selectively coated with a thin layer of SiO_2 to provide hydrophilicity while the surrounding area is subsequently functionalized with 1H,1H,2H,2H-Perfluorodecanethiol (PFDT) to amplify the hydrophobicity of the remaining Au nanowires. When an analyte solution is dropped and dried on the substrate, the solution is guided towards the hydrophilic center with minimum liquid contact line pinning on the hydrophobic surroundings. As a result, Raman measurements at the hydrophilic area show clear spectra of the dye and pollutant molecules up to attomolar concentrations compared to non-functionalized Au nanowire substrates with analytes spread over the entire surface.

Artificial Chirality Evolution in Micro-/Nano-Scale 3D Plasmonic Metamaterials Junsuk Rho[1,2]; [1]Pohang University of Science and Technology (POSTECH), Korea (the Republic of); [2]Pohang University of Science and Technology, Korea (the Republic of)

Plasmonic chiral metamaterials has attracted significant attention at it provides a new route to intriguing optical properties such as negative refractive index, light polarization filters, and phase modulation. However, the fabrication regarding with limited resolution in conventional synthesis and complexity of asymmetric synthesis pose a major hindrance for further development. In this study, a new class of three dimensional chiral plasmonic nanostructures was successfully fabricated using molecular shape modifiers and crystallographic control of nanoparticle. Previously, we developed three-dimensional chiral metamaterials based on photolithography overlay and electron-beam lithography overlay for terahertz and near-infrared, respectively. We found scaling down them further to visible frequency is extremely difficult. As an alternative solution, we discovered a novel system that characteristic of molecule is transformed into distinctive gold nanoparticle shape. On the basis of this system, chirality transfer between molecular modifier and gold surface allow us to achieve numerous chiral morphologies of gold nanoparticle, named plasmonic helicoids. Particularly, enantiospecific interaction of molecule and high index plane plays pivotal role to provide asymmetric structuring process on the gold surface, forming distinct chiral morphology in single nanoparticle level. One of the representative shapes of helicoid structure showed gammadion-like

structure, consisting of four highly curved arms of increasing width, in all six faces of cubic geometry. The unprecedented chiral morphology of plasmonic helicoid has remarkable optical activity (dissymmetry factor ~ 0.2 at 622 nm) even in a randomly dispersed solution, substantiated by direct visualization of macroscopic color transformation. Changes in molecular recognition and growth parameter led to different morphological evolution, and structural alterations provided a straightforward means of tailoring optical response, such as optical activity, handedness, and resonance wavelength. Also, our aqueous phase synthesis is readily scalable without losing exquisite chiral structure at nanoscale. In these aspects, our approach, chirality evolution in single nanoparticle, provides a truly new paradigm and valuable insight for chiral metamaterial fabrication. Such unique fabrication technique will provide the opportunity to achieve the significant step making metamaterials from science to technology. References 1. S. Zhang et al., Phys. Rev. Electrically Reconfigurable Metasurface for Spatial Light Modulation Junghyun Park, Byung Gil Jeong, Sun Il Kim, Duhyun Lee, Kyoungho Ha and Hyuck Choo; Samsung Advanced Institute of Technology, Korea (the Republic of)

We have demonstrated an ultrafast, ultra-compact, and all-solid-state metaphotonic spatial light modulator (M-SLM) which can dynamically shape light in reflection. The M-SLM is an array of electrically controlled plasmonic nanostrip cavities, and it can continuously adjust the phase of reflected light from 0 to 360 degrees and, at the same time, independently modulate the amplitude over its full range. The fabricated M-SLM contains 50 active pixels and measures 250×250 ?m2 in dimensions. By tuning the voltages applied to the M-SLM, we have demonstrated beam steering and beam splitting with a steering angle up to 8°, the side mode suppression ratio of +2.7 dB (the highest value reported in the field), and the deflection efficiency up to 48%. The experimentally measured modulation speed marks 5.6 MHz while the energy consumption per pixel is calculated to be as low as 354 pJ per switching. Accomplishing arbitrary light manipulation using active metaphotonics has remained challenging, especially due to coupling between the phase and amplitude during modulation which resulted in unwanted background noises. To overcome this limitation, we have delved into the fundamental modeling of the light wave and observed that it would require minimum two variables, for example, the real and imaginary coefficients, to properly express the phase and amplitude of the light wave. Based on this observation, we developed the two-control-parameter algorithm and translated the concept into the hardware design. In the array of the designed M-SLM, each plasmonic nanostrip cavity is a stacked double-gated structure with an indium-tin-oxide layer as an active intermediate channel, which allows an application of two independent control voltages to the top and bottom gate metals. We have also performed extensive numerical investigation and confirmed that the highly versatile light-manipulating capability of the designed M-SLM, including arbitrary phase and amplitude modulation, originates from the superposition of the effects generated by the voltages applied independently to the top and bottom metals. To our knowledge, the M-SLM is the first all-solid-state, electrically controlled metasurface that accomplishes the 360-dgree full phase sweep and independent amplitude modulation. Unlike previously reported work, our M-SLM does not involve the use of slow, temperature-sensitive liquid crystals, stiction-and-vibration-prone micro-electromechanical systems (MEMS), or an array of pre-fabricated size-varying structures to achieve phase changes. The M-SLMs extremely low power consumption, ultrafast modulation speed, ultra-compact form factor, outstanding predicted reliability, and the use of standard IC-fabrication processes promises wide adaptation and proliferation of the ultrafast and extremely power-efficient SLMs for 3-dimensional real-time holographic display, light detection and ranging (LiDAR), and wearable display for virtual reality. We look forward to sharing and discussing the details of our M-SLM design philosophy, hardware design & fabrication, and testing results with the audience at the MRS 2020 Spring.

Extreme Nonlinear Optics in Epsilon-Near-Zero Materials Yuanmu Yang; Tsinghua University, China

In this talk, I will present our recent efforts to drastically enhance the efficiency of high-harmonic generation (HHG) and broadband terahertz (THz) generation in ultra-thin transparent conducting oxide films leveraging the epsilon-near-zero (ENZ) effect. HHG has been used to generate extreme ultra-violet (EUV) light sources to probe fast electron dynamics in the attosecond time scale. While traditionally observed in rare-gas atoms, HHG has also recently been reported in solids with reduced threshold pump field. Here, we use the ENZ effect to greatly boost the efficiency of the HHG process in solids. We report high-harmonic emission up to the 9th order directly from a low-loss, solid-state ENZ medium: indium-doped cadmium oxide, with an excitation intensity at the GW cm-2 level. Furthermore, the observed HHG signal exhibits a pronounced spectral red-shift as well as linewidth broadening, resulting from the photo-induced electron heating and the consequent time-

dependent resonant frequency of the ENZ film. THz technology has undergone much development in the past few decades, yet it still remains a grand challenge to realize THz sources on an integrated platform. The intensity and spectral bandwidth of typical nonlinear THz sources are limited by the phase matching condition in the nonlinear medium. Here, we demonstrate broadband THz emission, both in transmission and reflection configurations, from a commercially available 10-nm-thick indium tin oxide (ITO) film, leveraging the ENZ effect in ITO. The bandwidth of the THz signal generated from the ultrathin ITO film is unrestricted by the phase matching condition.

5:45 AM *F.NM02.04.04
Tunable Chiral Optical Properties in Semiconductor Nanocrystals and Metamaterials Vivian Ferry; University of Minnesota, United States

Optical nanomaterials offer the ability to bend, twist, guide, and confine light in nanoscale dimensions. Among these materials, chiral nanostructures particularly show promise for applications ranging from polarization manipulation to 3D displays, sensing, and spin-selective transport. Compared to their molecular counterparts, chiral nanomaterials exhibit orders of magnitude stronger dissymmetry factors, but have only been realized in a limited set of materials systems. We have recently demonstrated different strategies to tune and manipulate the polarization response of chiral metamaterials that combine metallic nanostructures, dielectric materials, and semiconductor nanocrystals. By controlling the refractive index of the dielectric components in different architectures, we show that the sign of the circular dichroism can be reversed, and the polarization and directionality of the outcoupled luminescence from nearby nanocrystals can be controlled. To create light-emitting metamaterials, it is additionally useful to create nanostructured elements comprised entirely of photoluminescent materials. We have recently developed patterning methods to transform semiconductor nanocrystals into patterned nanocrystal solids, realizing lateral feature sizes as small as 30 nm and heights in excess of 100 nm without degradation of the photoluminescence. We show that by designing the shape of the nanocrystal solid at this length scale and controlling connectivity between the nanocrystals, the refractive index and nanostructure absorptivity can be tailored. This work points to new strategies to design dynamically tunable metamaterials and control nanoscale light-matter interactions.

Reststrahlen-Band Photonics—Extreme Infrared Light Control with Semiconductors Stavroula Foteinopoulou; University of New Mexico, United States

Heteropolar or polar covalent semiconductors can have their opposite-phase transverse phonon vibrations activated by an impigning infrared (IR) light beam. Thus, strong coupling occurs between the incoming light and the matter vibrations resulting in a hybrid mode known as phonon polariton (PhP). This hybrid PhP mode has a frequency gap in its photonic dispersion, typically refered to as the reststrahlen band, which signifies a regime of forbidden light propagation inside the material; hence bulk PhP material are near-perfect reflectors. This is why PhP material have been largely overlooked as the material of choice to control the flow of infrared light for modern photonic applications. However, in the recent years there has been a heightened attention around PhP materials which now are prominent candidate materials for infrared photonics. PhP materials owe this recent growing interest to the versatile photonic responses within and around the reststrahlen band which include plasmonic-like responses similar to those of noble metals in the visible spectrum as well as epsilon-near-zero (ENZ) responses. In this talk, we discuss how to bring judiciously together material patterning and PhP photonic responses for extreme light control in the mid- and far-IR. We present paradigm PhP-based systems exhibiting unconventional infrared effects such as uni-directional, almost all-forward, thermal emission and ultrathin near-perfect PhP absorbers. These effects can have a vast applications range such as for bolometric detectors, high-intensity one-way THz/infrared sources, or thermal-management devices.

Nonlinear Dielectric Metasurfaces—Towards High Efficiency and Full Spatial Phase Control Thomas Zentgraf; Paderborn University, Germany

For efficient nonlinear processes, the engineering of the nonlinear optical properties of the used materials becomes an important task. The most well-known technique for spatially engineering nonlinear optical properties is the quasi-phase-matching scheme for second-order processes like second-harmonic generation. However, the widely used technique of periodic polling of natural crystals only provides a binary state for the nonlinear material polarization, which is equivalent to a discrete phase change of π of the nonlinear polarization. The continuous tailoring of the phase of the nonlinear susceptibility can greatly enhance the flexibility in the design and reduce parasitic effects, like the generation of other undesired frequency components.
Metasurfaces have the potential to address some of the issues with the continuous phase tailoring in nonlinear processes. In

the linear optical regime, they have shown great promise for tailoring the wavefronts of beams for a large variety of applications, ranging from lenses for imaging and vector beam generation to optical holography. For that different concepts were used to address the issue of tailoring the spatial phase and amplitude. One promising concept is the Pancharatnam-Berry phase that appears for a polarization conversion of the light. However, this concept is not directly transferable to nonlinear metasurfaces, where each meta-atom performs also a nonlinear optical process, like a harmonic generation. The reason is the coupling of different spatial field components through the nonlinear susceptibility tensor, which complicates the design and can give even rise to different phase factors at the same time. Furthermore, the optimization for a particular phase factor might counteract the goal for high conversion efficiency.
Here, we will discuss the concepts of enhancing nonlinear processes with simultaneously engineering the phase for the manipulation of third-harmonic generation from metasurfaces and the arising restrictions for symmetry and geometry of meta-atoms. We theoretically and experimentally studied the nonlinear geometric-phases associated with the THG process occurring in silicon metasurfaces. The THG process involves the wave coupling among the different components of the fundamental field excited inside the dielectric nanoresonators. This gives rise to different geometric-phases carried by the THG signal. We show that the dielectric nanofin structures with various in-plane rotational symmetries generate circularly polarized TH signals carrying the geometric-phases as predicted by the selection rule for nonlinear processes. However, additional phase terms can arise due to the complexity of the mode field inside the nanoresonators. The experiment results agree with our theoretical model.
Furthermore, by tailoring the geometry of high index resonators can result in the excitation of a particular magnetic dipole or higher-order modes that result in relatively strong fields and high conversion efficiencies. We analyze how such modes can be used for tailoring the nonlinear phase utilizing the Pancharatnam-Berry phase approach. By using the recently introduced concept of bound states in the continuum in nanoresonators, we demonstrate that a relatively high conversion efficiency can be obtained for a third-harmonic generation while preserving the spatial phase control possibility using the geometrical phase effect. Controlling the properties of nonlinear metamaterials has fundamental significance in nonlinear optics and for tailored nonlinearities, as such materials provide a further degree of freedom in the design of nonlinear materials.

Wave-Matter Interaction in Spatiotemporal Metastructures Nader Engheta; University of Pennsylvania, United States

Manipulation of waves is mostly achieved by materials with spatial inhomogeneities. However, exploiting the dimension of time, in addition to the three dimensions of space, for variation of material parameters can bring additional functionalities in such tailoring and sculpting the wave. The spatiotemporal metastructures in which the material parameters are engineered with spatial and/or temporal inhomogeneities exhibit special features that enrich the functionality of light-matter interaction. In my group, we are investigating a variety of scenarios in which such four-dimensional (4D) spatiotemporal material platforms can be exploited. These scenarios include 4D materials that provide us with temporal aiming, temporal anisotropy, anti-reflection temporal coatings, frozen waves, phase conjugation, asymmetric diffusion, temporal effective medium methods, etc. In this talk, I will give an overview of our most recent results in this area

6:45 AM *F.NM02.04.09
Metamaterials Defined by Connectivity C.T. Chan; The Hong Kong University of Science and Technology, Hong Kong

We report on the study of some metamaterials whose properties, including dispersions and topological characteristics, are determined by the connectivity of a network rather than the resonance of individual resonators.

Metamaterials are described using effective medium theories in the long-wavelength limit in the sense that their optical properties can be described using local permittivity and permeability tensors. We will see that some metallic structures cannot be described using such a language. Their properties depends on the network connectivity, where braiding can create effective sythetic gauge fields that induce shift in momentum space. The consequence is that such materials can have their index ellipsoids centered not at k=0, and they can possess multiple index ellipsoids centered at arbitrary nonzero k-points. The number of modes that are allowed at zero frequency can be described by Betti numbers. Such systems differ from conventional metamaterials because the functionality does not come from the resonances of individual resonators and as such, their functionalities tend to be broadband.

We will also discuss network structures that have non-trivial topology in momentum space and these materials can couple orbital angular momenta with the wave vector. The topological character originates from the connectivity of the network and goes beyond typical space group descriptions. Such systems can exhibit angular momentum-dependent one-way edge states, and their properties can be described using local Chern numbers. Such systems can also be used to realize other interesting topological systems such as high order topological insulators and topological Anderson insulators, and topological systems in

which the topological order cannot be described by integers.

Scalable Light-Matter Interactions in Nanoparticle Lattices Teri W. Odom; Northwestern University, United States

Rationally assembled nanostructures exhibit distinct physical and chemical properties beyond their individual units. This talk will describe fundamentals and applications of metal nanoparticle lattices that show long-range diffractive interactions when the lattice spacing is close to the wavelength of incident light. These collective excitations are known as surface lattice resonances (SLRs) or lattice plasmons. We will discuss advances in nanofabrication techniques that have enabled the patterning of a wide range nanoparticle materials over macroscale (> in^2) areas and with units that are highly uniform in size, shape, and crystallinity. Such patterned substrates support SLRs with wavelengths that approach the theoretical limit. We will also describe how different lattice symmetries can result in band-edge modes at high symmetry points in reciprocal space. The confined electromagnetic fields of SLRs can manipulate processes such as exciton-plasmon coupling, nanolasing, and imaging via tunable, flat optics.

7:15 AM *F.NM02.04.12
Flexible Holographic Metasurfaces Andrea Di Falco; University of St Andrews, United Kingdom

Optical metasurfaces [1] can be fabricated in flexible substrates [2,3]. Flexibility brings additional advantages to MSs respect to their rigid counterpart, in terms of scalability, conformability, and tunability [4-7]. When metasurfaces are used as supports to encode computer generated holograms, flexibility allows to harness the shape and topology of the target substrate as an additional degree of freedom to encode the holographic information [8,9].

Here we show that this platform can be scaled from the visible to the mm-wave range. This in turn opens the way to the exploitation of flexible holographic metasurfaces for a large number of applications, from security holograms that display the correct image only when the substrate has a determined shape, to the possibility to interface the metamaterials technology to biophotonics systems or to create holographic patches to retrofit existing antennas infrastructures for telecommunication applications [10].

Tunable and Time Modulated Active Metasurfaces Mohammad Mahdi Salary, Seyedali Forouzmand, Raana Sabri, Hooman Barati Sedeh and Hossein Mosallaei; Northeastern University, United States

Realization of active optical metasurfaces capable of tunable phase modulation of light in response to variations in an external stimulus has recently stimulated a great interest in nanophotonics community as it can pave the way toward achieving flat ultrathin optical components offering reprogrammable functions with real-time control. In this talk, we will give an overview of our works on realization of active metasurfaces with robust voltage-controlled phase response. We will demonstrate that the integration of electro-optical tuning mechanisms based on free-carrier and quantum-confined effects into the constituent building blocks of metasurfaces can be exploited for achieving wide phase tuning in reflection and transmission modes. We will discuss the routes toward attaining optimal tunable performance based on field effect modulation of carrier density in degenerately doped semiconductors such as indium-tin-oxide. We will also explore novel photonic design paradigms based on extreme light-matter interactions for enhancing the tunability of optical response arising from the weak electro-refractions due to double carrier injection in p-i-n junctions and carrier accumulation in p-n junctions of moderately doped semiconductors, as well as quantum-confined Stark effect in multi-quantum well structures by

leveraging high-Q resonant modes such as cavity modes, guided mode resonances, and quasi-bound states in the continuum. As the next frontier of active metasurfaces, we will examine time-modulated optical metasurfaces which render a four-dimensional design space and give rise to a myriad of novel physical phenomena through generation of higher-order frequency harmonics. We will illustrate that the phase of higher-order frequency harmonics generated by a time-modulated metasurface can be tuned with uniform amplitude via a non-resonant dispersionless geometric phase shift induced by the modulation phase delay. This dispersionless phase elevates time-modulated metasurfaces beyond their quasi-static counterparts relying on resonant phase delays in terms of dynamic wavefront engineering capabilities in that it increases the functionality bandwidth and minimizes spurious spatial scattering by providing access to the full phase span (2π) with uniform amplitude. Moreover, we will show that frequency conversion operations in space-time gradient metasurfaces can break the time-reversal symmetry and lift the Lorentz reciprocity constraint. We will highlight the required conditions toward achieving strong nonreciprocal responses and will demonstrate high-Q time-modulated metasurfaces can serve as free-space optical isolators by providing access to the non-adiabatic modulation regime with small electro-optical modulation frequencies.

Machine-Learning-Assisted Photonics Alexandra Boltasseva, Zhaxylyk Kudyshev, Alexander Kildishev and Vladimir Shalaev; Purdue University, United States

Abstract:
Discovering novel, unconventional optical designs in combination with advanced machine-learning assisted data analysis techniques can uniquely enable new phenomena and breakthrough advances in many areas including on-chip circuitry, imaging, sensing, energy, and quantum information technology. Topology optimization, which has previously revolutionized aerospace and mechanical engineering by providing non-intuitive solutions to highly constrained material distribution problems, has recently emerged as a powerful architect for advanced photonic design. Compared to other inverse-design approaches that require extreme computation power to undertake a comprehensive search within a large parameter space, topology optimization can expand the design space while improving the computational efficiency. This talk will highlight our most recent findings on 1) merging topology optimization with artificial-intelligence-assisted algorithms and 2) integrating machine-learning based analysis with photonic design and quantum optical measurements. Particularly, we will discuss our studies on implementing deep-learning assisted topology optimization for advanced metasurface design development, focusing on highly efficient thermal emitter/absorber development for thermal-photovoltaics applications. We will outline our recent work on merging topology optimization technique with quantum device design for achieving ultrafast single-photon source that offers efficient on-chip integration. Finally, we will outline our recent works on implementing a novel convolutional neural network-based technique for real-time material defect metrology at the quantum level that outperforms all existing approaches in terms of speed and fidelity. This new method rapidly extracts the values of the single-photon autocorrelation function at zero delays from sparse data and ensures one order speed up on solving “bad”/”good” emitter classification problem in comparison with conventional techniques.

Recent Advances in Mid-Infrared Graphene Plasmonics: Electrically Tunable Metasurface for Complex Amplitude Modulation Min Seok Jang; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The use of reconfigurable metasurfaces to dynamically control the complex amplitude modulation of scattered light has stimulated the interest of the research community. Despite an extensive cumulative body of knowledge in metasurfaces, insights and observations for the most intriguing possibilities have remained elusive due to the lack of design methodology. All proposed designs thus far can only control the optical phase over a fraction of a wavelength, and, furthermore, they are highly inefficient, and couple the phase and amplitude of the scattered light. In short, the current strategies offer very low prospects of creating a transformative optical device. This fundamental problem poses severe performance limitations – particularly for applications relying on accurate spatiotemporal complex field modulation, which includes dynamic holography, high-resolution imaging, optical tweezing, and optical information processing.

Tunable plasmonic modes offered by graphene provide new opportunities to create electo-optically active devices with novel characteristics that have thus far been impossible to be realized by using conventional media. In this talk, we present a new strategy for dynamically controlling the local complex amplitude of light. We devise “metamolecules” consisting of a pair of subwavelength graphene plasmonic metaatoms. Independent tuning of the two metaatoms secures the complete control of both amplitude and phase of light. Our proposed metasurface allows for 2π phase shift as well as large amplitude modulation including perfect absorption. The capabilities of the proposed metasurface were proven by demonstrating active beam steering and holographic wavefront reconstruction with an unprecedented figure-of-merit. Our proposed metamolecule represents a conceptual advancement to metasurface design, allowing for complete amplitude and phase control of light, and should find its application in active thermal engineering and real-time hologram systems beyond the mid-infrared.

8:15 AM *F.NM02.04.16
Kerr Metasurfaces Enabled by Metallic Quantum Wells Zhaowei Liu; University of California, San Diego, United States

Optical metasurfaces have emerged as promising candidates for multi-functional devices. Dynamically reconfigurable metasurfaces have been introduced by employing phase-change materials and/or by applying voltage, heat, or strain. While existing metasurfaces exhibit appealing properties, they don’t express any significant nonlinear effects due to the negligible nonlinear responses from the typical materials used to build the metasurface. In this work, we propose and experimentally demonstrate one kind of Kerr metasurfaces that shows strong intensity-dependent responses. The Kerr metasurface is composed of a top layer of gold antennas, a dielectric spacer, and a ground layer of metallic quantum wells (MQWs) made by TiN/Al_2O_3multilayer stack. Due to the large Kerr nonlinearity supported by the MQWs, the effective optical properties of the MQWs can change gradually from metallic to dielectric with increasing of the input intensity, leading to dramatic modifications of the metasurface responses. This opens up new routes for tunable metasurface applications in the fields of nonlinear optics and extremely fast meta-optics.

8:30 AM *F.NM02.04.17
Soft Metamaterials—From Isotropicity to Quantum Interaction Sui Yang and Xiang Zhang; University of California, Berkeley, United States

Metamaterials are artificially engineered structures designed to shape electromagnetic responses not found in nature including superlensing, cloaking and communications. They traditionally comprise an array of fabricated subwavelength anisotropic structures on a planar geometry, which inevitably limit their responses in certain directions. We explore a novel type of soft metamaterial to overcome such limitations, in which building blocks and overall configurations that can be freely tailored, even after formation. In particular, we explored the complex soft metamaterial nanoarchitectures with tailored symmetries that achieved isotropic negative index at the optical frequency. Moreover, we expand such soft metamaterial design that created the first Casimir quantum trap in solution by manipulating electromagnetic waves from quantum fluctuations. These results provide new insights that facilitate and expand novel metamaterial design and applications.

8:45 AM *F.NM02.04.18
Tunable Flat Optoelectronics Jinghua Teng; Institute of Materials Research and Engineering (IMRE), A*STAR, Singapore

Metasurfaces and flat optics with sub-wavelength structures fabricated on a thin film have shown their strong power in light manipulation and potentials in compact optical device applications. Metasurfaces normally are constructed by sub-wavelength meta-atoms such as disks or pillars spatially arranged according to the design and the function of the device. Meta-optics having a flat surface with meta-atoms embedded within the film would facilitate multi-layer integration for an optical system and ease the electrical control layout for active devices besides the benefits of robustness. Tunable flat optoelectronics allowing dynamic control of the light wave is highly desirable to increase the functionality and flexibility of the optical device and system design. On the other hand, the emergence of two-dimensional (2D) transition metal dicharcogenides (TMDCs) semiconductors offer great opportunities for optoelectronic applications for their strong quantum confinement and the easiness in forming heterostructures enabled by the out-of-plane van der Waals bonding. The intriguing exciton characters in 2D TMDCs and their heterostructures render new dimensions to realize tunable flat optoelectronic devices operable at a wide spectral range from ultra-violet (UV) to mid-far-infrared (IR).

In this talk I will introduce several of our work on tunable flat optoelectronics including programmable flat optics through continuously reversible refractive index change in the phase change materials GST by laser pulse writing, electrical and thermal tuning of terahertz response and complete reflection suppression in an atomically smooth Si metasurface produced by CMOS compatible process, and the gate tunable absorption in TDMC heterostructures by manipulating the interlayer excitons for room temperature high responsivity mid-far IR photodetection, and the 2D flat lens made on 10 nm thick

TMDCs for sub-diffraction limit focusing and imaging at 450 nm wavelength.

9:00 AM *F.NM02.04.19
Dynamic 2D Quantum Metasurfaces Mark L. Brongersma; Stanford University, United States

Since the development of diffractive optical elements in the 1970s, major research efforts have focused on replacing bulky optical components by thinner, planar counterparts. The more recent advent of nanophotonic metasurfaces has further accelerated the development of flat optics through the realization that resonant optical antenna elements can be utilized to facilitate local control over the light scattering amplitude and phase. In this presentation, I will highlight recent efforts to realize electrically-tunable metasurfaces employing nanomechanics, electrical gating, microfluidics, and phase change materials. I will pay particular attention to the opportunity of realizing dynamic metasurfaces from atomically-thin semiconductors. Such elements are capable of active wavefront manipulation for optical beam steering and dynamic holography. I will illustrate how the proposed optical elements can be fabricated by scalable fabrication technologies, opening the door to many commercial applications.

9:15 AM *F.NM02.04.21
High Quality Factor Phase-Gradient Metasurfaces Jennifer A. Dionne, Mark Lawrence, David R. Barton, Dixon Jefferson, Elissa Klopfer and Sahil Dagli; Stanford University, United States

High quality factor ("High Q") cavities have revolutionized information processing, communications, sensing, and nonlinear optics by increasing photon storage times and significantly enhancing light-matter interactions. However, when the size of dielectric cavities is reduced to the nanoscale, resonant modes start to resemble point sources, scattering an incident wave in many different directions. While this scattering has been leveraged to create remarkable metasurfaces that precisely control the phase, amplitude, and polarization of light in an ultrathin footprint, metasurfaces generally exhibit high radiative loss rates and thus low Q-factors. Indeed, to date, resonant features in the far-field transmission of metasurfaces have Q-factors on the order of ten.

Here, we describe a general strategy for generating high quality factor resonances in a phase gradient metasurface. Resonances are created by including subtle structural changes in individual resonators to weakly couple free-space light into otherwise bound modes. We experimentally demonstrate control over the quality factor and resonant wavelengths in this scheme, achieving record metasurface Q's greater than 2500. We also show via simulations that Q-factors can exceed millions. We highlight this scheme's general applicability by designing and fabricating metasurfaces that act as beamsteerers to different angles, beam splitters, and lenses. We also show how this platform can be integrated with electro-optic materials for low-power metasurface modulation. Finally, we describe applications of high-Q metasurfaces spanning i) free-space optical sensors of COVID-19 antigens and antibodies; ii) all-optical magnetic switching; and iii) an all-optical self-isolating laser.

9:30 AM *F.NM02.04.22
Metasurfaces for Holography and Light Harvesting—New Approaches with Orbital Angular Moment Modes and Tailored Disorder Stefan A. Maier[1,2], Haoran Ren[1] and Changxu Liu[1]; [1]LMU Munich, Germany; [2]Imperial College London, United Kingdom

Metasurfaces significantly widen the parameter space for control over light, mainly via the many ways phase control can be achieved and varied within the plane of the surface. Here, we take a closer look on how to further widen these possibilities via introducing elements such as control over amplitude and phase simultaneously, i.e. the complex amplitude of the impinging light field, and secondly via disorder.
As a first application, we examine the use of beams of higher orbital angular momentum coupled to metasurfaces in a context of holography. We demonstrate the design and implementation of metasurface phase holograms with strong orbital angular momentum selectivity, based on nanostructured gallium nitride. This opens up a new degree of multiplexing, allowing lensless reconstruction of distinct holographic images in each orbital angular momentum channel. We further show how metasurfaces with additional variation in the height of the underpinning nanostructures allow for complete control over the complex amplitude of the impinging wave. We demonstrate that this significantly reduces cross talk between different orbital angular momentum coding channels, enabling up to 200 independent orthogonal image frames for realistic parameters.
The second application is in a context of energy harvesting. Based on a disordered array of plasmonic nanoresonators, we show how deterministic coupling of this effective photonic layer to an external cavity can lead to two different regimes of operation — broadband absorption and narrow-band reflection. As an example, we demonstrate the use of such coupled disordered-layer / cavity systems for colour generation.

9:45 AM *F.NM02.04.23
Dielectric Nano-Structures Functionalized Optical Fibers—A Novel Pathway Towards Single-Fiber Optical Trapping and Boosting In-Coupling Efficiencies Markus Schmidt[1,2,3], Malte Plidschun[1,3], Henrik Schneidewind[1], Uwe Huebner[1], Matthias Zeisberger[1], Torsten Wieduwilt[1], Jisoo Kim[1,3], Ronny Foerster[1], Oleh Yermakov[4], Yuri Kivshar[4,5], Andrey Bogdanov[4], Haoran Ren[6] and Stefan A. Maier[6]; [1]Leibniz Institute of Photonic Technology, Germany; [2]Otto Schott Institute of Materials Research, Germany; [3]Abbe Center of Photonics and Faculty of Physics, Germany; [4]ITMO University, Russian Federation; [5]The Australian National University, Australia; [6]Ludwig Maximilian University of Munich, Germany

The interfacing of nano-structures or meta-surfaces with optical fibers represents a promising approach to unlock novel types of functionalities within a multitude of fields including biophotonics, quantum technologies or optical sensing. Here commonly used top-down implementation strategies are hard to employ in case fiber end-faces are considered due to the intrinsic mismatch of the fiber geometry with wafer-based fabrication technology.
Within this presentation, we would like to report on two implementation pathways to circumvent the mentioned bottleneck, namely (i) 3D nano-printing and (ii) modified electron-beam lithography. Both approaches allow for the implementation of sophisticated nano-structures on the end-face of optical fibers leading to significant performance improvements compared to fibers with unstructured end faces. These improvements are shown here on the examples of (i) optical trapping using only one single-mode fiber via the integration of dielectric meta-surfaces and (ii) boosting in-coupling efficiencies into fibers at almost grazing incidence via dielectric ring-type nano-structures .

(i) A tight focus of light plays an essential role in a vast number of applications including optical imaging, optical manipulation, material processing, biophotonics, microscopy and quantum technology. Here optical fibers show fundamental limitations due to the divergence of light emerging from the fiber facet which for instance has limited the use of single fibers within optical trapping, demanding numerical apertures >0.8. In this presentation we show that 3D nano-printing via direct laser writing allows for the integration of ultra-high numerical aperture meta-lenses on the facet of single-mode fibers that include beam expansion sections. Record-high numerical apertures of up to 0.9 and diffraction-limited spots have been reached. The capabilities of this device have been demonstrated by optically trapping microbeads and biologically relevant bacteria (E. coli) for the first time with one single-mode fiber, solving a serious limiting factor within fiber optics research.

(ii) Optical fibers are particularly difficult to use within the context of wafer-based implementation technologies due to the large aspect ratios of fibers, being complementary to wafers. Using an additional planarization step prior to nano-fabrication we open up a novel pathway to implement dielectric nano-structures onto the end-face of optical fibers via electron-beam based technology. Here, we show that by integrating dielectric gratings consisting of concentric rings located on the core of single-mode fibers, in-coupling efficiencies can be increased by more than four orders of magnitude at almost grazing incidence compared to fibers with unstructured end faces. Specifically, application relevant in-coupling efficiencies of several percent at angles of more than 75° have been reached, suggesting a clear pathway to solve one serious bottleneck of optical fibers which has imposed limitations on applications of optical fibers.

10:00 AM *F.NM02.04.24
Vortical Reflection and Spiraling Fermi Arcs with Weyl Metamaterials Shuang Zhang; Univ of Birmingham, United Kingdom

Weyl points are linear band crossings at discrete points in the momentum space, corresponding to three-dimensional (3D) extensions of the two-dimensional (2D) Dirac nodes, and functioning as monopoles of Berry flux with topological charges defined by the Chern numbers. In photonics, Weyl points have been realized in systems with broken inversion symmetry such as photonic crystals and metamaterials, with broken time reversal symmetry such as magnetized plasma and in synthetic dimensions. As a key signature of Weyl systems, Fermi arcs that connect between the projections of Weyl points of opposite topological charges have been observed. However, the manifestation of the topological nature of Weyl points in their interaction with free space radiations remain obscure in both quantum and classical systems.
Scatterings and transport in Weyl semimetals have caught growing attention in both condensed matter and classical physics. In condensed matter systems, the chiral zero modes and the associated magnetoresistance and chiral magnetic effects underlie some highly unusual scattering and transport properties of Weyl semimetals. It has also been proposed that Weyl semimetals may have handedness dependent Imbert–Fedorov shift within the bulk Weyl material. Electrical conductance is usually measured in the experiments, which has contribution from both the bulk Weyl nodes and the fermi arcs. However, it is generally difficult to perform momentum resolved scattering and transport studies, since the leads that transport the electrons to the Weyl semimetals, by their nature, cannot control the momentum of the input electrons. Therefore, previous attempts to associate the topology to scattering matrix mostly remain theoretical.

In this work, vortical phase profile in the momentum space is demonstrated for elliptically polarized electromagnetic waves reflected by a photonic Weyl system, which represents a key signature of the topological nature of the Weyl points and could lead to alignment-free phase plates for vortex beams generation. The nontrivial topology of Chern insulator can not only be revealed by the number of surface states, but also by the scattering matrix S, i.e. the total winding number in 2π of the phase of the eigenvalues of the scattering matrix. It has been rigorously proven that the topological classification of the Hamiltonian and the scattering matrix are equivalent. The scattering matrix method however, are more accessible for investigation in photonics with the readily available optical components from visible to microwave wavelengths to perform the angle resolved measurements.
We further discover a novel type of spiraling guided mode in a hybrid waveguide system formed by the Weyl metamaterial and a metal plate, enabled by the vortical phase profile in the momentum space. we demonstrate that the fermi arcs possessing arbitrary number of windings around the projected Weyl points can be realized in a photonic Weyl semimetal-waveguide hybrid system, revealing a new intriguing physical properties of photonic Weyl systems. The metamaterial-waveguide hybrid system is formed by an air layer sandwiched between a metallic ground plane and an ideal Weyl metamaterial. In such a system, the surface arc states exponentially decay into the Weyl metamaterial, while forming waveguide modes in the thin air layer between the Weyl metamaterial and the confining metallic plate. By measuring the electromagnetic field distribution inside the waveguide, we are able to visualize the Fermi arc's iso-frequency contour in the momentum space through Fourier transformation, and demonstrate the windings of the Fermi arcs in the vicinity of the Weyl frequency.

Plasmonic, Photonic and Excitonic States Interfaces—Time-Modulated Flat Optics and Time-Resolved Measurements Harry Atwater; California Institute of Technology, United States

Plasmonic, photonic and excitonic states at interfaces govern the optical response of tunable nanophotonic structures such as active metasurfaces, photodetectors and photocatalysts. I will discuss how we can harness plasmonic and excitonic states at interfaces to enable power-efficient phase modulation of active metasurfaces and discuss implications for time-modulated flat optics. Specifically, I will discuss avenues for increasing the power density and power efficiency of plasmonic conducting oxide metasurfaces for temporal phase and amplitude modulation and requirements for time-modulated photonic applications, such as multi-frequency generation and realization of non-reciprocal metasurfaces. I will also report on how time-resolved measurements of plasmonic and excitonic states at interfaces can yield insights about fundamental light-matter interactions in these systems. Specifically, I will discuss i) how electron-hole correlations affect the dynamics of hot carrier relaxation in plasmonic Au/GaN photodetectors and photocatalysts and ii) how time-resolved measurements of excitons generation inform our understanding of carrier dynamics and transport in transition metal dichalcogenides such as WS_2 and MoS_2.

10:30 AM *F.NM02.04.26
Multi-Objective and Robust Global Optimization of Nanophotonic Devices Jonathan Fan; Stanford University, United States

Inverse design algorithms enable metasurfaces and other nanophotonic devices to achieve new functionalities and high efficiencies. We will discuss recent advances in inverse algorithms based on global topology optimization networks (GLOnets), in which global optimization is framed as the training of a generative neural network. We will show how reparameterization methods, in which device layouts are recast in a latent space, can be used to strictly enforce design constraints such as minimum feature size and robustness to fabrication imperfections. We will also show how multi-objective problems, such as those involving the selection of materials from a materials database, can be solved using GLOnets. We apply these concepts to a range of devices, from metasurfaces and thin film stacks to grating couplers, showing how GLOnets can produce nanophotonic devices operating near the physical limits of structured media.

10:45 AM *F.NM02.04.27
Remote Structuring of Near-Field Landscapes Federico Capasso[1], Vincent Ginis[1,2], Marco Piccardo[1,3] and Michele Tamagnone[1]; [1]Harvard University, United States; [2]Vrije Universiteit Brussel, Belgium; [3]Istituto Italiano di Tecnologia, Italy

The electromagnetic near-field enables subwavelength applications such as near-field microscopy and nanoparticle manipulation. Present methods to structure the near-field rely on optical antenna theory, involving nanostructures that locally convert propagating waves into confined near-field patterns. We develop a theory of remote rather than local near-field shaping, based on cascaded mode conversion and interference of counterpropagating guided waves with different propagation constants. We demonstrate how to structure at will the longitudinal and transverse variation of the near-field, allowing for

distributions beyond the conventional monotonic decay of the evanescent field. We provide an experimental realization that confirms our theory. Our method applies to fields with arbitrary polarization states and mode profiles, providing a new path towards unprecedented three-dimensional control of the near-field.

Novel Insights on the Field Enhancements and Time Dynamics in All-Dielectric Antennas Through Their Quasinormal Modes Rémi Colom[1], Brian Stout[2] and Nicolas Bonod[2]; [1]Zuse Institute, Germany; [2]Aix Marseille Univ, CNRS, Centrale Marseille, Institut Fresnel, France

All-dielectric nanostructures composed of high refractive index host Mie resonances that yield resonant light scattering and enhanced internal field [1-4]. Mie resonances result from the existence of complex eigen-frequencies. In the framework of the multipolar theory, the Mie scattering coefficients have an infinite set of complex eigen-frequencies. The scattering matrix can be expanded with respect to the eigen-frequencies of the nanostructure [5,6] which allows to calculate the internal and scattered fields with respect to the eigen-frequencies of the cavity. A thorough convergence analysis shows that the convergence is faster for the internal field and that the field can almost be fully retrieved by taking into account a very limited number of eigen-frequencies [6]. This theoretical framework turns out to be of high interest to explain the formation of anapoles that correspond to non-radiating current distributions [7]. Anapoles have attracted a strong interest to enhance light matter interactions in subwavelength dielectric nanostructures with applications in second and third harmonic generation or enhanced Raman signal [8]. Anapoles can be well identified in the spectrum of the dipolar and electric Mie coefficient as a strong dip that closely follows a peak. It turns out that the anapole is spectrally close to the maximum of the electric dipolar polarizability. Two eigen-frequencies can be found in this spectral range, with a common real part and a large and a weak imaginary part. In other words, two modes associated with high and small quality (Q) factors will influence the optical response. The low Q-mode does not influence the internal field that only results from the high Q-mode. However, the low Q-mode contributes to the external field. The external field is the result of an interference between three terms: the fields associated with the low and high Q-modes plus an non resonant term. Depending on the phase of these terms, the external field can feature a maximum of a minimum. The important result is that neither the maximum nor the minimum correspond to the real parts of the poles, due to the contribution of the non resonant term. As a result, the spectral location of the anapole does not correspond to the maximum of the internal field that is given by the real part of the high Q-mode [7].
In a second step, a Fourier transform of the modal scattering matrix (S- or T- matrix) provides a time dependant scattering matrix. The impulse response function (IRF) of the S-matrix can be found by considering an incoming field described by a Dirac distribution. This modal IRF allows us to retrieve the outgoing field when the Mie scatterer is excited by any kind of pulse. A case of special interest is the case of a causal sinusoidal excitation field, consisting of a sinusoidal excitation behind a Heaviside. The sharp excitation in the time domain of the dielectric cavity yields a transient field. Once the sharp excitation is over and the excitation driven exclusively by the sinusoidal field, the transient regime vanishes and is replaced by a permanent regime. The modal analysis of this problem reveals that the eigen-modes of the cavity contribute only to the response of the cavity during the transient regime, and not during the permanent regime [9]. This study shows that how quasinormal modes turn out to be excellent tools to unveil the complex time dynamics of dielectric cavities.

Shaping Microwaves with Tunable Metasurfaces—From Concepts to Applications Geoffroy Lerosey; Greenerwave, France

Electromagnetic waves are essential to our lives, due to the information they carry, be it through the sense of vision in the visible domain or in our everyday wireless communications within the lower frequency range of the microwaves. Controlling them dynamically is hence of paramount interest. Several approaches have been proposed in the past, using large numbers of independently controlled sources, such as in the concept of phased arrays originally used in radars and now in massive MIMO. Yet these systems are extremely complex and costly, especially for large apertures containing high number of sources, if not impossible to design for instance in the optical domain. In this domain, a paradigm shift has been proposed 10 years ago with the introduction of wavefront shaping, where one does not control the emission of waves, but rather their reflections [1]. This is achieved using large arrays of tunable reflectors, namely spatial light modulators, that are based on micrometric liquid crystal cells or movable micro-mirrors. Due to its simplicity and versatility, wavefront shaping has recently opened avenues for applications, from imaging inside scattering media to communicating with multimode fibers [2]. In this talk I will show that the concept of wavefront shaping can be transposed to the microwave domain using tunable metasurfaces that are controlled by real time electronics. Starting from conventional approaches to beamforming in the radiofrequency domain such as phased array or time reversal, I will first discuss the drastic hardware simplifications that

allow the use of tunable metasurfaces alongside algorithms inspired from wavefront shaping [3]. To do so I will introduce the concept of spatial and temporal degrees of freedom that are levers to the physicist to control the propagation of waves. This will allow me to connect the various concepts introduced before.
Further, I will briefly introduce various applications we develop at Greenerwave using wavefront shaping in the radiofrequency domain, from the low frequency of RFID to the millimeter wave range. More specifically, I will first demonstrate how any box such as a fridge or a cabinet can be made smart using wavefront shaping of microwaves, ensuring error-free RFID detection at very low power and cost. Then, I will focus on the millimeter wave range and prove that a leaky cavity dressed with a tunable metasurface can turn a simple electromagnetic dipole into a dynamically reconfigurable antenna whose properties are unique, paving the way to low cost and fully electronically steerable antennas for 5G and satellite applications. Finally, I will explain how the concept can also turn a cheap detect and avoid system into a powerful imaging device. This tool is an ideal complement to camaras and lidars that are currently used in the context of autonomous vehicles, notably in difficult weather conditions.

A Janus Radiative Cooler for Migrating the High Temperature of the Automobile Seyeon Heo, Gil Ju Lee, Do Hyeon Kim, Yeong Jae Kim and Min Seok Kim; Gwangju Institute of Science and Technology, Korea (the Republic of)

As car is one the most important transportation for each individual, cooling private vehicles has highly demanded. In particular, the extreme temperature can develop in stationary automobile under the greenhouse effect, when the windows are transparent for incoming solar radiation but opaque for outgoing long-wave thermal radiation. The temperature inside the cabin tremendously increased to approach 60 °C, which is causing human discomfort and car aging problem. Current car cooling methods mostly rely on vapor compression and fluid-cooled systems. However, 28.4% of the total vehicle power is consumed for space cooling and place enormous stress on fuels consumption and CO_2 emission. Passive cooling strategy, which is sustainable alternatives to active cooling technologies, can release heat without energy consumption or pollutant emission.

Recently reported passive radiative coolers have shown outstanding sub-ambient cooling during the daytime. Those coolers are attached on exterior materials, roof, or human skin to draw heat from the periphery through conduction and convection. However, this attractive solution has explicit limitation in thermally sealed space (e.*g.,* stationary automobiles). Since most of conventional radiative coolers only consider emissivity of the side exposed to the sky, they cannot thermally access to inside of the enclosure. Emissivity of the inner side could open the path to inside of the enclosure and allow the trapped heat to escape by increasing the inner radiation flux. Accordingly, strategic design of emission spectra on both sides of the cooler is vital for releasing the trapped heat.

Here, we propose a *Janus* cooler that acts as a selective emitter on the top side and a broadband emitter on the bottom side. This design effectively draws heat from enclosure because the bottom side can absorb thermal input in a broad spectral range while the top side emits heat to space without disturbing ambient radiation. We first design a *Janus* cooler comprising of an Ag-polydimethylsiloxane layer on micro-patterned quartz substrate. The induced spoof surface plasmon polariton helps overcome inherent emissivity loss of the polymer, and creates near-ideal selective and broadband emission on the separate sides. Next, we demonstrated several modification methods to improve adaptability as a car roof, such as scalability and mechanical strength, while maintain its optical properties. Consequently, we obtain large-scaled *Janus* cooler with affordability by replacing quartz substrate to PMMA and PDMS and high elastic modulus and scratch resistance by using harder material.

Last, we theoretically and experimentally demonstrate the remarkable cooling performances of *Janus* cooler for enclosures. We numerically solved the steady-state heat transfer model of enclosed space to estimate the impact of emissivity of each layer on cooling. The *Janus* cooler was more effective in drawing heat away as compared to materials with no emissivity and one-directional emissivity. Using *Janus* bi-directional emission characteristics, the *Janus* cooler lowered the temperature of a radiative object inside an enclosure by ~4 °C compared to the Conventional radiative cooler in experiments simulating a stationary automobile environment. The significance of the *Janus* cooler for migrating the high temperature of the automobile is illuminating the importance of emissivity of the substrate itself meanwhile designing the selective emitter in an

interpretive way. With the superior ability to passively cool the enclosure, this advanced design leads to comfortability and cost effectiveness in unconscious way, which are critical demands for situation where heat entrance is present and exit is absent.

Late News: Asymmetric Light Generation in Nonlinear Metasurfaces Sergey Kruk[1,2], Lei Wang[2], Basudeb Sain[1], Dong Zhaogang[3], Joel Yang[4,3], Thomas Zentgraf[1] and Yuri Kivshar[2]; [1]Universität Paderborn, Germany; [2]Australian National University, Australia; [3]A*Star, Singapore; [4]Singapore University of Technology and Design, Singapore

Recent studies of nanoresonators with strong confinement of light opened the way towards efficient nonlinear processes at the subwavelength scales [1]. All-dielectric nanostructures are particularly promising to enhance the efficiency of nonlinear processes. Such nanostructures can support nontrivial optical modes, including optically induced magnetic dipole resonances, higher-order multipoles, and composite resonances [2]. High field enhancements at the magnetic dipole modes and composite resonances increase the efficiency of nonlinear processes by orders of magnitude. Being assembled in 2D layouts such nanoresonators may form ultra-thin flat optical components – metasurfaces – in which the nonlinear response enables functionalities beyond their linear counterparts. [3]

Here we demonstrate experimentally a novel class of nonlinear metasurfaces with an asymmetric response. We fabricate translucent dielectric metasurfaces that generate images in transmission at third-harmonic frequency. Compared to conventional holograms, such metasurfaces generate completely independent images being illuminated from the opposite sides.

We employ cylindrical dielectric nanoresonators as our building blocks for the metasurface. The resonators consist of two layers of materials with different optical constants: Si and SiN, which introduce asymmetry in the direction normal to the metasurface. The resonators further support two Mie resonances – electric and magnetic dipoles overlapped spectrally. Asymmetric bi-layer design leads to magneto-electric coupling between the two dipole modes, where the coupling constant (positive or negative) depends on the direction of excitation as well as on the resonator geometry. In the linear optics regime, such bi-layer nanoresonators demonstrate identical forward-scattering for the illumination from both sites. However, for the two illumination cases, the near-field distributions are drastically different due to positive/negative magneto-electric coupling between the two Mie resonances hosted within the resonators. For high intensities of light, the nonlinearities of the constituent dielectric materials start playing a role, whereas the different near-field distributions lead to different nonlinear changes of the material parameters when the transmitter and receiver positions are exchanged. Such changes generally have small effects on the light scattering at the fundamental frequency in particular for low-loss materials as well as within the approximations of perturbative nonlinearities and the nondepleted pump approximation. These processes however lead to a striking contrast in the efficiency of the nonlinear generation of optical harmonics.

We employ a set of four dissimilar resonators that allows us to assemble metasurfaces generating independent images for two opposite directions of excitation due to asymmetry in the nonlinear light generation. We fabricate such metasurfaces with standard electron-beam lithography and conduct their optical diagnostics with a tuneable short-pulse laser system.

We discuss connections between asymmetric third-harmonic generation in our metasurfaces and nonlinearity-induced optical nonreciprocity [4]. We believe that the ability to engineer optical interactions at the subwavelength scale beyond the electric dipole type to induce a strong artificial magnetic response and strong magnetoelectric coupling pave the way towards optical nonreciprocity at the nanoscale.

Atomic Layer Engineering of Al-Doped Zinc Oxide Thin Films with Controllable Epsilon-near-Zero Optical Nonlinearity Sudip Gurung[1], Subhajit Bej[1], Zhenhuan Yi[2] and Ho Wai (Howard) Lee[1]; [1]Baylor University, United States; [2]Texas A&M University, United States

Giant Kerr-type optical nonlinearity of transparent conducting oxide (TCO) thin films in their epsilon-near-zero (ENZ)

region (i.e. the region where the real part of their dielectric permittivity approaches zero), have been reported recently [1,2,3]. Under excitations of plasmon-polariton modes near the ENZ wavelength (?ENZ), effective nonlinear optical properties of these films can be further boosted. Due to ultra-fast response time of these nonlinear processes, the ENZ TCO films could open distinct functionalities to the path to revolutionary nanoscale nonlinear optics and ultrafast on-chip optical applications. In this work, we present a method to engineer the nonlinear refraction coefficients (n2) and the nonlinear absorption coefficients (?) of Al-doped zinc oxide (AZO) ENZ thin films synthesized by atomic layer deposition (ALD) technique. To engineer the effective nonlinear optical properties, we first design the linear absorption and electric field intensity enhancement (FIE) associated with ENZ modes in these AZO nanolayers via control over the ENZ wavelengths and optical losses by ALD deposition parameters such as dopant ratio and number of macro cycles. The dopant ratio determines the material dispersion and ENZ wavelength whereas the marco cycle regulates the film thickness. Since the optical Kerr nonlinearity has cubic dependence on the electric field confined inside the TCO films, the controllable and enhanced FIE of the ENZ mode could lead to an enhancement of the ENZ nonlinearity. AZO thin films with ENZ wavelengths varying between 1400-1600 nm and thicknesses ranging from 55 to 205 nm are fabricated via ALD technique to examine the ENZ nonlinearity [4]. The nonlinear optical properties of the fabricated films are measured using Z-scan and degenerate pump-probe spectroscopy techniques with linearly polarized femto-second laser pulses (pulse duration ~70 fs, repetition rate 1 KHz, peak wavelength ?p tunable between 1200-1600 nm). Experiments are performed for normal and oblique incidences of TE/ TM polarized light pulses and for different pulse peak wavelengths (?p= ?ENZ, ?p> ?ENZ, and ?p< ?ENZ). Wavelength and angular dependence of n2 and ? values of the films are evaluated upon fitting the close and open-aperture Z-scan data. Results suggest that ENZ nonlinear refraction and nonlinear absorption properties of AZO films are enhanced by excitation of the ENZ modes and can be engineered by changing the mode-strengths via control over either the excitation angles or by ALD engineering of material dispersion/ film thickness. Measured values as large as n2(eff)?10-9 mm2/Watt and ?2(eff)?-10-5 mm/Watt are obtained along with approximately an order of magnitude tunability. The temporal dynamics of the nonlinear processes are also measured. The rise and fall-times of the nonlinear processes are evaluated to be sub-picosecond. We believe that giant ultra-fast Kerr nonlinearity of these ALD AZO films in their ENZ region and their controllability will be important for efficient all-optical signal processing. [1] a) M. Z. Phonon-Polaritons in Calcite Nanostructures Daniel Ratchford, Vanessa M. Breslin, Alexander J. Giles, Adam Dunkelberger and Jeffrey C. Owrutsky; U.S. Naval Research Laboratory, United States

Nanophotonics has incredible potential for developing new mid-infrared technologies for applications including free-space communications and spectroscopic-based sensing. Phonon-polaritons, electromagnetic modes of a polar material resulting from the coupling of light with optical phonons, are a particularly promising area of mid-infrared nanophotonic research because these modes can enhance light-matter interactions through their ability to concentrate light to nanoscale dimensions. We report on the confinement of phonon-polaritons in calcite, a ubiquitous polar material. We fabricated calcite nanopillars with varying aspect ratio using focused ion beam etching. In the mid-infrared reflection spectra of the nanopillars, we observe multiple phonon-polariton modes with frequencies that depend on the aspect ratio. The modes are supported in the spectral region where calcite's permittivity is hyperbolic, i.e., where the principal components of the permittivity tensor have opposite sign, and the modes are identified as volume-confined modes. Our interpretation of the modes as aspect-ratio dependent volume modes is reinforced by the good agreement with FDTD simulations. The results demonstrate the basic properties of phonon-polaritons in calcite and highlight the material's potential for developing mid-infrared nanophotonic devices.

12:10 PM F.NM02.04.34
Tunable Indium Tin Oxide for Metamaterial Perfect Absorbers and Nonlinear Devices Evan M. Smith[1], Joshua Hendrickson[2], Justin W. Cleary[2], Kevin Leedy[2], Junpeng Guo[3] and Shivashankar Vangala[2]; [1]KBR, United States; [2]Air Force Research Laboratory, United States; [3]The University of Alabama, United States

Indium tin oxide (ITO) has become a very useful plasmonic and nonlinear material for NIR and MWIR applications in that it has highly tunable electric and optical properties, and has exhibited strong optical nonlinearity. In particular, ITO exhibits interesting properties at and around its epsilon-near-zero (ENZ) wavelength. We present here the detailed process parameters of a high temperature reactive sputter process to finely tune the ENZ wavelength throughout the NIR up to the MIR

spectrum. Films are characterized by spectroscopic ellipsometry, X-ray diffraction and energy dispersive spectroscopy. Electrical characterization is also reported. Films are designed to be integrated into a NIR perfect absorber that exhibits second harmonic generation.

12:20 PM F.NM02.04.36

Optical Fourier Surfaces Nolan Lassaline[1], Raphael Brechbühler[1], Sander Vonk[2,1], Korneel Ridderbeek[3], Korneel Spieser[4], Samuel Bisig[4], Boris le Feber[1], Freddy Rabouw[2] and David J. Norris[1]; [1]ETH Zurich, Switzerland; [2]Utrecht University, Netherlands; [3]Helmholtz Pioneer Campus, Germany; [4]Heidelberg Instruments Nano/SwissLitho, Switzerland

Gratings and holograms are patterned surfaces that tailor optical signals by diffraction. Despite their long history, variants with remarkable functionalities continue to be discovered. Further advances could exploit Fourier optics, which specifies the surface pattern that generates a desired diffracted output through its Fourier transform. To shape the optical wavefront, the ideal surface profile should contain a precise sum of sinusoidal waves, each with a well-defined amplitude, spatial frequency, and phase. However, because fabrication techniques typically yield profiles with at most a few depth levels, complex "wavy" surfaces cannot be obtained, limiting the straightforward mathematical design and implementation of sophisticated diffractive optics. Here we present a simple yet powerful approach to eliminate this design-fabrication mismatch by demonstrating optical surfaces that contain an arbitrary number of specified sinusoids. We combine thermal scanning-probe lithography and templating to create periodic and aperiodic surface patterns with continuous depth control and sub-wavelength spatial resolution. Multicomponent linear gratings allow precise manipulation of electromagnetic signals through Fourier-spectrum engineering. Consequently, we immediately resolve an important problem in photonics by creating a single-layer grating that simultaneously couples red, green, and blue light at the same angle of incidence. More broadly, we analytically design and accurately replicate intricate two-dimensional moiré patterns, quasicrystals, and holograms, demonstrating a variety of previously impossible diffractive surfaces. Therefore, this approach provides instant benefit for optical devices (biosensors, lasers, metasurfaces, and modulators) and emerging topics in photonics (topological structures, transformation optics, and valleytronics).

12:30 PM F.NM02.04.37

Anticounterfeiting Visible Metaholograms Multiplexed with Spin, Direction and Wavelength Inki Kim[1], Muhammad A. Ansari[2], Muhammad Q. Mehmood[2] and Junsuk Rho[1,1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Information Technology University of the Punjab, Pakistan

Computer-generated holography (CHG) involves iterative numerical algorithms to obtain the phase and/or amplitude profiles needed to physically realize holograms. Metasurfaces consist of arrays of subwavelength nanoresonators that can control the wavefront of light in a desired way. They recently proved themselves to be an effective platform for CGH by surpassing the quality of traditional holograms in terms of image resolution and field-of-view. These metasurface holograms showed prospects not only in imaging and display but also in security applications [1]. In particular, applying metaholograms to anticounterfeiting applications requires not only the technology of encoding multiple pieces of information, but also the manufacturability of highly efficient devices. To meet these complex needs, we have implemented a highly efficient metahologram based on hydrogenated amorphous silicon (a-Si:H) [2]. Compared to well-known titanium dioxide (TiO2) and gallium nitride (GaN)-based metasurfaces, a-Si:H metasurfaces offer easier nanofabrication thanks to a low aspect ratio of 3~5 (cf. TiO2/GaN: 10~15) and is more suitable for mass production using CMOS fabrication methods. In this abstract, I will discuss our efforts in realizing multifunctional a-Si:H metaholograms that can encode multiple pieces of information in a monolayer device for anticounterfeiting applications. First, I will present a spin-multiplexed visible metahologram [3]. A straightforward method for encoding multiple pieces of information in a single metahologram device is using polarization. To obtain significant birefringence for the control and reversal of photon spin, two sets of nanorods are designed, and depending on their orientation, they imprint inversed spin photons along their corresponding geometrical phase. As a result, this allows switching between two different images by simply flipping the handedness of the circularly polarized light on the transmission-type metahologram with 61% diffraction efficiency. Second, I will introduce a direction-multiplexed visible metahologram [4]. This approach is to multiplex two distinct pieces of information onto a monolayer metahologram operating in the forward and backward directions depending on the direction of light incident on the device. Particularly, in this part we will reveal underlying physics of high transmission efficiency (around 75%), which is the antiferromagnetic resonances in the a-Si:H nanorod. Finally, I will propose a wavelength-multiplexed visible/NIR metahologram. The device consists of a-Si:H and gold (Au) metasurfaces in a monolayer device, which is fabricated by the electron beam lithography overlay process. The a-Si:H metasurfaces generate a visible hologram and the Au metasurfaces produce a NIR hologram simultaneously with low crosstalk. I believe our efforts for making a multiplexed metahologram will lead to pragmatic anticounterfeiting applications. [1] I. Kim et al., ACS Photonics 5, 3876-3895 (2018) [2] I. (2019) (DOI:10.1039/c9nh00460b)

12:40 PM F.NM02.04.39
All-Optical Control of Magnetism in Ferromagnetic Thin Films with Silicon Metasurfaces John M. Abendroth[1], Michelle Solomon[1], Mohammed S. El Hadri[2], David R. Barton[1], Eric E. Fullerton[2] and Jennifer A. Dionne[1]; [1]Stanford University, United States; [2]University of California, San Diego, United States

Controlling magnetism and spin as a state variable in devices for high-performance computing has received increased attention as an energy-efficient alternative to processing and storing data with electric charge. This approach circumvents increasing power requirements that accompany Moore's Law scaling of transistors. Deterministic reversal of ferromagnetic domains using circularly polarized, ultrafast light pulses arising from magnetic circular dichroism promises an all-optical approach towards high-performance data storage, non-volatile memory technologies, and quantum computation. However, domain-size criteria haave limited helicity-dependent switching in ferromagnet films, placing restraints on available materials and film thicknesses/coercivities in devices for deterministic magnetization reversal with light. Moreover, using light to control magnetization for high-density recording requires reduction of the size of optically switched areas below the diffraction limit. Here, we show how metasurfaces can locally confine, tune, and enhance these magneto-optical effects, leading to more precise control over magnetic ordering for energy-efficient memory and logic architectures. Metasurfaces amplify both electric and magnetic field strengths while preserving the complex phase angle between them. In particular, periodic nanoscale dielectric disks can enhance the electromagnetic density of chirality, C, controlling magnetic circular dichroism in ferromagnetic films. We fabricated Si nanodisk arrays via sputter deposition and electron-beam lithography on ferromagnetic [Pt (0.7 nm)/Co (0.6 nm)]N multilayers, where N = 1,2, or 3. The Co/Pt films are designed to exhibit perpendicular magnetic anisotropy, with the easy-axis of magnetization out-of-plane. The radii of the Si nanoantennas are varied between 130-190 nm in 5 nm increments, supporting electric and magnetic resonances that overlap and cross with increasing radius; transmission measurements confirm spectral overlap at wavelengths spanning 700-1000 nm depending on Si disk radius. Magnetic circular dichroism of the films, detected by asymmetry in transmission and reflection, is measured using left- and right-handed circularly polarized light for substrates magnetized parallel vs antiparallel to the direction of light propagation at normal incidence. Increasing disk radii modulates the magnetic circular dichroism of the Co/Pt multilayer films with local maxima and minima of increasing amplitude as N is increased from 1 to 3. We find a maximum enhancement of transmission asymmetry of 2x over unpatterned films, correlating with overlap of electric and magnetic dipole resonances as predicted by full-field electromagnetic simulations. To deconvolute near-field enhancements from Fabry-Pérot cavity effects, we vary the separation distance between the ferromagnetic metal layers and Si disks using an SiO2 spacer region with thickness of 0, 30, and 100 nm. This modulation and enhancement in magnetic circular dichroism is translatable to diverse materials including metamagnetic films, chiral magnetic nanostructures, and single-molecule magnets, and can be utilized directly in the design of waveguide magneto-optical modulators and non-reciprocal device elements. Our presentation will also describe ultrafast magnetization dynamics for Co/Pt films patterned with Si metasurfaces showing how they can enhance all-optical control over magnetic domain switching.

12:50 PM F.NM02.04.40
Elucidating the Design of Nanophotonic Materials with Interpretable Convolutional Neural Networks Aaswath P. Raman; University of California, Los Angeles, United States

Reaching the true potential of nanophotonic materials devices requires the arbitrary control of spectral and angular selectivity in the absorption and emission of electromagnetic waves. To this end, previously investigated design methods for nanophotonic structures and have encompassed both conventional inverse-optimization approaches as well as nascent machine-learning (ML) strategies. However, inverse-optimization processes are computationally-intensive, and image generation-based ML design techniques which can facilitate the generation of complex geometries require exhaustive investigation to produce stable results. Moreover, the possibility of using machine learning approaches to enable forward design (that is, to effectively function as an electromagnetic simulator) has largely been unexplored. Here, we demonstrate that stable and well-established deep learning architectures such as convolutional neural networks (CNN) can effectively enable "forward design" and thereby replicate the functionality of a traditional numerical electromagnetics solver, for a limited class of nanophotonic structure. We then show that the same networks can also be utilized for "inverse design" by leveraging neural network interpretability and visualization methods. To illustrate this capability, we trained a CNN model with 10,000 images of selective mid-infrared thermal emitters and their corresponding absorption spectra. The trained CNN established the relationships between nanophotonic structures and their responses, then predicted the responses of new and unknown designs with over 95% accuracy. After training the CNN, we applied the Shapley Additive Explanations (SHAP) algorithm to the model to determine features that made positive or negative contributions towards specific spectral points, thereby informing which features to create or eliminate in order to meet a target spectrum. These explanations, for the first

time, allow us to systematically understand the underlying physical relationship between a given nanophotonic structure and its electromagnetic response. We demonstrate a concrete example of the CNN and SHAP algorithms recovering a previously known analytical relationship between the length of a metal-insulator-metal metamaterial resonator and its resonance wavelength. We also show how this approach can yield insights into why more complex, optimized designs are able to perform well, for instance in terms of their spectral peaks or shapes of their electromagnetic modes. Furthermore, using this strategy, we show that a starting electromagnetic metasurface design can be selectively manipulated to create or remove spectral peaks, thus demonstrating that inverse design can be achieved by exposing the valuable information that is hidden within a neural network. More broadly, our results highlight that emerging approaches to opening the 'black box' of neural networks can yield real physical insights into the relationship between a given nanophotonic structure and its electromagnetic response. Deep learning approaches such as the one we implement can thus enable physics discovery and elucidate the design of broad classes of nanophotonic materials and devices.

Non-Hermitian Selective Thermal Emitters Using Hybrid Metal-Semiconductor Resonators Gururaj Naik; Rice University, United States

Thermal emitters always have absorption losses and hence are open systems. Open systems are non-Hermitian and are best described by non-Hermitian physics. Here, we develop a non-Hermitian description of resonant thermal emitters and thereby take advantage of absorption loss in the system. Further, the non-Hermitian description provides new design tools such as symmetry, phase, and topology to control the properties of thermal emission. We demonstrate such a thermal emitter using coupled plasmonic and photonic resonators. A lossless silicon photonic resonator is coupled to a lossy tungsten plasmonic resonator via a spacer. As the spacer thickness is increased, the thermal emission from the device held at 1000 K exhibits a transition from PT-symmetric to symmetry-broken phase through an exceptional point. The thermal emission from the device breaks the trade-off between emission brightness and spectral selectivity and simultaneously achieves both. Further, we show that the internal phase of resonators is a powerful tool to control the thermal emission from this device. Overall, this work is an unorthodox approach towards designing not only thermal but also other nanophotonic light sources.

Full and Grey-Scale Structural Colors Using Array of Engineered Mie-Resonators Jaehyuck Jang and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Mie-resonators scatter when its size is comparable to the wavelength of the incident light. The scattering modes of Mie-resonator are determined by its size and refractive index. The nanostructures composed of high index material such as silicon can have multipole scattering modes in visible regime. When Mie-scatterers are arrayed, the scattering response can be greatly amplified; the subwavelength arrays of the resonators are called metasurfaces. To properly design metasurface, the hybridization of radiation mode of scatterer and lattice effect, i.e. guided-mode resonance (GMR), must be understood. Nevertheless, the exact mechanism behind the scattering response of metasurface has not been fully addressed so far. A precise understanding of the scattering mechanism may enable to design metasurface as spectral filters, i.e. metasurface structural coloration [1-3].
Herein, we would like to provide the scattering mechanisms behind the hybridization between individual scattering mode and lattice effect, and use them to realize full and grey-scale structural coloration by silicon-based metasurface [4]. The array of silicon resonators play three roles: (i) Diffraction grating for momentum matching to allow lattice coupling, (ii) waveguide of laterally propagating light through lattice, (iii) outcoupler which determines radiation modes to free-space. Through multipole expansion and RCWA simulation, we have successfully verified our design method to modulate bandwidth of lattice coupling and resonant peaks of radiation. For experimental demonstration, we chose two types of silicon for metasurface: silicon(P25) and (P45). Silicon(P25) has a higher refractive index and extinction coefficient than silicon(P45) so that radiation modes coupled to lattice differ from each other under the same geometry. As an application, silicon(P25)- and (P45)-based metasurface has been utilized for full and grey-scale structural colors, respectively. We believe that a solid understanding of the coupling between individual Mie resonators and the lattice resonances can be a strong basis for designing all-dielectric structural colors for applications in advanced imaging, ultrahigh-definition television (UHDTV), and other display technologies.

Wavefront Shaping and Modulation with High-Q Electro-Optic Metasurfaces David R. Barton, Mark Lawrence and Jennifer A. Dionne; Stanford University, United States

Metasurfaces sculpt the phase, amplitude, and polarization of light at subwavelength scales, allowing for unprecedented control of the far field. For applications spanning LIDAR, LiFi, and AR/VR, it is imperative that metasurfaces be reconfigurable, for example able to steer light to particular directions, change their focal lengths, and otherwise react to their environment. However, the subwavelength size of metasurface constituents makes modulation and reconfigurable designs challenging to realize, as the interaction of light and matter is generally very weak. Here, we introduce an electro-optic scheme for reconfigurable and modulatable metasurfaces. Using Lithium Niobate (LNO) as part of the nanoantenna design, we utilize an electric field to change the refractive index, which modifies the phase gradient response. While the electro-optic effect is generally quite weak (r_{33} ~30 pm/V), we employ high quality factor resonances to increase the environmental sensitivity of the diffraction, significantly reducing the required DC electric field strength. We provide designs in the near infrared based on 1 dimensional arrays of 600 nm tall silicon nanobars on top of a 200 nm layer Lithium Niobate. A design consisting of bar widths of 175 nm, 236 nm, and 350 nm repeated every 1.8 microns leads to beamsteering metasurfaces with 70% diffraction efficiency of 1400 nm light into the $+1^{st}$ diffraction order. Subtle periodic purturbations in the form of grooves into the largest bar couples normally incident light into guided mode resonances. On resonance, at wavelengths near 1400 nm, the beamsteering efficiency drops from 70% to less than 7%, with an increase in the -1^{st} diffraction intensity (~20%). In addition to this strong contrast (~10 dB), light is trapped within the silicon bar and leaks into the LNO layer. We capitalize on both of these effects to create an efficient electro-optically tunable metasurface with an applied DC electric field. We show with full-field electromagnetic simulations that applying a DC electric field modifies the refractive index of the LNO, shifting the spectral position of the guided mode resonance. At 1400nm, this manifests in the far field as an obvious change in the diffraction spectrum from beamsteering in the $+1^{st}$ order to the -1^{st} order with an applied electric field. Using full device simulations we show that, due to strong modal overlap with the electro-optic material and the high quality factor of the guided resonance, electrically tunable beamsteering and beamsplitting metasurfaces can be achieved with low (less than 15V) operating voltages. Via preliminary simulations, we also demonstrate methods to push this dynamic metasurface design principle to visible wavelengths using lithium niobate, rather than silicon, as the metasurface element. Our work shows the broad applicability of high-Q resonant LNO-based metasurfaces as reconfigurable optical devices, for applications spanning ultra-compact LIDAR, efficient and dynamic focusing elements for ultrathin cameras and displays, and dynamic manipulation of light at the nanoscale.

1:30 PM F.NM02.04.45
Roll-to-Roll Fabrication of Dielectric Metasurfaces Joon-Suh Park[1], Xinghui Yin[1], Karl K. Stensvad[2,2], Robert L. Brott[2,2], Martin B. Wolk[2,2], James M. Nelson[2,2] and Federico Capasso[1]; [1]Harvard University, United States; [2]3M, United States

In recent years, the idea of using structures of subwavelength scale has led to the birth of what is now called “Flat Optics” or “Metasurfaces.” Metasurfaces locally impart phase shifts, amplitude modulations, and polarization changes to the outgoing light, and therefore achieve the resulting wavefront that performs one or more optical functions. As the metasurfaces can be as thin as the wavelengths with which they interact while achieving near-ideal optical functionalities, the reduction of volume and weight compared to those of the traditional refractive optical elements poses a great advantage in applications where footprint and payload are of concern.
Many experimental demonstrations of metasurfaces were designed to work in the visible or near-infrared wavelengths and therefore were required to use optically transparent materials. Their structure dimensions range from tens to hundreds of nanometers and require high-resolution lithography techniques such as electron beam lithography. When such fabrication methods limited size scalability and mass-producibility, other widely used CMOS compatible, wafer-based fabrication techniques, such as deep-ultraviolet (DUV) lithography and nano-imprint lithography (NIL), were also introduced as promising approaches.
In this presentation, we depart from the conventional wafer-based approaches and instead use roll-to-roll (R2R) fabrication methods to realize optically functional metasurfaces. As demonstrated by the many film manufacturing industries, R2R methods provide scalability in size, and throughput, while reducing the per-unit cost for large volume applications. An example of an industrial R2R film format would be rolls of film with lengths on the order of 1 km.
However, the transition from the wafer-based approach to a R2R compatible process has introduced a pair of challenges to overcome. First, as the R2R fabricated products are wound into rolls of film, free-standing nanostructures are undesirable for

reasons related to robustness and integration. We therefore design metasurfaces comprising high-refractive index nanostructures embedded in an optically transparent, low-refractive index material for process and end use compatibility. Second, embedding the nanostructures comes at a cost: The overall height of the nanostructures needs to be increased from that of the free-standing metasurface elements to compensate for the refractive index contrast loss and to achieve the same optical functionality. This requires a departure from direct replication techniques of NIL, which have intrinsic limitations on aspect-ratio.
Successful implementation of a R2R process to fabricate a metasurface requires careful reconsideration of the optical design step. The optical design not only needs to consider the optical properties of the constituting materials, but also constraints arising due to process demands, such as sidewall draft angles. In this presentation, we discuss both design and fabrication strategies to create embedded metasurfaces using a R2R process and also show resulting fabricated examples. In detail, we present a R2R fabricated, TiO2-based embedded metasurface with optical functionality in the visible spectral region. We believe that the presented method paves the way to industrial-scale production of metasurfaces.

Dynamic Manipulation of Hybridized Epsilon-Near-Zero Resonances in Optical Fibers Jingyi Yang[1], Khant Minn[1], Aleksei Anopchenko[1] and Ho Wai (Howard) Lee[1,2]; [1]Baylor University, United States; [2]University of California, Irvine, United States

Optical fiber is a well-established waveguiding technology that has been employed in a wide variety of applications such as data communications, spectroscopy, and imaging, remote sensing, surgeries, seismic activity monitoring, etc. However, the defining attributes of an optical fiber (for instance, mode intensity and propagation loss) are fixed after drawing fabrication due to the dielectric properties of the constituent materials. Zero-index photonics, with vanishing permittivity (epsilon) and permeability values, have been studied for unique and extreme optical properties [1]. Ultrathin epsilon-near-zero (ENZ—the real part of permittivity approaches zero) layer can support plasmon polariton mode with enhanced and highly confined optical field [2]. Recent studies on ultrathin transparent conducting oxide (TCO) ENZ films have reported various optical applications such as enhanced nonlinearity [3, 4] and electrically tunable meta-devices [5, 6] among others.
In this work, we demonstrate for the first time the active nonlinear optical and electrical control of hybrid ENZ resonances in thin aluminum-doped zinc oxide (AZO) film integrated onto D-shaped optical fiber. The AZO film is deposited on the polished side of the fiber via atomic layer deposition (ALD) and possesses ENZ property in the near-infrared regime. The guided core mode of unpolished fiber is launched at the input. At the D-shaped portion of the fiber, the evanescent optical field interacts with the AZO layer on the polished side, coupling to the ENZ mode in the ultrathin film which can be detected at the output as a dip in the transmission. Meanwhile, a pump beam from an ultrafast femtosecond laser at the ENZ wavelength is incident on the AZO film from the air. The enhanced pump field due to the ENZ effect inside the AZO layer induces enhanced Kerr nonlinearity, leading to the modulation of complex refractive index and the shift in the ENZ resonance of the coupled fiber mode which is detected at the output as modulated transmission. As a result, the polarization-dependent propagation loss of AZO-coated fiber can be tuned with modulation strength of ~3.5 dB/mm near the ENZ wavelengths with the fs laser intensity of 150 GW/cm^2. On the other hand, due to the tunable optical properties of the AZO film, the mode propagating in the ENZ optical fiber can be dynamically manipulated by introducing the AZO-HfO_2-Au gate structure and applying bias. Our preliminary results show that the transmission dip of the hybridized epsilon-near-zero resonance redshifts ~20 nm with an applied bias of 5 V. The dynamic control of optical fiber modes by hybridization with ENZ resonance offers an alternative way of manipulating the ENZ property and functionality of optical fiber, which can find applications in tunable attenuator, polarization-controller, and other active optical fiber devices.

Light Driven Space Exploration Artur Davoyan; University of California, Los Angeles, United States

At present deep space exploration is limited by transit time and overall mission costs. Conventional spacecraft make use of chemical or electric engines, which have fundamental limitations on the possible speed one can achieve. Light driven propulsion offers a conceptually different approach to space travel. Without a need to carry propellant and power on board, spacecraft propelled by the forces of radiation pressure can attain very high velocities, potentially close to relativistic speeds. In this talk we will discuss our recent work on solar and laser driven spacecraft propulsion.

Specifically we will discuss the use of high power laser radiation for space exploration within our solar system. We outline key dynamical equations and solve for possible trajectories. We show that with realistic systems parameters month long planetary missions are possible. We then discuss laser requirements, such as power and aperture. And show that relatively moderate power lasers (~1MW) may be utilized. Next we also study materials and photonic designs. We analyze a tradeoff between mass, reflectance and a need for a radiative cooling. Finally, suggest a range of materials and designs that can yield a desired performance.

In the talk, we will also touch upon the use of solar radiation pressure to propel a spacecraft. We show that solar sails with high area-to-mass ratio may be propelled to >30 AU/year velocities (i.e., more than 8 times faster than the Voyager – fastest space probe we've ever built). Achieving such velocities will pave the way to a new era of affordable and scalable deep space exploration. At the same time such velocities are achieved by a very close perihelion slingshot, where the spacecraft may face extreme conditions. We perform a feasibility study. Specifically, outline conditions needed for maximizing excess velocity and, hence, minimizing mission time, while at the same time ensuring spacecraft durability over the course of the mission. Our estimates show that sails based missions with >30 AU/year are feasible.

Enhanced Photoluminescence of MoS_2 Monolayers on Epsilon-Near-Zero TiN Films Aleksei Anopchenko[1], Khant Minn[1], Ching-Wen Chang[2], Yu-Jung Lu[3,4], Shangjr Gwo[2,3] and Ho Wai (Howard) Lee[1,5]; [1]Baylor University, United States; [2]National Tsing-Hua University, Taiwan; [3]Academia Sinica, Taiwan; [4]National Taiwan University, Taiwan; [5]University of California, United States

We present a study of room-temperature photoluminescence (PL) of MoS_2 monolayer flakes on TiN thin films. The TiN films of several thicknesses are grown on sapphire substrates by molecular beam epitaxy (MBE) [1] and magnetron sputtering [2]. The permittivity and thickness of TiN films are obtained by spectroscopic ellipsometry that shows the presence of a region of near-zero permittivity (ENZ) in visible wavelengths. Monolayer MoS_2 flakes, grown on silicon substrates using chemical vapor deposition, are transferred onto TiN and sapphire substrates using the dry-stamping method [3]. Before transferring MoS_2 monolayers, the TiN films were coated by a thin layer of aluminum oxide (Al_2O_3 spacer) using atomic layer deposition to avoid PL quenching due to metallic TiN.
PL spectra are obtained using a confocal laser scanning microscope with 405, 445, 488 and 561 nm excitation wavelengths. PL signal has neutral A- and B-exciton peaks and charged A^- trion peak. The observed PL is stronger for the MoS_2 monolayers on TiN than sapphire substrates for all used excitation wavelengths. The PL enhancement factors are measured as the ratio of areas under the PL peaks for TiN and sapphire substrates and calculated using a luminescence modelling method based on the dyadic Green's functions [4-6]. A good agreement is observed between measured and calculated enhancements. For small Al_2O_3 spacer thickness, the PL enhancement has the maximum at the excitation wavelength that matches the ENZ wavelength of TiN films. An 8-fold PL enhancement is observed for a thicker spacer due to a positioning of MoS_2 monolayer in the anti-node of the standing wave above the TiN film. Larger PL enhancements are reported for MBE-grown than sputtered TiN films because of the lower optical losses of single-crystalline TiN films.
We also calculated absorptance and electric field intensity enhancement in MoS_2 monolayer as a function of the excitation wavelength. The increase in absorptance and field enhancement around the ENZ wavelength of TiN films is observed. Thus, the ENZ substrate enhances absorption and electric field of light excitation in MoS_2 monolayer and hence enhances its spontaneous emission. This study will enrich the fundamental understanding of spontaneous emission on ENZ substrates that might find applications for the development of advanced nanophotonic light sources.

Al:ZnO with Enhanced Doping Efficiency by Atomic Layer Deposition as a Platform for Near-Zero-Index Photonics Dhruv Fomra, Kai Ding, Vitaliy Avrutin, Ümit Özgür and Nathaniel Kinsey; Virginia Commonwealth University, United States

In the last two decades, several technological breakthroughs have been closely linked to material discovery and development. Just as development of gallium nitride, high purity silica, and high-k dielectrics provided the foundation for the progress in solid state lighting, optical fibers, and integrated circuits, near-zero-index materials (NZI) have great potential to drive advancements in nanophotonics, nonlinear optics, and quantum optics. In addition to exhibiting enhanced light-matter interaction due to slow light effects, these materials offer excellent electrical and optical tunability. Due to these unique properties, NZI materials have already led to demonstrations of dynamic metamaterials, ultrafast photonic modulators, and extreme all-optical processes. Among a wide range of NZI materials explored for these applications, Al doped ZnO, which has a vanishing index in the telecommunication bands, is particularly attractive combining high electrical conductivity and transparency in the visible range, well-established ZnO fabrication technology, high solubility limits of Al, and the abundance of Zn in nature. To realize the potential of ZnO as a material platform for NZI photonics, there is a need for scalable deposition methods yielding high-quality material. Atomic layer deposition (ALD) is a versatile technique due to its ability to provide conformal, uniform, and pin-hole free thin films with sub-nanometre thickness control over large area at low deposition temperatures. However, NZI films grown by ALD have typically suffered from poor optical quality, exhibiting reduced free-carrier density and higher loss when compared to those grown by other methods.
In this work, we overcome the limitations impeding the deposition of high quality ZnO:Al by improving the doping efficiency (ratio of electron concentration to total Al content in the matrix) of the ALD method from 13% commonly reported in literature to 54%. As a result, we demonstrate films with low losses ($\varepsilon'' < 0.35$), high conductivity ($\rho \sim 2.8\times10^{-4}$ Ω-cm) and sufficiently high carrier density (8.5×10^{20} cm^{-3}) to enable Al doped ZnO films with NZI regions tunable across both O and C telecommunication bands, for the first time. This significant material improvement became possible by moving away from the conventional ALD process of depositing doped films in a “digital” manner, wherein one dopant layer of AlO_x is incorporated periodically into the ZnO matrix and Al:ZnO is formed by the out-diffusion of Al into ZnO. Intuitively, such a process is very inefficient and leads to the creation of an inhomogeneous film where dopant atoms do not contribute to the free carrier density, but rather form clusters that increase carrier scattering and reduce the metallicity. However, moving away from the surface saturation condition during the Al precursor pulse, which is characteristic of the conventional ALD approach, leads to enhanced Al incorporation in each dosing cycle. This has been realized by utilizing H_2O/DEZ/TMA pulse sequence to increase competition between Zn and Al precursors (diethyl zinc, DEZ, and trimethyl aluminium, TMA) for the surface sites, thus reducing the amount of Al precursor supplied in each pulse to decrease surface coverage of Al precursor, and by concurrently increasing the substrate temperature to lower the density of OH groups on the surface, which act as active sites. Such growth conditions allowed us to incorporate the dopant cycle 4x more frequently in the growth process (every 0.5 nm, as opposed to every 2 nm for conventional ALD) and ensure a more uniform distribution of Al throughout the film, simultaneously increasing the doping efficiency and reducing density of clusters. Furthermore, this process provides a pathway to improve the electrical and optical properties of other emerging doped binary semiconductors such as doped GaN, CdO, and Ga_2O_3 grown using ALD.

Plasmonic Modes and Spasing in Metaphotonic Nanostructures Viktoriia Babicheva; University of New Mexico, United States

Plasmonic nanostructures can significantly enhance electric and magnetic fields at nanoscale dimensions. Fields localized at nanosized plasmonic nanostructures can be several orders of magnitude higher than the incident light field, and this field enhancement strongly affects light-matter interaction processes in plasmonic nanostructures. Here, we study field enhancement in nanoparticle clusters and periodic arrays and analyze surface plasmon amplification by stimulated emission (spaser) in such nanostructures. We consider both sphere and disk plasmonic nanoparticles and employ full-wave numerical simulations for modeling field enhancement. Planar optical elements with efficient light control at the nanoscale can be

designed based on transdimensional photonic lattices that include three-dimensional-engineered nanoantennas supporting multipole Mie resonances and arranged in the two-dimensional arrays to harness collective effects in the nanostructure. Periodic arrays of nanoparticles have gained special attention because of extraordinary lattice resonances in proximity to the wavelength of diffraction, the so-called wavelength of Rayleigh anomaly. Using full-wave modeling, we numerically observe plasmonic modes with even and odd field distributions in nanoparticle clusters and identify spatial regions with nodes and anti-nodes of the field enhancement. We use quantum density matrix (optical Bloch) equations for the spaser, calculate the plasmon amplification, and show its correspondence to the total mode characteristics. Because of the strong field enhancement in the plasmonic nanostructures, amplification of plasmons in nanoparticle clusters and periodic arrays is more efficient than ones in the proximity to a single nanoparticle and can be used an ultra-compact light source in optical devices and medical applications. Acknowledgment. This material is based upon work supported by the Air Force Office of Scientific Research under Grant No. FA9550-19-1-0032.

Color Tuning with Nanoparticle Decorated TiO2 Electrospun Fibers in Electrochromic Applications Cavit Eyovge; University of Twente, Netherlands

Titanium dioxide (TiO2) has attracted a lot of attention in plenty of applications varying from batteries, photo/electro-catalysis to optoelectronics and sensors. Although there are many different procedures for synthesizing sound TiO2 layers, methods leading to one dimensional (1D) structures are of interest due to having superior properties. Electrospinning is one of those methods to synthesize 1D mesoporous TiO2 fibers. Having the advantages of high surface area and ease of functionalization, those fibers can be quite beneficial in optoelectronic applications. Here in this study, nanoparticle (NP) decorated TiO2 fibers were formed with a modified electrospinning method and used as an active layer in an electrochromic (EC) device. A coaxial nozzle was used to form a core/shell type of TiO2/NP fibers. Structural and morphological properties were characterized by various techniques, such as scanning electron microscopy (SEM), transmission electron microscopy (TEM) and x-ray diffraction (XRD). Fibers of 198.66±21.47 nm average diameter were confirmed to have the anatase phase of TiO2. The effects of different NPs such as silver (Ag), gold (Au) and copper(II) oxide (CuO), on optical properties were also investigated. The ultraviolet/visible/near-infrared spectroscopy (UV/Vis/NIR) revealed that depending on the absorption wavelength of the decorative NPs used, it is possible to tune the band gap of TiO2/NP final composite structure. Governing effects of the composite structures on electrochemical properties were evaluated in half-cell configuration in which EC layers were cycled in between ±3V. It was observed that the color attained can also be altered with different NPs. For instance, Ag shows a black-brown color while Au yields dark blue and CuO leads to a dark green color under negative bias. In addition, fast switching times below 10 seconds were possible in each TiO2/NP configuration. This is attributed to the faster kinetics of electrospun fibers in redox reactions.

5:10 AM F.NM02.05.02
Surface Plasmon Polaritons for Energy-Tunable Hot Carriers and Electrochemical Probing of Strong Coupling Blake S. Simpkins[1], Wonmi Ahn[2], Jeremy H. Pietron[3] and Igor Vurgaftman[1]; [1]U.S. Naval Research Laboratory, United States; [2]Excet, United States; [3]Lawrence Livermore National Laboratory, United States

We use surface plasmon polaritons (SPPs) as the foundation for examining two important phenomena. First, SPPs were used to generate energy-tunable hot carriers that can be injected into semiconductors or molecular systems, opening a new pathway to drive photo-induced chemical reactions. [1] Unlike metal nanoparticles that suffer from resonance inhomogeneity and limited spectral tunability, metal films support SPPs that are homogeneous in-plane and accessible by simply tuning an illumination angle in a broad spectral range. We measured light-induced electrochemical currents of a metal/semiconductor heterofilm (Ag/TiO2) and a bare metal film (Au) interfaced with a sodium hydroxide:methanol solution. We observed plasmonic electrochemical currents and extracted a strong photon-energy dependence of the photon-to-carrier conversion efficiency. This phenomenon was described using a Schottky transport model. Secondly, we examined strong optical coupling between the SPP mode and a thin molecular dye film. The dye, methylene blue (MB), is redox active enabling examination of the electrochemical response under strong coupling conditions. Our results demonstrate full modulation of the Rabi splitting, a diffusion-limited redox process, and imaging of molecular adsorption/desorption on the metal surface. All of

these results have important implications for chemistries enhanced or enabled by light-matter interactions. [1] Ahn, W., Vurgaftman, I., Pietron, J. J., Pehrsson, P. E., and Simpkins, B. S. "Energy-Tunable Photocatalysis by Hot Carriers Generated by Surface Plasmon Polaritons" J. Mater. Chem. A., 2019, 7, 7015-7024.

5:20 AM F.NM02.05.03
Delineating Photothermal and Photoexcitation Effects in the Photoelectrodeposition of Cuprous Oxide James Lowe and Robert Coridan; University of Arkansas, United States

Cuprous oxide (Cu2O) is an earth-abundant, p-type semiconductor of interest to photovoltaic and photoelectrochemical applications. Cu2O can be synthesized direclty into its semiconducting phase by electrodeposition, rather than requiring a high-temperature calcining step as is necessary for most other electrodeposited metal oxides. as a result, Cu2O electrodeposition rates can be enhanced by illumination during growth. in recent work, we showed that photoelectrodeposition forms a composite of Cu2O doped by Cu nanocrystals throughout, resulting in a black film with high abosorptivity across the visible spectrum. Continued growth is enhanced even for illumination with energies smaller than the band gap of Cu2O due to the sensitivity of the Cu2O electrodeposition to local temperatures at the electrode-electrolyte interface. Here, we describe experiments to discriminate the local photothermal and photoelectrochemical effects in the photoelectrodeposition of Cu2O. Identifying the role of each effect will lead to more robust control over the composition and structure of Cu2O-based interfacial heterostructures. In addition to standard spectroscopic and electrochemical characterization, we will describe novel experiments that use in situ high-speeed microscopy to unveil the complex interplay between light and heat on the electrodeposition of Cu2O.

5:30 AM F.NM02.05.04
Discerning Between All Possible Activation Mechanisms in Plasmon-Driven Nanoparticle Syntheses Rifat Kamarudheen, Guus Aalbers, Ruben Hamans and Andrea Baldi; Dutch Institute for Fundamental Energy Research, Netherlands

Noble metal nanoparticles find applications in a wide range of fields, from (photo)catalysis, to bioimaging, and surface enhanced Raman spectroscopy. One of the most striking characteristics of these nanoparticles is that they can sustain localized surface plasmon resonances (LSPRs), light-driven oscillations of conduction electrons that give rise to strong scattering and absorption of light. These LSPRs can be used to activate a wide range of chemical and physical processes at the metal surface. For example, plasmon resonances have been used to perform the light-driven synthesis of hierarchical metal nanoparticles in solution with high yields and precise morphologies.1,2 The growth of these nanostructures can be linked to the decay of LSPRs via several different mechanisms: 1) plasmonic enhancement of the electromagnetic field at the nanoparticle surface that activates photosensitive precursors, 2) photothermal heating that accelerates kinetically limited reactions following the Arrhenius law, and 3) plasmonically-generated (intraband) and photo-generated (interband) electrons and holes that can catalyze redox reactions. In most plasmon-driven chemical reactions, however, these mechanisms are challenging to disentangle and typically occur simultaneously. Furthermore, the relative weight of their contributions is heavily dependent on the illumination and sample geometries.3 For these reasons, it would be ideal to develop a plasmon-driven process in which all the possible activation mechanisms can be assessed independently. Here, we develop a plasmon-assisted synthesis of Au@Ag core@shell nanorods in which interband “hot” holes are the only driving force of the reactions. Using a combination of extinction spectroscopy, transmission electron microscopy, thermal characterization, and finite-difference time-domain (FDTD) simulations, we can unequivocably exclude any effects due to photothermal heating, near-field enhancement, and intraband electrons and holes. In our experiments, we compare the growth rate of Ag shells while exciting either the transverse or the longitudinal resonances of Au nanorods using 532 nm and 730 nm continuous wave lasers, respectively. The laser powers in the two cases are modulated to obtain the same total amount of absorbed optical power in the solution and therefore the same magnitude of photothermal effects. We find that the Ag shell growth rate under 730 nm irradiation equals the one in the dark and therefore shows no plasmonic enhancement. On the contrary, the rate is strongly enhanced under 532 nm irradiation, although such enhancement slowly decreases and becomes negligible as the Ag shell approaches ~5 nm in thickness. The striking rate disparity under identical total absorbed power demonstrates the non-thermal nature of the enhancement mechanism. Furthermore, using FDTD we show that the intensity of the scattered electromagnetic fields at the nanorod surface increases with increasing Ag shell thickness. Near-field enhancements cannot therefore explain the observed time evolution of the reaction rate when using 532 nm light. Finally, the absence of any enhancement rate under 730 nm irradiation, which corresponds to an energy just below the interband transition of gold, shows that d-band “hot” holes in gold are the main responsible for the effects observed under 532 nm irradiation. Strikingly, these holes have typical mean free paths of a few nanometers, corresponding to the Ag shell thickness at which plasmon-driven effects are quenched. Understanding the mechanism of plasmon-activated chemistry at the surface of metal nanoparticles is of paramount importance for a wide range of applications, from the rational design of novel light-assisted

nanoparticle syntheses to the development of plasmonic nanostructures for catalytic and therapeutic purposes. 1. Jin, R. et al. Science 294, 1901–1903 (2001) 2. Zhai, Y. et al. Nat. Mater. 15, 889–895 (2016) 3. Kamarudheen, R. et al. ACS Nano 12, 8447–8455 (2018)

Nanometer-Resolution Electron Spectroscopy of Plasmonic Nanostructures in Reactive Liquid Environments Alan Dai, Michal Vadal and Jennifer A. Dionne; Stanford University, United States

Sustainable and industrial photochemical and photocatalytic reactions, including artificial photosynthesis, organic synthesis, and pollutant degradation, require nanoparticle catalysts in liquid environments for physically significant reactivity. Plasmonic nanostructures have emerged as materials which promise enhanced efficiency and selectivity at milder conditions compared to traditional metal catalysts. However, developing more efficient plasmon catalysts requires investigating them at the single and sub-particle level, monitoring their properties at particular spatial and temporal coordinates throughout a reaction. This approach both prevents the averaging of plasmonic responses across an ensemble of particles as well as enables the capture of variations in plasmonic and catalytic behavior across and within a single particle. In-situ transmission electron microscopy (TEM) has seen recent use in vacuum and gaseous environments to obtain real-time information of plasmonic nanostructures and monitor plasmon-driven reactions at sub-particle spatial and millisecond time resolution. Here, we bring these techniques to aqueous- and organic-phase environments via in-situ liquid TEM. We perform combined scanning TEM and monochromated electron energy loss spectroscopy (EELS) on a model system of individual Au nanoparticles, measuring and comparing their plasmon resonance energies for distinct chemical environments. We use a variety of particle shapes ranging from 30–100 nm in size, synthesized both through colloidal (reduction of AuCl4 in CTAB solution) and lithographic (e-beam lithography and metal lift-off) methods onto a specially designed liquid cell chip. Two such chips are used to enclose a small pocket of liquid for stable imaging and spectroscopy in the TEM. Selecting particles located in thinner regions of liquid (< 100 nm thick), we demonstrate that plasmon resonances can be measured with sub-second total acquisition times while maintaining sufficient signal-to-noise ratios, circumventing the dominant liquid background signal and without any interfering electron-induced side reactions. Furthermore, we observe that enough spectral resolution is maintained to differentiate resonances corresponding to spatially dependent visible modes in each shape of particle. For example, across colloidally synthesized Au rods bound to a SiN membrane, we measure longitudinal and transverse resonances which normally lie at 700-900 nm and 500-600 nm in vacuum but experience a 30-50 nm and 5-10 nm redshift, respectively, in water. Likewise, for lithographically fabricated triangular prisms we map edge and tip modes around 490 and 520 nm, respectively, in vacuum, and we observe a similar redshift to that of the rods when immersed in water. These trends quantitatively agree with calculated results from BEM methods for the geometries examined. We then change the solvent in the liquid cell via flow tubing, showing that Au particles experience a shift in plasmon resonance arising from the refractive index change of varying liquid environments vs. vacuum, agreeing with simulations. This work provides the foundation for in-situ TEM characterization of plasmonic catalysts for critical reactions in solution such as biosynthesis and water splitting.

Ultrafast Carrier Dynamics of GaAs by mid-IR Pump-Probe Spectroscopy Roisul H. Galib, John A. Tomko, David Olson, Ashutosh Giri, John Gaskins and Patrick Hopkins; University of Virginia, United States

Ultrafast laser spectroscopy is a versatile technique that is commonly used to both understand and manipulate carrier scattering mechanisms in semiconductors. We report the observation of excited carrier relaxation times in GaAs using optical pump mid IR probe spectroscopy. We find a sharp change in relaxation times occurs at the intervalley transitions of GaAs. Our results also show the relaxation times becomes faster with increasing photoexcitation fluence. These results provide direct evidence that excited carrier decay at greatly different rates based on their energy relative to the conduction band minimum. These findings provide additional insight into the energy-dependent nature and rate of phonon emission during electronic relaxation.

Orientation Sensing from Optical Microscopy Images by Deep-Learning Jingtian Hu[1], Tingting Liu[1], Priscilla Choo[1], Shengjie Wang[2], Thaddeus Reese[1], Alex Sample[1] and Teri W. Odom[1]; [1]Northwestern University, United States; [2]University of Washington, United States

Automated particle-tracking techniques are important for studying biological processes ranging from tissue deformation to cellular uptake. Existing tracking methods, however, only focus on visualizing the translational motion but not rotational motion, which can also provide critical information on cellular activities such as membrane protein diffusion. The development of next-generation particle-tracking platforms that can characterize rotational dynamics requires concurrent

advances in imaging strategies and computational analyses.
This presentation reports a deep-learning rotation-tracking platform based on 3D nanoparticle imaging probes and differential interference contrast (DIC) microscopy. We obtained libraries of DIC images at each sampled nanoparticle structure and orientation for training the prediction models based on convolutional networks. These models predicted the in-plane orientation of gold nanorods based on simulated and measured DIC images with an accuracy only limited by the inherent resolution of the technique. Using low-symmetry gold nanostars as imaging probes, the method could resolve particle rotations in the full 0-360° range by accounting for DIC patterns at multiple wavelengths simultaneously. This deep-learning method could make consistent orientation predictions that are insensitive to varying imaging backgrounds. Finally, we demonstrated the simultaneous prediction of in-plane and out-of-plane orientations from a 3D nanostar by analysis of DIC images collected at multiple wavelengths.

Phase-Resolved Surface Plasmon Scattering Probed by Cathodoluminescence Holography Nick Schilder, Harshal Agrawal, Erik C. Garnett and Albert Polman; AMOLF, Netherlands

We introduce cathodoluminescence holography to directly retrieve the phase of light scattered from nanoscale objects. We use 30-keV electrons to coherently excite with a nanoscale spatial precision surface plasmon polaritons (SPP) that subsequently scatter from either nanoholes made in a Ag film or single-crystalline Ag nanocubes. We use transition radiation excited at the electron impact position as a broadband reference to create a far-field interference pattern that is collected in both angular and spectral domain. From the holography data we directly resolve the SPP dispersion and probe the phase of resonant coupling of SPPs to individual nanoscatterers. From the far-field wave fronts we derive the full basis of scattering dipoles using a modal decomposition analysis and unravel the relative strength and phase of all SPP-excited dipolar modes. We also show that scattering from a SPP off a helical nanoaperture leads to chiral light in the farfield. We observe experimentally a topological charge of -1. Cathodoluminescence holography takes advantage of the nanoscale electron excitation source and can find a broad range of applications to probe surface wave scattering by individual nanoscatterers.

Plasmonic Surfaces as Optical Components for Infrared Sensing and Imaging Jyotirmoy Mandal and Aaswath P. Raman; University of California, Los Angeles, United States

In recent years, infrared (IR) optical systems have been increasingly used in imaging and sensing applications, as evidenced by a surge in demand for infrared sensors during the COVID-19 pandemic. However, cost and ease of fabrication of germanium-based optical elements used in IR systems remains a major barrier to widespread adoption, particularly in low-resource settings.

In this talk, we will demonstrate spectrally selective plasmonic surfaces as scalable and low-cost IR optical components that absorb ultraviolet-to-shortwavelength IR radiation, while showing a specular behavior in the longer infrared wavelengths. These surfaces can be conveniently manufactured at large scales, and alone or in combination with other materials, used as reflective or transmissive IR optical components.

The talk will present FDTD simulation results that validate the concept, and present experimental demonstration of the optical capability (selectivity, specularity and integrability into optical systems) using a specific plasmonic design. Since the fabrication, physical operation and application of our designs span different fields, a short, interdisciplinary overview of related challenges and opportunities will also be presented.

Acknowledgments: Jyotirmoy Mandal was supported by Schmidt Science Fellows, in partnership with the Rhodes Trust.

Enhancing Graphene's Plasmonic Tunability via Its Dielectric Environment Amun Jarzembski, Michael Goldflam and Thomas Beechem; Sandia National Laboratories, United States

Graphene's high mobility, linear band structure, and two-dimensional density of states result in tunable optical properties within the infrared (IR) that present new opportunities for dynamic multifunctional detectors and filters. Being atomically thin, however, necessitates field confinement to achieve practical utility. Graphene plasmons serve this purpose by both concentrating the electric field while "carrying" the tunability, which is dependent upon the charge concentration within graphene. In addition to graphene's electronic properties, its surrounding optical environment has a profound effect on the plasmonic response. Thus, design of the dielectric layers used to facilitate the electrostatic doping of graphene- required for active tunability- is of critical importance. Recognizing this fact, we examine here how dielectric layers can be chosen to enhance the spectral tunability of graphene plasmonic devices. To this end, the tunability of graphene's plasmonic dispersion is quantified relative to the dielectric atop of which it sits by solving for poles in the imaginary part of the reflection coefficient in a multilayer model. By solving for the dispersion at varying Fermi-levels (i.e., charge concentrations), the extent of tunability is quantified. Tunability varies appreciably between several materials typically employed in graphene plasmonic devices-HfO2, SiO2, and Al2O3. The causes for this material variation are then examined by assessing the dependence of tuning relative to parameters making up the transverse-optical longitudinal-optical (TOLO) dielectric function, which typically describes the optical properties of the dielectrics employed. Paths are highlighted by which synthetic multilayer oxides can be designed to enhance tuning in graphene devices beyond that presently attainable.

Non-Reciprocal Electrodynamics and Axion Field in Weyl Semimetal Co3Sn2S2 Dennis M. Nenno[1,2], Christina Garcia[1], Claudia Felser[2] and Prineha Narang[1]; [1]Harvard University, United States; [2]Max Planck Institute for Chemical Physics of Solids, Germany

Co3Sn2S2 is an ideal Weyl semimetal in its magnetic phase [1]. Its ground state is antiferromagnetic and electromagnetic fields can induce a phase transition between the two states [2]. Using ab-initio tools, we analyse the axion field [3] and the linear and non-linear optical responses in the two phases of this time-reversal breaking compound. Our calculations include both electron-electron scattering events, as well as interactions with phonons [4]. We discuss how the phases can be distinguished from each other by their optical and electrical response, how the axion field in the Weyl semimetal state provide a way to realise non-reciprocal thermal emitters [5] and finally, present results on the shift-current generation and second-harmonic emission.

Origin of Energy Blueshift in a Tunable Microcavity with 2D-Perovskite Based on Free-Standing Thin Films Karolina Lempicka[1], Magdalena Furman[1], Marcin Muszynski[1], Mateusz Król[1], Adam Wincukiewicz[1], Katarzyna Rechcinska[1], Rafal Mazur[2], Maria Kaminska[1], Wiktor Piecek[2], Pawel W. Majewski[1], Jacek Szczytko[1] and Barbara Pietka[1]; [1]University of Warsaw, Poland; [2]Military University of Technology, Poland

Recently, interest in organic-inorganic perovskites has increased due to their application in photovoltaics, photonics and optoelectronics. They have also been used as a strong light emitters in the microcavities, due to the possibility of obtaining strong light-matter coupling regime, and the occurrence of coherent macroscopic effects, such as Bose-Einstein condensation of exciton-polaritons. Compared with multi quantum wells heterostructures produced by epitaxial growth of inorganic semiconductors, 2D perovskites displays stronger dielectric confinement in the inorganic layers, whereas excitons in such materials are characterized by a higher binding energy and exhibits strong nonlinearities. It indicates that the devices based on polaritons in 2D perovskites layers can work stable at the room temperature.

Optical and electronic properties of perovskites can be easily tuned by changing the thickness, which makes them an ideal system for the investigation of strong light-matter coupling phenomena. In this direction, we studied the unusual photoluminescence (PL) behavior in function of temperature of a 2D-layered perovskite-type semiconductor, $(C_6H_5(CH_2)_2NH_3)_2PbI_4$ deposited on a dielectric

mirror prepared from a solution using spin-coating technique as well as free-standing layers of 2D-perovskite with substrate from solution P2611:NMP. The low-temperature (〈110 K) photoluminescence of 2D perovskite reveals two distinct emission peaks. Furthermore the bandgap exhibits an unusual blueshift (about 7 nm) with increasing temperature from 4.5 to 295 K. The temperature-driven additional photoluminescence peak can be attributed to the presence of molecularly disordered domains.

We demonstrate a strong light-matter coupling regime between the excitonic resonance in 2D-perovskite and cavity photon in an open, tunable microcavity at room temperature. Exciton-polaritons in this material are expected to show unusually strong non-linear effects due to significant third order Kerr nonlinearity. At strong excitation conditions (up to 1 mW) we observe emission blueshift up to 8 meV from polariton mode. We demonstrate that this blue-shift can be attributed to the non-linear polariton interaction and the change of exciton-photon interaction strength. Exploring emission characteristics of a 2D-perovskites in wide range of temperatures and under strong light-matter coupling conditions provides a lot of important information regarding the performance of a light-emitting device, solar cell based on perovskites and physics phenomena related to non-linear effects observed previously only at cryogenic temperatures.

5:00 AM F.NM02.07.01
A Refractive-Index-Controllable Si Nanoparticle-Polymer Composite Material for Terahertz-Range Optical Devices and Anti-Reflective Coating Application Junshi Soeda[1], Yoichi Kawada[2], Hiroshi Satozono[2], Hironori Takahashi[2], Masayuki Chokai[1] and Yoshinori Ikeda[1]; [1]Teijin Limited, Japan; [2]Hamamatsu Photonics K.K., Japan

Owing to advancements in related technologies over the last few decades, terahertz waves possess the potential to be utilized in fields related to imaging, non-destructive testing, analysis, and next-generation telecommunication, among others. Optical elements are also currently being explored as tools that can extend the applicability of terahertz (THz) waves. One obstacle in the development of THz optical elements is that there are fewer feasible materials that have different refractive indices in THz frequencies than there are such materials in other frequency ranges. Specifically, the options for transparent optical materials are limited to polymethylpentene, other olefin-based polymers, and highly resistive silicon.
In this study, we developed a highly transparent composite material composed of polymer and silicon nanoparticles (SiNPs) for THz optics; the refractive index can be controlled by varying the fraction of SiNPs in the composite. We also demonstrated its applicability as an anti-reflection (AR) coating for Si optical elements prone to reflection loss due to the large discrepancy between the refractive indices of Si and air.
Highly pure SiNPs with a typical diameter of 100 nm were employed to control the refractive index of the composite. The SiNPs were fabricated via a laser pyrolysis method. This method entails laser irradiation to decompose semiconductor-grade monosilane gas; hence, the SiNPs have extremely low metal impurity (i.e., on the order of ppb) and consequently, high resistivity. The utilization of highly resistive Si creates favorable conditions for THz waves as it allows for the composite material to be transmitted without absorption. Furthermore, the problem of wave scattering is eliminated, as the typical diameter of the SiNPs is smaller than the wavelength of THz waves by a factor of 1000.
We first characterized the basic optical properties of the SiNPs and its composite with a polymer chosen for present study. THz-wave transmission was characterized via THz time-domain spectroscopy of the SiNP films deposited on highly resistive Si (HR-Si) wafers. The transmission spectrum was observed to be in agreement with the spectrum calculated from the thickness, porosity of the film, and refractive index of Si; this indicated that the THz waves were not significantly absorbed or scattered by the film.
The refractive indices of the SiNP-polymer composites were also evaluated from the transmission spectrum of the composite films on HR-Si. The refractive index was controlled between 1.52 and 1.95 under a Si-content range of approximately 0–30 vol%.
Subsequently, for demonstration, we designed and fabricated bilayer AR coatings to apply to the Si plates. The SiNP-polymer composite layer (n = 1.95) and polymer layer (n = 1.52) were stacked on both sides of the Si plates. The amplitude transmittance of the Si plates with AR coatings exceeded 90%, with a bandwidth of 0.8 THz at around 1 THz, whereas in the case of Si plates without AR coatings, the transmittance was expected to be 70%.
In conclusion, we developed a novel refractive-index-controllable SiNP/polymer composite material for THz-range optics. The SiNPs demonstrated negligible absorbance and scattering of THz waves, confirming their suitability for THz-range

optics applications. Additionally, the refractive index of the composite was controlled between 1.52 and 1.95. This range addresses several existing limitations regarding THz-range optical element designs. Furthermore, the AR coating developed using the proposed composite material successfully increased the transmittance of THz waves through Si. Thus, the proposed composite material can be applied in the design of various types of THz-range optical elements and has the potential to be used for developing optical elements with higher functionality.

ITO-Based Epsilon-Near-Zerp Photonics—From Modulators to Optical Limiters Volker J. Sorger, Mario Miscuglio, Yaliang Gui and Rubab Amin; George Washington University, United States

The material class of transparent conductive oxides features a variety of properties that are interesting and useful for optical and opto-electronic applications. ITO belonging to this class has shown to be either processed (Gui et al, Nat. Sci. Rep. 2019), or electro-statically-biased (Sorger et al., Nanoph. 2012) into the ENZ regime. Here, I review our latest work including; (1) ITO ENZ material deposition control, (1) the first ITO-based phase-shifters in silicon photonics with VpL=0.5V-mm (Amin et al, APL 2018) and 0.06V-mm performance (Amin et al, arXiv 1907.11131 2019), (2) electro-optic nonlinear activation function in feed-forward photonic neural networks (Amin et al, APL Mat. 2019), (3), optical-phase array in silicon-ITO photonics for GHz-fast beam steering, (4) a metatronic circuit board towards an analog photonic computer for PDEs, and (5) strong nonlinearity in ENZ ITO showing ~10dB of optical limiting.

5:20 AM F.NM02.07.04
Spray-Deposited Metal-Chalcogenide Photoconductors and Photodiodes for Low Cost Infrared Imagers Tommy O. Boykin II[1], Nagendra Dhakal[1], Javaneh Boroumand[1], F. Javier Gonzalez[1], Isaiah Oladeji[2], Pedro Figueiredo[2], Stephen Neshul[3] and Robert Peale[1]; [1]University of Central Florida, United States; [2]Truventic, LLC, United States; [3]iCRco, United States

Low cost, light-weight, low-power, large-format, room-temperature, mid-wave infrared (MWIR) detectors are needed for drones, unmanned aerial systems (UAS), unmanned aerial vehicles (UAV), and other reduced-scale aircraft. An opportunity, suggested by direct-read X-radiography systems, is the use of thin-film transistor (TFT) array as read-out integrated circuit (ROIC) for low-cost sensors deposited directly and unpatterned onto this ROIC. TFTs have already been thoroughly optimized for power, weight, large-format and cost by the flat panel display industry. We present experimental investigation of aqueous-spray-deposited, mid-wave-IR, metal-chalcogenide photoconductors and heterojunction photodiodes for this application. Measured responsivity, detectivity D*, and photoresponse spectra are reported for ternary PbSSe photoconductors and PbS/CdS photodiodes.

5:30 AM F.NM02.07.05
Vertically Heterogeneous n-Doped CdO Films as a Platform for Infrared Nano-Photonics—Mode Coupling and Hyperbolicity Joshua Nolen[1], Angela Cleri[2], Thomas Folland[1], Evan Runnerstrom[3,4], Kyle P. Kelley[5,4], Mingze He[1], Simone De Liberato[6], Nader Engheta[7], Jon-Paul Maria[2] and Joshua D. Caldwell[1]; [1]Vanderbilt University, United States; [2]The Pennsylvania State University, United States; [3]U.S. Army Research Office—Materials Science Division, United States; [4]North Carolina State University, United States; [5]Oak Ridge National Laboratory, United States; [6]University of Southampton, United Kingdom; [7]University of Pennsylvania, United States

Doped transparent conducting oxides (TCOs) have recently found utility as potential alternative plasmonic materials. One highly promising TCO which has been demonstrated to exhibit broad tunability while maintaining exceptionally low optical losses is highly-doped CdO. This is due to CdO possessing both a low effective mass (ranging from 0.12-0.26 in epitaxially-grown films with carrier densities ranging from 1019-1020 cm-3) as well as electronic mobilities extending upwards to 500 cm2/V-s with carrier densities ranging from 1019 to 1020 cm-3. Unique to this material is a range of carrier densities where increasing values result in increasing mobilities. Due to the low optical losses and broadly tunable plasma wavelength, CdO has been shown to support, carrier tunable surface plasmon polaritons (SPP) and epsilon-near-zero (ENZ) modes throughout the mid-infrared (MIR). These ENZ modes are associated with extreme electric field confinement, enabling control over light-matter interactions such as resonant perfect absorption and strong nonlinear interactions. Here we show how vertically heterogeneous films of doped CdO can be leveraged to create different nanophotonic phenomena across the infrared. Careful control over the carrier density during film growth has opened the door to achieving multilayer homoepitaxial CdO films. Despite the homogeneity of the crystal structure, the elevated carrier density and carrier density dependent changes to Fermi energy and effective mass confine carriers to their constitutive layers. Owing to this material's low carrier diffusivity multilayer stacks composed of deeply subwavelength thickness CdO films, each supporting ENZ modes at different frequencies, exhibit multifrequency absorption/emission. Further, prior work has shown that epitaxially-grown bilayer stacks

of CdO, with bottom and top layers supporting SPP and ENZ modes respectively, exhibit strong coupling between the ENZ and SPP modes. The combined ENZ-SPP dispersion of these bilayer films displays a prominent anti-crossing with a separation that is dependent on both the spectral and spatial overlap of the modes. Here we have extended our focus to trilayer CdO films, where an unintentionally-doped (Nd ~ 1x1019 cm-3, much less than Nd of the SPP or ENZ layers) CdO film is grown between the SPP and ENZ layers. The spacer layer thickness modifies the spatial overlap of the constituent electric fields as well as alters the effective index of the region above the SPP layer, decreasing the degree of spectral splitting and shifting the anti-crossing position to higher momentum. The strong carrier confinement in doped CdO also allows for the engineering of extreme anisotropy in multilayer CdO films. By growing CdO layers of subwavelength thickness and alternating carrier densities (low-doped acting as a dielectric layer, high-doped as a metallic layer) hyperbolic metamaterials can be realized in a fully plasmonic, homoepitaxial system. In these metamaterials, the sign of the in- and out-of-plane components of the dielectric function are opposite in sign. This leads to an open hyperbolic dispersion relation which allows for the propagation of high-momentum, and therefore highly-confined, optical modes. Through careful control over the carrier densities and thicknesses of the CdO layers, tunable hyperbolic resonances can be supported throughout the MIR, allowing for the potential realization of next generation emission devices and subwavelength imaging.

5:40 AM F.NM02.07.06
Ultra-Short-Period Undulators for the Next Generation X-Ray Free Electron Lasers Derya Berkin Gurel[1], Omer Polat[1], Nilay Gunduz Akdogan[2] and Ozan Akdogan[1]; [1]Bahcesehir University, Turkey; [2]Piri Reis University, Turkey

There is a growing interest on the compact XFELs to be used in applications such as medical science (surgery, fat removal), material science and military. In order to build a compact XFEL, constructing an undulator with sub-millimeter period (?u) is mandatory. Many problems arise due to miniaturization of undulators; such as keeping the magnetic field high while still having a considerable gap to minimize beam scraping. In this work, RADIA program has been employed for the modeling of sub millimeter period undulators (20 μm < ?u < 400 μm) with three different magnet configuration; namely Up-Down(↑↓↑↓…), Halbach (Wiggler) (↑→↓←↑…) and Hybrid(→↑←↓→…). Effects of sub-millimeter undulator period and gap on the magnetic field pattern of the undulator have been discussed. This work was supported by TUBITAK project: 118F319

5:50 AM F.NM02.07.08
Super Mossian Nanophotonic Demonstrated with Iron Pyrite Chloe F. Doiron and Gururaj Naik; Rice University, United States

All dielectric nanophotonics has opened new pathways for engineering optical metamaterials, enabling a wide range of optical devices including perfect reflectors, magnetic mirrors, and flat optics. One method to decrease the size of nanophotonic resonators and increase the quality factor of resonances is to use materials with larger refractive index. However, it is commonly stated that the bandgap and refractive index of semiconductors are related to a constant through the empirical rule $n^4 \times E_g \approx 95$ eV referred to as the Moss rule. From this rule, it is expected that any increase in refractive index comes at the cost of decreased bandgap. Because of the corresponding increase in optical losses, this is detrimental to optical devices operating in the sub-bandgap region. While the constant of 95 eV works for a variety of materials, this constant only works for materials with similar band structures. Here, we experimentally demonstrate iron pyrite (FeS2) as a high index material platform for nanophotonics with refractive index greater than 4.5 in the mid-IR. This high refractive index is obtained with a bandgap of 0.95 eV, resulting in FeS2 surpassing the common form of the Moss rule by over 40%, making iron pyrite a super Mossian optical material. Furthermore, we will present experimental results of an optical bound state in the continuum (BIC) in nanoscale FeS2 resonators showing the potential for high index super Mossian materials in nanophotonics. Finally, we will conclude with a discussion on the electronic and optical properties to screen for to aid in the identification of additional super Mossian materials.

6:00 AM F.NM02.07.09
Optical Isolation in III-Nitride Photonics Ganapathi Subramania[1], Keshab Sapkota[1], Nicholas Karl[1], Adam Backer[1], George Wang[1], Igal Brener[1], Zachary Meinelt[2] and Daniel Feezell[2]; [1]Sandia National Laboratories, United States; [2]The University of New Mexico, United States

III-Nitride based nanostructures can be designed to create photonic crystals or metamaterials that operate in the visible frequency regime. Nanophotonic devices that are important for many applications like solid-state lighting and quantum information science and flat optics can be enabled using such structures. A key issue in creating optical nanostructures in III-nitrides has been in creating optical isolation from the high refractive index GaN growth template due to a lack of compatible natural low index materials. In silicon photonics this is mitigated by using silicon-on-insulator substrate that provide a low

index silicon oxide cladding, while in III-V semiconductors such as GaAs this is achieved by oxidation of high Al content AlGaAs buffer layer. While there are some examples in III-nitrides such as observation of low threshold lasing in nanowire array geometry photonic crystals [1], achieving simple optical isolation for membrane PhC, metasurfaces and VCSEL structure has been a challenge. A recent work [2] has demonstrated electrochemically etched nanoporous layers can provide lower index isolation. Here we will discuss achieving optical isolation in III-nitride nanophotonic devices using electrochemical/ photo-electrochemical [3] etching techniques. We will describe the fabrication of GaN nanowire array with optical isolation and present optical response to demonstrate the effectiveness of this approach.
Sandia National Laboratories is managed and operated by NTESS under DOE NNSA contract DE-NA0003525..

Electromechanically Tunable Metaphotonic Color-Imaging Devices Min Ho Lee[1], Sung-Min Lee[2] and Kyung Cheol Choi[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Kookmin university, Korea (the Republic of)

Metaphotonic materials and systems can create unusual optical properties through the interaction between light and artificial nanostructures. Such unusual properties can allow color imaging devices over the diffraction limit level (~100,000 dpi) that cannot be simply implemented with conventional imaging technology. Although these ultra-high resolution imaging technologies have shown substantial potential for applications that handle static images, such as color filters and printing, the feasible options for dynamic imaging technology using passive metaphotonic elements have not been fully demonstrated, impeding their application in active display devices.
Motivated by these issues, we introduce electrically controllable active color imaging metaphotonic devices consisting of metal/insulator/metal nanodisk stacks; the resonance modes of these stacks can be reversibly changed by structure deformation. To achieve the function of electrically driven mechanical deformation, disk elements of inconsistent size are designed, and electric potential is applied between the upper and lower metal disks, where the large upper metal disk can be bent by columbic force of induced reciprocal charges. The tunable gap between the stacked metal disks provokes resonance mode change, thereby resulting in variation of the transmission/reflection spectra. The fabricated metaphotonic nanodisk stacks exhibited a reasonable shift in reflectance spectra when sufficient electrical voltage was applied, which demonstrated the feasibility of sub-wavelength imaging technology for application in display devices.

Optical and Electrical Properties of Organic Semiconductor Thin Films on Aperiodic Plasmonic Metasurfaces Zhongkai Cheng, Nasir Javed and Deirdre O'Carroll; Rutgers, The State University of New Jersey, United States

Metal electrodes are playing an increasingly important role in controlling photon absorption and in promoting optimal light management in thin-film semiconductor devices. For organic optoelectronics devices, it is challenging to control the surface of the metal electrode to promote good light management because metal electrode deposition is used as the last step in the conventional device fabrication approach. However, an inverted fabrication approach that builds the device on top of a metal electrode, makes it possible to control the morphology of the metal surface, independently of the organic semiconductor active layer, to achieve a variety of photonic and plasmonic behavior useful for optoelectronic devices. Silver (Ag) is one of

the most suitable metals for fabrication of nanostructured electrodes with plasmonic behavior (i.e., plasmonic electrodes) because of its low parasitic absorption loss and high reflectivity.

In this work, we study the physical and optical characteristics of Ag nanoparticle (AgNP) aperiodic plasmonic metasurfaces. Then, we investigate the photonic and electrical behavior of the AgNP plasmonic metasurfaces when interfaced with thin films of the organic semiconducting polymer, poly(9,9-dioctylfluorene-alt-benzothiadiazole) (F8BT), using the inverted fabrication approach. The luminescence quantum yield of F8BT thin films increases from 29% on planar silver up to 66% on AgNP metasurfaces due to the Purcell Effect and the improved extraction of emission coupled to surface plasmon polariton (SPP) modes. In particular, we show that plasmonic enhancement can overcome ohmic losses associated with metals and metal-induced exciton quenching. According to the current-voltage characteristics of F8BT hole-only devices with and without plasmonic metasurfaces, we conclude that AgNP plasmonic metasurfaces have comparable electrical behavior to planar metal electrodes while having superior light management capability.

All Plasmonic Nanophotonic Device Displaying Passive PT-Symmetry Frank Yang, Chloe F. Doiron and Gururaj Naik; Rice University, United States

In quantum mechanics, Hamiltonians exhibiting real eigenvalues are often Hermitian. However, non-Hermitian systems that respect parity-time (PT) symmetry can also possess real eigenvalues. PT-symmetric Hamiltonians display unconventional behavior, such as the coalescence of eigenmodes at exceptional points. This unconventional behavior allows optical devices to take advantage of symmetry, topology, and phase, enabling new functionalities in ultra-sensitive sensing and lasing. There are two approaches to satisfying PT-symmetry in optics: active and passive. Active PT-symmetry requires a system with balanced optical gain and loss. Because of the difficulty of adding gain in nanophotonic systems, passive PT-symmetry is an ideal method for demonstrating PT-symmetry at the nanoscale. In comparison, passive PT-symmetry requires both nearly zero and large optical losses. While plasmonics has enabled many new optical devices, there have been no demonstrations of PT-symmetry in all plasmonic systems due to the large optical losses of plasmonic materials, which limit loss asymmetry. Here we will present an experimental demonstration of an all plasmonic system demonstrating passive PT-symmetry. To achieve this, we engineer a coupled plasmonic antenna system exhibiting large loss asymmetry. The system undergoes a PT phase transition as the coupling, or separation, between the antennas is varied. At high coupling, the system is in a PT-symmetric phase with two resonant absorption peaks. With decreased coupling, the peaks coalesce at the exceptional point. Further decreasing the coupling results in an optical phase transition to a broken PT-symmetric phase with a single resonant absorption peak. Using our nanophotonic PT-symmetric system, we will conclude with a discussion on guidelines for implementing PT-symmetry in nanophotonic devices.

F.NM02.08.07
Unity Order Index Tunability at Room Temperature in 1T-TaS2—A Strongly Correlated Material Weijian Li, Ming Yi, Kevin Kelly, Gururaj Naik and Frank Yang; Rice University, United States

Strongly correlated materials could greatly respond to a stimulus due to their collective behavior. Thus, strongly correlated materials are well studied in the past for their tunable properties, especially electrical and thermal. However, their optical properties remain to be explored. In this work, we study the optical properties of 1T-TaS2, a quasi-2D material supporting charge density waves (CDW). 1T-TaS2 is the only material to exhibit a nearly commensurate CDW phase at room temperature and its electrical and thermal properties are shown to exhibit a large change with temperature, DC and AC biases, pressure, and light. Here, we study the optical properties of 1T-TaS2 under DC and AC biases, different intensities of optical illumination, and at different temperatures. Under all these conditions, we observe a unity-order change in the refractive index of thin films of 1T-TaS2. We hypothesize that the stacking of CDWs in this material changes with stimulus resulting in its optical constants to change. ARPES and STM measurements are underway to verify the hypothesis. Our discovery of the large tunability of optical constants of 1T-TaS2 presents opportunities in studying light-matter interaction in strongly correlated materials and its application to nanophotonic devices.

A Novel Approach to Tailor the Band Structure of Metal-Organic Framework Nanocrystals in One-Dimensional Periodic Array for Light Induced Energy Transfer Applications Sujoy Saha, Joseph Sarobin and Hemali Rathnayake; JSNN, University of North Carolina, United States

The study of band structures of different types of Metal-Organic Frameworks (MOFs) is indispensable for the advancement

of nanoelectronics. We designed a novel approach to predict and tailor the band structure of MOFs nanocrystals in a one-dimensional periodic array through the variation of structural and materials parameters. From the Bloch condition of the Schrodinger equation, we could predict the amplitude of potentials, ? and ? for periodically arranged MOFs only in one-dimension using experimental values of dielectric constant, absorption and emission peaks of MOFs. Predicting energy band structures of the one-dimensional array of an isoreticular MOF, IRMOF-8A using a theoretical method combined with experimental values of dielectric constants and amplitude of potentials provide insight into electronic band energy to tailor optoelectronic properties of MOFs and understanding their energy transfer capabilities with respect to the different ligand type. The dielectric constants of three different IRMOFs synthesized from the same metal precursor (Zn2+) and three different organic ligands with varying conjugation length were predicted from this novel approach. Band gap depends on the amplitude of potentials, which is a function of the conjugation length of the ligand and its dielectric constant. Thus, the effective conjugation length of the ligand in MOFs have a significant impact on the jumps between two allowed bands in energy band structures of the 1-D array of MOFs. This design method can widely applicable for predicting band energy for any designed MOFs and serves as a versatile tool to tailor and predict the electronic properties of MOFs with different ligand units.

F.NM02.08.09
Hybrid Plasmonic Nanostructures for Biomolecular Sensing Debadrita Paria[1], Chi Zhang[1], Steve Semancik[2] and Ishan Barman[1]; [1]Johns Hopkins University, United States; [2]National Institute of Standards and Technology, United States

Metal nanostructures are well known for various ultra-sensitive spectroscopic applications because of their ability to concentrate and enhance the local electromagnetic field due to a phenomenon called localized surface plasmon resonance (LSPR). The intense light localization, also known as "hotspot", becomes more pronounced near a narrow plasmonic gap. In this work, we report tailored hybrid metal nanostructures for LSPR sensing and surface enhanced Raman spectroscopy (SERS) of serum albumin. Using a combination of physical vapor deposition and thermal annealing, different hybrid metal nanostructure configurations have been fabricated, which create well defined arrangements of hotspots. The hybrid metal nanostructures have multiple resonance peaks, which demonstrate the capability of the identification of ultra-low differences in refractive index (0.001) when combined with machine learning algorithms. A detailed FEA simulation of these plasmonic nanostructures provides a quantitative estimate and the spatial distribution of hotspot closely match our experimental observations. The simulations also help us understand the various interactions between the nanostructures via their near field. Finally, these structures also show potential for sensitive label-free SERS detection. Overall, our study explores an integrated multimodal biosensing platform featuring LSPR combined with machine learning and surface enhanced Raman spectroscopy (SERS) for quantitative determination of concentration and molecular fingerprinting.

F.NM02.08.11
Optical Properties of Random Nanoparticle Films Made of Spheres with an Overlapping Electric and Magnetic Dipole Response Parker Wray and Harry Atwater; California Institute of Technology, United States

We investigate theoretically the unidirectional optical scattering properties of random monolayer particle films composed of dielectric particles that support overlapping electric and magnetic dipoles. The particle films exhibit dramatic reflection and transmission behavior which are manifest in the forward-to-backward scattering ratio of the nanoparticle building block. We also show that these films do not exhibit polarization dependent scattering and lack a traditional Brewster's angle. Our theoretical analysis uses a generalized version of Mie theory, which accounts for particle coupling effects, and was validated by full-wave simulations. For fill fractions up to 40% the average scattering response of an embedded particle is shown to accurately predict the behavior of the random film, and the overlap of the electric and magnetic dipole resonances are found to be robust to effects of particle coupling. Continuing research will extend this analysis to multi-layer particle films. This work indicates potential for the design of optical filters and anti-reflective coatings using single materials, without the need for self-assembly.

Imaging Single Particle Enhanced Upconversion Luminescence from NaYF4:Yb3+,Tm3+ Nanoparticles on Plasmonic Substrates Anahita Haghizadeh[1], Aravind Baride[2], Stanley May[2] and Steve Smith[1]; [1]South Dakota School of Mines and Technology, United States; [2]University of South Dakota, United States

We use single particle spectroscopic imaging and statistical analysis to assess the plasmonic enhancement of NIR-to-visible upconversion luminescence (UCL) from single ?-NaYF4:Yb3+:Tm3+ upconverting nanoparticles (UCNPs) supported on substrates consisting of random arrangements of Ag nanowires (NW) and Au nano-cavity arrays. We measure both apparent luminescence enhancement, which is power dependent due to the nonlinear kinetics of energy transfer upconversion (ETU),

and the excitation enhancement, defined as the ratio of the excitation intensity needed to produce a given UCL emission, divided by the equivalent power needed to produce the same emission on the plasmonic substrate1. By examining the effects at the single particle level, and accumulating a statistical sampling of single particle emitters, both on and off the plasmonic substrates studied, we can eliminate the effects of particle fluctuations on the apparent UCL emission enhancement and map out the statistical distribution of excitation and luminescence enhancement on the plasmonic substrates. The distributions obtained are reproduced by Finite Difference Time Domain (FDTD) calculations of the fields near the plasmonic substrate, assuming the variations are due to variations in UCNP coupling to the plasmonic substrate based on an exponential decay with distance. We compare these results to statistical analysis of ensemble measurements made of Er3+ doped UCNPs supported on random Ag NW substrates2 and both wide field and confocal spectroscopic imaging of single UCNPs on and off the plasmonic substrates. F.NM02.08.14

Full Factorial Experimental Optimization of Gold Nanostructures Fabrication by Solid-State Dewetting for SERS Siarhei Zavatski[1,2], Hanna V. Bandarenka[3,2] and Olivier J. Martin[1]; [1]Ecole Polytechnique Federale de Lausanne, Switzerland; [2]Belarusian State University of Informatics and Radioelectronics, Belarus; [3]Arizona State University, United States

The optimization of nanostructures for a specific application is a rather complex task, often akin to shooting in the dark with the hope of hitting the right target, viz. the best performing nanostructure. This difficulty stems from the usually large number of experimental parameters that can be changed in a nanotechnology process. This is the case for example in the fabrication of plasmonic nanostructures for surface enhanced Raman scattering (SERS): the choice of metal, its thickness, the shape of the nanostructures as well as their distribution on the substrate are all parameters that determine the overall Raman enhancement. Even for a relatively simple design, exploring all possible combinations of parameters is a prohibitive task both in terms of nanofabrication time and costs. In that contribution, we focus on the large scale fabrication of plasmonic nanostructures using solid-state dewetting and demonstrate how a full factorial design technique can efficiently optimize the process. In that approach, a target response for optimization and two specific values for the n fabrication parameters are first chosen, leading to an initial set of 2n experiments [1]. Here, as experimental parameters we consider the gold film thickness, the annealing temperature and time, and the heating rate; with the objective of maximizing the intensity of the SERS signal, specifically the 1363 cm-1 vibrational band of Rhodamine 6G. The corresponding 16 experiments provide a model of the dependency of the Raman enhancement on the four experimental parameters considered here. In the classical optimization procedure by full factorial design, this dependency is chosen linear. The set of experimental parameters that is obtained in this first fit of linear model does not necessarily lead to the strongest Raman enhancement and another set of experiments may be required. However, the full factorial approach also provides the direction in the parameter space in which one needs to move these parameters to reach a better solution. After such a solution is found, the linear model may need to be refined using second order functions to clarify the optimum region. This is usually done with the central composite experimental design [2]. The optimization process for the fabricated samples is documented in detail by studying the morphology and optical properties of each sample by scanning electron microscopy and UV-Vis spectroscopy. The gold nanostructures we fabricated this way have typical dimensions in the 50 nm range, which is in good agreement with data reported in the literature [3]. Furthermore, the optimized plasmonic substrate can be used to identify non-resonant bioorganic macromolecules such as bovine serum albumin. This work reveals an effective approach to optimize nanofabrication processes for large-scale and cost-effective production of uniform and highly sensitive SERS substrates. [1] Leardi, R. Analytica chimica acta 2009, 652(1-2), 161-172. [2] Box, G. E., & Wilson, K. B. J. R. Stat. Soc. Series B Stat. Methodol. 1951, 13(1), 1-38. [3] Krug et al. J. Am. Chem. Soc. 1999, 121, 9208-14.

F.NM02.08.15

Planar Nanophotonic Structures for Intensity-Based Readout Refractive Index Sensing of Dissolved Methane Morgan Blevins[1,2,3], Anna Michel[1] and Svetlana Boriskina[2]; [1]Woods Hole Oceanographic Institute, United States; [2]Massachusetts Institute of Technology, United States; [3]MIT-WHOI Joint Program, United States

As global temperatures rise, permafrost in the Arctic is thawing, stimulating increased release of methane, a key greenhouse gas. Accurate measurements of the dissolved methane concentration in seawater and freshwater are important for finding and quantifying the release of natural seabed and Arctic methane seeps to better understand how these sources are contributing to increasing global methane levels. In surface waters, the methane concentration can be as low as 3-10 nM (atmospheric

equilibrium) while concentrations as high as 800-1000 nM are found in methane saturated deep seawater and near thawing permafrost. To measure the concentration of dissolved methane, changes in the refractive index (RI) of polymers functionalized to selectively trap methane molecules can be measured via an optical readout mechanism. However, the range of the RI change is very narrow, from 1.41198 to 1.41358 for atmospheric to saturated methane concentration levels ranging from 0 nM to 300 nM, which requires the use of highly sensitive optical sensors. This paper analyzes and compares three simple and low-cost planar nanophotonic and plasmonic structures as optical transducers for measuring refractive index change of polydimethylsiloxane (PDMS) polymer films doped with cryptophane-A molecules, which selectively trap methane. These structures include (i) a Bragg reflector with a defect layer, (ii) a hybrid plasmonic-photonic multi-layer stack that supports a Tamm plasmon mode, and (iii) a hybrid plasmonic-photonic stack that acts as a magnetic mirror, and can be used in a simple intensity-based measurement scheme with low cost light sources and detectors. Through numerical simulations, we evaluate the sensitivity of the proposed structures in both the angular-resonant-mode shift readout mode and in the reflectance intensity readout mode and compare them to the standard surface-plasmon-polariton-mode Spreeta sensor as a reference. Our results show that the planar Bragg reflector with a defect layer exhibits the largest intensity response and is the most promising design for a low cost and robust photonic chip for dissolved methane sensing. A practical implementation of this chip with a simple intensity-based measurement scheme is proposed. Integration of this planar structure into a small, portable, and low-cost dissolved methane sensor offers a way to make climate monitoring more widespread and accessible to researchers. The structures evaluated here all show promise for other chemical and biological sensing applications that require monitoring very small RI changes. Significantly, each structure has been designed to support resonant modes in both s and p polarizations, which allows enhanced sensitivity by calculating the ratio of the spectral responses of orthogonal polarizations, similar to the complex reflectance ratio measured with ellipsometry. Importantly, the response in both polarizations only needs to be monitored in the reflectance intensity readout mode, avoiding the use of expensive and large ellipsometry equipment.

F.NM02.08.16
Identifying Plasmon-Like Excited States in Bare and Ligand-Protected Metal Nanoclusters Rebecca Gieseking; Brandeis University, United States

Noble metal nanoclusters containing dozens to hundreds of metal atoms are of great interest because of their unique optical properties. Classical electrodynamics fails to describe the optical properties of clusters smaller than a few nm, so quantum mechanical models are needed to describe these clusters. However, it is challenging to identify which features of the computed excited states indicate plasmon-like character, particularly in a way that is generalizable to the ligand-protected clusters that are commonly studied in experiments. We present an analytical method to identify plasmon-like excited states using three quantifiable indicators that must be considered in combination: (1) large superatomic character, (2) large collectivity among single-particle excitations, and (3) large additivity of contributions of these single-particle excitations to the transition dipole moment. Visualizing these three indicators on a single plot enables rapid classification of hundreds of excited states into plasmon-like, collective, single-particle, or interband categories, or as intermediate between these categories. This method is used to identify excited states with plasmon-like character in both bare and ligand-protected Ag clusters at the TDDFT level. Using these three nearly orthogonal indicators in combination provides more information than any one criterion can provide.

F.NM02.08.18
Stable Dispersion of Titanium Nitride Nanoparticles Idalis Hernandez, Eric Bartlett, Sanchari Chowdhury and Michaelann Tartis; New Mexico Tech, United States

Alternative plasmonic titanium nitride nanoparticles (TiN) are attractive photothermal agents because of their ability to strongly absorb a broad spectrum of light ranging from visible to near-infrared and convert that into heat. Additional advantages of low cost and stability of these refractory nanomaterials make them attractive for different applications ranging from photothermal cancer therapy to solar energy mediated catalytic reactions. In this work, we are developing a method to obtain a stable and monodispersed TiN nanoparticles solutions, which is an important prerequisite for most of their applications. Moreover, our goal is to optimize a solution based coating method to obtain a uniform well dispersed thin film of TiN nanoparticles on the substrate, which will be useful for their application in the device. However, preventing aggregation of TiN nanoparticles in a solvent has been a challenge. We have optimized protocols based on ultra-probe sonication and centrifugation, to obtain relatively monodisperse and stable TiN nanoparticles in an aqueous solution. We have applied our method to commercially available polydisperse TiN nanoparticles of average size 80nm and 20 nm. Using the optimized method we were able to decrease the polydispersity index (PDI), the measure of the distribution of nanoparticles in a solution, from 0.351 to 0.18 indicating a significantly more monodispersed solution. Moreover. we used a sol-gel based method for incorporating nanoparticles in transparent silica gels. There was no aggregation of the TiN

nanoparticles observed during the sol-gel transition. UV-Vis spectroscopy and dynamic light scattering method confirm that incorporating TiN nanoparticles in silica gel preserved both of their optical properties and the dispersibility as in the original solution. The nanoparticles stay stable in the solution for several days. A biocompatible silica coating on TiN nanoparticles can be useful for drug delivery and photothermal therapy. In summary, we are developing a simple commercially viable method to efficiently disperse and stabilize titanium nanoparticles in solution and subsequently coating them on the substrate which can easily be applied for large scale applications.

Confined Nucleation of ErAs NPs in Er:InAs QDs to Fabricate Nanoparticle Quantum Dot Hybrids Kurt Eyink, Yuanchang Zhang, Albert M. Hilton and Krishnamurthy Mahalingam; Air Force Research Laboratory, United States

Directed assembly has been the subject of extensive research over the years due to the desire to grow structures at specific locations. This is accomplished by increasing the probability of nucleation at the desired location. Mechanisms such as reduction of the diffusion of species, reduction of the strain to lower the bulk free energy to reduce the critical nuclei size, or a lowering of the surface energy which also reduces the critical nuclei size have previously been used. In all these cases, nucleation of the desired phase occurs directly on the substrate. Here we propose and demonstrate a scheme for directed assembly in which we confined the nucleation of the desired material to the region of a nanostructure formed on the surface. We accomplish this through the use of a dilute alloy containing the desired material and subsequent removal of the major constituent of the alloy inducing nucleation at some point after the dilute species exceeds it solubility limit. In particular, we use this approach to control the nucleation of ErAs nanoparticles from Er:InAs quantum dots by evaporation of InAs. We studied ErAs NP formation from InAs QD nominally doped to concentration of 1.25% and 2.5% on GaAs (001). The Er:InAs quantum dots were grown using normal conditions for the growth of undoped InAs and produced similar quantum dot densities (near 100/square micron). We explain these observed results in terms of normal nucleation and growth given the mesoscopic concentration of Er atoms expected in the InAs QD. A comparison of the undoped and Er-doped InAs quantum dots before and after InAs evaporation show the number of the ErAs nanoparticles is less than the original quantum dot density showing nanoparticle do not form in every quantum dot and suggests a critical number of Er atoms needed for nucleation. We have used our confined nucleation process in conjunction with normal direct assembly processes for InAs QDs to produce hybrid structures composed of InAs QDs and ErAs NP. We have formed vertically stacked Er:InAs QD over undoped InAs QDs to form ErAs NP over InAs QDs. We have formed Er:InAs quantum dots formed in ErAs divots to form ErAs nanoparticle clusters and have used Er:InAs to place ErAs in patterned surface. Transmission electron microscopy of these structures show that at times multiple nucleation sites are possible in the structure and suggest the potential of forming rich hybrid structures using this approach.

Optical Parameters of Bioinspired Sub-Monolayer Nanoparticle Arrays Sean R. Dinneen[1], Richard M. Osgood[1], Zhuangsheng Lin[2], Camille Martin[2], Michael Okamoto[1], Ihsan Uluturk[1] and Leila Deravi[2]; [1]Combat Capabilities Development Command Soldier Center, United States; [2]Northeastern University, United States

Cephalopods have the ability to take advantage of pigmented and structural coloration when camouflaging, signaling, or otherwise communicating through their adaptive coloration. The chromatophore, which is the actuating organ responsible for pigmented color within cephalopods, is populated with 500-600 nm diameter particles composed of pigment and protein called pigment granules. The pigment, identified as xanthommatin, has been found to have a uniquely high refractive index and contributes highly to the scattering of light with broadband optical properties. Developing metamaterials out of synthetic pigment granules, where the particle periodicity is smaller than the wavelengths of light with which they interact, was the next logical choice for us to not only further our understanding of the complex photonic system of cephalopods, but to explore its application in adaptable optical systems and possibly chemical sensing.

In this work, we aim to leverage our knowledge of biomaterials (namely the biopigment xanthommatin) to generate sub-monolayers of synthetically made pigment granules. Xanthommatin is encapsulated within polystyrene-co-maleic anhydride (PSMA) nanoparticles with good physical retention while maintaining its coloration. Sub-monolayer arrays are prepared via Chumanov-style roll-coating on substrates within a vial containing the solution of particles, and are physically characterized by scanning electron microscopy. We then show the arrays' optical properties measured by integrating sphere spectrophotometry and broadband multi-angle ellipsometry. Depending on the spacings of the particles, the arrays will resonate at certain wavelengths within the visible. Our updated models, taking into account the particle's refractive index and contribution from the pigment, will show a dependence of spacing and material on wavelength resonance. With the pigment as a functional feature within the particles, we explore the retained chemical properties (such as absorption changes with pH) with the possible inclusion of chemical sensing.

F.NM02.08.22
Spatial Inhomogeneity of Optical Binding in Many-Body Systems Fei Han; Clarkson University, United States

Optical matter can be formed by electrodynamic interactions of metal nanoparticles in an optical field. This light-mediated self-organization of nanoparticles offers a route to study mesoscale electrodynamics interactions in many-body systems. By controlling the intensity, phase, and polarization of light, the optical field can be tailored to assemble stable optical matter with up to 101 nanoparticles. Here we report that the spatial inhomogeneity of circularly polarized optical binding in a many-particle system. The spatial stability of self-organized nanoparticles is strongly influenced by the laser intensity and polarization state. In particular, the nanoparticles in the central area of an optical matter array are more stable than those on the edge. Moreover, larger arrays are self-protected from fluctuation-induced instability by incorporation more nanoparticle constituents. This study provides important information about the spatial inhomogeneity of optical binding interactions in mesoscale nanoparticle arrays.

A General Phase Function of Micro/Nanoparticle Composites Junxin Wang, Annica Nilsson and Gunnar Niklasson; Uppsala University, Sweden

Light scattering from particles show unique angular scattering patterns, which are strongly dependent on the particle size to incident wavelength ratio and the refractive index contrast between host medium and the particles. Multiple scattering becomes important when the particle concentration increases, which complicates the angular scattering distributions. In many cases, empirical phase functions have to be applied. A novel empirical phase function was introduced to describe the angle-dependent distribution of scattered light from a collection of micro/nanoparticles inside a thin layer. Angular dependence of light scattering from a polymer host containing sub-micron dielectric and metallic particles was measured. The method gives an excellent approximation to the angular effects of multiple scattering arising from aggregation, non-spherical shape and surface roughness. In addition, it is also a good approximation in the single scattering regime, since it closely reproduces scattering phase functions of particles in the Rayleigh, Mie and geometrical optics regimes. The feasibility of our approach was demonstrated by its ability to fit experimental data on the forward and backward scattering profiles of plasmonic and dielectric submicron particle composite layers. The robust and wide applicability of our method is expected to attract a board interest from researchers in physics and materials science.

F.NM01.10.02
Arylazopyrazole-Fused PDMS Composites as Solid-State Photo-Switchable Materials Ikemefuna Uba, Demetris Geddis, Kesete Ghebreyessus and Uwe Hommerich; Hampton University, United States

Arylazopyrazoles (AAP) show significant potential as a new family of molecular photoswitches owing to their efficient reversible trans-to-cis photoisomerization behavior and the high thermal stability of their metastable cis-isomer. Herein, we report on the design and synthesis of new arylazopyrazole based molecular switches with different spacer length and functional (OH, COOH) groups. The new AAPs were used for the fabrication of solid-state photoswitchable polydimethylsiloxane (PDMS) based composite films. The thin films were prepared by using PDMS as a polymer matrix and different concentrations of AAPs as chromophores at room temperature *via* spin-coating. The photoswitching behavior of the PDMS-AAP blend films and the neat AAP samples induced by irradiation with specific wavelength of light were investigated. We found that the as prepared PDMS-AAP blend films showed rapid and near-quantitative reversible trans-to-cis isomerization rates upon alternating irradiation with UV (l = 365 nm) and green (l = 525 nm) light which is comparable to the isomerization behavior of the neat AAP chromophores in solution. This indicates that the excellent photoswitching properties of AAPs are preserved in the PDMS-AAP composite films. Additionally, the as prepared PDMS-AAP films in the cis-form possess outstanding thermal stability and long-term optical stability. The results also show that the optical properties

of the PDMS-AAP composite films can be tuned by using different ratios of the AAP chromophores and exposure to UV irradiation. This methodology provides a new approach for exploring the fabrication of polymers with solid-state photoswitching functionality. The effect of concentration of the AAPs on the reversible *trans*-to-*cis* isomerization processes of the PDMS-AAP composite films will be discussed in this presentation.

F.NM01.10.09
Late News: Fabrication of a Fine-Pattern Flexible Nanowire Photodetector by Shadow Mask Mustafa A. Yildirim and Kasif Teker; Marmara University, Turkey

Recently, ultraviolet photodetectors (UVPDs) have been used on large scale applications such as environmental monitoring, flame detection, space communication, biomedical applications, pharmaceutical, and chemical analysis. Besides, advances in internet technologies such as the internet of things (IoT) endorse the integration of sensors more rapidly in every aspect of our lives. This trend demands the fabrication of smaller, lighter, less complicated, and low power devices. Therefore, designing low cost, self-powered, highly sensitive, flexible UVPD nanodevices are becoming a hot research area for near future optoelectronics. Silicon carbide (SiC), a wide bandgap semiconductor, is an excellent contender to fulfill those expectations. In addition to having characteristics of one-dimensional nanostructure such as high surface to volume ratio, high crystalline quality, SiC nanowires also possess superior material attributes like high breakdown voltage, high thermal conductivity, high drift velocity, excellent chemical and physical stability. In this study, we propose a very cost-effective, flexible, self-powered single SiC nanowire ultraviolet photodetector (SiCNW-UVPD) fabricated on a polyvinylchloride (PVC) substrate.
The self-powered flexible SiCNW-UVPD was fabricated via a commercially available transmission electron microscopy (TEM) grid (physical mask) and a sputter coater system. Gold (Au) electrodes of 110 µm x 110 µm and a gap of 4 µm were successfully achieved without the use of complicated and expensive methods like photolithography. Two-probe photocurrent-time (I-t) and I-V measurements were performed to reveal photoresponse characteristics such as the photo-to-dark current ratio (PDCR), sensitivity, and responsivity under 254 nm wavelength UV light at 0 V bias. A shallow dark current around 0.087 pA and a good PDCR value of 18 are obtained. Moreover, sensitivity and responsivity values are calculated as 1756 and 170 mA/W, respectively. In addition, the specific detectivity calculations, the effect of bias, and vigorous bending test results are discussed as well. Our work provides the following unique advantages: (i) to the best of our knowledge, the first demonstration of a single SiC nanowire PD on a flexible substrate with great performance, (ii) a very cost-effective fabrication method and readily applicable to any substrate, (iii) exhibiting high sensitivity and responsivity values under UV light at 0 V bias. Therefore, our SiCNW-UVPD device presents an opportunity for low-cost, easy to fabricate, self-powered photodetectors for upcoming future technologies such as wearable sensors, electronic skins, and the internet of things.

Late News: Combined, Localized Plasmonic Heating and Temperature Measurement in Nanocomposite Hydrogels Wei Yu, Olivier Deschaume, Stijn Jooken, Pengfei Zhang, Jolan Wellens, Fanglei Guo, Christ Glorieux and Carmen Bartic; KU Leuven, Belgium

As scaffold materials for tissue engineering applications, hydrogels can mimic many important functions of extracellular matrices found in living tissues. Local temperature gradients can greatly impact the bioactivity of the matrix and cellular processes such as adhesion, migration and differentiation [1,2], while the knowledge of local temperature is essential understanding and modulating the cell properties and their responses. Various methods have been developed and applied for thermal measurements at the nano- and micro-scales, relevant to living tissues, such as infrared thermography [3], micro-thermocouples [4], AFM with thermocouple [5] and fluorescence-based thermography [6]. However, only a limited number of successful applications have been reported regarding three-dimensional localized temperature measurements as the first three methods can only be applied in two-dimensional cases [3-5]. In this contribution, we report a versatile platform to realize localized, simultaneous heating and temperature readout in both two and three dimensions. Localized heating was implemented in hydrogels by functionalizing them with gold nanorods (GNR) with high absorption around 785 nm, while the local temperature is reported by the incorporated Rhodamine B (RhB)-loaded silica particles or quantum dots. For these thermal nano-probe, the fluorescence intensity decreases when temperature increases. In combination with the nanomaterials, a versatile optical stimulation and readout platform was developed. We demonstrate that plasmonic NIR heating could lead to localized, up to 10 degrees temperature changes in hydrogel-based cellular matrices that can be monitored in situ by fluorescent nanoprobes, both in 2D and 3D.

Optical and Electrical Properties of Organic Semiconductor Thin Films on Aperiodic Plasmonic Metasurfaces Zhongkai Cheng, Nasir Javed and Deirdre O'Carroll; Rutgers, The State University of New Jersey, United States

Metal electrodes are playing an increasingly important role in controlling photon absorption and in promoting optimal light management in thin-film semiconductor devices. For organic optoelectronics devices, it is challenging to control the surface of the metal electrode to promote good light management because metal electrode deposition is used as the last step in the conventional device fabrication approach. However, an inverted fabrication approach that builds the device on top of a metal electrode, makes it possible to control the morphology of the metal surface, independently of the organic semiconductor active layer, to achieve a variety of photonic and plasmonic behavior useful for optoelectronic devices. Silver (Ag) is one of the most suitable metals for fabrication of nanostructured electrodes with plasmonic behavior (i.e., plasmonic electrodes) because of its low parasitic absorption loss and high reflectivity.

In this work, we study the physical and optical characteristics of Ag nanoparticle (AgNP) aperiodic plasmonic metasurfaces. Then, we investigate the photonic and electrical behavior of the AgNP plasmonic metasurfaces when interfaced with thin films of the organic semiconducting polymer, poly(9,9-dioctylfluorene-alt-benzothiadiazole) (F8BT), using the inverted fabrication approach. The luminescence quantum yield of F8BT thin films increases from 29% on planar silver up to 66% on AgNP metasurfaces due to the Purcell Effect and the improved extraction of emission coupled to surface plasmon polariton (SPP) modes. In particular, we show that plasmonic enhancement can overcome ohmic losses associated with metals and metal-induced exciton quenching. According to the current-voltage characteristics of F8BT hole-only devices with and without plasmonic metasurfaces, we conclude that AgNP plasmonic metasurfaces have comparable electrical behavior to planar metal electrodes while having superior light management capability.

All Plasmonic Nanophotonic Device Displaying Passive PT-Symmetry Frank Yang, Chloe F. Doiron and Gururaj Naik; Rice University, United States

In quantum mechanics, Hamiltonians exhibiting real eigenvalues are often Hermitian. However, non-Hermitian systems that respect parity-time (PT) symmetry can also possess real eigenvalues. PT-symmetric Hamiltonians display unconventional behavior, such as the coalescence of eigenmodes at exceptional points. This unconventional behavior allows optical devices to take advantage of symmetry, topology, and phase, enabling new functionalities in ultra-sensitive sensing and lasing. There are two approaches to satisfying PT-symmetry in optics: active and passive. Active PT-symmetry requires a system with balanced optical gain and loss. Because of the difficulty of adding gain in nanophotonic systems, passive PT-symmetry is an ideal method for demonstrating PT-symmetry at the nanoscale. In comparison, passive PT-symmetry requires both nearly zero and large optical losses. While plasmonics has enabled many new optical devices, there have been no demonstrations of PT-symmetry in all plasmonic systems due to the large optical losses of plasmonic materials, which limit loss asymmetry. Here we will present an experimental demonstration of an all plasmonic system demonstrating passive PT-symmetry. To achieve this, we engineer a coupled plasmonic antenna system exhibiting large loss asymmetry. The system undergoes a PT phase transition as the coupling, or separation, between the antennas is varied. At high coupling, the system is in a PT-symmetric phase with two resonant absorption peaks. With decreased coupling, the peaks coalesce at the exceptional point. Further decreasing the coupling results in an optical phase transition to a broken PT-symmetric phase with a single resonant absorption peak. Using our nanophotonic PT-symmetric system, we will conclude with a discussion on guidelines for implementing PT-symmetry in nanophotonic devices.

Unity Order Index Tunability at Room Temperature in 1T-TaS2—A Strongly Correlated Material Weijian Li, Ming

Yi, Kevin Kelly, Gururaj Naik and Frank Yang; Rice University, United States

Strongly correlated materials could greatly respond to a stimulus due to their collective behavior. Thus, strongly correlated materials are well studied in the past for their tunable properties, especially electrical and thermal. However, their optical properties remain to be explored. In this work, we study the optical properties of 1T-TaS2, a quasi-2D material supporting charge density waves (CDW). 1T-TaS2 is the only material to exhibit a nearly commensurate CDW phase at room temperature and its electrical and thermal properties are shown to exhibit a large change with temperature, DC and AC biases, pressure, and light. Here, we study the optical properties of 1T-TaS2 under DC and AC biases, different intensities of optical illumination, and at different temperatures. Under all these conditions, we observe a unity-order change in the refractive index of thin films of 1T-TaS2. We hypothesize that the stacking of CDWs in this material changes with stimulus resulting in its optical constants to change. ARPES and STM measurements are underway to verify the hypothesis. Our discovery of the large tunability of optical constants of 1T-TaS2 presents opportunities in studying light-matter interaction in strongly correlated materials and its application to nanophotonic devices.

A Novel Approach to Tailor the Band Structure of Metal-Organic Framework Nanocrystals in One-Dimensional Periodic Array for Light Induced Energy Transfer Applications Sujoy Saha, Joseph Sarobin and Hemali Rathnayake; JSNN, University of North Carolina, United States

The study of band structures of different types of Metal-Organic Frameworks (MOFs) is indispensable for the advancement of nanoelectronics. We designed a novel approach to predict and tailor the band structure of MOFs nanocrystals in a one-dimensional periodic array through the variation of structural and materials parameters. From the Bloch condition of the Schrodinger equation, we could predict the amplitude of potentials, ? and ? for periodically arranged MOFs only in one-dimension using experimental values of dielectric constant, absorption and emission peaks of MOFs. Predicting energy band structures of the one-dimensional array of an isoreticular MOF, IRMOF-8A using a theoretical method combined with experimental values of dielectric constants and amplitude of potentials provide insight into electronic band energy to tailor optoelectronic properties of MOFs and understanding their energy transfer capabilities with respect to the different ligand type. The dielectric constants of three different IRMOFs synthesized from the same metal precursor (Zn2+) and three different organic ligands with varying conjugation length were predicted from this novel approach. Band gap depends on the amplitude of potentials, which is a function of the conjugation length of the ligand and its dielectric constant. Thus, the effective conjugation length of the ligand in MOFs have a significant impact on the jumps between two allowed bands in energy band structures of the 1-D array of MOFs. This design method can widely applicable for predicting band energy for any designed MOFs and serves as a versatile tool to tailor and predict the electronic properties of MOFs with different ligand units.

Hybrid Plasmonic Nanostructures for Biomolecular Sensing Debadrita Paria[1], Chi Zhang[1], Steve Semancik[2] and Ishan Barman[1]; [1]Johns Hopkins University, United States; [2]National Institute of Standards and Technology, United States

Metal nanostructures are well known for various ultra-sensitive spectroscopic applications because of their ability to concentrate and enhance the local electromagnetic field due to a phenomenon called localized surface plasmon resonance (LSPR). The intense light localization, also known as "hotspot", becomes more pronounced near a narrow plasmonic gap. In this work, we report tailored hybrid metal nanostructures for LSPR sensing and surface enhanced Raman spectroscopy (SERS) of serum albumin. Using a combination of physical vapor deposition and thermal annealing, different hybrid metal nanostructure configurations have been fabricated, which create well defined arrangements of hotspots. The hybrid metal nanostructures have multiple resonance peaks, which demonstrate the capability of the identification of ultra-low differences in refractive index (0.001) when combined with machine learning algorithms. A detailed FEA simulation of these plasmonic nanostructures provides a quantitative estimate and the spatial distribution of hotspot closely match our experimental observations. The simulations also help us understand the various interactions between the nanostructures via their near field. Finally, these structures also show potential for sensitive label-free SERS detection. Overall, our study explores an integrated multimodal biosensing platform featuring LSPR combined with machine learning and surface enhanced Raman spectroscopy (SERS) for quantitative determination of concentration and molecular fingerprinting.

Optical Properties of Random Nanoparticle Films Made of Spheres with an Overlapping Electric and Magnetic Dipole Response Parker Wray and Harry Atwater; California Institute of Technology, United States

We investigate theoretically the unidirectional optical scattering properties of random monolayer particle films composed of dielectric particles that support overlapping electric and magnetic dipoles. The particle films exhibit dramatic reflection and transmission behavior which are manifest in the forward-to-backward scattering ratio of the nanoparticle building block. We also show that these films do not exhibit polarization dependent scattering and lack a traditional Brewster's angle. Our theoretical analysis uses a generalized version of Mie theory, which accounts for particle coupling effects, and was validated by full-wave simulations. For fill fractions up to 40% the average scattering response of an embedded particle is shown to accurately predict the behavior of the random film, and the overlap of the electric and magnetic dipole resonances are found to be robust to effects of particle coupling. Continuing research will extend this analysis to multi-layer particle films. This work indicates potential for the design of optical filters and anti-reflective coatings using single materials, without the need for self-assembly.

Imaging Single Particle Enhanced Upconversion Luminescence from NaYF4:Yb3+,Tm3+ Nanoparticles on Plasmonic Substrates Anahita Haghizadeh[1], Aravind Baride[2], Stanley May[2] and Steve Smith[1]; [1]South Dakota School of Mines and Technology, United States; [2]University of South Dakota, United States

We use single particle spectroscopic imaging and statistical analysis to assess the plasmonic enhancement of NIR-to-visible upconversion luminescence (UCL) from single ?-NaYF4:Yb3+:Tm3+ upconverting nanoparticles (UCNPs) supported on substrates consisting of random arrangements of Ag nanowires (NW) and Au nano-cavity arrays. We measure both apparent luminescence enhancement, which is power dependent due to the nonlinear kinetics of energy transfer upconversion (ETU), and the excitation enhancement, defined as the ratio of the excitation intensity needed to produce a given UCL emission, divided by the equivalent power needed to produce the same emission on the plasmonic substrate1. By examining the effects at the single particle level, and accumulating a statistical sampling of single particle emitters, both on and off the plasmonic substrates studied, we can eliminate the effects of particle fluctuations on the apparent UCL emission enhancement and map out the statistical distribution of excitation and luminescence enhancement on the plasmonic substrates. The distributions obtained are reproduced by Finite Difference Time Domain (FDTD) calculations of the fields near the plasmonic substrate, assuming the variations are due to variations in UCNP coupling to the plasmonic substrate based on an exponential decay with distance. We compare these results to statistical analysis of ensemble measurements made of Er3+ doped UCNPs supported on random Ag NW substrates2 and both wide field and confocal spectroscopic imaging of single UCNPs on and off the plasmonic substrates. F.NM02.08.14

Full Factorial Experimental Optimization of Gold Nanostructures Fabrication by Solid-State Dewetting for SERS Siarhei Zavatski[1,2], Hanna V. Bandarenka[3,2] and Olivier J. Martin[1]; [1]Ecole Polytechnique Federale de Lausanne, Switzerland; [2]Belarusian State University of Informatics and Radioelectronics, Belarus; [3]Arizona State University, United States

The optimization of nanostructures for a specific application is a rather complex task, often akin to shooting in the dark with the hope of hitting the right target, viz. the best performing nanostructure. This difficulty stems from the usually large number of experimental parameters that can be changed in a nanotechnology process. This is the case for example in the fabrication of plasmonic nanostructures for surface enhanced Raman scattering (SERS): the choice of metal, its thickness, the shape of the nanostructures as well as their distribution on the substrate are all parameters that determine the overall Raman enhancement. Even for a relatively simple design, exploring all possible combinations of parameters is a prohibitive task both in terms of nanofabrication time and costs. In that contribution, we focus on the large scale fabrication of plasmonic nanostructures using solid-state dewetting and demonstrate how a full factorial design technique can efficiently optimize the process. In that approach, a target response for optimization and two specific values for the n fabrication parameters are first chosen, leading to an initial set of 2n experiments [1]. Here, as experimental parameters we consider the gold film thickness, the annealing temperature and time, and the heating rate; with the objective of maximizing the intensity of the SERS signal, specifically the 1363 cm-1 vibrational band of Rhodamine 6G. The corresponding 16 experiments provide a model of the dependency of the Raman enhancement on the four experimental parameters considered here. In the classical optimization procedure by full factorial design, this dependency is chosen linear. The set of experimental parameters that is obtained in this first fit of linear model does not necessarily lead to the strongest Raman enhancement and another set of experiments may be required. However, the full factorial approach also provides the direction in the parameter space in which one needs

to move these parameters to reach a better solution. After such a solution is found, the linear model may need to be refined using second order functions to clarify the optimum region. This is usually done with the central composite experimental design [2]. The optimization process for the fabricated samples is documented in detail by studying the morphology and optical properties of each sample by scanning electron microscopy and UV-Vis spectroscopy. The gold nanostructures we fabricated this way have typical dimensions in the 50 nm range, which is in good agreement with data reported in the literature [3]. Furthermore, the optimized plasmonic substrate can be used to identify non-resonant bioorganic macromolecules such as bovine serum albumin. This work reveals an effective approach to optimize nanofabrication processes for large-scale and cost-effective production of uniform and highly sensitive SERS substrates. [1] Leardi, R. Analytica chimica acta 2009, 652(1-2), 161-172. [2] Box, G. E., & Wilson, K. B. J. R. Stat. Soc. Series B Stat. Methodol. 1951, 13(1), 1-38. [3] Krug et al. J. Am. Chem. Soc. 1999, 121, 9208-14.

F.NM02.08.15

Planar Nanophotonic Structures for Intensity-Based Readout Refractive Index Sensing of Dissolved Methane Morgan Blevins[1,2,3], Anna Michel[1] and Svetlana Boriskina[2]; [1]Woods Hole Oceanographic Institute, United States; [2]Massachusetts Institute of Technology, United States; [3]MIT-WHOI Joint Program, United States

As global temperatures rise, permafrost in the Arctic is thawing, stimulating increased release of methane, a key greenhouse gas. Accurate measurements of the dissolved methane concentration in seawater and freshwater are important for finding and quantifying the release of natural seabed and Arctic methane seeps to better understand how these sources are contributing to increasing global methane levels. In surface waters, the methane concentration can be as low as 3-10 nM (atmospheric equilibrium) while concentrations as high as 800-1000 nM are found in methane saturated deep seawater and near thawing permafrost. To measure the concentration of dissolved methane, changes in the refractive index (RI) of polymers functionalized to selectively trap methane molecules can be measured via an optical readout mechanism. However, the range of the RI change is very narrow, from 1.41198 to 1.41358 for atmospheric to saturated methane concentration levels ranging from 0 nM to 300 nM, which requires the use of highly sensitive optical sensors. This paper analyzes and compares three simple and low-cost planar nanophotonic and plasmonic structures as optical transducers for measuring refractive index change of polydimethylsiloxane (PDMS) polymer films doped with cryptophane-A molecules, which selectively trap methane. These structures include (i) a Bragg reflector with a defect layer, (ii) a hybrid plasmonic-photonic multi-layer stack that supports a Tamm plasmon mode, and (iii) a hybrid plasmonic-photonic stack that acts as a magnetic mirror, and can be used in a simple intensity-based measurement scheme with low cost light sources and detectors. Through numerical simulations, we evaluate the sensitivity of the proposed structures in both the angular-resonant-mode shift readout mode and in the reflectance intensity readout mode and compare them to the standard surface-plasmon-polariton-mode Spreeta sensor as a reference. Our results show that the planar Bragg reflector with a defect layer exhibits the largest intensity response and is the most promising design for a low cost and robust photonic chip for dissolved methane sensing. A practical implementation of this chip with a simple intensity-based measurement scheme is proposed. Integration of this planar structure into a small, portable, and low-cost dissolved methane sensor offers a way to make climate monitoring more widespread and accessible to researchers. The structures evaluated here all show promise for other chemical and biological sensing applications that require monitoring very small RI changes. Significantly, each structure has been designed to support resonant modes in both s and p polarizations, which allows enhanced sensitivity by calculating the ratio of the spectral responses of orthogonal polarizations, similar to the complex reflectance ratio measured with ellipsometry. Importantly, the response in both polarizations only needs to be monitored in the reflectance intensity readout mode, avoiding the use of expensive and large ellipsometry equipment.

F.NM02.08.16

Identifying Plasmon-Like Excited States in Bare and Ligand-Protected Metal Nanoclusters Rebecca Gieseking; Brandeis University, United States

Noble metal nanoclusters containing dozens to hundreds of metal atoms are of great interest because of their unique optical properties. Classical electrodynamics fails to describe the optical properties of clusters smaller than a few nm, so quantum mechanical models are needed to describe these clusters. However, it is challenging to identify which features of the computed excited states indicate plasmon-like character, particularly in a way that is generalizable to the ligand-protected clusters that are commonly studied in experiments. We present an analytical method to identify plasmon-like excited states using three quantifiable indicators that must be considered in combination: (1) large superatomic character, (2) large collectivity among single-particle excitations, and (3) large additivity of contributions of these single-particle excitations to the transition dipole moment. Visualizing these three indicators on a single plot enables rapid classification of hundreds of excited states into plasmon-like, collective, single-particle, or interband categories, or as intermediate between these categories. This method is used to identify excited states with plasmon-like character in both bare and ligand-protected Ag

clusters at the TDDFT level. Using these three nearly orthogonal indicators in combination provides more information than any one criterion can provide.

F.NM02.08.18
Stable Dispersion of Titanium Nitride Nanoparticles Idalis Hernandez, Eric Bartlett, Sanchari Chowdhury and Michaelann Tartis; New Mexico Tech, United States

Alternative plasmonic titanium nitride nanoparticles (TiN) are attractive photothermal agents because of their ability to strongly absorb a broad spectrum of light ranging from visible to near-infrared and convert that into heat. Additional advantages of low cost and stability of these refractory nanomaterials make them attractive for different applications ranging from photothermal cancer therapy to solar energy mediated catalytic reactions. In this work, we are developing a method to obtain a stable and monodispersed TiN nanoparticles solutions, which is an important prerequisite for most of their applications. Moreover, our goal is to optimize a solution based coating method to obtain a uniform well dispersed thin film of TiN nanoparticles on the substrate, which will be useful for their application in the device. However, preventing aggregation of TiN nanoparticles in a solvent has been a challenge. We have optimized protocols based on ultra-probe sonication and centrifugation, to obtain relatively monodisperse and stable TiN nanoparticles in an aqueous solution. We have applied our method to commercially available polydisperse TiN nanoparticles of average size 80nm and 20 nm. Using the optimized method we were able to decrease the polydispersity index (PDI), the measure of the distribution of nanoparticles in a solution, from 0.351 to 0.18 indicating a significantly more monodispersed solution. Moreover. we used a sol-gel based method for incorporating nanoparticles in transparent silica gels. There was no aggregation of the TiN nanoparticles observed during the sol-gel transition. UV-Vis spectroscopy and dynamic light scattering method confirm that incorporating TiN nanoparticles in silica gel preserved both of their optical properties and the dispersibility as in the original solution. The nanoparticles stay stable in the solution for several days. A biocompatible silica coating on TiN nanoparticles can be useful for drug delivery and photothermal therapy. In summary, we are developing a simple commercially viable method to efficiently disperse and stabilize titanium nanoparticles in solution and subsequently coating them on the substrate which can easily be applied for large scale applications.

Confined Nucleation of ErAs NPs in Er:InAs QDs to Fabricate Nanoparticle Quantum Dot Hybrids Kurt Eyink, Yuanchang Zhang, Albert M. Hilton and Krishnamurthy Mahalingam; Air Force Research Laboratory, United States

Directed assembly has been the subject of extensive research over the years due to the desire to grow structures at specific locations. This is accomplished by increasing the probability of nucleation at the desired location. Mechanisms such as reduction of the diffusion of species, reduction of the strain to lower the bulk free energy to reduce the critical nuclei size, or a lowering of the surface energy which also reduces the critical nuclei size have previously been used. In all these cases, nucleation of the desired phase occurs directly on the substrate. Here we propose and demonstrate a scheme for directed assembly in which we confined the nucleation of the desired material to the region of a nanostructure formed on the surface. We accomplish this through the use of a dilute alloy containing the desired material and subsequent removal of the major constituent of the alloy inducing nucleation at some point after the dilute species exceeds it solubility limit. In particular, we use this approach to control the nucleation of ErAs nanoparticles from Er:InAs quantum dots by evaporation of InAs. We studied ErAs NP formation from InAs QD nominally doped to concentration of 1.25% and 2.5% on GaAs (001). The Er:InAs quantum dots were grown using normal conditions for the growth of undoped InAs and produced similar quantum dot densities (near 100/square micron). We explain these observed results in terms of normal nucleation and growth given the mesoscopic concentration of Er atoms expected in the InAs QD. A comparison of the undoped and Er-doped InAs quantum dots before and after InAs evaporation show the number of the ErAs nanoparticles is less than the original quantum dot density showing nanoparticle do not form in every quantum dot and suggests a critical number of Er atoms needed for nucleation. We have used our confined nucleation process in conjunction with normal direct assembly processes for InAs QDs to produce hybrid structures composed of InAs QDs and ErAs NP. We have formed vertically stacked Er:InAs QD over undoped InAs QDs to form ErAs NP over InAs QDs. We have formed Er:InAs quantum dots formed in ErAs divots to form ErAs nanoparticle clusters and have used Er:InAs to place ErAs in patterned surface. Transmission electron microscopy of these structures show that at times multiple nucleation sites are possible in the structure and suggest the potential of forming rich hybrid structures using this approach.

Optical Parameters of Bioinspired Sub-Monolayer Nanoparticle Arrays Sean R. Dinneen[1], Richard M. Osgood[1], Zhuangsheng Lin[2], Camille Martin[2], Michael Okamoto[1], Ihsan Uluturk[1] and Leila Deravi[2]; [1]Combat Capabilities Development Command Soldier Center, United States; [2]Northeastern University, United States

Cephalopods have the ability to take advantage of pigmented and structural coloration when camouflaging, signaling, or otherwise communicating through their adaptive coloration. The chromatophore, which is the actuating organ responsible for pigmented color within cephalopods, is populated with 500-600 nm diameter particles composed of pigment and protein called pigment granules. The pigment, identified as xanthommatin, has been found to have a uniquely high refractive index and contributes highly to the scattering of light with broadband optical properties. Developing metamaterials out of synthetic pigment granules, where the particle periodicity is smaller than the wavelengths of light with which they interact, was the next logical choice for us to not only further our understanding of the complex photonic system of cephalopods, but to explore its application in adaptable optical systems and possibly chemical sensing.

In this work, we aim to leverage our knowledge of biomaterials (namely the biopigment xanthommatin) to generate sub-monolayers of synthetically made pigment granules. Xanthommatin is encapsulated within polystyrene-co-maleic anhydride (PSMA) nanoparticles with good physical retention while maintaining its coloration. Sub-monolayer arrays are prepared via Chumanov-style roll-coating on substrates within a vial containing the solution of particles, and are physically characterized by scanning electron microscopy. We then show the arrays' optical properties measured by integrating sphere spectrophotometry and broadband multi-angle ellipsometry. Depending on the spacings of the particles, the arrays will resonate at certain wavelengths within the visible. Our updated models, taking into account the particle's refractive index and contribution from the pigment, will show a dependence of spacing and material on wavelength resonance. With the pigment as a functional feature within the particles, we explore the retained chemical properties (such as absorption changes with pH) with the possible inclusion of chemical sensing.

Spatial Inhomogeneity of Optical Binding in Many-Body Systems Fei Han; Clarkson University, United States

Optical matter can be formed by electrodynamic interactions of metal nanoparticles in an optical field. This light-mediated self-organization of nanoparticles offers a route to study mesoscale electrodynamics interactions in many-body systems. By controlling the intensity, phase, and polarization of light, the optical field can be tailored to assemble stable optical matter with up to 101 nanoparticles. Here we report that the spatial inhomogeneity of circularly polarized optical binding in a many-particle system. The spatial stability of self-organized nanoparticles is strongly influenced by the laser intensity and polarization state. In particular, the nanoparticles in the central area of an optical matter array are more stable than those on the edge. Moreover, larger arrays are self-protected from fluctuation-induced instability by incorporation more nanoparticle constituents. This study provides important information about the spatial inhomogeneity of optical binding interactions in mesoscale nanoparticle arrays.

F.NM05.07.01
Observation of Strong Electron-Phonon and Electron-Photon Interactions in Topological Weyl Semimetals Kunyan Zhang[1], Tong Wang[2], Xiaoqi Pang[2], Fei Han[3], Nguyen Tuan Hung[2], Ahmad R. Nugraha[2,4], Mingda Li[3], Riichiro Saito[2] and Shengxi Huang[1]; [1]The Pennsylvania State University, United States; [2]Tohoku University, Japan; [3]Massachusetts Institute of Technology, United States; [4]Indonesian Institute of Sciences, Indonesia

Electron-phonon interaction plays an important role in the electronic properties of topological materials by affecting the dispersion and lifetime of phonon and electronic states. For example, Kohn anomaly describes the phonon softening phenomenon when the dielectric screening from conducting electrons in a metal is disrupted. Another evidence of strong electron-phonon interaction is Fano resonance, the interference between discrete and continuous states, featured by an asymmetric Breit-Wigner-Fano lineshape. In this work, we present the anisotropic Kohn anomaly and Fano resonance in a type-II Weyl semimetal candidate LaAlSi by polarized Raman spectroscopy. The B_1 phonon mode in our Raman spectra shows excitation-wavelength-dependent phonon-softening and lineshape asymmetry. In type-I Weyl semimetal TaP, abnormal symmetry breaking of another B_1 mode in polarized Raman spectroscopy has been observed, attributed to the quantum interference of degenerate carrier pockets with different symmetries. The experimental observations combined with density-functional theory (DFT) calculations provide valuable insights into microscopy scattering pathways and transport properties of the type-II Weyl semimetal candidate LaAlSi and type-I Weyl semimetal TaP.

1.5 µm Telecom-Wavelength Single Photon Source of InAs/InP Quantum Dot via Strain-Controlled Growth Youngho Ko[1], Mireu Lee[1,2], Hosung Kim[1], Won Seok Han[1], Je-Hyung Kim[2] and Jung Jin Ju[1]; [1]Electronics and Telecommunications Research Institute, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)

Owing to the rapid development of quantum information technology including quantum communication, quantum sensor, and quantum computer, realization of quantum light source, an essential element for the photonic quantum information applications, have been required. There have been numerous efforts to obtain single photon sources as a quantum light source by using various solid-state material platforms including semiconductor quantum dots (QDs), defect-based color centers in diamond and SiC, QDs in two-dimensional material of WS_2 and WSe_2, and etc. III-V semiconductor QDs have been widely considered as a promising platform for the single photon source due to their various advantages of high generation efficiency of single photon, wavelength tunability, and favourable integration with various semiconductor-based photonic circuits. Single photon emission in 1.5 μm telecom-wavelength range was quite important because of compatible with quantum communication and photonic integrated circuits of silicon photonics. However, single photon emission in telecom-wavelength range was still challenge. InAs QDs are normally grown by Stranski–Krastanov growth mode with molecular-beam epitaxy or metal organic chemical vapor deposition (MOCVD). Because the diameter and height of the self-assemble InAs QDs are determined by strain originated from lattice mismatch with host materials, it was difficult to obtain telecom-wavelength single photon emission from InAs/GaAs or InAs/InP QDs. In this study, we obtained 1.5 μm telecom-wavelength single photon emission from InP-based InAs QDs by using strain-controlled layer of InAlGaAs. The single photon source was fabricated with circular bragg grating structure to obtain high collection efficiency of single photon emission. Moreover, we proposed integrated single photon devices to realize integrated quantum light source with photonic integrated circuits. For the strain control during the growth of InAs QDs, tensile-strained InAlGaAs layers as a host material were grown on the InP substrate. The InAs QDs were grown by Stranski–Krastanov growth mode in MOCVD. lattice-mismatched InAlGaAs on InP showed 0.74 % tensile strain with InP, which was characterized by x-ray diffraction measurement. We monitored the structural properties of InAs QDs by atomic force microscopy and transmission electron microscopy with changing the strain-controlled layers of InAlGaAs, InGaAs, and InP and with changing the thickness of strain-controlled layers. To optimize the size and density of the QD, InAs samples were grown with various growth condition including the temperature, growth rate, and the III/V ratio. We found that the size of InAs QDs were strongly dependent on the density and As flow was critical for emission efficiency of QD and wetting layer. Through systematic study, we could obtain low enough density of InAs QD from 10^7 /cm^2 to 10^9 /cm^2 for fabrication of single photon emitter. We carried out the micro-photoluminescence measurement at 3.4 K for optical analysis of QDs. The single QD emission peak was exhibited from 1.5 to 1.6 μm wavelength. The second-order correlation function was measured for single photon analysis through Hanbury-Brown Twiss experiment. We designed circular bragg grating structures with InAs/InAlGaAs QD for collection efficiency and Purcell enhancement of cavity. Optical simulation of the QD in cavity was performed by finite-difference time domain simulation. The collection efficiency of the circular bragg grating structure was more than 80 % to objective lens of NA 0.7. We also designed the integrated single photon source with Si photonic circuit. InAlGaAs waveguide was designed as the nano tapered waveguide and SiO_2 interlayer was adopted to efficiently couple the single photon emission with Si waveguide. The QD-based telecom-wavelength single photon source of high collection efficiency and integrated single photon source could provide a solution for on-chip quantum photonic devices.

Optical Control of Spin Transfer in Hybrid Perovskites-TMDC Heterostructures Anna Stadlbauer[1], Lissa Eyre[1], Jonathan Zerhoch[1], Sean A. Bourelle[2] and Felix Deschler[1]; [1]Walter Schottky Institute - Technical University of Munich, Germany; [2]University of Cambridge, United Kingdom

It is a fundamental question how material properties of heterostructures can control spin transfer. This work investigates how spin can be transferred in a heterosystem of a hybrid metal-halide perovskite and a 2D material, with focus on transition metal dichalcogenide (TMDC) layers. Metal halide perovskites and TMDC have already been combined in type II heterostructure devices such as photodetectors [1,2]. However, spin transfer has not yet been reported to the best of our knowledge, which would open up opportunities for optical control in spintronics applications.

Following our study of spin-exciton interactions and spin depolarization times in hybrid perovskites, we aim to investigate how the properties of the heterostructures control spin transfer. The most suitable 2D materials for this approach are semiconducting TMDCs due to their reported controllable valley degree of freedom [3,4]. To benefit from the coupling between spins and valleys in TMD layers, the components in the investigated heterosystem require not only a suitable combination of bandgaps and appropriate band alignment but also positions in k-space that fulfill the optical selection rules [3].

We analyze the obtained heterostructures with ultrafast time resolved photoluminescence spectroscopy, circularly polarized transient absorption spectroscopy and Faraday rotation to resolve the excitation and spin dynamics.

From our fundamental insights into the spin transfer in TMDC-perovskite-heterosystems, we anticipate to discover avenues

and design guidelines for application of our for emerging spintronic technologies.

Our Efforts on Industrializing Carbon Nanotubes Don Futaba, Shunsuke Sakurai, Guohai Chen and Takashi tsuji; National Institute of Advanced Industrial Science and Technology, Japan

In the nearly 30 years since the elucidation of the carbon nanotube structure, the reality of mainstream commercial applications, such as touch panels, sealing materials, high performance power sources, etc. are now in the foreseeable future. However, to realize this vision, the practical developmental obstacles need to be resolved. This is precisely the work which is undertaken by the CNT-Application Research Center, AIST. Over the past 15 years, our Center has been working in collaboration with academia and industry to support the establishment of a carbon nanotube industry in Japan by addressing the various stages of research spanning discovery, development, application, scale-up, and commercialization for the general top vital to the development of applications, such as synthesis, processing, and evaluation. In this way, our center works to bring scientific discoveries and bring them to society.
This presentation will provide an overview of our recent progress in the synthesis and application of highly efficient synthesis of millimeter-scale, vertically-aligned single-walled carbon nanotubes using the water-assisted "Super-growth" CVD. In one section of my presentation, I will describe our efforts toward the economical mass-production of single-walled carbon nanotubes (SWCNT). I will then present our progress on the development of commercial applications, and finally I will present some or our work in developing the new technology for the synthetic control of SWCNTs.

5:15 AM *F.NM03.01.02
Chiral Carbon Nanotube Control via Size Resolved Solid Catalysts Adam Boies, Xiao Zhang, Brian Graves and Michael De Volder; University of Cambridge, United Kingdom

Single-walled carbon nanotubes (SWCNTs) with controlled chirality possess superior performance in many sensor and electronic applications. However, direct growth of SWCNTs with a narrow chirality distribution is still challenging. Recently, catalysts that remain solid state during growth have renewed the possibility to achieve chirality controlled through direct growth. To facilitate scaled-up SWCNT production and clarify the mechanism behind chirality selection, we show the synthesis of high melting point metal nanoparticles with near monodisperse sizes in the range of 1 to 5 nm using a continuous, gas-phase synthesis process. Random and aligned SWCNTs with a narrow range of chiralities are grown on substrates. Chiral angles of 19±5° are particularly prevalent with their abundance reaching over 93%. We attribute the mechanism to the extension of growth time afforded to fast growing chiralities. The solid catalysts are also shown to be effective via floating catalyst growth. The facile production of chirality-controlled SWCNTs increases their availability for broad academic and industrial applications.

5:30 AM F.NM03.01.03
Conversion of Waste Plastic into CNTs Using Stainless Steel Catalyst—An Optimization Approach to Maximize the Yield Aidin Panahi, Xiao Sun, Di Chang and Yiannis Levendis; Northeastern University, United States

As a result of China's recent ban on the import of most plastic waste, the US and other industrialized countries that have been exporting their plastic waste to China for recycling will need to find new ways to handle the disposal of their waste as much of it is already starting to pile up in landfills. In research conducted at Northeastern University, plastic wastes have been thermally recycled by pyrolytic gasification to carbon nanotubes (CNTs) and gaseous fuel. To achieve this conversion, a

laboratory-scale pyrolytic gasifier was fed with waste plastics including (polyethylene, polypropylene, polyethylene terephthalate, polystyrene, etc.) in an inert N_2 or He or Ar or CO_2 atmospheres with different flow rates (0.1-2 l/min). The plastic wastes were gasified in an electrically heated reactor at 600-800 °C. Under these conditions, the polymer pyrolyzed into a gaseous mixture of hydrocarbons and hydrogen. The pyrolyzate mixture was then conducted into a separate reactor where it was used as a carbon precursor for chemical vapor deposition process to synthesize carbon nanoparticles. The second reactor was set at temperatures in the range of 800-1000 °C. The catalytic substrate used for the nanoparticle growth consisted of different grades of stainless steel mesh (SS-304, SS-316 and SS-316L). The wire cloths were used either as-received or upon chemical etching by acid wash and/or heat-treatment in air, nitrogen or helium at 800 °C followed by rapid air quenching. In those cases, the yields were determined by the mass of the product relative to the mass of feedstock and ranged from 1% to 30%. With the purpose of purification and sorting, the catalysts and the produced CNTs were investigated from synthesis, structure and property characterization by the use of SEM, TEM, AFM, TEM+EDX, HAADF, and TGA. Results showed that the catalyst type, composition and pre-treatment, carrier gas and flowrate as well as the type of waste plastic, are all influential on the yields and physical characteristics of the synthesized CNTs.

5:40 AM F.NM03.01.05
Diffusion Inhibitors in Catalyst Particles for Growth of Ultra-Long Carbon Nanotubes Michael J. Bronikowski; University of Tampa, United States

This report presents recent results from studies of growth of Carbon Nanotubes (CNTs) by CVD using metal catalyst particles doped with heavy refractory metals. In such growth, the heavy metal acts as a diffusion inhibitor to prevent erosion and Ostwald ripening of the catalyst particles, extending the lifetime of these particles in the CVD environment and thus allowing the growth of longer carbon nanotubes than would normally result. This effect has been demonstarted in several of our recent studies. Here, we report extension of our results to new reactive systems utilizing new catalyst/inhibitor combinations and new carbon feedstock gases. Implications for the growth of ultra-long (tens of cm or more) CNTs will be discussed.

5:50 AM F.NM03.01.06
Large Area, High-Density SWCNT Forests with Remarkably Invariant Structural Properties Over a Wide Range of Synthesis Conditions Sei Jin Park, Eric Meshot, Kathleen Moyer, Steven F. Buchsbaum, Melinda Jue, Kuang Jen Wu and Francesco Fornasiero; Lawrence Livermore National Laboratory, United States

Driven by the exceptional thermal, electrical, optical, mechanical and fluidic properties of single-walled carbon nanotubes (SWCNT), commercial use of vertically aligned “forests” are on the horizon for applications[1] ranging from optical absorbers and thermal interfaces to selective membranes and advanced fabrics.[2,3] Large-area SWCNT forests with high densities and small diameters are especially important for many applications, yet they are conspicuously absent from the literature due to synthesis challenges.
Here, we demonstrate synthesis of high-density (> 10^{12} CNTs/cm^2), small-diameter (~ 2 nm) SWCNT forests with structural characteristics that remain uniform over large areas (up to 6-in. diameter)[4] and, surprisingly, largely unchanged over a wide range of synthesis conditions. We also find that our growth regime enables a record-high carbon conversion efficiency and a stable mass kinetics, both of which are invariant with catalyst type (Fe vs Fe/Mo mixes). To identify the limiting steps in the SWCNT growth kinetics and the factors contributing to the process robustness, we determine the dependence of the reaction rate and carbon conversion efficiency on broad ranges of synthesis parameters. Effects of catalyst area (from 1 × 1 cm^2 to 6-in wafers), growth pressure (20-790 mbar), gas composition (30-fold acetylene partial pressure, hydrogen-argon ratio), and flowrates (8-fold variation) are presented. The observed growth rate trends can be explained quantitatively with a simple kinetic model in which bulk diffusion of acetylene in gas phase is the limiting step in CNT production and hydrocarbon byproduct formation becomes dominant at high hydrogen partial pressure.
Our demonstration of such robust and reproducible growth of high-density forests over a wide range of synthesis conditions provides valuable insights for future scale-up efforts of SWCNT forest production, which are key for widespread adoption of advanced CNT technologies.

Origin of Catalysts for the Synthesis of Boron Nitride Nanotubes Sambhawana Sharma[1], Siqi Zhang[1], Rodney Oakley[2], Dongyan Zhang[1] and Yoke Khin Yap[1]; [1]Michigan Technological University, United States; [2]StabiLuX Biosciences Inc., United States

Abstract
Boron Nitride Nanotubes (BNNTs) have been of great interest due to their electrically insulating, optically transparent, and biocompatible properties. As we have demonstrated, these properties make BNNTs attractive nanomaterials for novel electronic [1-3] and biomedical[4] applications. All these applications require high-quality and high-purity BNNTs. One promising approach is by the use of catalytic chemical vapor deposition (CCVD), where the synthesis of BNNTs are well controlled by the use of catalyst[5-6]. Therefore, understanding the catalytic behavior and growth mechanism will enable better control of the quality and purity of BNNTs.
Here we describe the discovery of a new compound $Mg_x(SiO_2)_y$, as the original catalyst for the growth of BNNTs. Based on the growth-vapor trapping (GVT) approach, we have demonstrated the growth of high-quality BNNTs in a regular tube furnace often use for the synthesis of carbon nanotubes, graphene, and many other two-dimensional (2D) materials.[5-6] Such CCVD approach enable the growth of BNNTs using the boron oxide chemistry without involving dangerous and corrosive materials. We found that MgO powders are the effective "catalyst" for our synthesis. However, our results suggest that MgO will work well only on Si substrates, not on other inert substrates. Detailed experiments and analysis suggest that $Mg_x(SiO_2)_y$, is the actual catalyst responsible for the growth of high-quality BNNTs. We further compare the synthesis of BNNTs using various Magnesium based compounds, some of which favorite the growth of BNNTs in very small tube diameters. A detailed study of these results will be presented at the meeting.

Late News: Fullerene Nanopottery—Precise Dimerization of Hollow Compartments Fei Han[1] and Hongyu Chen[2]; [1]Nanyang Technological University, Singapore; [2]Nanjing Tech University, China

Pottery brings the dawn of manufacturing in human history. With it, one can readily design, build, and assemble hollow containers with tailored shapes for various applications. However, this important concept has yet to be emulated in nanoscience. We report a facile synthetic methodology: Nanopottery, where hollow fullerene compartments with tailored shapes and precise stoichiometry can be readily created and assembled via the manipulation of their liquid template, advancing from isolated hollow units to multi-compartment vessels.[1]
Precisely controlled docking, merging, and welding of hollow nano-/micro-structures are essential in constructing sophisticated hollow systems, in ways similar to the building of plumbing and biosystems. To this end, regioselectivity during the processes is an important milestone demanding new tools.
We bring steric effect, a powerful regioselective method in organic reactions, to nanoscale for the precise assembly of fullerene nanobowls, reaching dimers of 93.6% purity in one-step. To the best of our knowledge, the dimerization sets a new record of the highest purity sample before purification. *M*-xylene liquid nanodroplets that template the growth of bowls can be readily docked and merged, producing the dimers and tetramers. The regioselectivity is controlled by steric

hindrance, *i.e.,* the relative size of the exposed liquid droplets vs. the hemispherical shell, so that the docking process can be readily modulated to govern the stoichiometry. The mechanism is studied in detail and further supported by geometrical models. We believe that the development of new regioselective tools and the understanding in docking and welding hollow structures would expand the horizon of nanoscience, opening new possibilities for designing sophisticated hollow nano-systems.[2]

DNA/Carbon Nanotube Interactions at the Short DNA Oligomer Limit Ming Zheng; National Institute of Standards and Technology, United States

DNA-carbon nanotube (DNA-CNT) hybrids are useful constructs for CNT sorting and biosensing applications. Historically, shorter sequences (~ 10 to 12 mers) are found to give rise to better separation outcome. Even though it is known that sequences shorter than 10 mers leads to less stable dispersions, the length limit has never been explored systematically in terms of dispersion stability and separability. We have recently combined experimental and machine learning guided search to explore short (N ≥5) DNA sequence space in a non-biased manner. In this talk, I will present our new CNT resolving sequences identified through this work, and their utility in chiral sensing of small molecules.

5:15 AM *F.NM03.02.02
Comparing Resonant Raman Spectroscopy and Atomic Resolution Transmission Electron Microscopy for SWCNT Sample Characterization Alice Castan[1], Salomé Forel[2], Frédéric Fossard[1], Dmitri Levshov[2], Wim Wenseleers[2], Sofie Cambré[2] and Annick Loiseau[1]; [1]LEM, CNRS-ONERA, France; [2]University of Antwerpen, Belgium

Having access to SWCNTs samples enriched in certain structures is a fundamental goal in order to exploit their properties within the scope of specific applications. One way to produce such samples is to achieve structurally selective growth of SWCNTs. Aside from the obvious scientific challenges related to this very active research field, being able to precisely and accurately assess the composition of a growth sample is a key point for understanding the phenomena underlying growth selectivity.
A widely used characterization methodology for assessing the selectivity of CVD grown SWCNT on flat substrates is based on resonant Raman spectroscopy mappings using a set of discrete laser lines. In this work we thoroughly investigate the reliability of this methodology through cross-characterizations with other techniques on specifically chirality- and /or diameter-sorted samples. By comparing, first, Raman results with atomic resolution transmission electron microscopy statistical analyses, we evidence significant discrepancies between the two techniques. Further comparison with photoluminescence and optical absorption measurements shows that the observed discrepancies clearly stem from the chirality-dependence of SWCNT Raman cross-sections and the patchy vision offered by the use of only a few discrete excitation wavelengths, allowing us to propose some insights for a more reliable methodology.

5:30 AM F.NM03.02.03
Precise Synthetic Control of sp^3 Defects for Tunable Light Emission from Semiconducting Carbon Nanotubes Felix J. Berger[1], Simon Settele[1], Sebastian Lindenthal[1], Nicolas F. Zorn[1], Abdurrahman Ali El Yumin[1], Jesus Alejandro de Sousa[2], Nuria Crivillers[2] and Jana Zaumseil[1]; [1]Heidelberg University, Germany; [2]Institut de Ciencia de Materials de Barcelona, Spain

Narrowband emission in the near-infrared and electrical generation of excitons make long, polymer-sorted semiconducting single-walled carbon nanotubes (SWNTs) desirable materials for light-emitting devices. Their successful functionalization with sp^3 defects acting as luminescent exciton traps (ACS Nano 2019, 13, 9259) has emerged as a powerful route to accomplish red-shifted emission with increased efficiency and even single-photon emission at room temperature. Since the

emission properties of individual defects depend crucially on their binding configuration to the SWNT lattice and the nature of the attached functional group, they can be tuned over a certain energy range. Here, we present functionalization strategies enabling precise control of the defect binding configuration and thus emission wavelength and lifetime in polymer-wrapped (6,5) and (7,5) SWNTs. Electroluminescence from the introduced defects is readily achieved by incorporating such tailored SWNTs into a light-emitting field-effect transistor structure. To add further functionality, we have created sp^3 defects bearing stable organic radicals. These paramagnetic and redox-active moieties respond to magnetic and electric fields and thereby allow for unprecedented control of the electronic structure at the defect site.

5:40 AM F.NM03.02.05
Liquid-Vapor Phase Transition of Water in Individual Single-Walled Carbon Nanotubes Matthias Kuehne[1], Samuel Faucher[1], Mohan Teja Dronadula[2], Mohammad Heiranian[2], Narayana Aluru[2] and Michael Strano[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Illinois at Urbana-Champaign, United States

The thermodynamic properties of fluids confined within nanometer-sized pores greatly differ from the ones of their bulk form. In particular, as the pore size becomes comparable to the size of the fluid's constituent molecules, the continuum assumption breaks down and peculiar size-dependent physicochemical behavior emerges. Here, we use Raman spectroscopy to probe the liquid-vapor phase transition of water inside individual, free-standing single-walled carbon nanotubes of different diameters. We report controlled and reversible vaporization of the nanoconfined water by varying the laser power of the Raman excitation laser. The Raman G band serves as built-in thermometer of the local nanotube temperature. We show that our measurements can be described by a diffusive heat transfer model, which allows extraction of the diameter-dependent phase transition temperature based on the characteristic redshift of the nanotube's radial breathing mode upon vaporization. We further perform all-atom molecular dynamics simulations to computationally corroborate our experimental results and to elucidate the underlying molecular behavior of water in these single-digit nanopores. Our results shed new insights on the physicochemistry of nanoconfined fluids, and will inform ongoing efforts in the field towards establishing a unified force field for water.

Spin Filtering with Fluorinated Boron Nitride Nanotube Ranjit Pati; Michigan Technological University, United States

Spin filtering, which is an important prerequisite for spin logic, involves the selective transmission of spin-polarized carriers. A perfect spin filter allows all majority (or minority) spin carriers to pass through a *channel* while blocking the minority (or majority) carriers. Since the discovery of magnetism in polymerized C_{60}, the search for a novel low-dimensional metal-free material that would exhibit magnetism at a higher temperature with excellent spin filtering property has been intensively pursued. In this talk, I will give an example of a spin filter comprised of a metal-free fluorinated single-wall boron nitride nanotube (F-BNNT) coupled to non-magnetic electrodes to elucidate the physics of spin filtering. Upon functionalization with fluorine, BNNT is found to display long-range ferromagnetic ordering of spins that is stable at a temperature much above the room temperature.The quantum transport approach is adopted to model the spin filter. Spin filter efficiency as high as 99.8% is found in a model F-BNNT junction.

5:15 AM *F.NM03.03.02
Computational Modeling of Nanomaterials for Their Applications in Transistors and Layered Anodes Swapan K. Pati; Jawaharlal Nehru Centre for Advanced Scientific Research, India

In recent years, many nanosystems, namely, carbon nanotube (CNT), graphene, BN sheet, metal dichalcogenides (MDC), borocarbonitride (BCN), black phosphorus (BP) etc. have been shown to exhibit many fold benefits for applications in a number of fields, namely, absorbates, chemical sensors, field effect transistors, solar cells, rechargeable battery, to name a few. In fact, recent experimental advancements on the control over the structural aspects of nanomaterials has enabled material scientists to tailor the material properties with improved reliability and functionality. We have been modeling these materials for their applications in electronic charge transport, as Li/Na/Mg Anode and various electronic and optical sensing

behaviors. We have derived relaxation time formulation from complete Boltzmann transport equation and obtained all the parameters from ab-initio density functional theory. Using this formalism, we have calculated charge carrier mobilities of a few BN-modified graphene layers and bilayer systems. We have shown that leading carrier transport in BCN layers can be changed from electrons to holes with high mobility values through change in surface topology[1]. We have computed mobility values for trilayer phosphorene and bilayer MoS_2 polytypes. The microscopic reason behind the carrier anisotropy and variation in terms of polytypes have been obtained [2,3]. In the case of rechargeable battery, we have looked at the potential of using Boron-sheet, BCN layer and BP as anode materials for Li, Na and Mg ion rechargeable battery and super-capacitors [4-6]. If time permits, I shall discuss Born-Oppenheimer Molecular Dynamics (BOMD) and DFT studies on trapping of BPA (Bisphenol A) with solvent [7], gaseous pollutants [8], DDT [9] on MDC, doped graphene and doped CNT respectively. We also have shown that it is possible to tune the interlayer coupling dynamically by signing light on the superlattices of graphene and BN sheet [10].

F-NM03

5:00 AM F.NM03.04.01
Ultra-High Brightness Fluorophores Based on Nanotubes Yoke Khin Yap[1], Nazmiye Yapici[2], Rodney Oakley[2], Xiuling Liu[1], Steve Tokarz[2] and Dongyan Zhang[1]; [1]Michigan Technological University, United States; [2]StabiLux Biosciences, United States

We have developed a new nanotube technonogy for producing a series of dyes with ultra-high fluorescent brightness for biomedical application [1]. The brightness of our dyes is widely tunable, up to 1000 times brighter than any known dyes. Based on this technology, we have synthesized three types of new dyes NovoLux® 488 (488/515 nm), NovoLux® 560® (560/580 nm), and NovoLux 640® (640/660 nm). The design, synthesis, antibody conjugation, and extinction coefficient data of these new dyes will be presented in the meeting.

Organic dyes, and fluorescent proteins are widely used for biomedical application such as fluorescent microscopy and flow cytometry. Conventional organic dyes are not as bright as protein dyes such as PE (extinction coefficient, $\epsilon = 2.5 \times 10^6$ M^{-1} cm^{-1}; quantum yield, QY= 0.8) and APC ($\epsilon = 7.0 \times 10^5$ M^{-1} cm^{-1}, QY=0.68). Our new platform dye technology allows us to synthesize ultra-high brightness dyes with extinction coefficient as high as 10^{10} M^{-1} cm^{-1} [1]. Our dyes are constructed by three components: DSPE-PEG(5000)Amine, 1,2-distearoyl-sn-glycero-3-phosphoethanolamine-N-[amino(polyethylene glycol)-5000] as the polymeric linkers, carbon nanotubes (CNTs) and boron nitride nanotubes (BNNTs) as the nanocarriers,

and organic dyes as the fluorescent elements. DSPE-PEG (5000) Amine are *used as the linkers to* conjugate organic dye molecules and antibody on CNTs or BNNTs. BNNTs are chosen because they are electrically insulating and optically transparent (band gap of 6eV) [2-4]. BNNTs also offer defect-free surfaces with fully coordinated hexagonal boron nitride (h-BN) network that allow simple pi-pi conjugation of polymer linkers. Because of these unique properties, hundreds of organic dyes can be self-assembled on the surfaces of BNNTs through the DSPE-PEG linkers without quenching. This contributes to the high extinction coefficient and high-brightness of our dyes. Details of the design, synthesis, antibody conjugation, and extinction coefficient data of these new dyes will be presented in the meeting.

5:10 AM *F.NM03.04.02
Ultra-High Brightness Dyes with Tunable Brightness for Flow Cytometry Nazmiye Yapici[1,2], Rodney Oakley[1], Xiuling Liu[2], Dongyan Zhang[2] and Yoke Khin Yap[2]; [1]Stabilux Biosciences, Inc., United States; [2]Michigan Technological University, United States

We have developed a platform technology which allow us to synthesize new dyes with ultra-high brightness for flow cytometry applications. Our unique technology allows us tuning brightness to desired levels (10X to 1000X brighter than commercial dyes) for detection of undetectable by achieving femtomole detection level.
Brightness of dyes are defined by multiplication of quantum yield (QY) and extinction coefficient of a dye. The known brightest commercial dyes are PE and APC with extinction coefficients $2.5x10^6$ M^{-1} cm^{-1} (QY=0.8) and $7.0x10^5$ M^{-1} cm^{-1} (QY=0.7), respectively. To date, we have developed ultra-high brightness fluorescent dyes in three colors: NovoLux® 488, NovoLux® 560 and NovoLux® 640. For one of our NovoLux 488 samples, the extinction coefficient is $7x10^7$ M^{-1} cm^{-1} (QY= 0.5). This is brighter than FITC dye by 897X (extinction coefficient of FITC is $7.8x10^4$ M^{-1} cm^{-1} QY=0.5). This make NovoLux 488 the brightest dye in the 488 channels. On the other hand, one of our NovoLux 560 samples offers an extinction coefficient of $3x10^7$ M^{-1} cm^{-1} (QY=0.3), which resulted in 400X enhancement of conventional rhodamine B (extinction coefficient of $7.5x10^4$ M^{-1} cm^{-1}, QY=0.3). Furthermore, NovoLux 560 is more photostable than rhodamine B and 6X brighter than PE. Finally, we have developed NovoLux 640 as the photostable and brighter dye option in the 640 channel. One of our NovoLux 640 sample offers an extinction coefficient of $4x10^7$ M^{-1} cm^{-1} (QY=0.11). This NovoLux 640 sample is 110X brighter than Cy5.5 dye (extinction coefficient $2x10^5$, QY=0.2). Furthermore, NovoLux 640 is more photostable than Cy5.5 and 8X brighter than APC.
As mentioned, the fluorescent brightness of NovoLux dyes can be tuned for desired brightness to meet various sample needs. The extinction coefficient of NovoLux dyes can be as high as $1x10^{10}$ M^{-1} cm^{-1} [1].This unique property allow increase in signal to noise ratio, thus results in detection of rare antigens. The spectral properties, tunability, and application of NovoLux dyes in flow cytometry will be presented during the meeting.

Toxicological and Immunological Response Towards Carbon Nanomaterials—Hollow Carbon Spheres vs Graphene and Carbon Nanotubes Isabel Gessner[1], Sourav Mukherjee[2], Fernando T. Andón[2], Tim Ludwig[1], Michael Wilhelm[1], Bengt Fadeel[2] and Sanjay Mathur[1]; [1]University of Cologne, Germany; [2]Karolinska Institutet, Sweden

Carbon-based nanomaterials including low dimensional hollow carbon spheres (HCS) as well as graphene (GO) and carbon

nanotubes (CNTs) have found increasing application in various fields of our research and everyday life, being even considered as carriers for therapeutics and as intracellular imaging units. However, when it comes to medicinal applications of nanomaterials, toxicity remains a key issue. Approval of new therapeutic tools requires a detailed understanding of material-cell interactions starting with interactions with the first line of defense in our body, the immune system. We therefore synthesized HCS and GO nanosheets and evaluated their cytotoxic potential in comparison to single-walled CNTs (SWCNTs) towards human-monocyte derived macrophages. Besides electron microscopic evaluation of nanomaterial uptake and intracellular distribution, the formation of reactive oxygen species (ROS) and secretion of pro-inflammatory cytokines and chemokines was investigated revealing significant differences between carbon-based materials. Moreover, receptor line specific assays as well as by computational data were performed to analyze the roll of toll-like receptors (TLRs) in immunological nanomaterial sensing.

Late News: The 'Chemistry' in Chemical Vapour Deposition CNT Growth—Insight from Molecular Simulations Alister Page; The University of Newcastle, Australia, Australia

Over the last few decades, catalytic chemical vapor deposition (CVD) has matured as a synthetic technique for producing carbon nanotubes (CNTs) and graphene. The general mechanism of graphene and CNT formation during CVD is now well established [1]; nucleation and growth begin with the precipitation/aggregation of carbon atoms on a catalyst surface to form extended carbon chains, which quickly combine and oligomerise to form “islands” of sp^2-hybridized carbon. Larger nanostructures then form *via* the coalescence of these structures on the catalyst surface, which are stabilised through strong carbon-catalyst σ-bonding.

However, by and large this picture of nucleation has been developed by considering the chemistry of carbon by itself, when, in reality, there are many other chemical species present in a CVD reaction chamber. In this lecture I will discuss our recent work that shows the influence of such species on the nucleation and growth mechanisms of carbon nanomaterials during CVD (e.g. H_2 [2,3], H_2O [4], NH_3 [5], acetonitrile [6] etc.). I will also discuss how they influence catalyst formation and CNT nucleation during floating-catalyst CVD with ferrocene precursors [7]. Our simulations demonstrate how each of these parameters can potentially be exploited towards controlling growth. Importantly, we show that chemical etchants play key roles regarding growth control and kinetics, despite being overlooked in popular growth models to date.

Understanding Deformation and Exfoliation as a Route to Improved Exfoliation Yield and Topological Surface States Sarah J. Haigh[1], Zheling Li[1], Aidan Rooney[1], Yaping Yang[1], Robert Young[1], Feng Ding[2] and Artem Mishchenko[1]; [1]University of Manchester, United Kingdom; [2]Ulsan National Institute of Science and Technology (UNIST), Korea (the Republic of)

Scanning Transmission Electron Microscopy (STEM) is a key technique for probing the local defect microstructure of 2D materials and their parent crystals at the atomic scale. By combining STEM with electron energy loss spectroscopy and energy dispersive X-ray spectroscopy the local chemistry can also be investigated. Here we demonstrate the use of STEM imaging and analysis to investigate the microstructure of mechanically deformed and liquid phase exfoliated 2D van der Waals materials (graphite, boron nitride, $MoSe_2$).
We find that at the atomic scale the bending behaviour, and types of microstructural defect that result, can be predicted from

just the bend angle and thickness of the materials.[1] In particular, we find that above a critical thickness the deformed materials exhibit numerous twin boundaries and for large bend angles these can contain nanoscale regions of local delamination. Such microstructural features are proposed to be important in determining how easily the material can be thinned by mechanical or liquid phase exfoliation.[1] Recent work has extended these studies to consider the microstructure of liquid exfoliated 2D van der Waals materials at the early stages of processing.[2] We demonstrate that during ultrasonic liquid phase exfoliation, the transition from graphite flakes to graphene takes place in three distinct stages. Firstly, sonication leads to the rupture of large flakes and the formation of kink band striations on the flake surfaces, primarily along zig-zag directions. Secondly, cracks form along these striations, and together with intercalation of solvent, lead to the unzipping and peeling off of thin graphite strips that in the final stage are exfoliated into graphene.[2] We anticipate that the findings will be of great value in the quest to optimize the lateral dimensions, thickness and yield of graphene and other 2D materials for various applications.
Furthermore, we demonstrate that in deformed graphite, zigzag kink bands (and associated twin boundaries) induce local stacking faults. Thus, the Raman signature of zigzag kink bands in graphite can be used to determine crystallographic directions. A sequence of ideal zigzag twin boundaries produces a region of crystal with a complex and highly unfavourable stacking sequence AABBCC.[1] We find that by peeling along specific crystallographic direction mechanical exfoliation can be used to induce large areas of thermodynamically unfavourable rhombohedral (ABC) stacking in graphite. then perform directional encapsulation of ABC-rich graphite crystallites with hexagonal boron nitride (hBN). Encapsulation with hexagonal boron nitride, which is introduced parallel to the graphite zigzag edges, preserves ABC stacking, while encapsulation along the armchair edges transforms the stacking to ABA. [3] The ability to create and preserve ABC stacking has recently been used to reveal an abundance of exotic interaction-induced physics including topological surface states in this material. [4]

***In Situ* TEM Studies on 2D Materials** Xuedong Bai; Chinese Academy of Sciences, China

Two-dimensional (2D) materials show a variety of promising properties, and characterizing their structural properties is fundamental for basic research and practical applications. In-situ transmission electron microscopy (TEM) method is powerful in a way that it can directly correlate the atomic structure with physical and chemical properties. By using the in-situ TEM technique, the physical and chemical properties of nanomaterials have been investigated. In this presentation, we will report our progress on studies of electrochemical properties and phase transition mechanism of carbon nanostructures and 2D layered transition metal dichalcogenides (TMDs) by alkali metal storage. And the epitaxial growth of large-scale single crystal *h*BN monolayer will be also included.

6:00 AM *F.NM03.05.03
Defects and Interlayer Coupling in van der Waals Heterostructures Nedjma Bendiab[1], G. Nayak[1], Simone Lisi[1], D. Kalita[1,2], M. Lazzeri[3], J. Renard[1], V. Bouchiat[1], J. Coraux[1] and L. Marty[1]; [1]Univ. Grenoble Alpes, CNRS, Grenoble INP, Institut NEEL, France; [2]Sorbonne Université, MNHN, UMR CNRS, France; [3]CEA, INAC-PHELIQS, France

Van der Waals heterostructures give access to a wide variety of new phenomena that emerge due to the combination of layered materials with different properties. One of the key engineers the properties of 2D materials could be in the ability to alter their structure in a controllable way. Different methods are possible: functionalization, intercalation, inducing defects etc. Whatever the chosen method the consequences is a strong modification of their structure and thus on their electronic and vibrational properties. All these effects can be probed efficiently by optical phonons. Up to now various methods have been used as argon bombardment, electron beam irradiation, graphene oxidation, ..ect.

In this work we will try to unravel the structural modification induced by defects in the case of graphene and MoS2. In the case of few- and single-layer MoS2 hosting substantial defects densities, these defects are thought to influence the doping level, the crystal structure, and the binding of electron–hole pairs. We disentangle the concomitant spectroscopic expression

of all three effects and identify to what extent they are intrinsic to the material or extrinsic to it, i.e., related to its local. We discover a defect-bound state having a low binding energy of 20 meV that does not appear sensitive to strain and doping, unlike charged excitons. Conversely, the defect does not significantly dope or strain MoS2 [1].

We also show here that due to an enhanced interaction cross section in such structure, made of molybdenum disulphide and boron nitride, electron-hole pairs can be generated by incident electrons and give rise to cathodoluminescence. Using Raman spectroscopy and photoluminescence, we show that low energy electron beam irradiation can nevertheless cause irreversible structural damages in molybdenum disulphide. A correlation between molybdenum disulphide/boron nitride coupling and the defect creation is established. Our work demonstrates that cathodoluminescence is powerful tool images the electronic properties in van der Waals heterostructures at the nanometer scale.
In the case of graphene, we report the observation of an intense anomalous peak in the Raman spectrum in specific growth conditions that cannot be attribute to structural defects. In fact, bombardment with an electron beam demonstrates that this new peak is clearly distinct from the well-studied D' peak appearing as defects are created in graphene [3].

Electron-Beam Manipulation of Covalently Bound Lattice Impurities Toma Susi; University of Vienna, Austria

Covalently bound impurity atoms in crystal lattices can be manipulated using the atomically focused electron probe of an aberration-corrected scanning transmission electron microscope. This has unveiled new perspectives for top-down atomic engineering, with the potential to surpass existing techniques in both versatility and capabilities. Such advances have been made possible by developments in electron optics and instrument stability, and the incorporation of impurity elements using techniques such as ion implantation [1].

The first system where this potential was realized was incidental silicon impurities in single-layer graphene. Elastic backscattering of an energetic probe electron from a moving C nucleus [2] causes the Si to *directly exchange* places with one neighboring C atom via an out-of-plane displacement [3], and such dynamics can be controlled by directing the focused electron beam at the desired atom [4,5]. Recent experiments have demonstrated greatly improved control [6], with a manipulation rate already nearly on par with any atomically precise atom manipulation technique. Such manipulation is also possible in large-diameter single-walled carbon nanotubes [7].

Besides Si impurities, P dopants in graphene can be manipulated with an electron beam [8], but at least for the out-of-plane displacement mechanism, it seems there are physical limits on what is feasible since significantly heavier Ge impurities cannot be thus manipulated [9]. The curious replacement of irradiated impurities by carbon atoms has also emerged as a practical hurdle for the further scaling of the technique. However, there are many possible lattice impurity atoms whose atomic dynamics under electron irradiation have been observed, including N and B [10], though their manipulation has not yet been demonstrated.

Even more excitingly, the electron-beam manipulation of Bi dopants in bulk silicon was recently reported [11], although the precise mechanism remained unclear. We have applied our established *ab initio* modeling methodology [12] to address this question, revealing a novel type of mechanism we call *indirect exchange*. Contrary to the process in graphene, the primary knock-on atom does not end up as a neighbor of the impurity, but as a next-nearest neighbor, displacing another silicon atom during the dynamics. It is thus clear that electron-beam manipulation of lattice impurities has opened an exciting new frontier for materials science and nanotechnology.

7:00 AM F.NM03.05.05
Vertically Oriented Graphene Edges as a Tuneable Support to Preferentially Align Metal Electrocatalysts for Energy Conversion Reactions Constantine Tsounis[1], Nicholas Bedford[1], Rose Amal[1] and Zhaojun Han[1,2]; [1]UNSW Sydney, Australia; [2]CSIRO, Australia

Engineering the metal-carbon hetero-interface has become an increasingly important route toward achieving cost effective and high performing electrocatalysts. In general, these interfaces can alter the valence states of metal electrocatalysts, changing the adsorbate energy of intermediates, and thus the reaction kinetics. The unique properties of graphene edge sites, such as the high available density of states and extended unpaired π-bonding, make it a promising candidate to tune the electronic properties of metal catalysts. Yet to date, understanding and leveraging graphene edge-metal catalysts for improved electrocatalytic performance remains largely elusive.

We demonstrate an efficient yet tuneable method to synthesize graphene edge planes at scale by combining plasma-enhanced chemical vapor deposition (PECVD) methods with a post-treatment Ar plasma. PECVD results in the growth of vertically aligned graphene (VG), with high surface area, an open and interconnected 3D structure, good mechanical stability, and high conductivity, on a range of substrates such as metal foams, foils, and carbon fibers. On the other hand, the Ar plasma post-treatment acts to induce branching of the graphene edges, rearranging carbon atoms under the plasma induced electric field, systematically increasing their exposed surface. By employing this method, it becomes possible to synthesize carbon-based electrocatalytic supports with desirable properties and edge-states, at large scale.

To demonstrate a specific application which exploits the exposed edge planes of VG, we employed this combined PECVD method with Ar plasma post-treatment to synthesize edge-rich VG (er-VG), and used it as a support for electrodeposited Ni-Fe hydroxides in the oxygen evolution reaction (OER). The hybrid Ni-Fe/er-VG catalyst exhibits excellent OER performance with a mass current of 4051 A g^{-1} (at overpotential $\eta = 300$ mV) and turnover frequency (TOF) of 4.8 s^{-1} ($\eta = 400$ mV), outperforming Ni-Fe deposited on pristine VG and other metal foam supports.

To understand how the edges were able to influence the valence state properties of the deposited metal, angle-dependent X-ray absorption spectroscopy was used to show that the edge-rich VG support can preferentially template Fe-O units with a specific valence orbital alignment interacting with the unoccupied density of states on the graphene edges. This graphene edge-metal interaction was shown to facilitate the formation of undersaturated and strained Fe-sites with high valence states, while promoting the formation of redox-activated Ni species, thus improving OER performance.

These findings open new opportunities in rationally designing the graphene edge-metal interface in electrocatalysts for various energy conversion and chemical synthesis reactions.

Fast Ion Diffusion in Carbon Nanotube Channels Steven F. Buchsbaum, Melinda Jue, Chiatai Chen, Sei Jin Park, April Sawvel, Eric Meshot, Edmund Y. Lau, Tuan Anh Pham, Kuang Jen Wu and Francesco Fornasiero; Lawrence Livermore National Laboratory, United States

Many simulations and experiments have investigated pressure-driven fluid flow in carbon nanotubes (CNTs) and demonstrated enormous transport rates through these channels. Comparatively little attention has been given so far to concentration-driven transport[1,2] in CNTs despite its importance in a large variety of fields. While several studies assumed bulk/hindered diffusion for small molecules through nm-wide CNTs, other simulations have predicted self-diffusion coefficients several times larger than in the bulk. These large uncertainties in the magnitude of the diffusion rates through CNTs have hampered their full exploitation in nanofluidic devices.[3]

To obtain a precise quantification of the diffusive flow in CNTs, we have fabricated membranes with a large but known number of single-walled carbon nanotubes (SWCNT) as fluid transport pathways. Contrary to previous membrane systems, this platform enables us to minimize uncertainties in the calculation of the per-pore flow rate. A series of stringent control experiments confirms that these membranes are defect free and that transport occurs only through SWCNTs. Once corrected for the boundary layer resistance at the membrane/fluid interface, our measurements reveal that the transport diffusivity of

small ions in single-walled carbon nanotubes is more than one order of magnitude faster than in the bulk.[4] This flow enhancement scales with the ion free energy of transfer from bulk solutions to a nanoconfined, lower-dielectric environment. Together with indicating that CNT membranes could enable dialysis processes with unprecedented efficiency, these results have important implications for a broad range of applications such as energy storage/harvesting and chemical separation/detection, where ion permeation through nanoporous carbon materials is key.

Tailoring Electronic Structure of SWCNTs for Transparent and Conductive Film Applications Albert Nasibulin[1,2]; [1]Skolkovo Institute of Science and Technology, Russian Federation; [2]Aalto University, Finland

Single-walled carbon nanotubes (SWCNTs) are among the strongest candidates for the replacement of commonly used transparent and conductive films (TCFs) based on doped metal oxides, such as indium tin oxide. SWCNTs possess unique multifunctional nature, which is based on their outstanding combination of mechanical strength and flexibility, chemical stability, exceptional electrical conductivity and optical properties. However, to fully utilize these properties in modern transparent electrode applications, SWCNT-based TCFs have to demonstrate the optoelectronic performance at the level of high-end ITO-based TCFs. This has not been achieved for SWCNT films yet and as a result limit their practical usage.

Using gold chloride as the most effective dopant for the SWCNTs, we improve their optoelectrical characteristics by optimizing the doping solvent and conditions. We examined various solvents to push the optoelectrical performance of the TFCs based on SWCNTs. As a result, we obtained the sheet resistance as low as 40 Ω/sq at the transmittance of 90% (at 550 nm) using 15 mM $HAuCl_4$ solution. This optoelectrical performance is better than that of ITO on PET substrates and satisfy most of the requirements for modern applications and relatively stable without additional protection over two years storing under ambient conditions.

We propose a few interesting novel methods for SWCNT doping: aerosol doping and dip-coating methods will be discussed.

The effect of the presence of catalyst particles on the optoelectronic properties of the SWCNT films is also investigated.

Also, we propose a novel approach to enhance optoelectronic performance of SWCNTs using ionic liquid. The method provides fine and reversible tuning of optoelectrical properties of SWCNT films over a wide range of parameters. Using imidazolium-based ionic liquid with a wide electrochemical window (BMIM-PF_6), we achieved the film sheet resistance as low as 53 Ω/sq at the 90% transmittance, thereby shifting the SWCNT Fermi level up to 1.4 eV. We believe the results to promote collateral research of adjustable tuning of the electronic structure of carbon nanomaterials as promising components for future electronics, electrochromic devices, and ionotronics.

Although carbon nanotubes have been already demonstrated to be a promising material for bolometric photodetectors, the sensitivity enhancement while maintaining the speed of operation remains a great challenge. Here, we present a holey carbon nanotube network, designed to improve the temperature coefficient of resistance for highly sensitive ultra-fast broadband bolometers. Treatment of carbon nanotube films with low frequency oxygen plasma allows fine tuning of electronic properties of the material. The temperature coefficient of resistance of our films is much greater than reported values for

pristine carbon nanotubes, up to -2.8% K^{-1} at liquid nitrogen temperature. The bolometer prototypes made of the treated films demonstrate high sensitivity in a wide IR range, short response time, smooth spectral characteristics and low noise level.

And finally, we develop a novel transparent p-type flexible electrode based on SWCNTs combined with poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS), molybdenum oxide and SWCNT fibers. We achieved a record equivalent sheet resistance of 17 Ω/sq with a transmittance of 90% at 550 nm and a high degree of flexibility. We demonstrate that our solar cells based on the proposed electrode and hydrogenated amorphous silicon (a-Si:H) yield an outstanding short-circuit current density of J_{sc} = 15.03 mA/cm^2 and a record power conversion efficiency of PCE = 8.8% for SWCNTs/a-Si:H hybrid solar cells.

Selectivity, Ion Transport and Osmotic Power Generation in Boron Nitride and Carbon Nanotube Membranes Semih Cetindag[1], Aaditya Pendse[2], Richard Castellano[1], Joshua Yi[1], Robert F. Praino[3], Sangil Kim[2] and Jerry Shan[1]; [1]Rutgers, The State University of New Jersey, United States; [2]University of Illinois, Chicago, United States; [3]Chasm Advanced Materials, United States

Carbon nanotube (CNT) membranes are known to have enhanced transport of fluids, including water vapor, gases, and liquids. They are not known for having enhanced ion transport or being ion-selective, unless their pores are sub-nanometer in diameter or their tips/surfaces are functionalized. On the other hand, recent experiments with single ~30-80nm-diameter boron-nitride nanotubes (BNNTs) have reported large surface charge in aqueous solution, and ion selectivity for diameters beyond the well-known Donnan exclusion that is typical of separation membranes. When placed in a salt-concentration gradient, the single BNNT generated electrical power from the Gibbs free energy of mixing at power densities up to 4,000 W/m^2 when extrapolated to macroscopic membranes. However, no such macroscopic BNNT membranes have ever been fabricated, and their performance at large scales and pore densities has been unknown.

Here, we describe the scalable fabrication of the first macroscopic, vertically aligned- (VA-) BNNT membranes with pore densities of 10^7 open-BNNTs/cm^2, and report their remarkable osmotic-power-generation performance. We make comparison to vertically aligned carbon-nanotube membranes fabricated by the same solution-based technique, which have similar atomically perfect, 1D (but uncharged) pores. We find that that the fast, selective ion transport in 3 and 12 nm-diameter BNNT pores arises from enhanced diffusio-osmotic transport of concentrated cations next to the negatively charged surface, coupled with the deformation or removal of hydration shells around the ions. Due to nanoscale confinement and surface charge in their pores, the BNNT membranes were highly cation-selective, generating an open circuit potential of 295mV and a short circuit current of 20μA, even for 1M solution for which the Debye length is smaller than the nanotube radius. In comparison, CNT membranes with the same 3 nm-diameter pores showed no selectivity and generated negligible osmotic power. The BNNT pores showed fast cation transport rates under a concentration gradient, exceeding the rate of bulk diffusion by at least 21× for Li^+. This ultrafast, selective cation transport in BNNT pores generated osmotic power via reverse electrodialysis at extraordinary power densities of 14,000 W/m^2 of open pore area for 1M:1mM LiCl solutions at pH 11. With surface-dominated transport, novel ion-selective membranes with 1D BNNT pores overcome the traditional trade-off between selectivity and transport rates in polymeric membranes, and may enable harvesting of blue energy, as well as efficient desalination and other separations, via a fundamentally different mechanism than conventional systems.

Molybdenum Disulfide Quantum Dot-Sensitized Zinc Oxide Thin-Film Solar Cells Jeff Kabel[1], Amit Acharya[1], Mingxiao Ye[2,1], Dongyan Zhang[1] and Yoke Khin Yap[1]; [1]Michigan Technological University, United States; [2]The University of Texas at Dallas, United States

Thin-film solar cells show promise for light-weight, low-cost, large area, flexible devices. Unlike competing materials, zinc oxide (ZnO) and molybdenum trioxide (MoO_3) are relatively abundant, environmentally stable, and have been proven effective for use in quantum dot-sensitized solar cells. The surfaces of nanostructures are often dominated with dangling bonds capable of trapping charges and limiting effective charge transport after electron-hole separation. Thus, it is anticipated that quantum dot-sensitized ZnO solar cells will be more efficient than devices constructed with traditional ZnO nanostructures. Molybdenum disulfide (MoS_2) has attractive features, including its semiconducting nature and indirect-to-direct band gap transition when cleaved from bulk to monolayer. MoS_2 quantum dots have been shown to have broad absorption bands, potentially making them invaluable for QD-sensitized photovoltaic devices. In this work, we use

conventional thin film technology to fabricate MoS_2 QD-Sensitized ZnO thin film solar cells.

A top-down approach was employed to convert bulk MoS_2 powder into QDs via sonication and solvothermal methods. The MoS_2 QDs absorb a wide spectrum of white, ranging from 320 nm to 520 nm, and fluoresce wavelengths ranging from 385 nm to 569 nm. This broad absorption wavelength contains the peak of the solar radiation spectrum, which enables effective photoelectron production in our device. Additionally, the QDs were found to exhibit fluorescence dependent on the excitation wavelength, enabling the production of excitons from a wider range of solar wavelengths.

Morphological characterization of the produced MoS_2 QDs was carried out using transmission electron microscopy (TEM) and atomic force microscopy (AFM), and statistical analysis of the lateral dimension and thickness was conducted. The MoS_2 QDs range from 2 – 40 nm in dimension. The devices were fabricated by depositing ZnO, MoS_2 QDs, MoO_3, and Au respectively onto commercial indium tin oxide (ITO) glass using pulsed laser deposition (PLD).Fluorometry measurements were conducted following each deposition to obtain the fluorescence spectra. The current-voltage characteristics of the devices were measured under the illumination of a solar simulator, and the fill factor and power conversion efficiency (PCE) were calculated. A detailed discussion of the results of optimized devices will be had during the presentation.

Morphology and Structure Optimization of Freestanding Reduced Graphene Oxide Films as Highly Conductive and Flexible Electrodes Tim Ludwig, Minyeong Je, Heechae Choi, Michael Wilhelm and Sanjay Mathur; University of Cologne, Germany

Lithium-ion-batteries (LIBs) are one of many applications that is expected to benefit from mechanical strength, high surface area and electrical conductivity of graphene when incorporated into electrode materials. For the integration in commercial LIBs, it is important to develop simple, cost effective and scalable methods for the production of graphene-like structures. Here we report on a green and simple wet chemical synthesis for the controlled formation of freestanding paper-like structures of regularly arranged graphene oxide (GO) flakes, using GO as starting material. As obtained structures were mechanically stable, scalable to mass production and could be used as flexible electrode materials in LIBs. Besides superior mechanical properties, rGO films led to increased volumetric energy densities due to the reduction in weight, making use of a current collector and the preparation of a battery slurry obsolete.
Moreover, morphology and structure of the material was significantly influenced by pre-reduction and vapor treatment of the films leading to enhanced electrical conductivities and lithium storage capacities. Especially in terms of defects and interlayer distances the results confirm the subtle interplay of chemical treatments and electronic properties of graphene oxide materials, which was additionally proven by DFT calculations.
In terms of cathode materials, freestanding rGO films served as a highly conductive backbone for lithium sulfide/rGO-composites, in which the active material was well-distributed within the carbon matrix. This prevents the agglomeration of lithium sulfide, buffers the volume change during cycling and offers a good accessibility for charge carriers.
Our results demonstrate the integration of freestanding and flexible rGO films into LIB half-cells highlighting their exceptional versatility and high application potential.

5:45 AM F.NM03.06.06
Porous Organo-Heterostructure Based Reduced Graphene Oxide Materials for Hydrogen Storage Feng Yan and Petra Rudolf; University of Groningen, Netherlands

Hydrogen is a promising sustainable alternative to conventional fuels that can push forward the energy transition because of its prominent advantages such as high energy density (142 MJ kg^{-1}), great variety of potential sources, light weight, and low environmental impact, while the storage remains a formidable scientific challenge. Magnesium hydride, with its inherently high gravimetric and volumetric density (7.6 wt.% & 110 g L^{-1}), presents a compelling platform for hydrogen storage, however, two major impediments hindered its practical utilization: the sluggish hydrogen kinetics of uptake and release process and high temperature operation.
Herein, a novel porous heterostructure material with high specific surface area and narrow pore size distribution was synthesized by sol-gel reaction of Graphene Oxide and an organosilicon precursor, followed by MgH_2 particle (d <5nm) grown in the framework. The material was characterized with BET, SEM, XRD and TEM and shows remarkable crosslinked layered structure with narrow interlayer distance. Studies of hydrogen storage properties showed that hydrogen released at low temperature (110 °C) and centred at 350 °C with kinetics dependent to some extent on the particle size.

Device Applications of One-Dimensional Van der Waals Hetero-Nanotubes Shigeo Maruyama; The University of Tokyo, Japan

We have synthesized a new coaxial nanotube structure, in which mono- or few-layer hexagonal boron nitride nanotube (BNNT) seamlessly wrap around a single-walled carbon nanotube (SWCNT); SWCNT@BNNT [1]. We named these as one-dimensional van der Waals hetero-nanotubes, because we found no correlation between chiral angle of inner SWCNT and outer BNNT for 'double-walled' SWCNT@BNNT. We have further developed the 1D coating CVD of transition metal dichalcogenide nanotubes (TMD-NT), such as MoS_2 nanotubes [1]. These nanotubes can be labelled as SWCNT@BNNT@MoS_2. Because BNNT is thermally more stable than SWCNT, we can remove SWCNT from SWCNT@BNNT by the gentle oxidation process. Hence, we can produce BNNT with inner diameter determined by the original SWCNT. Then, the MoS_2 CVD can result BNNT@ MoS_2. These hetero-nanotubes are characterized by HR-TEM, STEM-EELS, absorption, Raman and photoluminescence (PL) spectroscopy. We found the bright PL from MoS2 nanotubes for BNNT@ MoS_2. From DFT calculations, we expect that the K point direct band gap for 2D MoS_2 should appear for MoS_2 nanotubes with larger diameter such as 3-4 nm. The PL from MoS_2 was quenched by inner SWCNT (metallic or small band-gap semiconductor) in the hetero-nanotube, SWCNT@BNNT@MoS_2. So far, the coating growth can be efficiently performed for vertically aligned array of SWCNT, suspended SWCNTs between pillars, zeolite based bulk sample and dry-deposited random network films. For field effect transistor (FET) devices, we need to start from suspended SWCNTs. We will demonstrate the growth of suspended hetero-nanotubes between pillars and the transfer to Si/SiO_2 substrate for device characterizations.

Raman Response and Transport Properties of Tellurium Atomic Chains Encapsulated in Nanotubes Peide P. Ye; Purdue University, United States

Tellurium can form nanowires of helical atomic chains. With their unique one-dimensional van der Waals structure, these nanowires are expected to show physical and electronic properties that are remarkably different from those of bulk tellurium. Here, we show that few-chain and single-chain van der Waals tellurium nanowires can be isolated using carbon nanotube and boron nitride nanotube encapsulation. With this approach, the number of atomic chains can be controlled by the inner diameter of the nanotube. The Raman response of the structures suggests that the interaction between a single-atomic tellurium chain and a carbon nanotube is weak, and that the inter-chain interaction becomes stronger as the number of chains increases. Compared with bare tellurium nanowires on SiO2, nanowires encapsulated in boron nitride nanotubes exhibit a dramatically enhanced current-carrying capacity, with a current density of 1.5 × 108 A cm−2 that exceeds that of most semiconducting nanowires. We also use our tellurium nanowires encapsulated in boron nitride nanotubes to create field-effect transistors with a diameter of only 2 nm. The work is in close collaborations with the research teams of Profs. Moon J. Kim, Wenzhuo Wu, Xianfan Xu, Hai-Yan Wang, Li Yang, Yoke Khin Yap.

Surface Functionalization of Nanocarbon Field-Effect Transistors Using Diazonium Chemistry Delphine Bouilly, Claudia Marcela Bazan, Anouk Béraud and Amira Bencherif; Université de Montréal, Canada

In field-effect transistors made of atomically-thin nanomaterials such as carbon nanotubes or graphene, functionalization of the nanocarbon surface is necessary to control its interaction with surrounding media, especially for applications as chemical or biosensors. Aryldiazonium salts are a common approach to form covalent adducts on nanocarbon materials, but controlling the density and position of grafts is a challenge. In this presentation, I will describe the recent development of approaches based on nanolithography and electrochemistry to control the distribution of aryldiazonium-based adducts on nanocarbon materials. I will discuss differences between carbon nanotubes and graphene, as well as applications of such functionalized

field-effect transistors for biosensing and single-molecule experiments.

Nafion/CNT Passivated Charge Selective Contacts for Silicon Photovoltaics Ben Flavel; Karlsruhe Institute of Technology, Germany

In the past, the application of carbon nanotube-silicon solar cell technology to industry has been limited by the use of a metallic frame to define the active area in the middle of a silicon wafer. In our work, we use industry standard device geometries with a front- and back-junction design which allow for the entire wafer to be used as the active area. These are enabled by the use of an intermixed Nafion layer which simultaneously acts a passivation, antireflective and physical blocking layer as well as a nanotube dopant. This leads to the formation of a hybrid nanotube/Nafion passivated charge selective contact (PCSC) and solar cells with active areas of 1 – 16 cm^2 are fabricated. Record maximum power conversion efficiencies of 15.2% and 18.9% are reported for front- and back-junction devices for 1 cm^2 and 3 cm^2 active areas, respectively. By placing the nanotube film on the rear of the device in a back-junction architecture many of the design related challenges for carbon nanotube silicon solar cells are addressed and their future application to industrialized processes are discussed.

Additionally, traditional silicon solar cells extract holes and achieve interface passivation with the use of a boron dopant and dielectric thin films such as silicon oxide or hydrogenated amorphous silicon. Without these two key components, few technologies have realized power conversion efficiencies above 20%. We now develop a carbon nanotube/Nafion ink that can be spin coated directly onto a silicon wafer to serve simultaneously as a hole extraction layer, but also to passivate interfacial defects. This enables a low-cost fabrication process that is absent of vacuum equipment and high-temperatures. Power conversion efficiencies of 21.4% on an device area of 4.8 cm^2 and 20% on an industrial size (245.71 cm^2) wafer are obtained.

6:00 AM F.NM03.07.07
Radio Frequency Heating of Carbon Nanomaterial-Based Structures—Universal Patterns and Application to Electronic Circuit Characterization Muhammad Anas[1], Mazin Mustafa[1], Daniel Carey[1], Lee Moores[2] and Micah Green[1]; [1]Texas A&M University, United States; [2]U.S. Army Engineer Research and Development Center, United States

Our group has recently demonstrated low frequency (1-200 MHz) and low power (<100 W) radio frequency (RF) heating of carbon nanomaterial-loaded structures such as thin films and polymer nanocomposites using an array of contact and non-contact applicators. These heating techniques have opened up routes for faster and efficient composite manufacturing, 3D printing, and fiber processing. It is known that electrical conductivity is required for RF heating of carbon-based nanomaterials. However, it is not well understood how RF heating rates vary with conductivity and if the pattern is generalizable for all types of RF susceptor-loaded structures. In this work, we use experiments and simulations to explore the universal patterns observed between RF heating rates and in-plane electrical conductivity for different nanomaterial-loaded thin films. We also show existence of similar patterns in chirality-sorted nanomaterial films, and finally we show a novel RF heating-based high-throughput quality screening technique for carbon nanotube circuits.
We synthesize multi-walled carbon nanotube (MWCNT) films, laser-induced graphene (LIG) films, and carbon nanofiber-polyamide (CNF-PA) composites of varying electrical conductivity by changing sprayed film thickness, laser parameters, and CNF content, respectively. We use a coplanar strip fringing-field applicator to assess RF heating behavior of nanomaterials in the frequency range of 1-200 MHz and at power of 2 W. This applicator allows for non-contact capacitive coupling of RF fields with the sample and heat it as high as 70°C/s at 2 W.
We find that for each of the nanomaterials tested, the highest heating rate observed across all frequencies is non-monotonically related with the in-plane electrical conductivity. This relationship has a distinguished maximum at approximately the same DC in-plane electrical conductivity (in the range of 0.1-0.2 mS) for all nanomaterials. We find that the point of maximum heating rate is closely associated with the percolation threshold. It is because at percolation a conductive network is formed and if the conductivity is increased further, reflections of RF fields lead to decrease in heat rates. This is also confirmed by our assessment of RF heating behavior of sorted and purified metallic (m-) and semi-conducting (s-) single-walled carbon nanotubes (SWCNTs). We find that 98% pure m-SWCNT film reflect RF fields and

heat at a highest rate of 2 °C/s compared to 100% pure s-SWCNT film's highest heating rate of 26 °C/s. We also find that the presence of impurities in the m-SWCNT film increases its heating rate to 10 °C/s due to disruption of the conductive network. These findings could make RF heating a promising metric for evaluating m-SWCNT film purity.
Finally, we apply the conductivity dependent RF heating behavior to demonstrate a reliable and high-throughput screening method for screen-printed MWCNT circuits. We show that large amounts of circuits can be simultaneously scanned over a fringing-field applicator which allows for rapid screening based on the uniformity of thermal response and the heating temperature observed using a thermal camera. This method is ideal for faster production of CNT circuits and replaces previous time-consuming quality metrics such as 2-point probe and 4-point probe measurements. It provides a tenfold increase in speed, allowing for real-time monitoring of circuits as they are produced. The scanning method is more reliable than the traditional metric in screening-out faulty circuits and can also be employed at various stages of the circuit manufacturing process.

6:10 AM F.NM03.07.08
Excess Polymer in Single-Walled Carbon Nanotube Field-Effect Transistors—Does It Really Need to be Removed Prior to Fabrication Nicole Rice[1], Brendan Mirka[1], Phillip Williams[1], Mathieu Tousignant[1], William J. Bodnaryk[2], Darryl Fong[2], Alex Adronov[2] and Benoit Lessard[1]; [1]University of Ottawa, Canada; [2]McMaster University, Canada

Single-walled carbon nanotubes (SWNTs) are promising nanomaterials for incorporation into solution-processed organic electronic devices (OEDs). As-synthesized SWNTs are insoluble and comprised of a mixture of metallic and semiconducting SWNTs (sc-SWNTs), necessitating dispersal and purification before integration into OEDs. Refinement of conjugated polymer extraction techniques has allowed for the isolation of sc-SWNTs from metallic in a reproducible and scalable manner, affording highly-soluble dispersions of sc-SWNTs for potential integration into inexpensive solution-processing techniques. Furthermore, the availability of ultrapure sc-SWNT materials has facilitated the production of field-effect transistors (FETs) with very high charge carrier mobilities and good on-off ratios, outperforming most organic semiconducting small molecules and polymers.
Despite the plethora of high-quality polymer-sorted sc-SWNT dispersions reported in the literature, the realization of commercial OED applications has not yet been achieved. This is partially attributed to the prohibitive time and materials costs associated with purifying sc-SWNTs. Current protocols for dispersing sc-SWNTs with conjugated polymers typically involve three broad steps: (1) dispersion of bulk SWNT material with the conjugated polymer, (2) removal of non-dispersed carbonaceous materials, and (3) removal of excess polymer through filtration or centrifugation. While the first two steps are relatively facile and can be performed on large scales, the final step of removal of excess polymer is laborious and resource-intensive. However, removal of excess polymer is viewed as essential for preparing high-performing FETs, as the conjugated polymer has much lower performance compared to SWNTs.
In this study, we performed the first systematic investigation of the effect of excess polymer during device fabrication on SWNT FET performance. Large numbers of replicate FET devices were characterized using several metrics, including mobility, threshold voltage, on/off ratios and hysteresis. Two different conjugated polymers were investigated at three different SWNT concentrations, with varying ratios of excess polymer added. Extensive analysis of the polymer-sorted sc-SWNT films through Raman spectroscopy and atomic force microscopy (AFM) showed that below a threshold amount of excess polymer, a simple rinsing step was sufficient to remove all unbound polymer from the substrate surface. The volume of solvent required for this rinsing step was substantially lower than that required for filtration or centrifugation; additionally, many literature procedures for sc-SWNT FET device fabrication already incorporate similar solvent rinses. Most importantly, at higher SWNT concentrations, the presence of excess polymer during device fabrication resulted in moderately improved device performance in both mobility and on/off ratios, with preeminent devices achieved from the original dispersions (before removal of excess polymer) for both polymer systems. Analysis of AFM images of these polymer-sorted sc-SWNT films with a novel Machine Learning algorithm showed that improved device performance could be attributed to more even sc-SWNT films and reduced bundling. Our results have important implications in the development of SWNT inks for commercial printing applications, as the presence of excess polymer can both increase the stability of the inks, as well as improve viscosity.

6:20 AM F.NM03.07.09
Late News: Electronic Properties of Bottom-Up Synthesized 17- and 13-Atom-Wide Graphene Nanoribbons Junichi Yamaguchi[1], Hironobu Hayashi[2], Hideyuki Jippo[1], Akitoshi Shiotari[3], Manabu Ohtomo[1], Mitsuhiro Sakakura[2], Nao Hieda[2], Naoki Aratani[2], Mari Ohfuchi[1], Yoshiaki Sugimoto[3], Hiroko Yamada[2] and Shintaro Sato[1]; [1]Fujitsu Laboratories Ltd. and Fujitsu Ltd., Japan; [2]Nara Institute of Science and Technology, Japan; [3]The University of Tokyo, Japan

Graphene nanoribbons (GNRs) exhibit unique electronic and magnetic properties that do not appear in two-dimensional graphene. These properties can emerge from the structural boundary conditions imposed by the atomically precise width and

edge structure of GNRs. For instance, armchair-edged GNRs (AGNRs) show sizable gapped electronic states established by the quantum confinement and edge effects. In graphene-based electronics, AGNRs with finite bandgaps at room temperature have attracted much attention for their potential reliability as semiconducting channels for field-effect transistors (FETs). For fabricating atomically precise GNRs, a bottom-up synthesis technique has recently been demonstrated via on-surface-assisted polymerization and subsequent cyclodehydrogenation of precursor monomers on metal substrates [1]. The bottom-up synthesis of *N*-AGNRs (where *N* is the number of carbon atom pairs across the ribbon) has been widely conducted because the bandgap of AGNRs can be tuned by changing their width. According to first-principles calculations using many-body perturbation theory (*GW* approximation) for freestanding *N*-AGNRs, the quasiparticle gap is predicted to be 3.80 eV for $N = 7$, 2.16 eV for $N = 9$, and 2.25 eV for $N = 13$ [2]. Previous studies on FETs using bottom-up AGNRs with widths of $N = 7$, 9, and 13 presented their electrical transport characteristics [3, 4]. However, in such GNR-based FETs, the intrinsic transport properties of AGNRs were obscured by a large Schottky barrier resistance between the AGNRs and metal contacts due to the large bandgaps in the above AGNRs, substantially exceeding 1 eV. These transport characteristics can be improved with wider AGNRs, as they are expected to have lower Schottky barriers arising from their small bandgap features.
In our presentation, we show the bottom-up synthesis of well-structured 17-AGNRs and 13-AGNRs on Au(111) by using 1,2-bis-(2-anthracenyl)-3,6-dibromobenzene and 1,2-bis-(2-naphthalenyl)-3,6-dibromobenzene, respectively [5]. To systematically control the width of these AGNR, in the precursor monomers, either two anthracene or naphthalene units were attached at the *ortho*-positions of *p*-dibromobenzene. Characterization of the atomic and electronic structures of the 17- and 13-AGNRs on Au(111) was carried out by combining scanning tunneling microscopy and spectroscopy (STM/STS) and non-contact atomic force microscopy (nc-AFM). In both AGNRs, STM and nc-AFM observations revealed their widths and armchair-edged structures at atomic precision. In the *GW* calculations, the quasiparticle gap for freestanding 17- and 13-AGNRs is predicted to be 0.63 and 2.25 eV, and their values are corrected as 0.20 and 1.29 eV considering the image-charge effects from the metal substrates [6]. By STS measurements, we revealed that the experimental gap is 0.19±0.03 and 1.34±0.03 eV for the 17- and 13-AGNRs on Au(111), which is consistent with the accordingly corrected quasiparticle gaps predicted from the *GW* calculations. For more detailed discussions on the electronic band dispersions of the 17- and 13-AGNRs, we carried out Fourier-transformed STS (FT-STS) measurements. We found that the FT-STS provides the electronic band dispersions, which reasonably match the simply rigid-shifted *GW* quasiparticle bands in both AGNRs. As far as we know, the bottom-up synthesis of 17-AGNRs is the first demonstration of GNRs having a bandgap smaller than 1 eV in a controlled manner, which will pave the way for the development of GNR-based electronic devices.

Global Alignment of Solution-Based Single-Wall Carbon Nanotube Films via Machine-Vision Controlled Filtration William Rice[1,2], Joshua Walker[1], Jeffrey Fagan[3], Adam Biacchi[3], Valerie Kuehl[1], Thomas A. Searles[4] and Angela Hight Walker[3]; [1]University of Wyoming, United States; [2]Charles Stark Draper Laboratory, United States; [3]National Institute of Standards and Technology, United States; [4]Howard University, United States

Over the past decade, substantial progress has been made in the chemical control of single-wall carbon nanotubes (SWCNTs). Large, horizontally aligned films can now be created out of post-processed SWCNT solutions, which has lead to advances in SWCNT physics, including the observation of intersubband plasmons, hyperbolic thermal emission, ultrastrong exciton-polariton coupling, nanotube quantum wells, and directional nanotube optoelectronics. Here, we use machine-vision automation to simultaneously produce globally aligned SWCNT films using pressure-driven filtration. Feedback control enables filtration to occur with a constant flow rate that not only improves the nematic ordering of the SWCNT films, but

also provides the ability to align a wide range of SWCNT types and on a variety of nanoporous membranes using the same filtration parameters. Using polarized optical spectroscopy, we show that under standard implementation meniscus combing produces a two-dimensional radial SWCNT alignment on one side of the film. After we flatten the meniscus through silanation, spatially resolved nematicity maps on both sides of the SWCNT film reveal global alignment across the entire structure. From experiments changing ionic strength and membrane charging, we provide evidence that the SWCNT alignment mechanism stems not from pre-existing membrane grooving, but from membrane charging.

Inner and Outer Side Doping of Single-Walled Carbon Nanotubes Anastasia E. Goldt[1], Mikhail Bulavskiy[1], Orysia Zaremba[1], Alexey P. Tsapenko[1,2], Konstantin V. Larionov[3], Zakhar I. Popov[3], Kimmo Mustonen[4], Pavel Sorokin[3], Fedor Fedorov[2] and Albert Nasibulin[1,2]; [1]Skolkovo Institute of Science and Technology, Russian Federation; [2]Aalto University, Finland; [3]National University of Science and Technology "MISiS", Russian Federation; [4]University of Vienna, Austria

Transparent conducting films are now in limelight of modern electronics driven by the expanding field of flexible devices that include displays, touch screens, solar cells, *etc.* Beside high transparency and good conductivity, such applications require rather good flexibility of materials to be preferably made under cost-effective fabrication protocols. As a result, the dominance of classical TCF material, indium tin oxide, is being impugned by alternatives like Ag nanowires mesh, PEDOT:PSS, graphene, reduced graphene oxide and single-walled carbon nanotubes (SWCNTs).

Here, we developed a novel easy strategy of simultaneous outer- and inner-surface SWCNT doping with $HAuCl_4$ ethanol solution for efficient optoelectrical performance enhancement. Application of the proposed strategy allowed us to obtain transparent conductive SWCNT films with a record equivalent sheet resistance value of 31 ± 4 Ω/sq at the annealing temperature of 400°C. We also showed that enhancement of optoelectrical properties of thermally treated SWCNT films should be attributed to the cap's removal during the annealing, thus providing feasible penetration of dopant solution into the inner SWCNT cavity under capillary forces. Electrochemical investigation of doping process confirmed more efficient *p*-doping of annealed SWCNTs in comparison to pristine. Besides, the origin of these differences was proposed to be switch of doping species from $[AuCl_4]^-$ to stronger electron-accepting $[AuCl_2]^-$. DFT-calculations of SWCNT doping proved more significant Fermi-level downshift in case of simultaneous doping from outside and inside of nanotube confirming stronger doping. Based on UV-vis-nIR and Raman spectroscopies we have established that caps' removal process starts from 300 °C annealing, while comparing the equivalent sheet resistances of doped films we found the optimal treatment temperature range to be 300 - 400 °C. The reliability of conclusions was confirmed by the results consistency of UV-vis-nIR and Raman spectroscopies, TEM imaging, electrochemical measurements and DFT-calculations.

The experimental part of the research was supported by the Russian Science Foundation (No. 17-19-01787).

Ultrahigh Thermoelectric Power Factors of Ultrahigh Conductivity Carbon Nanotube Fibers Natsumi Komatsu[1], Yota Ichinose[2], Oliver S. Dewey[1], Lauren W. Taylor[1], Mitchell Trafford[1], Yohei Yomogida[2], Matteo Pasquali[1], Kazuhiro Yanagi[2] and Junichiro Kono[1]; [1]Rice University, United States; [2]Tokyo Metropolitan University, Japan

Because of the rapid growth of integrated wireless sensor networks (WSNs), for diverse applications from health to environmental monitoring, recharge-free, safe, and flexible power sources are in urgent demand. Thermoelectric (TE) generators based on macroscopic, neat assemblies of carbon nanotubes are strong candidates due to their superb electrical, thermal, and mechanical properties, combining the advantages of inorganic and organic TE materials (*1*). Here we report an ultrahigh value of thermoelectric power factor at room temperature (14 ± 5 $mWm^{-1}K^{-2}$) for carbon nanotube fibers with an ultrahigh electrical conductivity ($>10^7$ Sm^{-1}). These fibers are also flexible, strong, and refractory at the same time (*2*). By combining these unique properties, we fabricated a wearable power generator. Through temperature and magnetic field dependent electrical conductivity measurements, we found that electrical transport in the fiber is highly metallic, showing small quantum corrections at the lowest temperatures (< ~40K). Our theoretical simulations, combined with Fermi-energy-dependent experiments through doping and gating, show that the observed ultrahigh power factor is a consequence of simultaneously enhanced conductivity and Seebeck coefficient when the Fermi energy is near a van Hove singularity in the electronic density of states of carbon nanotubes.

Carbon Nanotube-Cu Through-Si-via Interposer with Cu-Level Electrical Conductivity but Si-Comparable Coefficient of Thermal Expansion Guohai Chen, Rajyashree Sundaram, Asuko Sekiguchi, Kenji Hata and Don Futaba; National Institute of Advanced Industrial Science and Technology (AIST), Japan

In microelectronic packaging, an interposer is an intermediate substrate acting as a bridge connecting the nanometer-level I/Os at the die to the micrometer-level package at the substrate. A through-silicon-via (TSV) interposer is very common one with copper filled inside the via as interconnections. As electronic devices continue miniaturization, the significantly increased heat generation inside the miniature devices deteriorates their lifetime/reliability, generally caused by delamination or break at the interface due to the non-uniform strain distribution induced by the mismatch of the coefficient of thermal expansion (CTE) between Si and copper. Therefore, the demands for interposer materials with high electrical conductivity but low CTE are growing. Here we demonstrate a fabrication/application feasibility of carbon nanotube-copper (CNT-Cu) composite using as interposer utilizing its superior electrical and thermal properties. The CNT-Cu composite showed a Cu-level electrical conductivity (~2.5×10^5 S/cm) and Si-comparable CTE (~7 ppm/K). The CTE mismatch between CNT-Cu and Si was greatly reduced, only 1/5 of that between Cu and Si. Finally, we demonstrated several applications of CNT-Cu TSV interposer. The CNT-Cu TSV interposer may be one of potential candidates in microelectronic packaging.

5:45 AM F.NM03.08.05
Synthesis and Properties of Nanocomposites of Graphene Nanoribbons and Nanosheets Formed in Metals by an Electrocharging Assisted Process Lourdes G. Salamanca-Riba[1], Xiaoxiao Ge[1], Christopher Klingshirn[1], Madeline Morales[1,2], Oded Rabin[1,1], Manfred Wuttig[1], Christopher Shumeyko[2], Daniel P. Cole[2] and Shenjia Zhang[3]; [1]University of Maryland, United States; [2]U.S. Army Research Laboratory, United States; [3]General Cable, United States

Composites consisting of a metal matrix with embedded carbon nanostructures, such as graphene and carbon nanotubes, can have properties that take advantage of the excellent charge carrier mobility, thermal conductivity and mechanical strength of the carbon nanostructures and the high density of electrons in the metal. The combination of the composites' high mechanical strength with high electrical and/or thermal conductivities make them unique candidates in applications such as high power transmission lines, interconnects, heat exchangers, motors, photovoltaic cells and transparent electrodes, among others. Metal/nanocarbon composites made by chemical vapor deposition, friction stir, ball milling, and plasma spraying have yielded materials with enhanced hardness and tensile strength but unimproved electrical and thermal conductivities. We use an electrocharging assisted process to produce composites, which consists of the application of a high DC current to a mixture of liquid metal and particles of activated carbon. The high current density transforms the activated carbon particles from amorphous to crystalline graphitic nanoribbons in the liquid metal. Upon solidification of the metal the nanoribbons self-assemble with an epitaxial relation with the metal. We have used Al 1350 and activated carbon particles of <100 nm and obtained samples with global electrical conductivities more than 5% higher than the parent alloy as well as enhanced local stiffness, measured by nanoindentation. The conductivity enhancement is correlated with increasing crystallite size and concentration of the produced graphene nanoribbons. Molecular dynamic simulations of nanoindentation tests into the nanocarbon metal composite show how the graphene nanoribbons impede dislocation motion and increase hardness with little to no impact on elastic properties. Conductive AFM shows an increase in the local conductivity from these samples compared to the parent aluminum alloy.

Late News: High Aspect Ratio Pt Single-Walled Carbon Nanotube Composite Electrocatalysts for Sustainable Hydrogen Economy Olli Sorsa[1], Hua Jiang[1], Kari Laasonen[1], Toma Susi[2], Rachel Backhouse[3] and Tanja M. Kallio[1]; [1]Aalto University, Finland; [2]University of Vienna, Austria; [3]ITM Power, United Kingdom

Based on the IEA energy outlook [1], both solar and wind based energy supply will increase by more than one decade by the year 2040. This development lays foundation for the hydrogen economy concept where hydrogen serves as an energy carrier. Hydrogen utilization requires, however, introduction of efficient, durable and economically feasible electrochemical conversion technologies for converting electrical energy into hydrogen bond energy and *vice versa*. Electrochemical water splitting electrolyzers and fuel cells based on low-temperature membrane technologies can meet these expectations if their

key components, such as electrocatalysts for hydrogen reactions, can be improved to meet the sustainability and cost requirements. Today scarce platinum group metals (PGMs) are utilized to electrocatalyze the hydrogen evolution and oxidation reactions met in electrolyzers and fuel cells, respectively. In addition to PGM availability and cost issues, these electrocatalysts suffer from inadequate durability.
Here, utilization of high aspect ratio electrocatalyst comprising of Pt nanowire (PtNW) and particles on single-walled carbon nanotubes (SWNTs) is suggested as low PGM electrocatalyst [2]. SWNTs have several beneficial properties needed for electrochemical applications: In addition to high conductivity and good chemical and electrochemical durability, they have appropriate properties for fabricating 3D electrodes needed for efficient mass transfer during the reactions.
The feasibility of composite Pt/SWNT electrocatalysts is verified in a single cell laboratory-scale polymer electrolyte electrolyzer. In terms of activity, even with one tenth of Pt mass loading at the cathode (0.02 mg_{Pt} cm^{-2}), this catalyst accomplishes close to the level of the state-of-the-art Pt/C. The high activity is attributed to favorable PtNW interaction with the SWNTs as well as exposed PtNW edge-sites which adsorb hydrogen optimally and help to alleviate repulsive interactions on the nanowire surface. In addition, the metallic nature of Pt, morphological effects and enhanced surface wetting contribute positively to the performance.
The stability and durability are confirmed with 8,000 h of chronopotentiometry measurements and 10,000 potential cycles in the electrolyzer. These are combined with in-situ electrochemical and post-mortem analysis to investigate the durability of the electrocatalyst and aging mechanisms. Overall, the Pt/SWNT compares favorably to the reference Pt/C.

Transparent, Transferrable and Flexible Pseudocapacitors from Ternary PEDOT/V_2O_5/ Graphene with Record Durability in Organic Electrolytes Sanju Gupta[1,2]; [1]CCNY-CUNY, United States; [2]WKU, United States

Transparent conductive electrodes (TCEs) are of enormous significance to the continued growth of optoelectronic devices and the emergence of flexible and wearable electronics in the foreseeable future. Versatile and tunable TCEs, featuring not only high optical transmittance but also intriguing features of electrochemical energy-storage capability, flexibility, and transferability, remain a significant challenge. Here we strategically develop a graphene-conjugated V2O5/poly(3,4-ethylene dioxythiophene (from hereon, V2O5/PEDOT) hybrid, serving as an easily transferable, transparent, capacitive active electrode films. The constructed electrodes exhibit a high areal capacitance of 50-60 mF cm−2 at optical transparency of > 60 percent with a record durability over thousands of cycles. As demonstrated by experimental results, both the kinetic blocking of the PEDOT layer and the anchoring capability of graphene upon soluble vanadium ions from V2O5 nanoribbons/nanotubes contribute synergistically to the unusual electrochemical stability and electroactivity shown using scanning electrochemical microscopy. Transparent symmetric and asymmetric solid-state supercapacitors made of the as-fabricated pseudocapacitive TCEs deliver a broad voltage window of 1.4 V or higher under two different electrolytes (aqueous LiCl and organic gel made from LiCl and polyvinyl alcohol) demonstrate highest power and energy density that outperforms all the previously reported transparent devices (< 0.1 microWatt h cm^-2).

Thermal Diode Based on Polyethylene Nanofiber Xiao Luo and Sheng Shen; Carnegie Mellon University, United States

Thermal diode is a two-terminal device which rectifies heat flow. For its non-linear nature, interest in thermal diode has been growing for more than 15 years. Thermal diodes have been numerically and experimentally realized with bulk as well as nanomaterial. Among them, phase transition material can realize high rectification with relatively narrower temperature bias.

Current optimization studies of phase transition junction thermal diode consider phase transition as a step function of temperature, while in some cases phase transition could happen in a temperature range in the same magnitude with temperature bias. In this study we simulated and optimized the thermal diode based on our recently experimentally realized phase transition of polyethylene nanofiber with a finite temperature range of phase transition.

There is a phase transition within polyethylene nanofiber with high degree of crystallinity: crystalline structure shifts from orthorhombic to hexagonal cell with a sharp decrease of thermal conductivity within about 5K temperature range at around 430 ~ 450K[1]. E-beam irradiation can alter the phase transition behavior. Phase transition retains with a lower critical temperature if irradiation is weak, while phase transition disappears if irradiation is strong[2]. Thus, heavily-irradiated-pristine (HI-P) and lightly-irradiated-pristine (LI-P) junction diode can be fabricated by partially irradiating the PE nanofiber with different exposure time. HI-P junction can rectify heat flow in one certain direction, while LI-P junction can rectify heat flow in both directions under different working temperature.

Calculation based on finite temperature range of phase transition shows a smooth heat flow curve with a better match with experimental data. Calculation based on step-function phase transition gives a limit of rectification value but tends to overestimate the rectification performance under small temperature bias. Optimization formula derived from step-function model can still be used for estimating optimized length fraction of e-beam irradiation despite the range of temperature bias, as maximum rectification value always occurs when interface temperature difference is zero. Specifically, a proper value of thermal conductance value is required for LI-P junction such that rectification performances in both directions can be optimized with one single length fraction of irradiation.

A GFET Nitrile Sensor Using a Graphene-Binding Fusion Protein Abubaker A. Mohamed[1,1], Mirano Tsukiiwa[2], Hironaga Noguchi[2], Takumi Komikawa[2], Chen Chen[2], Qadri E. Mubarak[1], Rachel Heath[1,1], Masayoshi Tanaka[2], Mina Okuchi[2], Samuel de Visser[1,1], Yuhei Hayamizu[2] and Christopher F. Blanford[1,1]; [1]University of Manchester, United Kingdom; [2]Tokyo Institute of Technology, Japan

A bottleneck in the development of enzyme-based graphene field effect transistors is the protein immobilization method used. Non-specific adsorption of protein on graphene is undesirable as it hinder access to the enzyme's active site whilst also changing the natural conformation of proteins by having surface residues bind to the graphene surface. Proteins require specific 3D conformation to be functional and so label-free immobilisation methods is preferred as it increases sensing capabilities of biosensors by maintaining proteins catalytic activity upon immobilization.

Here, a bi-functional self-assembling and graphene-binding peptide was fused to a QueF nitrile reductase protein to create a fusion protein for nitrile detection. The peptide was derived from silk protein fibroin and is capable of forming stable antiparallel β-sheet structure on graphene (1) and so is used to guide protein immobilization. Incorporating this tag into various proteins for enhancing biosensing applications offers a new and effective platform for enzyme-based graphene field effect transistors.

QueF nitrile reductase was chosen because it is the only known enzyme capable of NADPH-mediate nitrile to amine reduction (2). Surface topology of the fusion protein functionalized graphene was observed by atomic force microscopy and showed that both oligopeptide and the fusion protein incorporating it formed a monolayer with six-fold symmetry.

The QueF fusion protein sensing capabilities was first assessed on its natural nitrile substrate which upon immobilisation on graphene field effect transistor showed a 1.4-fold increase in binding affinity compared the wild-type protein which did not incorporate the peptide tag.
Fusion protein was also used to create an agricultural biosensor through the detection on benzyl cyanide. Benzyl cyanide is a chemical distress signal produced by plants and detection of this compound could therefore be used to provide means for crop monitoring and pesticide administration. The fusion protein showed a 3.3-fold increase in response to benzyl cyanide when compared to the wild-type protein. Work here provides a novel immobaliastion method for enzyme based graphene field effect transistor biosensing.

Fullerene C_{76}—An Plored Superior Electrode Material with Wide Operating Potential Window for High Performance Supercapacitors Nageh K. Allam, Basant A. Ali and Ahmed Biby; American University in Cairo, Egypt

Carbon materials have widely been used to enhance the performance of a plethora of supercapacitor electrode materials. In this regard, it is crucial to identify carbon materials that function over a wide pH range while enjoying a wide potential window. Herein, the DFT calculations were used to elucidate the electronic performance of C_{76} and the C_{76}/electrolyte interface. The electronic investigation revealed the nature of the conductivity and charge storage mechanism of C_{76} based on the bandgap and quantum capacitance calculations. Also, the electrochemical and electronic properties of fullerene C_{76} have been extensively investigated over a wide pH range; acidic H_2SO_4, basic KOH, and neutral Na_2SO_4. The results showed a promising performance in the three electrolytes. Moreover, C_{76} electrodes exhibited a potential window of 1.9 V in Na_2SO_4 electrolyte, resulting in capacitances of 171 F/g and 142 F/g at a scan rate of 1 mV/s in the positive and negative potential windows, respectively. The material showed a pseudocapacitance performance of 65% in Na_2SO_4 electrolyte in the positive potential window. We believe higher fullerenes provide a new class of materials for developing versatile supercapacitor devices for efficient energy storage

F.NM03.09.14
***In Situ* Formation of Graphene Stabilizes Zero-Valent Copper Nanoparticles and Significantly Enhances the Efficiency of Photocatalytic Water Splitting** Nageh K. Allam; American University in Cairo, Egypt

There is a growing need for new techniques to synthesize metallic copper nanoparticles due to their remarkable use in many advanced technologies. Herein, a novel method to synthesize stable and non-agglomerated zero-valent copper nanoparticles (ZVCNPs) via the in-situ formation of reduced graphene oxide (rGO) during the electrospinning process in the presence of polyvinylpyrrolidone (PVP) as a carbon source is presented. X-ray diffraction (XRD), Raman spectroscopy, electron paramagnetic resonance (EPR), transmission electron microscopy (TEM), and x-ray photoelectron spectroscopy (XPS) techniques were used to investigate the morphology, structure, and composition of the fabricated materials. The synthesized ZVCNPs were coupled with TiO2 nanofibers and rGO to form an efficient photoactive material to photocatalytically produce hydrogen via water splitting, resulting in 344% increase in the hydrogen yield compared to that of TiO2 nanofibers. The density functional theory (DFT) calculations showed that the ZVCNPs enhance the charge transfer and lower the energy needed for photocatalytic water splitting. This study suggests a novel method for metallic copper stabilization and illustrates the effect of metallic copper as a catalyst for the in-situ formation of rGO.

Topology Influence of Hydroxyl and Epoxide Functional Groups on the Mechanical and Fracture Behavior of Graphene Domain Akarsh Verma[1] and Avinash Parashar[2]; [1]University of Petroleum and Energy Studies, India; [2]Indian Institute of Technology Roorkee, India

Aim of this article is to study the effects of hydroxyl functional group with different coverage percentages on the mechanical strength and fracture toughness of graphene. The hydroxyl functional group forms the backbone of intrinsic atomic structure of graphene oxide (GO).

Molecular dynamics based simulations were performed in conjunction with reactive force field (ReaxFF) parameters to capture the mechanical properties and Mode-I fracture toughness of functionalized graphene. Moreover, these simulations helped in concluding that spatial distribution and concentration of hydroxyl functional group significantly affects the fracture morphology of graphene nanosheet. Room temperature (300 K) was used for the simulations and virial stress components were evaluated for predicting the stress tensor.

In contrast to literature investigations, here the atomistic simulations have predicted a transition in the failure morphology of hydroxyl functionalised graphene from brittle to ductile as a function of its spatial distribution on graphene sheet. This transition in failure morphology from brittle to ductile was gradual in nature and was observed at lower percentage coverage

of graphene in the range of 25-50%. Failure morphologies depict that hydroxyl groups tend to boost the ductility through atomic chains and elongated rings formation at lower percentage coverage.

As the graphene nanosheet is highly brittle in nature, so the authors have evaluated the fracture toughness of graphene with the help of Griffith's criteria. We then functionalized the graphene sheet (with an pre-crack) with epoxide functional group and observed that a chemical epoxide-to-ether chemical transformation enhanced the fracture toughness value by 25%, as compared to the pristine graphene.

From this investigation, we concluded that spatial distribution and concentration of functional groups significantly affects the mechanical and fracture behavior of oxide functionalized graphene nanosheet.

F.NM03.09.16
Anomalous Characteristics of Functionalized Grain Boundaries in Graphene—A Nano-Mechanics Study Akarsh Verma[1] and Avinash Parashar[2]; [1]University of Petroleum and Energy Studies, India; [2]Indian Institute of Technology Roorkee, India

Enduring an ultrahigh mechanical strength and thermal conductivity, pristine two-dimensional graphene is still a hypothetical concept in the scientific community. Fabrication techniques for this quantum confined two-dimensional nanomaterial in the experimental environment induce various defects in its polycrystalline domain such as the atomic level grain boundaries (GB). Various computational techniques such as the molecular dynamics and density functional theory have unravelled complex mechanisms operating in the presence of these boundary phases to tune graphene's mechanical, fracture and thermal properties.

Molecular dynamics-based simulations were performed in conjunction with reactive force field (ReaxFF) parameters to capture the mechanical properties of functionalized GB in graphene. Room temperature (300 K) was used for the simulations and virial stress components were evaluated for predicting the stress tensor.

Herein this article, the authors have predicted certain spatial configurations of epoxide functionalized bicrystalline graphene, which could dilute its catastrophic brittle nature and transform it into stable ductile behavior. Altering of failure path and epoxide-to-ether chemical transformations were the chief mechanisms behind the enhanced plasticity for functionalized graphene. Due to brittle nature of graphene, it was expected that failure of graphene would tend to take place from the GB, but in contrast, we found that the failure started from the interior of crystal. This tailoring of failure path induced plasticity in the domain and acted as an energy dissipation mechanism.

The present work provided new insights into the mechanical behavior of bicrystalline GO and predicts plasticity in epoxide functionalized sandwich structure. This persisting ductility of epoxide rich configurations would enable GO to absorb more energy prior to failure and amplified toughness as well, leading to improved structural integrity.

F.NM03.09.18
Atomistic Simulations to Explore the Water Interaction Mechanism Through a Defective 2D h-BN Nanosheet—Reactive Forcefield Development and Molecular Dynamics Study Akarsh Verma[1,2], Weiwei Zhang[1] and Adri v. Duin[1]; [1]The Pennsylvania State University, United States; [2]University of Petroleum and Energy Studies, India

Desalination corresponds to supplying of potable water from oceans and seas, which can dissolve the water scarcity problem for human consumption, agriculture use and energy needs. Conversion of earth's 97% salty water into a fresh source is still an ambiguous challenge for the research community. Moreover, conducting costly and time consuming commercial experimental techniques such as reverse osmosis and thermal desalination have consistently proved to be a brain storming challenge for the scientists. So, in order to rectify this problem, herein the authors have performed molecular dynamics simulations to investigate the transport of water molecules through artificially created pores on the honeycomb lattice domain of two-dimensional hexagonal Boron Nitride (h-BN) nanosheet. Initially, a reactive force field (ReaxFF) was developed that had water parameters in conjunction with vacancy defects data for monolayer h-BN derived from the density functional theory incorporated in it. We then checked the structural stability of an h-BN monolayer (both pristine and defected) at different temperatures (300, 500 and 800 K) and ensembles (NVT and NPT); thus, predicting that the developed ReaxFF showed a minimal out-of-plane displacement. From the interaction point of view, we revealed that the water molecules tend to accumulate (droplet formation) and form sharp contact angles (hydrophobic nature) with h-BN. Furthermore, on compressing water molecules by applying external pressure on h-BN nanosheet the water molecules tend to arrange themselves in a layered structure. Finally, we investigated the water dissociation mechanism on a defected h-BN nanosheet,

and noticed that the water molecule dissociates into hydroxyl group and hydrogen atom thereby getting attached to boron and nitrogen vacancy edge atoms, respectively (Relative energy barriers with respect to initial configurations were 0.395 and -2.18 eV). These outcomes on h-BN nanosheet may prove to be valuable for designing of 2D nanodevices/nanomembranes for water desalination purpose.

Synthesis and Functionalization of Carbon Nanospheres in One Step by APCVD Gerardo Patiño Guillén[1], Alan Arceta Lozano[1], Jessica A. Falcón Montes[1], Esmeralda García Díaz[2], Jorge Noé Díaz de León[3], Rafael Vázquez Duhalt[3], Miguel A. Méndez Rojas[1] and Jessica R. Campos Delgado[1]; [1]Universidad de las Américas Puebla, Mexico; [2]Benemérita Universidad Autónoma de Puebla, Mexico; [3]Universidad Nacional Autónoma de México, Mexico

A one-step synthesis/functionalization of carbon nanospheres (CNS) is presented. The synthesis was carried out *vía* the APCVD method using toluene and ethanol (0wt%- 5wt% ethanol) as precursors. Different weight percentages of ethanol were implemented in order to evaluate their effect on the CNS's solubility in water, size distribution, morphology, surface area and surface chemistry. Since this method is a one-step *in situ* functionalization (with oxygen-containing groups), there's no need of a post-treatment to functionalize the sample or the use aggressive chemical reactants that could significantly modify the nanomaterial. Characterization techniques implemented for this study included FT-IR, SEM, EDX, XPS, Raman spectroscopy, BET and solubility tests. Results indicated that CNS possess higher water solubility when a 3 wt% ethanol solution is implemented for the synthesis. It was also demonstrated that higher ethanol concentrations decrease CNS's diameter and induce polydispersion. Finally the increased solubility and stability of the functionalized CNS are highlighted, envisaging applications in the biomedical field were hydrophilicity and availability of functional groups are mandatory.

F.NM03.09.21

Precision Defect Engineering of Graphene for Applications Using Electron-Beam Chemistry with Radiolyzed Water Michael A. Susner[1,2], Ahmad Islam[1], Rahul Rao[1], Jennifer Carpena-Núñez[1,2], San-Hui Chi[1,2] and Benji Maruyama[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States

Defect engineering of graphene is attractive for a wide range of applications. Here, we present a mask-less, resist-free, and fully reversible process to engineer defects in graphene using electron-beam (e-beam) chemistry with radiolyzed water. This process was performed inside a variable pressure scanning electron microscope by generating radiolysis products using reactions between the e-beam and water vapor, which in turn reacted with the graphene at the location of the probe. These reactions enabled controlled chemistry on the graphene surface at a resolution of ~ 60 nm and hence created defects in precise locations defined by the e-beam. Detailed characterization and theoretical analyses suggested the presence of sp^3-type defects, the density of which was tuned by varying the e-beam dose. In addition, these sp^3-type defects were cycled in and out of graphene by alternating e-beam chemistry and thermal annealing. We present initial results showing the ability to manipulate the plasmonic response in graphene though the creation of quickly patterned nanoribbons.

F.NM03.09.23

Synthesis, Reversible Insulator-Metal Transition as Well as High Conductivity and Ampacity of Cobalt Oxide Based Misfit Nanotubes Kankona S. Roy; Indian Institute of Technology Bombay, India

Misfit layered compounds (MLCs) are consist of two alternating sub-lattices with different lattice constants at least in one of the directions. One can selectively alter one of the sub-lattices without affecting the other that can tune both the physical and electronic properties. Among them, calcium cobaltite ($Ca_3Co_4O_9$, CCO)[1] and strontium cobaltite ($Sr_3Co_4O_9$, SCO)[2] are gained interest as potential thermoelectric materials. Bringing them to low-dimensions could further enhance their thermoelectric properties. However, synthesizing them in a one-dimensional structure is extremely difficult. Recently, we have synthesized calcium deficient cobalt oxide-based misfit nanotube[3,4] from the bulk starting material. However, the yield of these nanotubes is rather low. Besides, the physical and electrical properties of these nanotubes have not been explored yet. Here, we present the synthesis of 1D nanotubes (NT) from oxide misfit compounds with a very high yield (80%) by a combination of solid-state and solution-based synthesis. We have also studied their electrical properties on individual nanotube level by patterning with electron beam lithography.

All the synthesized nanotubes are thoroughly characterized by a combination of X-ray diffraction pattern (XRD), scanning electron microscope (SEM,) high-resolution scanning transmission electron microscopy (HRSTEM), electron diffraction (ED) and X-ray photoelectron spectroscopy (XPS). It is found that the crystal structure varies in the case of nanotubes from the bulk starting material. Absorption studies show the bandgap of 2.7 eV and 1.7 eV in case of CCO and SCO NTs, respectively. We have fabricated source-drain channels on individual nanotubes by electron beam lithography to find out

their electronic properties. In the case of CCO nanotubes, it is found that the nanotubes are of p-type semiconductor with a high charge carrier concentration of $7.05*10^{19}$ per cm^3, which suggest that these NTs are promising conducting materials. The current-carrying capacity of these nanotubes is around $6.5*10^5$ A/cm^2 (for an individual nanotube). But surprisingly, in the case of SCO nanotube, it shows a very high current carrying capacity of $0.88*10^8$ A/cm^2 for a single NT. These values are close to the reported WS_2 NTs having the highest current carrying capacity (ampacity) of $2.4*10^8$ A/cm^2 among the inorganic nanotubes.[5] Temperature dependent resistivity measurements show that both the nanotubes are semiconducting in nature. However, we have observed a voltage-induced semiconductor to metal transition in the case of SCO NTs. We have observed the four-probe resistance for the SCO nanotube to be 10 kΩ which is lowest among the existing oxide-based inorganic nanotubes. We believe electronic properties can be further tuned by changing the chemical composition between Ca/Co and Sr/Co. These results demonstrate that the high conductivity of these nanotubes could be a potential building block for future thermoelectric devices and interconnects.

Getting Pristine Graphene-Like Behaving rGO—What Really Matters Mohammed Sedki[1], Pegah S. Mirabedini[1], Kenta Nakama[2], Garrett Stephens[3], Michael Groves[3], Mahesh R. Neupane[4] and Ashok Mulchandani[1]; [1]University of California, Riverside, United States; [2]Tokyo University of Agriculture and Technology, Japan; [3]California State University, Fullerton, United States; [4]U. S. Army Research Laboratory, United States

Chemically synthesized graphene or reduced graphene oxide (rGO) is very promising for many applications from coatings and fillers to electronics, as it is economic, easy to prepare and scale up, and has unique properties. Despite the huge expansion of GO/rGO market, there is a clear lack of experimental and computational studies on getting high quality GO and rGO nanosheets/thin films. This caused a huge variation in the reported properties of GO/rGO, with a majority of low quality and low competency in electronic applications. In this work, a detailed experimental study of the factors affecting GO/rGO properties, supported by Density Functional Theory (DFT) calculations, is introduced to help prepare pristine graphene-like rGO. In addition, the impact of lateral sheet size on GO/rGO properties, as one of the factors addressed in this work, was studied using DFT calculations and experimental measurements for the first time, to the best of our knowledge. Field-effect transistor (FET) was used to study and optimize rGO. The optimized rGO-FET device showed the lowest resistance (200±20 Ω) and the highest charge carrier mobilities (53279 and 39891 cm^2/V.s for holes and electrons, respectively) reported. Furthermore, FET characteristic curve of rGO-FET showed the ambipolar behavior of high-quality graphene, with Dirac point around zero. In addition, the optical band gap of rGO nanosheets (0.4 eV) prepared in this work is the smallest reported, so far. These results highlight the importance of this study for both researchers and companies aiming at using rGO as an alternative for graphene obtained by liquid phase exfoliation or chemical vapor deposition.

Electronic Functionality Encoded Laser-Induced Graphene for Paper Electronics Hyunjin Park, Minsu Kim, Byoung Gak Kim and Yun Ho Kim; Korea Research Institute of Chemical Technology, Korea (the Republic of)

Laser-induced graphene (LIG) has been utilized as a non-metallic conductor for the development of various electronics due to its facile, direct, and scalable synthesis process. Here, the graphitization degree of LIG is simply controlled by adjusting the lasing conditions to encode different electronic functionalities such as resistance and capacitance on commercially available papers. The effect of lasing conditions including the number of lasing scans and the lasing power on the graphitization degree of paper-derived LIG is systematically investigated by evaluating the optical, chemical, and electrical properties. The paper-derived LIG with various lasing conditions exhibits a relatively wide sheet resistance range of 61.5 to 9140 Ω sq^{-1}. The corresponding LIG is used to fabricate resistors and capacitors, and the different electronic functionality encoding is successfully demonstrated by monolithically fabricating non-volatile read-only memory and resistor-capacitor circuits and verifying the electrical performance of the fabricated devices. This work presents a practical approach to develop paper electronics for cost-effective and environmentally-friendly manufacturing.

Robust Microscale Superlubricity Under Airborne Contaminants Kunqi Wang; Tsinghua University, China

Structural superlubricity, which results from the incommensurability of directly contacted crystalline surfaces, achieves ultralow friction and inspires disruptive innovations in applications across length scales. It is a common belief that this phenomenon requires the contact interface being ultra-clean, ensured by either a clean environment or self-cleaning of the contact. However, in this paper, the observation of robust superlubricity with a contaminant-rich interface is reported. After intentionally introducing airborne contaminants into microscale superlubric graphite contacts, we surprisingly find that two important features of structural superlubricity are well preserved: the nearly-zero friction coefficient and the drastic commensurate/incommensurate anisotropy of frictional force. Moreover, contaminants are found to reduce the friction of a commensurate contact, but increase the friction of an incommensurate contact, which leads to the decrease of anisotropy ratio in friction as the contaminant concentration increases. Molecular dynamics simulations reveal the different roles of the third bodies in commensurate and incommensurate contacts. Our results encourage explorations of structural superlubricity in contaminant-rich environments that practical devices could be facing.

Revealing Structure–Activity Links in Hydrazine Oxidation—Doping and Nanostructure in Carbide–Carbon Electrocatalysts Tomer Burshtein[1], Eliyahu Farber[1], Kasinath Ojha[2] and David Eisenberg[1]; [1]Technion–Israel Institute of Technology, Israel; [2]Leiden University, Netherlands

The oxidation of hydrazine (N_2H_4) is an important challenge in electrocatalysis, with applications in direct hydrazine fuel cells and in medical and environmental sensing. Interest in alternative, nitrogen-based fuels for fuel cells was rekindled by recent advances in alkaline membranes, and by the surfacing of challenges in the transportation of hydrogen. Direct hydrazine fuel cells promise high theoretical voltage (1.56 V with O_2), clean emissions, and improved fuel transportability. We now report a multi-doped carbide–carbon composite with excellent hydrazine electro-oxidation (HzOR) activity in alkaline pH. While iron carbide containing materials are well known catalysts for several applications (e.g. oxygen reduction), our N-doped, Fe_3C-embedded carbons provide the first examples of a carbide-based HzOR catalyst. Multi-doping was thought to enhance reactivity (possibly through cooperation of M=Cu/ Zn, Fe, and edge N atoms), possibly by pore-etching, layers exfoliation or graphitization promotion, thus modulating surface area, mass transfer and conductivity.
To prepare the composites, we designed tunable multi-doped precursors: an organometallic structure combining iron with either copper, zinc, or iron, to investigate the effect of molybdenum-doping reported earlier. Pyrolysis and washing of the fore mentioned precursors yielded HzOR-active composites of Fe_3C nanoparticles and a hierarchically porous, partially graphitic N-doped carbon (NC). Thorough characterization by voltammetry and by a broad range of spectroscopic and microscopic methods revealed that the activity is ordered as: Cu-derived NC > Zn-derived NC > Fe-derived NC. While the catalysts had similar compositions, their nanostructure varied: both Zn- and Cu-doping induced the formation of micropores and small mesopores (5–13 nm diameter). The dopant-induced active site exposure (affecting micropore volume) and improved material flow (linked to mesopore volume) contributed to enhanced HzOR electroactivity. Furthermore, the intimate mixing of the metals in the precursor is hypothesized to homogenize and enhance the doping effect, as the structure enhancing metal ions (Zn^{2+} or Cu^{2+}) exposed the nearby catalytic Fe_3C sites. Acid washing of the pyrolyzed carbon was crucial for producing microporosity in the Cu-based carbon, but had little effect on the Zn-derived one. This revealed the importance of micropores and small mesopores for HzOR electrocatalysis, and the different nanostructuring mechanisms of the two dopants: while $Zn_{(g)}$ boils during pyrolysis and thus etches micropores into the carbon, $Cu_{(s)}$ diffuses and spreads throughout, making exfoliation by acid reaction more efficient. Further work in our group is dedicated to the catalytic activity of pure phase Fe_3C, and its modification by other dopants.

Synthesis of Flexible 3D Electrodes of TiN Nanotube Arrays Using Atomic Layer Deposition Seokjung Yun[1], Sang-Joon Kim[2], Jaesung Youn[1], Hoon Kim[1], Jeongjae Ryu[1], Changdeuck Bae[3], Kwangsoo No[1] and Seungbum Hong[1,4]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Research Institute of Chemical Technology, Korea (the Republic of); [3]Sungkyunkwan University, Korea (the Republic of); [4]KAIST Institute for NanoCentury (KINC), Korea (the Republic of)

Flexible nanoscale electrode can be used in many applications such as electrochemical energy storage, electrocatalysts and solid memory devices by providing higher density faradaic reaction sites. Although many processing techniques have been used to produce nano-structured electrodes on flexible substrates, prior ones lack the mechanical stability. Here, the mechanical properties and flexibility of the TiN nanotube array on the Pt substrate were improved using a Ti interlayer as an

adhesion promoter. Highly aligned TiN nanotube array was fabricated on a Pt substrate using an anodized aluminum oxide (AAO) template and atomic layer deposition (ALD) system. We show that with the use of a Ti interlayer as adhesion promoter between the TiN nanotube arrays and Pt substrate, the TiN nanotube arrays could perfectly attach to the Pt substrate without delamination and faceted phenomena. Peeling was not observed even when the bending test was performed at a high curvature (radius of curvature, -2 mm). In addition, reliable and uniform contact the nanotube and the substrate evidenced by conducting atomic force microscopy (C-AFM) analysis proved the excellent local transport properties of our electrodes. Furthermore, the mechanical bending test results attest to the excellent flexibility for use in flexible electronic devices. We envision that our 3D electrodes will be implemented as embedded electrodes in semiconductors as well as flexible plastic substrates.

Single Step Reduction and PEGylation of Nanographene Oxide for Drug Delivery and Photothermal Cancer Therapy Raquel Costa-Almeida[1,2], Diana Bogas[3], Cristiana Couto[3], Licínia Timochenco[3], Filipa A. Silva[1,2], José R. Fernandes[4], Inês C. Gonçalves[1,2], Fernão D. Magalhães[3] and Artur Moreira Pinto[1,2,3]; [1]Instituto de Investigação e Inovação em Saúde, Universidade do Porto, Portugal; [2]INEB - Instituto de Engenharia Biomédica, Portugal; [3]LEPABE, Faculdade de Engenharia, Universidade do Porto, Portugal; [4]CQVR – Centro de Química Vila Real, Universidade de Trás-os-Montes e Alto Douro, Portugal

Cancer is the second leading cause of death worldwide. Current treatments frequently rely on surgical resection, radiotherapy, and high-dose chemotherapy, with unsatisfactory outcomes and side effects. Thus, there is a great need for novel and more effective strategies. Photothermal therapy (PTT), a non-invasive alternative based on near-infrared (NIR) light energy conversion into heat, results in hyperthermia (39-47 °C) and induces higher nanoparticle/drug uptake due to increased membrane permeability and tumor cell apoptosis. Nanomaterials, like graphene-based materials (GBM), hold potential as photothermal absorbers to enhance PTT selectivity within the target tumor tissue toward achieving therapeutic temperatures using less total light energy, minimizing damage to the healthy surrounding tissue [1]. This study explored GBM and GBM loaded with 5-fluorouracil (5-FU), an anti-cancer drug, as platforms for combined chemo-photothermal therapy. Nanographene oxide (GOn) was produced through the modified Hummer's method [2] followed by ultrasonication in a custom-built industrial grade system. Following a one-step procedure, GOn was thermally reduced and non-covalent functionalized with poly(ethylene) glycol (PEG) to obtain stable aqueous dispersions (rGOn-PEG) [3]. GOn and rGOn-PEG (0.25 mg/mL) were mixed with 5-FU at a drug concentration varying between 0.25-5 mg/mL. GBM aqueous dispersions were irradiated with a LED source of 812.8±29.9nm (150 mW/cm2) and temperature recorded using a thermocouple. The effect of GBM and NIR irradiation was evaluated by resazurin cell viability assay using a human skin carcinoma cell line (A431 cells, ATCC).
Reduction and PEGlyation of GOn were confirmed by chemical characterization through FTIR, XPS and UV-vis spectroscopy, as well as thermal analysis by TGA. GOn and rGOn-PEG were obtained with mean lateral dimensions of 287 nm and 521 nm, respectively as determined by TEM. GOn and rGOn-PEG dispersions showed colloidal stability with zeta potential values around -25.6±0.8 mV and -10.2±0.3 mV (pH=7), respectively. Loading capacity of 5-FU on GBM reached 5.8±0.8 mg 5-FU/mg GOn and 3.6±1.2 mg 5-FU/mg rGOn-PEG by simple molecular physisorption. NIR irradiation increased rGOn-PEG temperature to 47 °C after 30 min, which is within temperature ranges of hyperthermia. rGOn-PEG in combination with NIR reduced A431 cells viability, in opposition to rGOn-PEG alone.
This study demonstrated the successful non-covalent functionalization and reduction of nanographene oxide, rendering a material with potential to be further explored for combined chemotherapy and PTT for cancer treatment.

Investigation of a Catalyst Ink Dispersion and Three-Dimensional Analysis of Catalyst Layer in Polymer Electrolyte Membrane Fuel Cells Dan Wu, Samindi M. Jayawickrama and Tsuyohiko Fujigaya; Kyushu University, Japan

Carbon-based supports have been widely used to support Pt catalysts in polymer electrolyte fuel cells (PEMFCs) [1]. In our group, we developed polybenzimidazole (PBI)-wrapping onto carbon support that successfully achieved higher cell performance [2].
In this study, we present a dispersion investigation of the catalyst ink using PBI-wrapped catalyst (CB/PBI/Pt) and non-wrapped (CB/Pt) catalyst with a wide range of ionomer: carbon ratio (I/C). The effects of ink parameters, which include carbon black structure, and ionomer concentration, on the ink microstructure of catalyst ink were studied using visual study in combination with dynamic light scattering (DLS). Heterogeneous porous structure of the catalyst layer in PEMFCs is a significantly important parameter because it strongly determines the gas diffusion properties of the catalyst layer. And the connectivity of the network structure is largely depended on the structure of the catalyst agglomerations as well as the homogeneity of the ionomer on the carbon supporting materials. Therefore, we used scanning electron microscopy combined with focused ion beam (FIB-SEM) to visualize the nano-scale pore structure of the catalyst layer. Post-processing of a series of two-dimensional images reconstructed the three-dimensional pore-space of the catalyst layer.
We found that the catalyst ink of CB/PBI/Pt remained as a very stable dispersion in the range of I/C = 0.2~1.4, whereas for CB/Pt, the catalyst ink easily forms aggregation at high I/C (>0.6). The FIB-SEM images of CB/Pt catalyst layer with optimum I/C = 0.6 and CB/PBI/Pt catalyst layer with optimum I/C = 0.2 was analyzed. It is found that the CB/Pt catalyst layer has isolated large pores with the porosity of 0.55, while CB/PBI/Pt catalyst layer shows a uniform porous structure with the porosity of 0.7. It is reported that the presence of isolated pores increases the O_2 transport resistance in the catalyst layer, resulting in lower fuel cell performance [3,4]. Therefore, we concluded that the dispersion stability of catalyst ink is enhanced by PBI wrapping onto the CB surface, thus ensuring a better porous structure of the catalyst layer in PEMFCs. Furthermore, the particle-particle interactions in catalyst ink will be discussed in the presentation.

Monitoring of Adsorption Behavior of Serum Albumin onto the Fatty Acid-Modified Single-Walled Carbon Nanotube Kenta Nakamura, Yoshiaki Niidome, Yukiko Nagai, Tanaka Naoki, Tomohiro Shiraki, Takeshi Mori, Yoshiki Katayama and Tsuyohiko Fujigaya; Kyushu University, Japan

Single-walled carbon nanotube (SWNT) are attracting increasing attentions in biological applications because of their unique thermal, physical and optical properties. To use SWNT for in vivo applications, SWNT need to be biocompatible. Up to date, coating of SWNT with biocompatible materials especially polyethylene glycol (PEG) has been investigated due to its stealth property. However, it was pointed that the PEG-modified materials are rapidly excreted from the blood due to an immune reaction when they are repeatedly administered, which is known as accelerated blood clearance (ABC) phenomenon. To avoid such a problem, serum albumin (SA) attracts recent attention as an alternative material of PEG since SA is a blood protein derived from a living body. However, since the adsorption coefficient of SA onto SWNT surface is lower than that of the other proteins, the increase of the adsorption to avoid the risk of the replacement might be necessary. Therefore, in this study, we introduced fatty acid onto the surface of SWNT to improve the binding of SA by utilizing the strong binding between SA and fatty acid , where the introduction of the fatty acid was carried out by the radical grafting of the fatty acid derivative onto the SWNT sidewall. Here, the adsorption behavior was monitored by monitoring of the unique red-shifted and brighter photoemission (PL) generated from the grafting site compared to that of the non-functionalized SWNT.

A Novel Route for Controlling and Improving the Texture of Porous Structures Through Dual Growth of Alumina Nanoparticles and Carbon Nanotubes Using Explosion Process of Solid Fuel Osama Saber and Adil Alshoaibi; King Faisal University, Saudi Arabia

Micro- and meso-porous structures of alumina have attracted attention for their potential use in different applications. In this research, a novel and facile route was introduced for dual growth of alumina nanoparticles and carbon nanotubes together to fabricate nanocomposites at low temperature 250°C through explosive processes of solid fuel. In this trend, series of alumina species with and without carbon nanotubes were prepared and characterized by X-ray diffraction, Raman spectra and transmission electron microscopy. The surface properties of the alumina-CNT nanocomposites were characterized and compared with the prepared nanoparticles of alumina by adsorption–desorption system. The specific surface area of the prepared alumina-CNT nanocomposites was increased from257.9 to 307.7 m2/g and 314.8 m2/g with growing CNTs inside the porous structure of alumina. These increments were observed because of the dual growth of nanoparticles and nanotubes by which new micropores inside their nanocomposites were created. When the source of CNTs was changed from ethanol to methanol, pure mesoporous structure with narrow pore size distribution was observed for the alumina-CNT nanocomposite. In addition, the surface area and the total pore volume increased to be 324.9 m2/g and 0.673 cm3/g; respectively. The detonation technique of an explosive solid has been used for the first time to improve and control the porous structure of alumina through dual growth of CNTs and alumina at low temperature to meet the special requirements of the markets of catalysis and water purification.

Failure Behavior and Mechanisms in Dense Highly Aligned Brittle Nanowire Structures Rebecca Gallivan and Julia R. Greer; California Institute of Technology, United States

Nanowires have become an increasingly prevalent nanomaterials in composites and devices. In both surface coatings and mechanically coupled sensing applications, arrays and other complex geometries provide numerous design advantages, such as pixel like features. However, little investigation has been done regarding the mechanical behavior of these micron sized structures. With contact and load bearing applications, both the failure behavior and the underlying failure mechanisms are critical for robust device design. Though in-situ microcompression experiments on highly aligned dense bundles of single crystalline zinc oxide (ZnO) nanowires we investigate these types of structures to build a model for better understanding structural failure.

The ZnO nanowires are formed through hydrothermal growth from an aqueous zinc nitrate solution with hexamethylenetetramine (HMTA) and electrolysis conditions to promote fast growing high aspect ratio nanowires. 2μm and 4μm diameter bundles with individual nanowires of approximately 300nm in diameter and 4μm tall were investigated. These structures provides a range of 10-130 nanowires per bundle and thus probes an order of magnitude in scale. Experiments show two regimes of failure in the nanowire bundles: localized non-catastrophic events and global structural failure. No size dependence is observed in either regime and failure stress ranges from 0.3-1.3GPa and 0.83-2.20GPa respectively. Localized failure corresponds to interfacial splitting between nanowires and can be modeled using a mode I double cantilever beam tests. Analysis of this mechanism provides insight to the flaw size and failure initiation in the structures. Ultimate global failure can be modeled by coupling the accumulation of local failure from interfacial splitting to specific failure parameters of the nanowire material. Utilizing Weibull statistics and experimental results, we demonstrate the validity of this technique for analyzing flaw distribution and predicting the expected failure stress range of the bundle structures. The technique shows the sensitivity of failure behavior to degree of alignment, flaw size, interfacial interactions of constituents, and structural surface effects. Through analysis of behavior in this specific system, we develop insight to broader fundamental mechanisms for local failure and statistical techniques for assessing and predicting failure behavior of highly aligned structures.

F.NM03.09.38
Relationship Between the Dispersibility of Carbon Nanotubes and the Properties of Their Polymer Nanocomposites Taiyo Shimizu, Ryoichi Kishi, Kazufumi Kobashi, Takahiro Morimoto, Toshiya Okazaki, Takeo Yamada and Kenji Hata; National Institute of Advanced Industrial Science and Technology (AIST), Japan

Polymer materials with superior properties have been more and more widely used in our daily life. As compared to metals, light weight and good-processability are particularly beneficial properties of polymer materials. However, there are also several properties of polymers which are required to be improved, e.g. mechanical, electrical and thermal properties, and thus a plenty of research to improve these properties have been conducted so far. Improving these properties can realize the extension of applicable fields of polymer materials.
In order to improve objective properties of polymers, incorporation of appropriate kinds of fillers into polymer matrix is frequently adopted. For instance, carbon nanotubes (CNTs) are one of the most prominent fillers with superior properties such as high mechanical strength and electrical conductivities. Nanocomposite materials with CNTs have been widely explored and various kinds of nanocomposites possessing improved properties have been fabricated so far. However,

addition of substantial amount of nanofillers, not limited to CNTs, is required in most cases, and thus the inherent properties of polymer matrix, such as good-processability, tend to be degraded. These kinds of nanofillers are basically aggregated in a pristine form, and are required to be dispersed properly in their nanocomposites, in order to extract their potential as a filler. In this presentation, we will describe the relationship between the dispersibility of CNTs and the resultant properties of their nanocomposites. As an example, the thermal stability of CNT nanocomposite will be focused on. We successfully fabricated the CNT/silicone rubber nanocomposites with high thermal stability achieved by well-dispersed single-walled CNTs. The temperature at 5 % weight loss ($T_{d,5\,\%}$) of silicone rubber, obtained from thermogravimetric analysis, was increased by incorporation of low amount of CNTs. Remarkably, we found that the degree of increase in the $T_{d,5\,\%}$ depends on the dispersion process of CNTs, and appropriate dispersion process can realize higher increase in the temperature than that of the CNT dispersion process only by stirring. This phenomenon is considered to be originated from the homogeneity in the distributions of CNTs in nanocomposites, which has been ascertained by analytical techniques. We also confirmed that the CNT/silicone rubber nanocomposites fabricated by appropriate dispersion process can retain rubbery elasticity after a thermal aging test, while pristine silicone rubber was embrittled soon after the onset of the test. These results indicate that appropriately dispersed CNTs can impart thermal stability in both short- and long-term to silicone matrix only by small amount of loading. Our findings indicate that appropriate dispersion of CNTs can enhance the effectiveness of incorporation of CNT to matrix, and we believe that these kinds of approach can be applicable to a broad range of matrix, not limited to polymers.

Elucidation of Adsorption Behavior of Polybenzimidazole on Carbon Material Surface by Adsorption Isotherm Measurement Nana Kayo[1] and Tsuyohiko Fujigaya[1,2,1]; [1]Kyushu University, Japan; [2]WPI-I2CNER, Japan

In polymer electrolyte fuel cells (PEFC), a composite of carbon black (CB) with platinum particles (Pt) is widely used as an electrode catalyst after mixing with acidic electrolyte. However, low platinum utilization efficiency because of the uneven distribution of acid electrolyte on the CB surface that caused the insufficient protons transport was the issue [1]. We reported that improvement of platinum utilization efficiency and power density by coating of polybenzimidazole (PBI) onto CB surface prior to the platinum loading [2], in which the distribution of the electrolyte become uniform by the coating of PBI. However, it coating homogeneity of PBI onto CB has not been clarified yet.
In this study, the adsorption state of PBI on CB was studied by estimating the adsorption isotherm and the interaction acting between the carbon materials and PBI was investigated.
From the adsorption isotherm of PBI on CB, it was revealed that PBI adsorption reached adsorption equilibrium from a low concentration, suggesting that PBI was adsorbed in a monolayer on the carbon materials efficiently. In addition, the PBI coverage at the coating concentration of 0.50 mg /mL, used for coating, calculated from the Langmuir equation showed as high as 99.9%. Therefore, we concluded PBI uniformly coats CB. Also, based on the calculation of thermodynamic parameters, it was found that ΔH and ΔS were 14 kJ/mol, and 0.11 kJ/mol, respectively. The temperature dependence of the isotherm revealed that this adsorption process was entropy driven since the PBI adsorption amount increased with increasing the temperature. The adsorption behavior and interaction of PBI with other carbon materials will be discussed in the presentation.

Combined Theoretical and Experimental Study of All-Carbon Transistors Ali D. Özdemir, Artem Fediai, Feliks Pyatkov, Pramit Barua, Ralph Krupke and Wolfgang Wenzel; Institute of Nanotechnology, Karlsruhe Institute of Technology, Germany

Low-dimensional all-carbon nanostructures are promising candidates for future flexible and transparent transistors, as well as light-emitters [Pyatkov *et al*, Nature Photonics 10 , 420–427 (2016)]. Carbon nanotube field-effect transistors with graphene electrodes offer high thermal stability and allow for ultra-flat devices able to carry high current densities. Understanding quantum transport in such systems is essential for device manufacturing. However, conventional simulation methods are limited to local contacts with an overlap width of only a few angstroms, and first-principle quantum transport calculations in systems with realistic contact geometries remained unfeasible. Simulation methods for extended CNT/metal contacts were presented in prior theoretical studies [Fediai *et al*, Nanoscale, 8, 10240 (2016)]. Here, we report quantum transport calculations based on the non-equilibrium Green function formalism and density functional theory, which are capable of treating ~100nm long CNT/graphene overlap regions and electrostatic gating at a pure ab-initio level. These calculations are

compared with experiments where graphene electrodes were fabricated and dielectrophoretically bridged with single semiconducting CNTs followed by an electrical characterization over a wide temperature range. The simulation results are in agreement with the experimental data and the fabricated devices exhibit ambipolar behavior, consistent with the theory. Due to large CNT/graphene spacing and small CNT/graphene overlap, only a fraction of the quantum conductance can be achieved for the on-state conductivity. A remarkable feature of the all-carbon transistor with graphene electrodes is electrostatically induced doping of the carbon-system in the contact regions caused by the gate electrode. This is made possible by the low density of states in graphene near the K-point. We hope that this newly developed and verified simulation approach will accelerate progress in fabrication as well as the understanding of advanced all-carbon devices.

Plasma Treated Single-Walled Carbon Nanotubes Decorated by RuO_x Nanoparticles for High Performance Hydrogen Evolution Reaction Fedor Fedorov[1], Daniel Settipani[2], Marthe Buan[2], Jani Sainio[2], Farhan S.M. Ali[2], Daniil Ilatovskii[1], Tanja M. Kallio[2] and Albert Nasibulin[1,2]; [1]Skolkovo Institute of Science and Technology, Russian Federation; [2]Aalto University, Finland

The constant and growing need in new catalysts for hydrogen evolution reaction is triggered by increasing energy demands and promises of its eco-friendliness combined with large gravimetrical storage capacity. Carbon nanotubes are also known to be quite promising for hydrogen (and oxygen) evolution reaction and are characterized by large specific surface area, excellent conductivity, and rather good durability.

We report a cathode material based on plasma-treated single-walled carbon nanotubes decorated by RuO_x nanoparticles using atomic layer deposition (ALD). We have examined cathode performance towards hydrogen evolution reaction by tailoring material wettability, conductivity yielded by plasma-treatment, and the catalyst loading [1]. We discuss that nucleation of particles is facilitated by the appearance of carboxylic and hydroxyl groups triggered by oxygen plasma action. The best performance is associated with samples containing RuO_x particles of 4-5 nm, which show hydrogen evolution onset potential to be about -5 mV (*vs.* RHE) in 0.5 M H_2SO_4 measured at a current density of -1 mA cm^{-2} and Tafel slope of 47.5 mV/dec. The material possesses stable performance at -10 mA cm^{-2} with a potential of about - 160 mV.

The reported study was funded by RFBR, project number 20-03-00804

Synthesis of Cu_xS/Graphene Aerogel for Photocatalytic Reduction of CO_2 Feng Wang and Liejin Guo; Xi'an Jiaotong University, China

Using solar energy to convert CO_2 into hydrocarbon fuel is a promising technique for harvesting solar energy storage and reducing carbon dioxide. Recently, Graphene-based semiconductor composites have been a topic of great interest, especially in the field of photocatalysis. Graphene has the advantages of high surface area, excellent conductivity, and anticorrosion capacity, which can overcome the limitations of traditional photocatalysts. Thus, graphene-based material can be a feasible photocatalyst for photocatalytic CO_2 reduction. Besides, as an environment-friendly and earth abundant material, Cu_xS has considered as a good candidate for photocatalytic reactions, due to its unique optical, electronic, physical and chemical properties. Herein, we report the photocatalytic reduction of CO_2 using Cu_xS/graphene aerogel as the photocatalyst, which was prepared by hydrothermal method. The as prepared Cu_xS/graphene aerogel exhibited pretty good activity for photocatalytic reduction of CO_2. C_2 products (ethanol, acetate) are main products. In this composite photocatalyst, graphene aerogel not only serves as a 3 dimensional support for Cu_xS, but also transfers the photo generated charges. Moreover, density functional theory calculations were performed to reveal the chemical reactions and the charge transfer between Cu_xS and graphene. Also, the study of Cu_xS/graphene aerogels photocatalyst presents useful information for efficient photocatalytic CO_2 reduction without noble-metals.

Graphene Encapsulated Nanoscale Vacuum Channel Transistors Girish Rughoobur and Akintunde I. Akinwande; Massachusetts Institute of Technology, United States

There is a growing need for devices that operate at THz frequencies, and with the end Moore's device scaling law approaching, alternatives to solid-state transistors need to be explored. The inherent limitation of solid-state transistors such

as the metal-oxide semiconductor field-effect transistor (MOSFET) is the semiconductor channel, which not only causes carrier scattering, velocity saturation of carriers due to optical phonon scattering, but is also susceptible to high temperature and radiation effects. Current research attempts to mitigate these negative effects focus on using wide bandgap semiconductor channels. In contrast, the use of 'empty-space', which can be regarded as the ultimate wide bandgap material, as the device channel could overcome these limitations. This is because in vacuum, there is no carrier scattering (ballistic transport), avalanche breakdown or thermal generation. The absence of any atoms further enhances the tolerance to high temperature as the channel retains its properties. Nanotechnology and nanofabrication has enabled the realization of nanoscale vacuum channel transistors (NVCTs) that could potentially surpass solid state devices of equivalent channel length owing to ballistic transport of electrons, shorter transit time and higher intrinsic breakdown field. Hence, transistors with a vacuum channels could have very high Johnson figure of merit ($J_{FoM} = E_{BD}v_{sat}/2\pi$) of ~$10^{14}$ V/s, even exceeding ultra-wide bandgap materials such as AlGaN and diamond.

We report the demonstration of NVCTs based on gated vertical silicon field emission arrays with two self-aligned gates. The two gates are separated by an oxide with thickness of 350 nm. A first gate with aperture diameter of 360 nm is used to extract electrons from a sharp emitter tip (radius < 7 nm) and the second gate, with aperture diameter of 570 nm, is used to focus the electron in to a vacuum channel. The emitter tips density is 10^8 emitters/cm^2. NVCTs with such electron sources are highly sensitive to barrier variations caused by surface adsorption of molecules on the tip in poor vacuum environment. Here we demonstrate the nano-encapsulation of the electron source for operation in poor vacuum, using several layers of graphene, which are transparent to electrons but impermeable to the larger gas atoms in a poor vacuum.This device architecture with two self-aligned gates also enables the application of a different voltage bias on the graphene and hence controlling the energy of the electrons in the channel, while reducing the encapsulation volume significantly. We demonstrate turn-on voltages below 10 V and operation in poor vacuum and at atmospheric pressure. This device architecture is highly promising to realize empty space electronics capable of functioning at higher power and harsher conditions (high radiation and high temperature, such as in space and in nuclear reactors) transcending the performance of solid state electronics.

Oil Dynamic Shell Surrounding Fullerenes Aaron Morelos-Gomez[1], Kunio Kondo[2], Hiroshi Ushiyama[3], Kazuhiro Omori[2], Ryuji Monden[2], Yu Gao[2], Masumi Kuritani[2], Taiki Yokokawa[1], Rodolfo Cruz-Silva[1], Syogo Tejima[3], Mauricio Terrones[4] and Morinobu Endo[1]; [1]Shinshu University, Japan; [2]Showa Denko K.K., Japan; [3]Research Organization for Information Science & Technology, Japan; [4]The Pennsylvania State University, United States

Given the increase in technology development the need for more energy efficient devices is required. In mechanical systems a large amount of energy is lost due to friction between sliding surfaces. For this reason, the creation of effective lubricants is needed. Transition metal disulfides such as WS_2 and MoS_2 fulleroids have been used as oil additives. However, disulfides are prone to oxidation and release of sulphide compounds under heat and may corrode metal surfaces creating metal sulphides. Carbon materials can exhibit higher chemical inertness and therefore exhibit longer lubrication lifetime under heat than transition metal disulfides. Among carbon materials; graphene, carbon nanotubes and fullerenes have been added into oil to decrease friction between two metal surfaces. Unfortunately, the molecular interaction between carbon nanomaterials and lubricants has not been fully understood. We studied the molecular interactions between fullerenes and mineral oil, known as "nano oil", by ultraviolet Raman spectroscopy and molecular dynamics simulations. The results indicate that aromatic molecules help to disperse individual $C_{60/70}$ molecules from aggregates whereas the alkane molecules help to stabilize fullerenes by forming a dynamic shell structure around them. Our findings demonstrate that fullerenes can be used as high-performance additives for effective lubrication.

Computational Geometry-Centric Evaluation for Electrical Conductivity Variation of Thin-Film Conducting Nanocomposites Jungmin Lee[1], Yesol Yun[2], Sang Hyun Lee[2] and Jinyoung Hwang[1]; [1]Korea Aerospace University, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

Hybrid carbon nanotube (CNT) composites consisting of multiple types of fillers have been developed to provide enhanced characteristics as compared to CNT single-filler composites. The incorporation of secondary fillers, such as silica, $CaCo_3$, and $BaSO_4$, yields remarkably improved mechanical strength and stiffness of the CNT composite and electrical conductivity of the hybrid composite network under the control based on geometry and content of the constituent particulate fillers. In particular, higher electrical conductivity can be attained with the addition of micro-scale secondary fillers to the CNT composite network, while the addition of nano-scale particulate fillers incurs lowering the electrical conductivity of the nanocomposite network. Such electrical conductivity transition is attributed to distinct variations in the network topology caused by the excluded volume originating from the loading of secondary fillers with different scales. Micro-silica

composites result in dense clusters of CNTs, thereby forming CNT conducting paths, while densely-dispersed nano-size fillers cause severely twisted CNTs, reducing forming a conducting network.
In this work, Monte-Carlo simulation is first conducted for the estimation of the electrical conductivity of the CNT network of hybrid composites. To obtain a realistic model, flexible CNTs are modeled as long thin cylindrical objects with many joints interconnected in a row. In addition, to take the resistance of the conducting CNTs into account, individual joints are considered to be tiny lumped resistor elements. A computational characterization approach based on numerical linear algebra technique is applied under various size and concentration configurations of composite components, and the corresponding electrical conductivity of the network is derived. The computational results exhibit that the ratio of the average diameter of the particulate filler to the nanotube length governs the tendency of the electrical conductivity variation, as compared to the change of filler contents only affecting the degree of the conductivity change. As the ratio of the silica diameter to the CNT length increases, the ratio of the conductivity without (σ_0) and with (σ) the secondary particulate fillers, i.e. σ/σ_0, increases from the value less than one to the value more than one. This indicates that the impact of the second fillers on the electrical conductivity of the composites shows a transition. By contrast, if the geometric configuration of the fillers is almost fixed, the degree of the conductivity variation increases as the silica content increases, while decreasing for the increasing CNT content. The electrical behaviors of hybrid composites can be simply characterized by the combination of computational geometry centric notions such as Voronoi tessellations and Swiss cheese model along with their associated percolation theory. In the developed model, the CNT dispersed around particulate fillers indicating effective conducting paths can be classified with tessellations from Voronoi cells. The conductance of each effective path is designated by local conductance determined from the density of CNTs in the local region. The reliability of the model is validated based on comparison with the numerical results obtained from the MC simulation. The developed approach achieves, as compared to the MC simulation, remarkable computing cost reduction. Therefore, the combined computational framework enables to provides a novel strategy to estimate for the electrical conductivity of the hybrid composites under the external deformation such as bending, stretching, and patterning, and it is a viable model for the design of the hybrid composites at hand.

Investigation of the Growth Mechanism for Hierarchical Polymer/Carbon Nanotube Nanohybrid Shish-Kebab Structures to Enable High-Performance Printable Thin-Film Transistors Kevin Schnittker and Joseph B. Andrews; University of Wisconsin-Madison, United States

Aerosol jet printing has gained a considerable amount of attention as a method to additively fabricate electronic device. In part, this is due to the compatibility with a wide range of ink viscosities (1-1000 cps) and the ability to print on non-planar surfaces. One elusive material for aerosol jet printed active electronics is a high-performance semiconducting ink with low-variability. One potential promising ink would be a combination of high-mobility carbon nanotubes (CNTs) with highly uniform semiconducting polymers. However, CNTs fully encapsulated by semiconducting polymers have not shown noteworthy improvement. One method to capture both positive attributes of CNTs and semiconducting polymers is through a hierarchical nanostructured composite. The conjugated polymer regioregular poly(3-hexylthiophene) (P3HT) has the ability to self-assemble and form periodic crystals on CNTs due to π-π interactions. These structures, coined nano-hybrid shish kababs (NHSKs), may directly improves charge carrier transport in printed thin-film electronic devices.
The objective of this project is to fabricate a novel semiconducting ink that consists of P3HT/CNT NHSKs. In developing this ink, we investigated the P3HT shish kabab crystallization and kinetic growth on (6,5) chirality SWNTs. This was done by manipulating the P3HT-SWNT concentrations, the solvent concentration, and crystallization temperature. The P3HT fibril shape, size, and period were found to be correlated to the above parameters. The morphology and purity/concentration were measured using atomic force microscopy (AFM) and ultra-violet/visible spectroscopy.
NHSKs were fabricated via a 6:1 P3HT to SWNT mass concentration solution mixed in 70°C anisole solution. The P3HT supramolecular structures were found to be 32±3.7 nm wide and 269±11.4 nm long. At higher mass ratios (40:1 P3HT to SWNT), full encapsulation was observed with little periodicity. In conclusion, this work investigates the growth mechanisms of P3HT polymer crystals on single chirality CNTs for semiconducting ink applications. Next steps include the manipulation of the solution to increase printability and the fabrication of NHSK-based thin-film transistors.

F.NM03.09.54
Enhanced Heat Transfer of Functionalized Graphene Nanoplatelets in Nanofluids for Energy Conversion and Storage of Solar Power Plants Michael Wilhelm[1], Tim Ludwig[1], Thomas Fischer[1], Dileep Singh[2] and Sanjay Mathur[1]; [1]University of Cologne, Germany; [2]Argonne National Laboratory, United States

The unique thermal conductivity of graphene makes it one of the most promising materials for next generation heat transfer applications that, given the increasing demand for energy supply from sustainable energy sources such as concentrated solar power, has emerged as key technology. The incorporation of graphene and graphene-like nanomaterials into conventional

heat transfer fluids has been shown to significantly improve their thermal transport properties. Due to their cost-efficient carbon-based starting material, its high surface area and sheet-like structure, graphene nanoplatelets (GNPs) are suitable for colloidal thermal conductive fluids demonstrating enhanced heat transfer efficiencies.
In this work, hydrophobic graphene nanoplatelets were used as starting material and surface functionalized by acid treatments to synthesize highly stable, exfoliated, surfactant-free and highly concentrated (4 wt.%) graphene nanofluids maintaining high thermal conductivity. Characterization by SEM, XPS, XRD, Raman and FT-IR spectroscopy revealed a significant influence of shape, reaction period, acid volume and temperature on the resulting thermal conductivity values of the nanofluids relative to the carrier fluid. After 14h of measurement in a dormant system, thermal conductivities up to 0.586 W/m*K (base fluid: 0.391 W/m*K) were measured. In combination with a low viscosity of 6.39 cP the overall efficiency of the functionalized particles could be increased to 77 % in comparison to the base fluid. The combination of both low viscosity and high thermal conductivity, even after 14h in a standing system, demonstrate the extraordinary properties of surface functionalized graphene nanoplatelets prepared in this work in comparison to other nanofluidic systems.

F.NM03.09.57
Modeling the Effective Electrical Conductivity of Nanocarbon-Metal Composites Made by the Electrocharging Assisted Process Christopher Klingshirn[1], Andrew Palughi[2], Xiaoxiao Ge[1], Madeline Morales[1], Jessica Ye[1], Christopher Shumeyko[3], Tahir Cagin[2] and Lourdes G. Salamanca-Riba[1]; [1]University of Maryland, United States; [2]Texas A&M University, United States; [3]U.S. Army Research Laboratory, United States

Robust materials with high conductivity are essential to electronic devices and systems. Nanocarbon-metal composites have the potential to improve upon the electrical conductivity of established metals and alloys such as Al and Cu by incorporating carbon nanostructures known for their superior electrical properties. During the fabrication of novel nanocarbon-metal composites called covetics, direct electric current applied to a metal melt containing a dispersion of carbon source material is believed to ionize carbon atoms and lead to the formation of nanoscale graphitic ribbons and chains that ultimately incorporate within the metal lattice upon solidification. The electrical conductivity of the resulting composites is consistently greater than the original alloy, but the magnitude of conductivity enhancement varies significantly from sample to sample, and the theoretical upper limit of conductivity enhancement in these systems remains unclear.

This work combines fundamental assumptions about the nature of covetics, specifically a tightly bound metal-carbon interface, with a simple effective-medium model to estimate the bulk conductivity of ideal Al and Cu covetics with randomly distributed graphene nanoribbons (GNRs). Density-functional theory estimates of charge transfer at the graphene-metal interface, local electrical conductivity measurements, and transmission electron microscopy investigation of the interface region provide inputs to the model. The implications of quantum confinement in narrow GNRs are also explored. We use the model to project a range of performance-enhancement goals for the covetics fabrication community and find the potential for conductivity improvements on the order of 10% under ideal conditions, however fabrication challenges remain before these gains may be realized on an industrial scale.

This work is supported by the U.S. Department of Energy under Award No. DE-EE0008313.

Carbon Nanotube Embedded Vertical Aligned PVDF Membraned with High Mechanical Properties for PRO Membrane Application Juran Noh, Mehdi Habibollahzadeh, Choongho Yu and Ahmed Abdel-Wahab; Texas A&M University at Qatar, Qatar

Water desalination has been a critical issue for reserving the freshwater for human survival, further civilization, industry development. Pressure retarded osmosis (PRO) is desalination technology emerging from the osmosis phenomenon; water flux through the membrane, excluding undesired macromolecules or ions with applying pressure. Thus, a high water permittable membrane with stronger mechanical strength to bear in high water pressure should be developed for a high-performance PRO desalination process. High mechanical strength and water permittivity could be a trade-off relationship based on thickness and porosity. Thus, vertical oriented polyvinylidene fluoride (PVDF) membrane with 3D connected carbon nanotube (CNT) is presented. Vertical pores made of hydrophobic polyvinyl fluoride (PVDF) and hydrophilic metal-organic framework (MOF) decorated on the surface improve their water permeability and salt rejection. The CNT embedded structure in the vertically aligned membrane improves mechanical strength along the in-plane direction. This work presents CNT additives can significantly improve the mechanical properties of water desalination membranes by smartly designing the morphology of the substrate and properly inserting functional materials in the active layer.

Near Infrared Photoluminescence Properties of Locally Functionalized Single-Walled Carbon Nanotubes with Proximal Modification Sites Aoki Haruka, Yu Boda, Tanaka Naoki, Tsuyohiko Fujigaya and Tomohiro Shiraki; Kyushu University, Japan

Single-walled carbon nanotubes (SWNTs) have attractive optical properties based on their unique one-dimensional nano structures. Especially, semiconducting SWNTs emits photoluminescence (PL) originating from the E_{11} emission of photogenerated exciton in the near infrared regions (900-1600 nm), which can be applied for bioimaging and telecom devices. Compared to such E_{11} PL, redshifted and brighter E_{11}^{*} PL have been recently reported by the sp^3 carbon defect doping to the crystalline sp^2 carbon lattice of SWNTs. The resultant SWNTs are locally functionalized SWNTs (lf-SWNTs) [1] that have the doped sites with narrower bandgaps and exciton trapping features. We have reported proximal modification using bis-aryldaizonium salts (bADs). The lf-SWNTs modified with bADs (lf-SWNT-bA) showed largely redshifted PL (E_{11}^{2*}) than E_{11}^{*} PL [2] and were found to show sensitive E_{11}^{2*} PL property changed depending on the chemical structures of bAD, in which the E_{11}^{2*} PL wavelengths were shifted with strong dependence of methylene spacer lengths and connected positions in the bADs [3]. Therefore, proximal modification is useful approach for remarkable PL property modulation of the lf-SWNTs compared to typical mono-aryl functionalized lf-SWNTs.

In this study, we newly synthesize modifiers having multiple reactive groups for structural changes of the proximal modification sites of lf-SWNTs.

The SWNTs (CoMoCAT, (6,5) chirality-rich) were solubilized in D_2O containing sodium dodecyl sulfate by sonication and separated by ultracentrifugation. A tris-aryldiazonium salt (tAD) having three aryldiazonium groups was mixed with the solubilized SWNTs for local chemical functionalization. After the chemical modification, multiple PL peaks appeared over typical E_{11}^{*} regions (>1200 nm). The NIR absorption and Raman scattering measurements supported the local chemical functionalization of the modifiers on the SWNTs, in which small absorbance changes at 980 nm and the increase of D-band intensity due to the defect introduction were observed, respectively. In addition, the reaction conditions such as solution concentrations were found to show significant influence on such new longer wavelength PL generation. The detail results including chemical structure effects of the modifiers and the reaction condition dependency will be discussed at the meeting.

Isopropanol-Assisted Hot Lamination for Facile Synthesis of Large-Area Atomically Thin Graphene Membranes Peifu Cheng[1], Nicole K. Moehring[1], Andrew Naclerio[1], Mattigan Kelly[1], Dahsong Lee[1], Juan C. Idrobo[2] and Piran Ravichandran Kidambi[1]; [1]Vanderbilt University, United States; [2]Oak Ridge National Laboratory, United States

Atomically thin graphene membrane has been considered as an ideal candidate for next-generation membrane-based technologies. While catalytic chemical vapor deposition (CVD) has been demonstrated to be an economical and versatile way of enabling the commercial production of high-quality graphene, CVD graphene has to be transferred from the growth substrate onto a porous support substrate to provide mechanical stability for membrane applications. However, commonly used polymer scaffold methods typically leave polymer residues detrimental to membrane performance, while transfers without sacrificial polymers suffer from low transfer yield leading to high membrane leakage. Hence, high-yield transfer of clean large-area graphene onto appropriately porous supports using scalable processes for membrane applications remains elusive. In this work, we systematically investigate the factors influencing the transfer of CVD graphene from a Cu foil onto a model polycarbonate track etch (PCTE) support for fabricating large-area atomically thin membranes via manual compression, mechanical press and scalable lamination approaches. Particularly, we report on a novel roll-to-roll manufacturing compatible isopropanol-assisted hot lamination that allows for facile, clean and scalable transfer of centimeter-scale graphene onto model PCTE supports with coverage ≥ 99.2% without compromising support porosity, which is one of the best values reported to this date for centimeter-scale atomically thin membranes. The remaining 0.8% of leakage is attributed to defects (>50 nm) primarily along wrinkles formed during CVD growth. Furthermore, water-assisted oxidation effectively detaches CVD graphene from the Cu foil and helps graphene transfer, but significantly damages (~10%) graphene along wrinkles. Finally, fully functional centimeter-scale atomically thin membranes are demonstrated. Our work provides a facile and effective method for the fabrication of atomically thin graphene membranes and can help on the progress towards the practical application of graphene membrane technologies relevant to gas separation, nanofiltration, desalination, ionic/molecular transport, energy and biomedical fields and beyond.

F.NM03.09.63

Effect of Orientation of Graphene Upon Dielectric and Electrical Characteristics of PBAT-PLA-Graphene Composites Radha Perumal Ramasamy[1], Xianghao Zuo[2], Yiwei Fang[2] and Miriam H. Rafailovich[2]; [1]Anna University, India; [2]Stony Brook University, United States

Graphene has several fascinating characteristics such as high thermal and electrical conductivity. Graphene polymer composites is usually made using molding. To enhance the application of graphene in nanocomposites controlling its alignment is important as graphene has different conductivity along and perpendicular to its surface. The orientation of graphene in polymeric materials is a challenging task. Recently 3D printing has been used for aligning graphene in composites. In this research varying amounts of graphene (grade H5 – XG Sciences) was mixed with PBAT-PLA mixture and molded. Also 3D printed PBAT-PLA-graphene composites were made. The dielectric measurements were made by placing the composites between two brass electrodes of diameter 1cm. The dielectric measurements were made using Wayne-kerr- 6500p LCR meter. The frequency was varied from 100 to 10^6 Hz. The measurements were made at room temperature (22 °C). The samples had cuboid shapes. The measurements were made along height and depth of the samples. The height corresponded to the direction of application of pressure during molding and the depth corresponded to the direction perpendicular to the direction of application of pressure and parallel the surface of the samples. The following observations were made. (A) The dielectric constant for 3D printed samples (along height) was less than dielectric constant for 3D printed samples (along depth) which was less than dielectric constant for molded samples (along height). (B) The dielectric constant for molded samples (along depth) was less than dielectric constant for molded samples (along height). (C) Along depth, for molded samples the dielectric constant becomes negative for 20% graphene containing samples indicating percolation. (D) The electrical conductivity for 3D printed samples (along height) was less than conductivity for molded samples (along height) and (E) Electrical conductivity for 3D printed samples (along depth) was less than electrical conductivity for molded samples (along depth). The observed variations in dielectric and electrical characteristics are attributed to the orientation of graphene in the composites.

F.NM03.09.64

Modification of P-Plasmon Energy in Single Walled Carbon Nanotube Induced by the Interaction Between Carbon Nanotube and Gold Nanoparticles Masahide Shima[1], Hiroki Kato[1], Noriaki Endo[1], Eiji Okunishi[1], Masaki Tanemura[2] and Yoshikazu Homma[3]; [1]JEOL Ltd., Japan; [2]Nagoya Institute of Technology, Japan; [3]Tokyo University of Science, Japan

Graphene, which is an atomic layer carbon with the honeycomb structure, has several interesting properties, such as high optical transparency, high electrical and thermal conductivities. Graphene possesses also unusual properties in plasmon, such as the confinement, long lifetime, and long propagation distances of plasmons. Due to the tunability of plasmon, graphene is promising for the plasmon-based application, such as THz technologies and gas sensors. For the device application, the investigation of interaction between graphene and metal is also essential, because the graphene-metal contacts are unavoidable of every graphene-based device, and the electronic properties of graphene strongly depends on the substrate. It is known that the plasmon in free standing graphene show the different properties from those supported by substrate. It is also known that the properties of plasmon in graphene depend on the materials used for substrate, which is important for graphene plasmonics. On the other hand, the interaction between the substrate and graphene is not fully understood. Especially in nanoscale structures, it is not well known how plasmons in graphene are affected by the metal substrate. In this study, p-plasmon in single-walled carbon nanotube (SWCNT) with and without the deposition of gold nanoparticles (Au NPs) was investigated using TEM-EELS (Transmission Electron Microscopy – Electron Energy Loss Spectroscopy) method as the first step to elucidate the effect of the gold substrate on p-plasmon in honeycomb structured carbon. The plasmons show the linear dispersion in monolayer graphene-metal interface similar to that in SWCNT-metal interfaces, and the controllability of Au NPs in shape and size is much higher on SWCNTs than on graphene. So, the investigation using SWCNT-Au NPs system would be the simplified model system for the honeycomb structured nanocarbon on metal substrates.

The solution of SWCNTs dispersed in an organic solvent, was dropped on the a microgrid for TEM. Then gold nanoparticles were vapor-deposited thereon. In order to avoid the contamination during TEM-EELS measurement, the microgrid thus prepared was pre-heated for 10 min in 1x 10^{-5} Pa. TEM observation and EELS measurement performed using JEM-F200 (JEOL) and GIF Quantum (Gatan), respectively. The accelerating voltage for the TEM observation and EELS measurement was 80 kV for preventing sample damage. The energy resolution of zero loss peak was below 0.5 eV.

On the microgrid, various types of SWCNTs with and without Au NPs were recognized such as isolated, bundled, and cross-linked ones. The peak shift in the energy loss spectra of p-plasmon was biggest for the bundled SWCNTs without Au NP. The peak shift increased for an isolated SWCNT with an Au NP, and was highest for SWCNTs sandwiching a Au NPs. These results showed the plasmon energy can be controlled by the configuration of SWCNTs and Au NPs.

F.NM03.09.66
Why Aren't Nano Carbon Based Composites Rise Up to Their Theoretical Potential and How Can We Get Them Closer? Noa Lachman; Tel Aviv University, Israel

Carbon Nanotubes (CNT) and graphene are considered highly promising nanomaterials for composite reinforcement. The nanoscale dimensions of the carbon structures provide ultra-high surface-to-volume ratio, nearly defect-free structure, and their exceptional properties: mechanical (1TPa – five times the value for steel), thermal conductivity (2000-6000 Wm-1K-1 – four to ten times the value for silver) and electrical conductivity (roughly equivalent to copper) makes them highly useful in very many applications. However, these same scale and properties complicate the processing and fabrication of polymer based nanocomposites: high surface-to-volume means that even in small filler concentrations composite process-affecting properties as melt viscosity, heat transfer and other characteristics will drastically change. Morphology control, and thus post-processing behavior prediction, are also challenging – as dispersion and orientation are applied indirectly in the process, and different mechanisms are dominant at different length-scales. Therefore, transferring the exquisite properties of the CNT and graphene to the composite level have been proven less than ideal, as the measured mechanical, electrical and thermal properties of the nanocomposites are usually lower than predicted by rule-of-mixture calculations.
In this talk, various approaches for carbon nanocomposite fabrications, both “top-down” and “bottom-up”, will be presented in case-studies. A few of the major issues inhibiting nanocarbon based composites from achieving their true potential will be highlighted. Effects of different fabrication techniques, including 3D printing, on the morphology of nanocomposites and the resultant behavior will be discussed, and possible solutions to the aforementioned issues will be presented. The new methods can provide better control for improved planning and designing of nano carbon based composites.

F.NM03.09.67
Flexible Devices Based on Poliurethane and Reduced Graphene Oxide Composites for Applications in Tactile Sensing Flavio A. Borges[1], Monica A. Cotta[1], Cecília d. Silva[2], Talita Mazon[3], Joao H. Clerici[1] and Daniel M. Ugarte[1]; [1]University of Campinas, Brazil; [2]MackGraphe – Graphene and Nanomaterials Research Center, Brazil; [3]Institute of Information Technology Renato Archer, Brazil

New opportunities have been created along with the advances of the wearable device technology. For pressure sensing and transduction in soft objects like human skin, direct contact between sensor and target area is necessary; therefore, sensor flexibility is a very important parameter for the viability of the sensing device.
In this work, we report on the development of a sensing system that translates the electric signals of low cost composites based on polyurethane (PU) and reduced graphene oxide (r-GO) fabricated in-house. The graphene oxide (GO) is deposited by dispersion in PU foam. The GO reduction is carried out by immersion in ascorbic acid. Different commercial foams were tested and sample heights could be reduced to 1mm with electrical resistance range of 1-100 kΩ for a 90% compression. Electrical resistances were measured in function of the applied force and an exponential character was identified. With the force range which the foams endure and the calibration curve obtained for the samples, a rigid device was developed by integrating an Arduino system to the sensors so that responses could be obtained via a graphical interface, adapted to visual feedback.
The foam shows great conformity with surfaces; flexible contacts, printed in Kapton film using conductive paint, are used to obtain the flexible device. We thus expect to have a flexible sensor integrated to a functioning system fully prepared to neurological rehabilitation applications.

F.NM03.09.68
Transition Metal Chalcogenide Nanostructures for High Energy Density Supercapacitors Harish Singh and Manashi Nath; Missouri University of Science and Technology, United States

Electrochemical capacitors (ECs) or supercapacitors (SCs) are considered to be most promising energy storage devices and have received great attention because of their excellent electrochemical performance with high output power, short discharging time and long-term cycle stability. Transition metal chalcogenides (especially selenides and tellurides) have recently attracted considerable attention for electrochemical applications mainly due to better electronic conductivity, facile charge transfer, redox tunability, and chemical stability. In the current project, transition metal telluride-based nanostructure composites were studied for supercapacitor applications. The nickel telluride nanostructures were grown directly on Nickel foam by hydrothermal method as well as electrodeposition process without addition of any binder to the catalyst. The capacitor performance was measured in a three-electrode system with the nickel-telluride electrode as the anode. A specific capacitance of 1826 F/g was achieved at a current density of 1 A/g. The composite electrode maintained cyclic stability of

more than 90 % at a higher current density of 10 A/g after 1000 cycles. Also, more than 80 % current density retention achieved at higher current density of 20 A/g. Moreover, doping effect on the transition metal site on the supercapacitor performance was also illustrated in this work. Doping in the transition metal site had a positive influence on the supercapacitor activity since, it led to lattice distortion, electronic structure modification as well as helped to tune the surface redox behavior. Also, combining different carbon-based materials (carbon nanotubes, activated carbons and graphene) with the active nickel telluride nanostructures enhanced specific capacitance and overall cyclic stability by increasing the active surface area and porosity of the composite. In this presentation we will discuss the supercapacitor performance of these telluride nanostructures as well as the effect of transition metal doping and carbon nanostructure additives, and explain how the chemistry of transition metal chalcogenides influences their electrochemical functionality and potential as future energy storage devices.

Nanopores in Multilayer Hexagonal Boron Nitride Mehmet Dogan[1,2], S. Matt Gilbert[1,2,3], Thang Pham[1,2,3], Brian Shevitski[1,2,3], Peter Ercius[2], Shaul Aloni[2], Alex Zettl[1,2,3] and Marvin L. Cohen[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Kavli Energy NanoScience Institute, United States

Controlling the size and shape of nanopores in two-dimensional materials is a key challenge in applications such as DNA sequencing, sieving, and quantum emission in artificial atoms. In single-layer hexagonal boron nitride (*h*-BN), under a high-energy electron beam with certain properties, triangular pores are formed whose edges are entirely made up of nitrogen atoms. This allows fabrication of triangular pores at will with matching orientation throughout the two-dimensional material. However, in multilayer *h*-BN, which is usually in the AA′ stacking, neighboring sheets are rotated by 60° with respect to each other, which causes triangular pores in consecutive layers to be misaligned. Here, we investigate experimentally and theoretically triangular vacancies in (unconventional) Bernal-stacked *h*-BN (AB-*h*-BN) formed using a high-energy electron beam. Due to the geometric configuration of AB-*h*-BN, triangular pores in different layers are aligned, and their sizes are controlled by the duration of the electron irradiation. Interlayer covalent bonding at the edge of the pore is not favored, as opposed to what occurs in the more common AA′-stacked BN. A variety of monolayer, concentric and bilayer pores in bilayer AB-*h*-BN are observed in high-resolution transmission electron microscopy and characterized using *ab initio* simulations. Bilayer pores in AB-*h*-BN are commonly formed, and grow without breaking the bilayer character. Nanopores in AB-*h*-BN exhibit a wide range of electronic properties, ranging from half-metallic to non-magnetic and magnetic semiconducting. Therefore, because of the controllability of the pore size, the electronic structure is also highly controllable in these systems, and can potentially be tuned for particular applications.

Enhanced Mechanical Properties of Polymer-Matrix Nanocomposites Reinforced with Graphene Synthesized in Atmospheric Plasmas Albert Dato, Jacob Knego, Nicole Subler, Taylor Sloop, Chance Bisquera and Kevin Nakahara; Harvey Mudd College, United States

Graphene can be synthesized in the gas phase using atmospheric plasmas. Gas-phase-synthesized graphene (GSG) is pure and highly ordered. Additionally, GSG contains graphitic nanocrystals that provide the two-dimensional material with significant mechanical stability and enable GSG sheets to resist deformation. GSG is also more environmentally friendly to produce than graphene that is obtained from graphite. These unique features make GSG a promising filler material for fabricating high-strength multifunctional nanocomposites that have a wide range of applications, such as automobiles, aircraft, and wind turbines.

Here we present the results of an investigation into epoxy-matrix nanocomposites reinforced with GSG. We show that as-synthesized GSG effectively disperses in epoxy resins and resists aggregation indefinitely. We report that incorporating a relatively low loading of GSG into epoxy (0.1 wt%) results in nanocomposites that exhibit significant increases in both strength and strain at break. In contrast, epoxy-matrix nanocomposites that were filled with 0.1 wt% graphene nanoplatelets had enhanced strength but diminished strain at break. Scanning electron microscopy images of nanocomposite fracture surfaces will be presented, which indicate much higher matrix reinforcement by GSG relative to graphene nanoplatelets. These results indicate that (1) GSG could overcome the challenges of contemporary graphene-based nanocomposites and (2) unique strengthening mechanisms exist in polymers reinforced with GSG.

Metal-Free, Highly Conductive Protein Carbon Nanotube Dispersions and Their Films for Biological Applications Ankarao Kalluri and Vijaya Kumar Challa; University of Connecticut, United States

A simple and facile method to produce highly concentrated (> 5 mg/ml) and high-quality multi-walled carbon nanotube (MWCNT) dispersions by ordinary benchtop magnetic stirrer is reported here. Exfoliation and debundling of the MWCNTs were possible by stirring in the presence of a protein, driving the adsorption of the protein onto the nanotube surfaces. High concentrations of the debundled nanotubes were obtained (6 mg/ml) after stirring for 5 days, and these are much higher than other reports in the literature. The bioCNT aqueous dispersions are stable up to 6 months, which is important for storage and practical applications. We also fabricated the facile, inexpensive, highly conductive and flexible CNT paper (Bucky paper) by vacuum filtration of the dispersion through an ordinary filter, which composed of self-assembled, randomly oriented, and highly packed CNTs. These metal-free CNT films were flexible and showed a high electrical conductivity of > 1000 S/cm than expected. These biological CNT dispersions used as conductive ink on cellulose paper, which can be used in printed and flexible electronics, bio-electrochemical sensors, bio-supercapacitor electrode applications. Therefore, inexpensive, highly concentrated biological CNT dispersions prepared by a simple method of stirring provides new opportunities for a wider range of CNT applications.

Sub-Nanometer Carbon-Nanotube Membranes with Anomalously Enhanced Water-Vapor Flux Da-Chi Yang[1], Richard Castellano[1], Melinda Jue[2], Ricardo P. Silvy[3], Robert F. Praino[3], Francesco Fornasiero[2] and Jerry Shan[1]; [1]Rutgers, The State University of New Jersey, United States; [2]Lawrence Livermore National Laboratory, United States; [3]Chasm Advanced Materials, Inc., United States

Fluid transport through the inner cores of carbon nanotubes (CNTs) is known to occur at extraordinary rates, exceeding classical predictions by several orders of magnitude, especially for very-small-diameter nanotubes. However, macroscopic, vertically aligned- (VA-) CNT membranes with sub-nanometer pores have not been previously fabricated due to the difficulty in growing aligned forests of such small CNTs. Here, we report the scalable, solution-based fabrication of the first macroscopic membranes with VA-CNTs of sub-nanometer diameter, and the first water-vapor transport measurements for such membranes. Membranes were fabricated from CNT powder using electric-field alignment and electrophoretic concentration of suspended nanotubes, followed by solvent replacement with a liquid prepolymer and UV curing. The single-wall nanotubes are grown in bulk by chemical-vapor deposition with a specialized catalyst, tuned to produce long, 0.8 nm diameter CNTs. After etching to open CNT pores, the membranes filter out dye solution and demonstrate sublinear conductance scaling with salt concentration at low concentrations. These observations indicate that our fabrication process produces defect-free membranes with CNT pores as the primary trans-membrane pathway. Based on KCl-conductance estimates for the total open pore area in the membranes, the concentration-driven water-vapor permeability is enhanced by many orders of magnitude, well above values reported in literature for larger-diameter VA-CNT membranes. Interestingly, the enhancement in concentration-driven water-vapor transport appears to considerably exceed the enhancement present in the pressure-driven flux of dry nitrogen gas in the pores. Additionally, due to the size of the CNT pores, and the charge present on carboxyl groups at the CNT tips, the membranes demonstrate cation selectivity in KCl solution. Coupled with the enhanced flux of liquid water, such membranes could increase the energy efficiency of membrane-based desalination techniques. These findings present new opportunities to scalably fabricate VA-CNT membranes with sub-nanometer pores and study their fundamental transport properties, with possible applications in breathable and protective garments as well as desalination technologies.

Growth Pressure Dependence of Graphene Direct Growth on A-Plane Sapphire Using Metal-Catalyst-Free Low-Pressure CVD Yuki Ueda, Takahiro Maruyama and Shigeya Naritsuka; Meijo University, Japan

Graphene direct growth on sapphire by metal-catalyst-free chemical vapor deposition (CVD) has attracted much attention as the method to avoid the transfer process [1]. The transfer process not only damages but also deteriorates the graphene. Recently, we reported a graphene direct growth on r-plane sapphire using metal-catalyst-free low-pressure CVD where the graphene grows very fast and quite uniformly comparing to that on c-plane sapphire [2]. However, there are many unknown parts in the growth mechanism. In this report, we focused on a-plane sapphire as a substrate, which is often used in horizontally-aligned growth of carbon nanotubes [3]. The growth pressure was systematically changed in metal-catalyst-free low-pressure CVD to reveal the growth mechanism.

Graphene was directly grown on a-plane sapphire using low-pressure CVD without using a metal catalyst. A mixture gas of N_2, H_2, and 3-Hexyne was flown in a reaction chamber at a constant flow rate of 1000 sccm. The growth temperature, H_2, and 3-Hexyne partial pressures were fixed at 1250 ºC, 500 Pa, and 0.3 Pa while the growth pressure was systematically changed from 5 kPa to 50 kPa.

Raman measurements show that graphene was only grown below 17 kPa and all the grown graphene was smooth and uniform with mono-layer-thick. At the same time, the D/G ratio decreased with decreasing the growth pressure. To

investigate the reason, the early stages of growth were studied between 5 kPa and 15 kPa. Consequently, AFM study showed that the density of graphene islands on the sample grown at 5 kPa was approximately 3 times lower than that of the sample grown at 15 kPa. On the contrary, the growth rate of graphene at 5 kPa was much faster than that at 15 kPa. A high growth rate usually means a high supersaturation, and, therefore, a high nucleation rate. In our case, however, the nucleation rate was slow at low growth pressure. This inconsistency suggests the existence of a special mechanism, which controls the nucleation. From the AFM study, the most graphene islands were found at the step edges of the sapphire substrate. At a low growth pressure, the thermal decomposition of the sapphire surface is enhanced and nucleation sites, in other words, surface steps are destroyed at the same time. This brings the difficulty to the graphene nucleation at the step edges even with a higher supersaturation at a low pressure. Consequently, excellent smooth monolayer graphene with a small D/G ratio of less than 0.2 was successfully obtained on a-plane sapphire at 5 kPa with forming larger grains.

Partially Reduced Graphene Oxide Enhancement of Thrombin Activation of Fibrinogen Clots Rebecca Isseroff[1], Juyi Li[1], Jonathan Lederer[2], Nava Schein[1], Abraham Balsam[1] and Miriam H. Rafailovich[1]; [1]Stony Brook University, The State University of New York, United States; [2]Columbia University, United States

Partially reduced graphene oxide (pRGO) has been found to enhance the enzymatic activity of microbial transglutaminase on the cross-linking of gelatin. To determine if this is a more general phenomenon in modification of enzymatic activity, we tested whether it has an effect on thrombin's ability to clot fibrinogen, an easily quantifiable effect to measure.

Three ml of 10 mg/ml fibrinogen solution in PBS were tested with 8 μ thrombin/ml as a control. Upon adding thrombin, rheometry was used to measure the clotting time as well as the clot modulus. Sharp increases in modulus, shorter clotting times, and stronger clots would indicate enhancement of thrombin, whereas slow increases in modulus, longer clotting time, and weaker clots would indicate inhibition of the enzyme. Test samples included 0.5 ml of 1 mg GO/ml PBS in the fibrinogen mixture, and 0.5 ml of 1 mg pRGO/ml PBS added to the fibrinogen. The pRGO solution produced a clot with an elastic modulus four times greater than the control, and 1.5 times greater than the clot with GO. Different concentrations of pRGO in PBS were then added to fibrinogen solutions and tested. Increasing pRGO concentrations increased the maximum elastic modulus and decreased the clotting time. The elastic moduli were found to be logarithmic, as the logarithmic trendlines had relatively high R^2 values. Higher concentrations of pRGO had higher coefficients, indicating shorter clotting times. Results suggest further future study of partially reduced graphene oxide as a modifier of enzymatic activity.

F.NM03.09.77
Interactions Between Graphene Oxide and Pyrrole Towards Understanding the Electro-Polymerized Substrates—A Molecular Dynamics Study Todd M. Richards and Isaac Macwan; Fairfield University, United States

Graphene Oxide, an oxidized form of graphene, a carbon allotrope, has many applications including the formation of conductive films for use in flexible electronics and chemical sensors, nanofiltration membranes, and even as a replacement for tin-oxide in batteries. One of the pressing issues with carbon allotropes in general and graphene oxide in particular, however, is that they cannot form freestanding films on their own, instead they rely on a secondary reactant to help aid in the synthesis of such films. To synthesize such nanocomposite substrates, cyclic voltammetry is a very commonly used technique, where an electrolyte containing a monomer to be electro – polymerized is used along with the nanoparticles. Electro-polymerized substrates consisting of GO and Polypyrrole (Ppy), an organic polymer created by polymerizing pyrrole, have drawn much attention owing to their applications in solid state supercapacitors, biosensing, tissue engineering, and artificial muscle studies. It has been proven theoretically and experimentally that Ppy and GO do interact and exhibit improvement in conductivity and thermal stability compared to pure Ppy and GO, but there is still very little information on the interactions at the molecular level between GO and pyrrole monomers especially during the synthesis of such nanocomposites. This work deals with the study of interactions at the interface of GO and pyrrole in order to better understand the evolution of polypyrrole over the surface of graphene oxide during the formation of these films. The system is

modeled using Visual Molecular Dynamics (VMD) and all – atom simulations are carried out using Nanoscale Molecular Dynamics (NAMD) at ten different temperatures based on the peak currents and scan – rate through the Randles – Sevcik equation. Each simulation is carried out for 100ns, thereby looking into a total of one microsecond long window of interactions between GO and 50 pyrrole monomers as the polypyrrole film is evolved over the surface of GO. Stability of the GO/ Ppy nanocomposite is quantified through RMSD (Root Mean Square Deviation), conformational energies and center of mass deviations. Interaction energies are calculated to understand the role of non – bonding interactions such as Van der Waals and electrostatics between the monomers and between monomers and GO. It is anticipated that pyrrole monomers form dimers in the bulk of the solution, trimers when near the surface of GO, and tetramers when adsorbed on the surface of the GO. Based on these results, a potential mechanism is proposed on the way monomers interact with the nanoparticles during electro – polymerization and the role of such interactions in synthesizing carbon – based free – standing films.

Development of Planar-Type Thermoelectric Device Using Carbon Nanotube Sheet for Wearable Application Tsuyohiko Fujigaya[1,2,3], Ryohei Yamaguchi[1] and Naoki Tanaka[1]; [1]Kyushu University, Japan; [2]Center for Molecular System, Kyushu University, Japan; [3]International Institute for Carbon-Neutral Energy Research, Kyushu University, Japan

Single-walled carbon nanotube (SWNT) is ideal materials for thermoelectric conversion because of their high Seebeck coefficient and electrical conductivity. Development of the wearable thermoelectric device using SWNTs is now investigated by taking advantage of their film toughness and flexibility. Up to date, π-shape structure has been proposed for the SWNT thermoelectric sheet. However, this structure needs to attach on a skin vertically and not preferable for the wearable application. Therefore, we proposed a new planar-type structure, in which the sheet can attach on the skin surface and preferable as a wearable device. Since sequential repeating of p-type and n-type properties are necessary for the devices, in this study, we investigated the patterned doping of p-type SWNT sheet into n-type. We found that the deposition of benzimidazole derivatives successfully turned un-masked area into n-type, giving a repeating of p and n-type structure. Detail characterization of the n-doping were carried out by Raman spectroscopy, X-ray photoelectron spectroscopy and Seebeck Coefficient measurements. Devise performance of the thermoelectric sheet will be introduced in the presentation.

Fabrication and Characterization of $PbTiO_3$ Multi-Layered Truss Structure Hyunji Kim, Kisun Kim, Hoon Kim, Seokjung Yun, Gun Park, Seokwoo Jeon and Seungbum Hong; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Future society will enjoy augmented reality, haptic displays, intelligent cars, and robots in everyday life. Those devices require tactile enhancement which would be improved by high piezoelectric coefficient and strain limit. $PbTiO_3$ is one of the piezoelectric materials which has high piezoelectric coefficient, low price and wide application but at the expense of low elastic strain limit. In this work, we applied nanoscale truss structure to enhance the elastic stress limit while maintaining the high piezoelectric coefficient of $PbTiO_3$. Fabricating $PbTiO_3$ in multi-layered truss structure around 20~30 nm, we expect to improve both piezoelectric coefficient and strain limit up to 300% respectively. We deposited 8 nm $PbTiO_3$ layer 3 times on the Nickel template and after deposition of multilayers, Nickel template was removed. Each layer of $PbTiO_3$ was formed by depositing TiO_2 using atomic layered deposition (ALD) and PbO gas reaction in the tube furnace. The crystallinity of each $PbTiO_3$ layer was confirmed by XRD. We expect multi-layered $PbTiO_3$ to show 100% higher piezoelectric coefficient than single-layered $PbTiO_3$ showing better crystallinity. [1] After measuring the crystallinity, thickness was measured by TEM. By measuring the deposition thickness according to the distance, we will set thickness of single-layered $PbTiO_3$ to 8 nm. This will be a significant experiment in that it stacks nano layers of targeted thickness. Also, our approach will provide insight into making piezoelectric materials that have both high piezoelectric coefficient and strain limit, and realize various tactile applications.

Layer-by-Layer Self-Assembly PEI/MWCNT-COOH Nano-Porous Coating for Enhanced Heat Transfer Characteristics of Heat Dissipation Devices Jaemin Lee, Daehyeon Kyeong, Ji heon Kim and Wonjoon Choi; Korea University, Korea (the Republic of)

With the development of AI, 5G, and autonomous vehicles, higher performance electronic devices are required for more data

collection and data processing. In addition, as electronic devices are gradually downsized and thinned, the amount of heat generated per unit area also increases exponentially, so conventional heat dissipation devices (e.g. Heat sink, Heat pipe and Vapor chamber) cannot satisfy these heat generation and electronic device manufacturing conditions. In order to improve the performance of these heat dissipating devices, many studies have improved heat transfer performance through various coating methods such as CVD, PVD, ALD and Spray coating. However, these coating methods are not suitable for heat sinks with complex shapes or heat pipes with a thin tube structure because they require special process conditions such as high temperature or vacuum, and the process cost is large or greatly affected by the shape and size of substrate.

The Layer-by-Layer (LbL) coating method is a solution-based technique which is a self-assembled coating using electrostatic force through the difference in zeta potential between positive and negative solution. Since the LbL coating method is based on a solution-based processing, it can be coated to the complex structures regardless of the size or shape of the substrate. This characteristic enables the direct applications to a heat sink within fin structures or a tubular heat pipe within an inner micro porous structure.

Herein, we present multi-functional LbL PEI/MWCNT-COOH nano-porous coatings based on a solution processing to improve the heat transfer characteristics of heat sinks and heat pipes. To investigate the direct correlation of the nano-porous coatings and the heat transfer characteristics, the LbL PEI/MWCNT coatings were prepared as bare, 10-bi, 20-bi, and 30-bi layers. The change in thickness and surface morphologies of LbL coatings was precisely analyzed through FIB and SEM image analysis, while the surface area and pore size distribution according to the number of LbL coatings was examined using BET surface area analysis. Furthermore, the wettability of the PEI/MWCNT coating was measured to confirm the capillary rise, which is one of the important factors to determine the heat transfer performances of the devices.

Through the natural convection test of the LbL coated heat sinks, it was confirmed that the enhanced thermal performances could be obtained due to increasing the porosity and surface area of the LbL coating. As the porosity and surface area was optimized in the number of coatings, the overall thermal performances including heat transfer coefficients were significantly improved up to 11% for 30 bi-layers coated heat sink due to the increase in the surface area, in comparison with that of the bare heat sink. Furthermore, the LbL functional coating layers could highly improve the heat transfer characteristics of the heat pipes, as well. Because a nano-micro sized bi-porous structure appeared in the microporous-sintered heat pipe with the LbL coating layers, such bi-porous structure could strengthen capillary wicking, fluid transportation, and superhydrophilicity as well as increasing surface area, thereby improving heat transfer efficiency and thermal resistance up to 14.3% in a 10 bi-layers coated heat pipe.

The PEI/MWCNT LbL nano-porous coating, which was used for the heat dissipation devices (i.e. heat sink and heat pipe) could show the enhanced heat transfer characteristics, while the fabricate process was based on the only simple and low-cost LbL coating technology. This multi-functional and thin PEI/MWCNT LbL nano-porous coating not only improved the performance of the conventional heat dissipation device, but also is expected the design trend of miniaturization, thinning, and lightweight electronic equipment.

Dielectrophoresis (DEP)-Aligned Semiconducting Carbon Nanotubes for Fabricating Electronic Devices Abram Jones, Lauren Williams, Brandon Whitaker, Rodricka Miller, Jhamaree Elam, Qunying Yuan and Zhigang Xiao; Alabama A&M University, United States

We report the deposition and alignment of semiconducting carbon nanotubes with the alternating electric field-directed dielectrophoresis (DEP) method and the fabrication of carbon nanotube-based electronic devices with the DEP-aligned semiconducting carbon nanotubes (CNTs). Semiconducting carbon nanotubes, which were dispersed ultrasonically in the n-methyl pyrrolidone (NMP) solution, were deposited and aligned onto a pair of gold electrodes using the dielectrophoresis method. The excellent alignment of carbon nanotubes was achieved by optimizing the AC voltage, frequency, and deposition time of the applied AC signal. The DEP-aligned tubes were further fabricated into carbon nanotube field-transistors (CNTFETs) and CNTFET-based electronic devices such as CNT-based inverters using the microfabrication techniques. Plasma-enhanced atomic layer deposition (PE-ALD) was used to grow hafnium dioxide ($HfO_{2)}$ as the high-k gate oxide in the fabrication of CNTFETs. The aligned carbon nanotubes and fabricated devices were imaged using the scanning electron microscope (SEM), and the electrical properties were measured from the fabricated devices using the semiconductor analyzer. About 70% yield was obtained from the semiconducting carbon nanotube-based CNTFETs, and the fabricated CNTFETs and CNT-based inverters demonstrated excellent current (I) – voltage (V) curves and transfer characteristics.

F.NM03.09.82

Inertial Sensor Based on Energy Harvesting Carbon Nanotube Yarn Ji Hwan Moon and Seon Jeong Kim; Hanyang University, Korea (the Republic of)

Inertial sensors are devices that can monitor inertial movements like linear acceleration and angular motions, in various applications such as industrial and human monitoring. For wearable and portable applications, inertial sensors are better to be self-powered and miniaturized. Here, we developed a self-powered inertial sensor with various applications having high accuracy based on carbon nanotube (CNT) yarn. Our inertial sensor can sense and monitor inertial movements without any external power by harvesting the mechanical energy to electric energy by the coiled CNT yarn. For applications, the sensor can monitor practical kinds of inertial movements, such as impact energy, vibrations, tilting, and body motions such as walking, running, jump and squatting motions. These results suggest that the self-powered inertial sensor shows the advantages of portable and wearable application in industrial and human motion monitoring system.

Formation of Nanosheets via Unfurling of Vanadate Nanoscrolls from Bulk Vanadium Oxide Md Shahidul Islam Khan[1] and John B. Wiley[1,2]; [1]The University of New Orleans, United States; [2]Advanced Materials Research Institute, United States

Vanadium oxide materials are renowned for their catalytic properties, super-capacitance, chemical sensing, and high energy density cathodic properties. A two-step synthesis method was applied to obtain 2D structures of vanadium oxide (V_2O_5) or vanadate ($V_{2-x}O_{5-x}$) nanosheets from bulk V_2O_5 where the first step involved the formation of vanadate nanoscrolls, 1D structures, that resulted from the dissociation of layered vanadium oxide. In the second step, the nanoscrolls were unfurled to obtain nanosheets, 2D materials. This latter step can be performed using a wet chemical process or annealing treatment. During the wet chemical process, vanadate nanoscrolls turn into thin-layered vanadate nanosheets, and with the annealing process, thin-layered vanadium oxide nanosheets are produced. The formation of these different types of nanosheets was confirmed by X-ray diffraction. Nanosheets obtained from the wet process showed the presence of organic groups that were detected using FTIR and Raman spectroscopy. Both the vanadate and vanadium oxide nanosheets were single or multilayered but only the latter one possesses irregular hexagonal shape which was confirmed through TEM.

F.NM03.09.84
Self-Assembly of Tetra-Peptides on Surfaces of Two-Dimensional Materials Wei Luo, CHEN CHEN and Yuhei Hayamizu; Tokyo Institute of Technology, Japan

As the novel “bottom-up” strategy for fabricating nanomaterials, molecular self-assembly has attracted considerable attention worldwide. On one hand, two-dimensional (2D) materials such as graphite and molybdenum disulfide (MoS_2) have been demonstrated as the platform for this self-assembly due to their unique electrical, optical properties, and atomically flat surfaces, etc. [1,2]. On the other hand, amphiphilic peptides with both of the hydrophobic and hydrophilic nature also have already been used as ideal building blocks for forming various sophisticated self-assembling materials with certain applications. Therefore, in order to functionalize the 2D material surface by peptides self-assembly, it is necessary for a deliberate understanding of the interaction between biomolecules and 2D substrate materials [3].
Molecular dynamics (MD) simulation provides insight into the molecular-scale structure detail of interface. Several works have been done on solid surface to understand the role of peptides, like on Au (111) for self-assembly [4] or on calcite for biomineralization [5]. More recently, peptides on graphene [6] or MoS_2 [7] have been studied because of the atomically flat surface and some progress in experiments exhibiting the molecular resolution morphology. From these, aromatic amino and charged amino acids are considered to have a meaningful interaction with those surfaces. Although the peptide-peptide interaction is also important for surface self-assembly of peptides, the understanding for both interpeptides and peptide-surface interactions are still limited.
In this work, we aim to utilize computational approaches to understand the molecular mechanism. For this purpose, we started with a tetrapeptide consisting of aromatic and charged amino acids, where these amino acids may play a role for the self-assembly. We performed the molecular dynamics simulation (MD) starting with single tetrapeptide on graphene surface. From this calculation, we obtained the most stable tetrapeptide structure on graphene surface. Analyses of center-of-mass distance between peptide and graphene surface, angle change of aromatic rings, and free energy distribution revealed that the balance between interpeptide and peptide-surface is a key to have a well assembled peptides on surface. Furthermore, information about binding process for tetrapeptide on 2D surface was also obtained. This work can be a foundation for building a conformation-property relation of amphiphilic tetrapeptide self-assembly on 2D material surfaces.

Formation of Various Cross-Linked Gel Layer Around Single-Walled Carbon Nanotubes Tsuyohiko Fujigaya[1,2,3] and Yukiko Nagai[1]; [1]Kyushu University, Japan; [2]Center for Molecular System, Kyushu University, Japan; [3]International Institute for Carbon-Neutral Energy Research, Kyushu University, Japan

Single-walled carbon nanotubes (SWNTs) have unique near-infrared (NIR) absorption and NIR photoemission that are attractive for in vivo biological applications such as photothermal cancer treatment and imaging. Therefore, a smart functionalization strategy for SWNTs to create biocompatible surfaces and introduce various ligands to target cancer cells without losing their unique optical properties of the SWNTs is strongly required. We developed novel coating technique of SWNTs inspired by emulsion polymerization method, in which the micelle dispersion of SWNT was used for free radical polymerization. In the dispersion, polymerization takes place in the surfactant micelle having SWNT in the core. Thus the SWNTs were coated by polymer layer. When the cross-linker was added, the SWNTs were coated by gel layer, offering the highly stable coating of SWNT
We have revealed the requirement for the formation of the thin cross-linked polymer-wrapped SWNTs, in which the use of monomers that can undergo polymerization inside the micelles was important. In our study, such hybrids were formed when using various monomers in aqueous SDS dispersions of the SWNTs in the presence of APS and BIS as the initiator and cross-linker, respectively in high yeild (>75%) except acryl amide and hydroxymethyl methacrylate. The present study provides useful insight into preparing many polymer-SWNT hybrids with designed functions due to the wide availability of the monomers.

Investigation of Electrocharging-Assisted Fabrication Parameters for Nanocarbon-Al Composites with Improved Electrical Conductivity and Tensile Strength Madeline Morales[1,2], Xiaoxiao Ge[1], Christopher Klingshirn[1], Christopher Shumeyko[2], Daniel P. Cole[3] and Lourdes G. Salamanca-Riba[1]; [1]University of Maryland, United States; [2]US CCDC Army Research Laboratory, Vehicle Technology Directorate, United States; [3]US CCDC Army Research Laboratory, Army Research Office, United States

Nanocarbon-metal composites are sought after for their excellent mechanical, electrical and thermal properties. Electrocharging-assisted processing of a novel class of materials, called “covetics,” presents a practical option for macroscale production of nanocarbon-metal composites. This process incorporates carbon on the order of several weight percent in metals such as Al and Cu where carbon solubility is in the low ppm range. Increased tensile strength and electrical conductivity have been measured in Al covetics; however, there is limited understanding of the electrocharging-assisted process and subsequently high variability in measured properties among trials. It has been found that under the influence of a high direct current applied to the molten metal, the activated carbon precursor is converted to sp^2 graphitic carbon with increased crystallite size, as measured by the Tuinstra-Koenig relation for Raman spectra. Electrical conductivity is also enhanced in areas that show increased graphitic carbon crystallite size. A series of experiments varying applied current have been carried out to understand the effect of current density on carbon crystallization rate and size of reaction volume within the Al-1350 melt where carbon crystallization occurs. Local electromechanical behavior is measured by nanoindentation and AFM to gain insight into the structure-property relationship at the nanoscale, which can be used to further inform optimization of the electrocharging-assisted process.

Direct *In Situ* Observation of Toughening and Fatigue Behavior in Alumina/Graphene Nanocomposites Qizhong Wang[1], Cristina Ramirez[2] and Nitin Padture[1]; [1]Brown University, United States; [2]Instituto de Cerámica y Vidrio, Spain

There is growing interest in using 2D graphene-related reinforcements to toughen brittle ceramics in nanocomposites. However, there is a lack of fundamental understanding of the toughening mechanisms and microstructural effects in such nanocomposites. To address this paucity, fully-dense nanocomposites of aluminum oxide (Al_2O_3) matrix and reduced graphene-oxide (rGO) reinforcements (~5 vol%) of different average-thicknesses and orientations are fabricated and characterized. The interactions between stably propagating cracks and rGO in the Al_2O_3/rGO nanocomposites are observed *in situ* inside a scanning electron microscope (SEM). Toughening by pullout of thick rGO in the crack-tip wake in the cross-section orientation is found to be the most effective, which is consistent with the highest fracture toughness (K_{IC} ~6.7 MPa.$m^{0.5}$) measured in those Al_2O_3/rGO nanocomposites. Interestingly, while achieving stable crack growth for flat punch compression of notched samples, we found that upon unloading and reloading, the intact rGO crack-bridges appear to crinkle and uncrinkle without a remnant crease, respectively, which is a unique deformation property of multi-layer graphene-like materials. Information extracted accompanied by the Raman spectroscopy studies has permitted to have a deeper understanding of the fatigue resistance mechanisms in this novel material. This is unlike conventional ceramic composites toughened by fibers or whiskers which have poor cyclic fatigue resistance due to the degradation of the crack-wake bridging and pointing to a possible new cyclic-fatigue resistance mechanism in the nanocomposites. The results from this study have implications for the creation of high-toughness, fatigue-resistant, and wear-resistant graphene-reinforced ceramic nanocomposites of the future.

Effects of Electrical Image Forces on Salt Dissolved in Water Jeffrey B. Sokoloff[1,2] and Andy Lau[2]; [1]Northeastern University, United States; [2]Florida Atlantic University, United States

Onsager and Samara have shown that electrical image charge forces acting on ions dissolved in water can explain the observed increase of the surface tension due to the presence of dissolved ions. Electrical image charge forces at the interface of a salt solution and air are repulsive, but at the interface between the salt solution and a dielectric of higher dielectric constant than that of the solution or a metal, in contrast, the force is attractive. It has also recently been shown that electrical image forces may play a role in the attraction of ions to the electrodes in capacitive desalination, and to play an important role in the freezing of a confined room temperature ionic liquid. Here, the effect of electrical image forces on the distribution of salt ions in a solution that is in contact with a metallic or dielectric surface is considered. It is shown that in the case of either a metallic or dielectric surface, the salt ion concentration near the surface can be very large, raising the possibility that this could result in precipitation of the salt. In fact, solidification of ionic liquids near a metallic surface with which they are in contact has been observed. Concentration of ions near a metallic surface could be used to desalinate salt water by pushing the salt water between an array of parallel plates of a conducting material. Graphene would be an excellent coating for these plates because the friction between flowing water and graphene is known to be extremely small. In order to support our prediction of a high ionic concentration near metallic and dielectric surfaces, we have performed a variational calculation of the grand canonical partition function to lowest order in the ion density, which is the Debye-Huckel approximation. This calculation supports our conclusion. Our calculation also confirms the concentration dependence of the surface tension found by Onsager and Samarasa in the small salt concentration limit.

Detection of Limonene Using Graphene Field Effect Transistor Modified by Self-Assembling Peptide Chishu Homma[1], Hironaga Noguchi[1], Yoshiaki Sugizaki[2], Atsunobu Isobayashi[2] and Yuhei Hayamizu[1]; [1]Tokyo Institute of Technology, Japan; [2]Toshiba Corporation, Japan

Graphene, a representative two-dimensional material, has excellent electronic properties due to its high mobility and specific surface area. Biosensors based on graphene field-effect transistor (GFET) are expected to be applied in various fields such as medical diagnosis, environmental monitoring, and security management. A number of studies on biosensors using GFET have been carried out so far. The surface functionalization with probe molecules is crucial, which gives a high affinity to the target molecule. In this process, covalent bonding and π-π interaction have been used to immobilize probe molecules to the surface. However, there are two disadvantages with these detection methods. Firstly, chemical modifications may degrade inherent electronic properties of graphene. Secondly, random adsorption of probe molecules on the surface may result in loss of the probe activity. These lead to a decrease in sensitivity as a sensor.
So far, there have been various demonstration of GFET biosensors reported. The target of the biosensors have been living cells, virus, DNA, and proteins. There is a still challenge here to detect relatively small molecules. These small molecules have low molecular weight and generally do not have a polarization. GFET-based biosensors have a drawback for these small molecules, because the detection mechanism depends on the Coulombic interaction between trapped molecules and graphene. In addition, most of the small molecules are volatile and insoluble. Therefore, in aqueous solutions, it is very difficult to detect volatile molecules dissolved in small amounts. This is also one of the challenges for biosensors.

To solve these problems, we suggest an alternative surface modification method using peptide self-assembly. Peptides are known to recognize crystalline structures of inorganic material surfaces and form uniform structures through interactions among molecules [1]. These peptides are physically adsorbed to the surface. Thus, the surface can be modified without losing their intrinsic electronic properties. These self-assembly of peptides has been demonstrated on gold, boron nitride (BN), transition metal chalcogenides, and graphene in previous studies. The self-assembly of peptides have potential as a scaffold domain for biosensors [2]. In this study, we aimed to develop a new technique to detect an odor molecule, which is relatively small and volatile. For this sake, we utilized rationally designed peptides as a molecular scaffold [3] and probe peptides on graphene surface. Then, we performed odor sensing with limonene, a representative molecule for the smell of lemons. We successfully detected limonene with high sensitivity. We also found that the sensitivity to limonene was altered by the amino acid sequence of the probe domain.
This work was supported by the Cabinet Office (CAO), Cross-ministerial Strategic Innovation Promotion Program (SIP), "An intelligent knowledge processing infrastructure, integrating physical and virtual domains" (funding agency: NEDO).

Direct Measurements of Tensile Properties and Current-Carrying Capacity of 14 cm-Tall Few-Walled CNT Forest Tatsuhiro Hayashi[1], Takayuki Nakano[1], Hisashi Sugime[2], Suguru Noda[2,2] and Yoku Inoue[1]; [1]Shizuoka University, Japan; [2]Waseda University, Japan

We have clarified the tensile properties and electron transport capacity properties of macro-sized continuous crystal few-walled CNT forests, which have a height of 14 cm. The present CNT is the highest forest ever reported. The CNT was grown by a CVD method using a Fe-Gd catalyst on Al oxide support [1]. The crystal structures of CNT were evaluated by SEM, TEM, and Raman measurements. Then, the bundle taken out from the CNT forest was converted to a cylindrical structure to define a cross-sectional area and weight density. The cylindrical specimens were tailored by passing through a pinhole with a diameter of 30-100 μm. The reshaped CNT bundle enables to measure tensile tests and electrical measurements by the conventional methods for macroscale specimen. From tensile measurements, it was found that the nominal tensile strength and Young's modulus of the individual CNT were 0.59 GPa and 48 GPa, respectively. This nominal tensile property was obtained by using the entire cross-sectional area, including the inner hole space of the tubular structure for calculation. These results are comparable with reported values, which were measured on various types of CNT by the microscopic methods, and it is lower than theoretical values. The difference between the theoretical and the experimental results is because the present extremely long bundle includes a large number of crystal defects. Also, bundling of millions of CNTs induces further weakening of tensile properties compared to those of micro-sized single CNTs. As for the electrical properties, conductivity and the current-carrying capacity, ampacity, were 140 S/cm and 6700 A/cm^2, respectively. These properties were improved significantly by heat treatment at 2800°C in Ar, up to 340 S/cm and 8800 A/cm^2, respectively. These results correspond to the specific conductivity of 1560 S*cm^2/g and ampacity per CNT of 5.2×10^4 A/cm^2. The ampacity of our CNT was as high as that of commercially available Cu wire (5.8×10^4 A/cm^2).

Copper Oxide Nanocrystals Catalyzed Growth of Nanospheres, Solid and Hollow Carbon Spheres in Thermally Stressed Jet A-1 Pooja Sharma Parihar; Indian Institute of Science, India

Aviation turbine fuel, Jet A-1 contains trace metals that catalyze carbonaceous nanostructures formation and their transformation to carbon spheres in the liquid phase at low temperature (190 ^{0}C) by flask tests. Thermal stressing of Jet A-1 produced nanospheres, solid and hollow carbon spheres in this work, which is consistent and continuation of a previous study [1]. Focus of the current study is to identify the trace metallic compounds that catalyze the growth of spherical nanoparticles and carbon spheres in thermally stressed Jet A-1. In the previous study [1], however, the formation of carbon spheres by self-assembly was observed, and their characterization was conducted. Heteroatoms and trace metals are precursors to the deposit formation in the thermally stressed jet fuel [2, 3]. The presence of trace metals and heteroatoms in the Jet A-1 deposits is validated by transmission electron microscopy (TEM), energy dispersive x-ray spectroscopy (EDS), scanning transmission electron microscopy (STEM) and high-angle annular dark-field (HAADF), and high-resolution transmission electron microscopic (HRTEM) micrographs. Heteroatomic species were also recorded by Fourier transform infrared (FTIR) spectroscopy. Trace metal copper oxide nanocrystals (CuO and Cu_2O) were identified by HRTEM and selected area electron diffraction (SAED) analysis. TEM EDS spectra provided the ratio of Cu and O; Cu to O ratio approximately 1:1 and 2:1.

Indexing of the polycrystalline SAED pattern generated the d-values corresponding with copper oxides nanoparticles. Copper oxides nanocrystals as constituents of spherical particles were confirmed by comparing the measured d-values and calculated Miller indices (h k l) for copper oxides with i) ICSD database and, ii) simulated diffraction pattern of the Cu_2O, CuO by Crystal Maker software. Furthermore, structure elucidation of Fe and S nanocrystals is in progress and can suggest the effect of trace metal catalysts on the spherical nanoparticles, and carbon spheres formation in the thermally stressed kerosene type fuel.

Keywords: Jet A-1, copper oxide, trace metals, carbon spheres, nanostructures

Late News: Carbon Nanotube Field-Effect Transistor Model for a Wide Temperature Range Junsung Park and Michael Shur; Rensselaer Polytechnic Institute, United States

The carbon nanotube field-effect transistor (CNT FET) has been intensively studied due to the high mobility and large current carrying capacity, thus considered as a promising material for nano-scale electronics. For the commercialization of the CNT FETs, the accurate and reliable model is an essential requirement. Especially, transport characteristics of the CNT FETs at high temperature (>300K) is crucially important since the CNT FETs typically operate at elevated temperature. We now report on an improved compact model of the CNT FET. The model is based on the unified charge control model (UCCM) suitable for implementation in standard computer-aided design (CAD) environment such as SPICE. The model accurately describes the current-voltage characteristics for all operation regimes over a wide range of temperatures from 295 to 523K. The model accounts for the temperature and bias effects on the threshold voltage and mobility as the key metrics impacting the CNT FET's performance. It reproduces the mobility, subthreshold swing, on- and off-state current, and threshold voltage behavior as functions of the operating temperature. The model is validated by comparison with the experimental data for the CNT FET reported earlier. The model applications include the device design, characterization, large scale simulation, and parameter extraction of the CNT-based devices and integrated circuits.

Late News: Laser Peening Enhances Tribological Resistance of Electrodeposited Cr Coatings Reinforced with Yttria Stabilized Zirconia and Carbon Nanotubes Pragya Tripathi, Kantesh Balani and Janakarajan Ramkumar; Indian Institute of Technology, India

Laser shock peening is performed on chromium based electrochemical coatings consisting of 3 mol% yttria stabilized zirconia nanoparticles (YSZ) and carbon nanotubes (CNT) as reinforcements, deposited on steel substrate as a suitable strategy to further enhance mechanical and tribological properties of protective coatings. Coated Cr has shown an increased hardness after laser peening from ~8 GPa to ~9.4 GPa, whereas, upto 26 GPa hardness is obtained for Cr-YSZ-CNT coating. Increased hardness might be accredited to high compressive stresses, ranging up to ~1757 MPa, induced as a result of laser peening. Synergistically reinforced with YSZ and CNT after laser peening treatment, minimum wear rate of $\sim 1.8\times10^{-5}$ mm^3/Nm by fretting wear test is recorded in the Cr matrix, which is concomitant with maximum dislocation density of $\sim 3.0\times10^{16}$ m^{-2}. An overall improvement in mechanical and tribological properties i.e. low wear constant of the order of 10^{-6} is achieved, out of which Cr-YSZ-CNT outperformed the other coating systems. Addition of YSZ strengthens the Cr matrix, whereas, multi-functionality of CNT provides with lubrication along with matrix strengthening as well as bridging effect to crack propagation. Therefore, synergistic effect of two reinforcements (YSZ, CNT) in Cr matrix combined with the laser peening treatment lead to superior properties of the coating (Cr-YSZ-CNT) capable enough of limiting the problems of wear and erosion.

Self-Assembled Peptides for Suppression of Non-Specific Binding of Biomolecules on Graphene Mirano Tsukiiwa, Yasuaki Nakata, Hironaga Noguchi, Chishu Homma and Yuhei Hayamizu; Tokyo Institute of Technology, Japan

Graphene is suitable for an active layer for biosensors with high-sensitivity because of their fascinating electrical properties with atomically-flat surface and high specific surface area. Biomolecular immobilization on the active layer of biosensing devices is of vital importance for the functionality, such as sensing with biomolecular probes and protecting from unnecessary unspecific adsorption of biomolecules. However, the immobilization by chemical bonding will introduce atomic defects for graphene, which influences its intrinsic properties to some extent. Self-assembled peptide can be a good candidate. Specific peptides spontaneously form ordered structures through non-covalent intermolecular interactions on the surface of graphene without losing the intrinsic electrical properties of the materials.[1][2][3] On the other hand, non-specific adsorption of biomolecule causes a background noise and decrease the sensing ability of a bio-probe. Therefore, the suppression of nonspecific adsorption is an important issue for the realization of high-performance biosensors. To solve these problems, in this research, we designed new self-assembled peptides and evaluated their performance, aiming at construction of surfaces with the anti-fouling property. The designed peptides consisted of three main domains. (1) antifouling domain: hydrophilic and zwitterionic, which is effective in reducing protein non-specific adsorption. The hydrophilic groups are known to form a hydration layer and create a physical energy barrier that prevents adsorption. (2) Peptide-to-peptide interaction domain: inspired by fibroin, a protein of silk thread. The repetitive sequences of glycine (G) and alanine (A) are introduced. Here we expect the formation of a strong and stable peptide monolayer derived from the β-sheet structure.[2] (3) Anchoring domain: electrons in tyrosine are expected to help to have a stacking of the aromatic ring with the surface of two-dimensional materials. The aqueous solution was placed on the surface of graphite to form a self-assembled film of peptides. The surface structure of these samples was characterized using atomic force microscopy (AFM). We found that peptides had a tendency coverage with increasing concentration. The peptide structure had a six-fold symmetry, which is same as one of underlying graphene lattice. The hydrophilic properties of the peptide film were characterized using contact angle measurements. Furthermore, the antifouling performance was evaluated by AFM and graphene field effect transistors (GFETs). It showed that the adsorption of proteins was greatly inhibited. The peptide offer to be a new molecular scaffold for sensitive graphene biosensors.

Late News: Application of Starch-Derived Graphene Quantum Dot Embedded Carbon Aerogel as Efficient Catalyst in Proton Exchange Membrane Fuel Cell Eric J. Kim and Sunil Sharma; Stony Brook University, The State University of New York, United States

Proton Exchange Membrane Fuel Cells (PEMFC) are considered to be one of the most promising clean energy sources to mitigate the global crisis of climate change and air pollution. However, its dependence on expensive catalyst materials with low durability, such as platinum, prevent this technology from being widely commercialized. In this study, we present the application of a metal-free starch-derived graphene quantum dot (GQD) supported on highly porous carbon aerogel (GQD/CA) in PEMFC to overcome these technical barriers. Structural, morphological, and crystalline features of GQDs and GQD/CA are analyzed using HRTEM, TEM, AFM, and XRD. Further electrochemical characteristics are investigated using cyclic voltammetry (CV), CO-stripping, ORR polarization, and fuel cell testing. Additionally, the durability of the catalyst is measured using the DOE2020 accelerated stress test (AST). The TEM imaging shows the small size and uniformity of GQDs, which allows for an even distribution of GQDs onto the support and a higher electrochemical surface area (ECSA). The presence of functional groups on GQD is shown to improve ORR performance by up to 10 times compared to platinum. In addition, the structural integrity of both GQD and CA create a synergistic effect to prevent the agglomeration of particles during AST. As a result, compared to a commercial standard catalyst, platinum supported on carbon black (Pt/CB), GQD/CA shows significantly higher electrocatalytic activity, with up to 220% increase in ECSA and 1432% increase in peak power density. After 30,000 cycles of AST testing, GQD/CA is shown to retain 92.9% of its ECSA, 97.1 % of its specific activity, and 98.4% of its mass activity. Thus, GQD/CA is demonstrated to be a highly efficient, durable, and economical catalyst for PEMFCs to mitigate the ever-present effects of climate change and air pollution.

Late News: Graphene-Protein Adhesion Interactions are Influenced by Substrate Properties Eleanor L. Brightbill, Katherine Young, Hilena F. Gezahagne, Decarle S. Jin, Bryce Hitchcock and Eric M. Vogel; Georgia Institute of Technology, United States

A wealth of studies utilizing graphene to sense biomolecules (such as glucose, DNA, Concanavalin A) across different sensing modalities (such as surface plasmon resonance, redox, field effect transistor) have been published due to graphene's unique properties including high surface area and conductivity. However, in any sensor device where graphene interacts with a biofluid, the graphene must be supported by some underlying substrate. Moreover, previous studies indicate that the substrate can influence graphene's properties, where substrate hydrophilicity can affect graphene's water contact angle and substrate polarity can affect the success of epitaxial growth through a graphene layer. Despite this, little to no work has been completed describing how the substrate support effects the graphene-biological solution interaction.

In this study, e*x situ* protein adsorption is measured via ellipsometry and X-ray photoelectron spectroscopy (XPS) of model small (Lysozyme), medium (Bovine Serum Albumin, BSA), and large (Fibrinogen) proteins on substrates with a variety of hydrophobicity and surface polarity with and without a transferred graphene monolayer. Additionally, we investigate the *in situ* adhesion of lysozyme on Si and Au substrates with and without transferred graphene via quartz crystal microbalance with dissipation (QCM-D) to monitor kinetic differences in attachment. Fully coalesced graphene was synthesized via Chemical Vapor Deposition and transferred onto various substrates using a wet transfer process and PMMA scaffold.

Ex-situ ellipsometry and XPS results reveal that the impact of the substrate on protein attachment to graphene depends on the protein studied. The largest model protein, Fibrinogen, shows a similar level of attachment across all 4 substrates regardless of the presence of graphene. Lysozyme, the smallest model protein, shows a difference in adsorption only when a graphene monolayer is added to non-polar substrates. The adsorption of BSA, the intermediate size protein, is influenced strongly by substrate hydrophilicity, where less adsorption is observed on more hydrophilic substrates with or without the presence of graphene. Overall, a more hydrophobic substrate leads to a larger amount of adsorption to graphene.

In-situ QCM-D results show that not only the equilibrium attachment, but also the kinetics of interaction, can be affected by the substrate. Modeling the attachment of lysozyme to graphene on Au and Si substrates indicates that the appropriate kinetic model may be determined by the substrate even in cases where differences in absolute adsorption are observed, further indicating that support substrates have a significant effect on protein adsorption behavior to graphene.

This work indicates that the substrate of a graphene-based biosensor is an important but currently overlooked parameter when understanding and optimizing the performance of the device. The *ex-situ* ellipsometry and XPS analysis of protein attachment indicates that the substrate can have a profound impact on protein-graphene interactions, to the extent that twice the BSA attachment to graphene is observed when graphene is supported by TaN rather than Si. The level of non-selective protein adsorption on graphene can be independently engineered through modifying the support substrate without directly modifying the graphene itself.

F.NM03.09.97

Nonlocal and Nonlinear Optical Response in Guided Nanoribbon Plasmons Alvaro Rodriguez Echarri[1], Javier Garcia de Abajo[1,2] and Joel Cox[3,4]; [1]ICFO - The institute of Photonic Sciences, Spain; [2]ICREA – Institució Catalana de Recerca i Estudis Avançats, Spain; [3]Center for Nano Optics, University of Southern Denmark, Denmark; [4]Danish Institute for Advanced Study, University of Southern Denmark, Denmark

Electrically-doped graphene supports highly-confined and actively-tunable plasmons that exhibit lower losses than their conventional noble metal counterparts, positioning the atomically-thin carbon layer as an ideal active ingredient in nanophotonic devices. These appealing properties are maintained in nanostructured graphene, which is emerging as a promising candidate for the excitation and guiding of propagating plasmons in future optoelectronic circuitry. Here we employ realistic quantum-mechanical simulations to describe the nonlocal optical response associated with highly-confined propagating plasmons in graphene nanoribbons, accounting for quantum finite-size and edge-termination effects in their electronic band structure. In addition to strong nonlocal effects manifesting in the linear dynamics of plasmons moving in the direction of transverse symmetry, we observe a stronger dependence on quantum finite-size effects in the nonlinear optical response, which involves additional transitions among the quantized electronic Bloch states. We further explore the breaking of inversion symmetry that occurs for optical excitation with large in-plane optical momenta along the transverse direction of the ribbon and reveal that even-ordered nonlinear optical processes such as a second-harmonic generation can occur with remarkably-high efficiency when enhanced by plasmonic resonances. These findings suggest possibilities to exploit the active tunability of graphene to engineer interactions among individual quantized propagating plasmons supported by 1-D

nanoribbons.

Structural Analyses of Single Walled Carbon Nanotubes Obtained by Highdensity Plasma Chemical Vapor Deposition Ronaldo D. Mansano and Ana Paula M. Mansano; University of São Paolo, Brazil

Carbon nanotubes have been an important subject of many recent studies owing to their possible potential applications in nano-scale technologies. Carbon nanotubes can be described as fiber like structures consisting of concentric graphite sheets nested along their long axis and extending to several micrometers. Single-walled carbon nanotubes (SWNTs) can be either metallic or semiconductors depending on the diameter and chirality . All the synthetic methods can be roughly categorized into three groups: the carbon arc-discharge method, laser vaporization of a graphite electrode and chemical methods . In this work, carbon nanotubes were obtained by chemical vapor deposition using high-density plasma processes. Structural studies of carbon nanotubes have relied heavily on Raman spectroscopy. Raman spectroscopy is an analytical technique largely used for characterization of different carbon based materials, either graphite-like or diamond-like. The great versatility of carbon materials rises from the strong dependence of their physical properties on the ratio of sp^2 (graphite-like) to sp^3 (diamond-like bonds). Raman spectroscopy of carbon nanotubes has attracted a lot of attention in recent years, both theoretically and experimentally. Theoretically, it is possible to predict morphological characteristics such as the diameter of the tubes or their conductance properties, especially of single wall carbon nanotubes. Experimentally, it is a powerful method for determining the degree of structural ordering or presence of contaminants [3]. In the Raman spectra of graphite and SWCNTs, there are many features that can be identified with specific phonon modes and with specific Raman scattering processes that contribute to each feature. The Raman spectra of SWCNTs can be provide us much information about the exceptional 1D properties of carbon materials, such as their phonon structure and their electronic structure, as well as information about sample imperfections (defects). Raman spectra provide much general information about the structure and properties of SWNTs. The Radial Breathing Mode (RBM) is a unique phonon mode, appearing only in carbon nanotubes and its observation in the Raman spectrum provides direct evidence that a sample contains SWNTs. The RBM is a bond-stretching out-of-plane phonon mode for which all the carbon atoms move coherently in the radial direction, and whose frequency w_{RBM} is about 100-500 cm^{-1} .
The results obtained with the Raman spectroscopy have been compared with the results obtained by Fourier Transformed Infrared (FTIR) spectroscopy, and by Scanning Electronic Microscopy (SEM) . The results obtained by these technical analyzes confirm the deposition of single-walled carbon nantotubes with metallic features by high-density plasma chemical vapor deposition.
The results obtained in this work, show the possibility to obtain higher aligned single-walled carbon nanotubes deposited at room temperature by HDPCVD. In this way, it was necessary the increase of the surface energy, that promotes the nano-structuration of the carbon materials, using diamond powder as a seed. It was observed the presence of carbon nanotubes and other kinds of nano-structures of carbon. The results obtained by SEM, Raman spectroscopy and Fourier Transformed Infrared spectroscopy FTIR, comproved the carbon nanotubes bundles and “islands” of amorphous carbon materials and, due the different of surface energy promoted by the precursor.

Late News: A Green Graphene-Based Ink for Artworks—Toward a Green Chemistry in Synthesis of Graphene Sepidar Sayyar, Jo Law, Agnieszka Golda, Helen McGregor, Aaron Burton and Gordon Wallace; University of Wollongong, Australia

Climate change is a major threat to the future of our planet and its inhabitants, and there is no doubt that human activities have been the dominant contributor. Scientists can play an important role in mitigating these contributing factors by utilising green approaches in manufacturing and developing eco-friendly materials in different fields. This work presents how our interdisciplinary collaborative research team, consisting of contemporary artists, a materials scientist, and a climate scientist, promote environmental sustainability through the development of ‘green‘ materials and techniques. The aim of the project is to develop a graphene-based ink through a green chemistry/engineering approach and use the ink to create conductive screen-printed e-texitle artworks that communicate climate science. Graphene is a unique two-dimensional carbon structure with excellent electrical, thermal and mechanical properties that make it ideal candidate for a variety of applications1,2. However, converting graphene to a processable material involves hazardous chemical reactions using toxic materials3. We developed a graphene-based ink without using any hazardous or toxic chemicals through a facile mechanical exfoliation method. The viscosity of the ink is easily tunable owing to its thermos-sensitive nature, which makes it a suitable material for screen-printing. The ink is used to screen-print electrically conductive patterns for the e-textile art works. The results of the phase 1 of the project were exhibited at the Museum of Applied Arts and Science in Sydney and attracted over 26,000 visitors. Preliminary experiments demonstrated that this material is a suitable candidate for developing sustainable sewable smart

electronics.

F.NM03.09.94
Hydrophobic Properties of Nano-Structured Carbon Films Obtained with Alumina Ceramic Powder Ronaldo D. Mansano, Ana Paula M. Mansano and Nelson Ordonez; University of São Paulo, Brazil

In this work, we have obtained nano-structured carbon films using ceramic powder (alumina) as seed and pure methane plasmas. The nano-structured carbon films were obtained using a high density plasma chemical vapour deposition system. The present study demonstrates the creation of hydrophobic surface using the nano-scale roughness inherent in high-aligned carbon nanotubes forest, when we used alumina as precursor material. The hydrophobic properties of the nano-structured carbon films were analyzed by Atomic Force Microscope (AFM), Scanning Electron Microscope (SEM) and Contact Angle Measurements (drop shape method), and the structural properties of the nano-films were analyzed by Far-FTIR.
The high-density plasma chemical vapour deposition (HDPCVD) system uses a new conception on plasma generation: a planar coil coupled in a RF system and an electrostatic shield for plasma densification. In this mode, are obtained high-density plasmas and for the ion acceleration we have used another RF system on planar configuration. The substrates used to deposit the films were 75 mm diameter silicon wafers, 380 μm thick and orientation (100). They were submitted to a Piranha clean, followed by a diluted HF dip, before the modification of the surface. The alumina ceramic powder presence promotes the increase of the surface energy of the silicon wafers. In this case, nano-structures are formed. Before the films deposition, alumina ceramic powder was deposited on the silicon wafers by spinner (1000 rpm, 30 sec.). The alumina powder dispersion was made in acid solution. We have used different final deposition times (30 min, 1h, 2h, 3h, 4h and 5h). After preparation of the sample, the DLC films were deposited. The parameters of the DLC films depositions were: 15 mTorr, 250 W (coil power, RF, 13.56 MHz, remote plasma), 40 sccm (methane).
The hydrophobic properties of the nano-structured carbon films were analyzed by Atomic Force Microscope (AFM), Scanning Electron Microscope (SEM) and Contact Angle Measurements (drop shape method), and the structural properties of the nano-films were analyzed by Far-FTIR. High-density plasma is quite for the growth of good quality nano-structured carbon films. But the properties of these films are largely dependent on the deposition conditions. The roughness of the nano-structured carbon films is important, in this situation, because it is affected by surface topography and the hydrophobic properties of these nano-materials.
The surface morphologies of the nano-structured carbon films obtained with alumina powder varied with the final time of deposition process. When the final time is increased, the atoms fill the holes and are accumulated around the islands (formed by the filled holes) and the roughness decreases. This effect promotes the reduction of the surface energy and the hydrophobicity of these films increases too. For longer deposition time, the atoms cover every nano-islands and the spaces between one island and another, forming a continuous film (for deposition time of 4 hours, the roughness was 40 nm). In this way, we noticed that the contact angle measurements showed that nano-structured carbon films obtained using alumina as precursor materials obtained for longer deposition time, showed more super hydrophobicity effect

F.NM03.09.101
Single-Walled Carbon Nanotube Growth from Ir Catalysts by Alcohol Gas Source Method Takahiro Maruyama, Takuya Okada, Takahiro Saida and Shigeya Naritsuka; Meijo University, Japan

Single-walled carbon nanotubes (SWCNTs) have been anticipated for applications in a lot of future nanodevices. However, there still remain several problems for realizing the SWCNT devices, and one of the most significant issues is high-yield growth of semiconducting SWCNTs. So far, to grow SWCNTs with high-yield, Al_2O_3 buffer layers are widely used, because they prevent migration of catalysts on the substrate surface at growth temperature and aggregation of catalyst particles are suppressed [1]. In this study, we attempted to grow SWCNTs using Ir catalysts without Al_2O_3 buffer layers, which have never been used as catalysts in SWCNT growth.
After deposition of Ir catalysts on SiO_2/Si substrates, SWCNT growth was carried out using alcohol gas source method in a high vacuum [2]. Growth Temperature and growth time were set at 800°C and 1 h, respectively. The ethanol pressure was varied between 1×10^{-3} and 1×10^{-1} Pa. The grown SWCNTs were characterized by FE-SEM, TEM and Raman spectroscopy. SEM and Raman results showed that, as the ethanol pressure increased, the SWCNT yield became higher and the SWCNT diameter became narrower. When the ethanol pressure was 1×10^{-1} Pa, high-density vertically aligned SWCNTs were grown, whose lengths were about 2 μm. Raman measurement showed that SWCNT diameter were distributed between 0.8 and 1.1 nm. Our results indicated that Ir catalysts are effective to obtain high-density vertically aligned and small diameter SWCNTs using no Al_2O_3 buffer layers.

Late News: Electrochemical Cathodic Exfoliation of Graphite into Graphene in Aqueous Solutions of Alkali Metal Salts Md Habibullah Dalal, Chong-Yong Lee and Gordon Wallace; University Wollongong, Australia

Electrochemical exfoliation has emerged as a green, effective and scalable route to mass production of graphene.[1] The use of reductive cathodic exfoliation of graphite, offers a direct production of high quality and low defect graphene.[2] However, cathodic exfoliation protocols reported to date use organic solvents in which often requires extended intercalation time, and post-treatment to further exfoliate the intercalated graphene layers.[3] In contrast, the employment of environmentally friendly aqueous-based electrolytes, coupling with a shorter exfoliation period would be attractive features of any new protocol. Here, we demonstrate for the first time, efficient cathodic electrochemical exfoliation of graphite to graphene in aqueous electrolytes using common and inexpensive alkali-metal salts such as KCl. The key to exfoliate graphite successfully in aqueous electrolyte is applying a sufficiently high voltage, and a high salt concentration which facilitates hydrated cationic intercalation, and promotes hydrogen evolution to exfoliate the graphene. The cathodic exfoliated graphene produced using KCl electrolyte exhibits a low defect density (I_D/I_G of 0.06, a C/O ratio of 57.8), high graphite exfoliation yield (>80%) in short time (< 10 mins for 1 cm^2 electrodes) and the highly conductive 6 to 7 layers graphene sheets served as an excellent support materials for electrocatalytic reactions. This environment-benign aqueous-based cathodic electrochemical graphite exfoliation approach opens a new opportunity in large-scale and low cost production of high quality graphene.

Late News: Multibit Optoelectronic Memory Using Graphene/Diamond (carbon sp^2-sp^3) Heterojunctions Kenji Ueda, Y. Mizuno and Y. Ito; Nagoya University, Japan

Recently, interfaces between graphene and diamond (carbon sp^2-sp^3 interfaces) has attracted much attention because the carbon sp^2-sp^3 interfaces become sources of various interesting physical phenomena and novel functions. Although there are many interesting theoretical predictions on the interfaces, experimental results regarding the electronic properties of such interfaces have rarely been reported. More recently, we found that vertically aligned graphene (carbon nanowalls: CNW)/diamond heterojunctions, that is, C sp^2-sp^3 interfaces became photo-controllable memristors [1], which are optically controllable memory-resistors with nonvolatile memory and switching functions. One of the most important application of the photo-controllable memristors is thought to be optoelectronic memory, which possess both photo-sensing and data storage function.
In this study, we show the CNW/diamond heterojunctions can be used as multibit optoelectronic memories, where light information stores as multilevel resistance in nonvolatile manner [2].
CNW were formed on B-doped diamond semiconductors in-situ by using microwave plasma CVD apparatus [1, 3]. Junctions using the CNW/diamond heterostructures were fabricated (area: 40-160 μm φ) and their current-voltage (*I-V*) characteristics were measured at room temperature in air, with or without photo-irradiation by using visible LED.
In the Raman spectrum of the CNW on diamond, four major peaks, which are characteristic of vertically aligned graphene, were observed: G, 2D, D' and D peaks, in addition to the diamond related peak (Dia.) at 1332 cm^{-1}. A SEM image of the CNW/diamond surface showed numerous wall-like structures, which also suggested formation of CNW on diamond. The transmission electron microscope (TEM) image of the interface of the CNW/diamond bilayers indicates that CNW with good crystallinity and clear interfaces were formed on the diamond semiconductors. These Raman, SEM and TEM results suggest CNW/diamond heterostructures with sharp interfaces were successfully formed. The CNW/diamond junctions exhibited hysteretic I-V behaviors. The resistance of the junctions was changed to low or high resistance states by the light irradiation with bias voltage application and the resistance states was maintained in nonvolatile manner. The mechanism for the photoconductive change is considered to be originated from oxidation-reduction of the CNW and/or CNW-diamond interfaces through the movement of oxygen ions by bias with photo-irradiation. The CNW/diamond junctions also show apparent response to optical pulses. The output current, that is, conductivity was increased (or decreased) step-by-step in proportion to the number of optical pulses under positive (or negative) bias. The numer of levels and heights of the current steps can be controlled by changing optical pulse intensity, pulse width, bias voltage, etc. To determine the relationship between output current and applied pulse numbers precisely, multiple (~10) optical pulses (38 μW/cm^2, 30 ms, 1 Hz) were

applied to the junctions. The output current, that is, conductance increased linearly from 2 nA to 142 nA in response to the total optical pulse numbers from 1 to 10. The linear relationship between the number of optical pulses (n) and the output current [$I(n)$ (nA)] can be expressed as "$I(n)= 14.26*n + 2.27$". Application of one optical pulse induces current increase of ~14 nA. This means that the junctions are also used as optical computing-memory devices with arithmetic functions such as counting, addition, and subtraction. These results indicate the CNW/diamond heterojunctions are capable of multibit optoelectronic devices, where light information is stored as multilevel resistance in nonvolatile manner and the stored information is processed immediately.

Late News: Nanoporous Free-Standing SWCNT Films Radovan Kukobat, Dragana Stevic and Katsumi Kaneko; Shinshu University, Japan

Nanoporous free-standing SWCNT films are essential for understanding porosity of these films which should be promising for catalyst supports and supercapacitors. The SWCNTs form networks of randomly distributed SWCNTs, giving materials such as transparent thin films and free-standing films. The transparent thin films of SWCNTs form two dimensional porous networks of randomly oriented SWCNTs whose pore sizes vary from micropores to mesopores, according to the SEM and TEM observation. On the other hand, porosity of the free-standing SWCNT films is not straightforward because the micropores and mesopores are hidden in the three-dimensional structures of these films. We use nitrogen adsorption at 77 K to characterize porosity of the free-standing SWCNT films. The nitrogen adsorption isotherm shows a prominent hysteresis loop over the wide relative pressure range of ~10^{-3} to ~1, which we assigned to the presence of ultramicropores of < 0.7 nm. These ultramicropores were open during ultrasonication treatment of the SWCNTs prior to the free-standing film fabrication. The ultramicropores are evidenced as defects on SWCNTs using Raman spectroscopy. The D- and G-band ratio increases from pristine SWCNTs of 0.04 to SWCNTs of free-standing films of 0.11. The surface area increases from pristine SWCNTs of 320 and 280 m^2/g (BET and αs) to free-standing SWCNT film of 605 and 590 m^2/g (BET and αs). Micropore volume increases from pristine SWCNTs to free-standing SWCNT film from 0.06 to 0.18 cm^3/g, respectively. High surface area of the free-standing SWCNT films is assigned to the ultramicropores. Also, the free-standing SWCNT film is composed of mesopores created by entangling of SWCNTs in the network as observed with SEM and TEM. Understanding porosity of the free-standing SWCNT films is important for developing the SWCNT electrodes of desired porosity and surface area for the electrochemical applications.

Organophilicity of Graphene Oxide for Enhanced Wettability of ZnO Nanowires Pavan Emani[1], Hisham A. Maddah[1], Arjun Rangoonwala[1], Songwei Che[1], Dieter Gruen[2], Vikas Berry[1] and Sanjay K. Behura[1]; [1]University of Illinois at Chicago, United States; [2]Dimerond Technologies, United States

Interfacing two-dimensional graphene oxide (2D GO) platelets with one-dimensional zinc oxide nanowires (1D ZnO) would create mixed-dimensional heterostructures suitable for modern optoelectronic devices. However, there remains a lack in understanding of interfacial chemistry and wettability in GO-on-ZnO heterostructures. Here, we propose a hydroxyl-based dissociation-exchange mechanism to understand interfacial interactions responsible for GO adsorption onto ZnO hydrophobic substrates. The proposed mechanism would allow us to overcome the poor wettability of the super-hydrophobic ZnO surface (with contact angle 140.5°) to GO, from the dispersion of GO suspension with various organic media prior to drop-casting of GO on the ZnO. The addition of different classes of organics into the relatively high pH GO suspension with a volumetric ratio of 1:3 (organic-to-GO) is believed to introduce free radicals (OH and COOH), which consequently result in enhancing adhesion (chemisorption) between ZnO nanowires and GO platelets. The wettability study shows as high as 75% reduction in contact angle ($\theta = 35.5°$) when the GO suspension is mixed with alcohols (e.g. ethanol) prior to interfacing ZnO nanowires. The proposed method brings forth a scalable tool for developing graphene-coated-ZnO heterojunctions for photovoltaics, photocatalysis, biosensors, and UV detectors.

Late News: Preparation of Large Surface Area Nanocarbon from Cellulose Nanocrystals and Its Carbonization Mechanism Jung-Eun Lee, Hyejin Ju, Min Jeong Kim, Ga-Hyeun Lee and Han Gi Chae; Ulsan National Institute of Science and Technology, Korea (the Republic of)

In the recent time, the biomass-derived carbon materials have attracted attention for application to energy storage and battery devices based on the abundant resources, low cost, and sustainability of precursors. Among them, cellulose nanocrystal (CNC), which can be obtained from the removation of amorphous region of cellulose materials by acid hydrolysis, is regarded as promising carbon precursor. Its high crystallinity (54-88%) compared to other conventional cellulose causes high mechanical integrity, high thermal stability, and the formation of more developed carbon crystallites after carbonization. Although it is prerequisite to thoroughly define the carbonization mechanism of CNC for use in a variety of applications, however, there is still an insufficient research. In particular, only speculations have been reported about the interesting phenomenon that the CNC often shows a graphitic phase at a low carbonization temperature of 1000 °C, unlike carbonized cellulose. Therefore, in the current study, we dried the CNCs by spray-freeze-drying method and carbonized them in the range of 1000-2500 °C. They showed interconnected fibrillar morphology and large surface area of 265.2 m^2/g after carbonization at 2500 °C, which is favorable to use as a carbon nanofiller, purification, or catalyst support. In addition, the different behavior between amorphous and crystalline region of cellulose materials was thoroughly analyzed based on HRTEM, Raman, WAXD, and MD simulation results. The current study will not only open the new application of CNC-based nanocarbons but provide in-depth mechanism of carbonization of cellulosic materials.

Late News: Effects of Water and Different Solutes on Carbon-Nanotube Low-Voltage Field-Effect Transistors Raphael Pfattner[1,2], Amir M. Foudeh[1], Shiheng Lu[1,3], Nicola S. Kubzdela[1], Theodore Gao[1], Ting Lei[1,4] and Zhenan Bao[1]; [1]Stanford University, United States; [2]Materials Science Institute of Barcelona (ICMAB-CSIC), Spain; [3]Duke University, United States; [4]Peking University, China

Semiconducting single-walled carbon nanotubes (swCNTs) are a promising class of materials for emerging applications. In particular, they are demonstrated to possess excellent biosensing capabilities, and are poised to address existing challenges in sensor reliability, sensitivity, and selectivity.[1,2] Functionalized and pristine individual CNTs have shown high sensitivity and selectivity down to the single molecule level.[3,4] However, single CNT devices are challenging to make and characterize compared to CNT networks which add further complexity due to inter-CNT contacts. Such systems may not be as sensitive or selective compared to single CNT devices, but may be a cost-effective alternative for particular environments.
Here, we report on the characteristics of single-walled carbon nanotube (swCNT) networks exposed directly to aqueous solutions containing different solutes.[1] This was made possible by employing a solid-state dielectric poly(vinylidene fluoride-co-hexafluoropropylene) (ePVDF-HFP), which has been demonstrated to be compatible with swCNTs and also enables low-voltage field-effect transistor (FET) operation.[5,6]
These devices exhibit small device-to-device variation as well as high current output at low voltages (<0.5 V), making them compatible with most physiological liquids. Using this platform, the swCNT devices are directly exposed to aqueous solutions containing different solutes to characterize their effects on FET current–voltage (FET I–V) characteristics. Clear deviation from ideal characteristics is observed when swCNTs are directly contacted by water.
Such changes are attributed to strong interactions between water molecules and sp^2 -hybridized carbon structures. Selective response to Hg^{2+} is discussed along with reversible pH effect using two distinct device geometries. Additionally, the influence of aqueous ammonium/ammonia in direct contact with the swCNTs is investigated. Understanding the FET I–V characteristics of low-voltage swCNT FETs may provide insights for future development of stable, reliable, and selective biosensor systems.

F.NM03.09.113
Late News: Effect of Cellulose Nanocrystal(CNC) on Polyacrylonitrile(PAN) Polymer Chain Structure in the PAN/CNC Fibers Prepared Through an *In Situ* Polymerization Hyejin Ju, Jung-Eun Lee, Min Jeong Kim and Han Gi Chae; Ulsan National Institute of Science and Technology, Korea (the Republic of)

In-situ polymerization of polyacrylonitrile (PAN) polymer in the presence of cellulose nanocrystal (CNC) is conducted to produce CNC reinforced PAN nanocomposite fibers for high-performance carbon fiber. Cellulose is the most abundant organic material available on earth, therefore it can be an environmentally sustainable resource for producing carbon materials and carbon fiber. Also, CNC is useful for the reinforcing agent in nanocomposite materials due to its excellent properties such as high crystallinity and mechanical properties.
In the current study, there are two main effects 1) CNC into the nanocomposite fiber and 2) the impact of in-situ polymerization. We have conducted the thorough characterizations of CNC dispersion and radical polymerization of PAN polymer in the presence of about 1.5 wt% CNC. In-situ PAN/CNC nanocomposite fiber was produced by the dry-jet wet spinning method right after the polymerization was terminated.
From the mechanical and crystal orientation measurement, CNC is able to affect improving polymer chain orientation through interaction between PAN and hydroxyl groups of CNC. Furthermore, as the in-situ PAN/CNC nanocomposite solution is used directly without any removing PAN polymer with low molecular weight, it is supposed that they can act as plasticizers during the fiber spinning and affect the polymer chain structure transition during the heat-treatment process. Besides, using thermal analyses, the heat treatment conditions of precursor fiber have been set for manufacturing CNC reinforced high-performance carbon fiber. And the evolution of the structure from polymer chain to the graphite form during the stabilization and carbonization in the presence of CNC has been investigated.

F.NM03.09.124
Late News: Bifacial Float Transfer of Multilayer Graphene Joseph Andrade[1], Jan Folkson[1], Mohamed Boukhicha[2], Amanda Carr[1] and Matthew Eisaman[1]; [1]Stony Brook University, The State University of New York, United States; [2]Brookhaven National Laboratory, United States

We present a method for graphene transfer we refer to as “bifacial transfer” that allows transfer of multilayer chemical vapor deposition (CVD) graphene from both sides of a native metal substrate, such as an as-received nickel catalyst. In traditional transfer methods, the graphene on the “non-preferred” side, i.e. the bottom of the substrate, is removed with oxygen plasma before removal of the metal catalyst in etchant solution. Although this treatment prevents undesired aggregation of the graphene films, it fails to utilize both sides of CVD-grown graphene. Our bifacial transfer method reduces the cost of multilayer graphene by allowing the transfer of graphene from both sides of the substrate. After hot-press lamination to a polymer film and a temporary metal etching step, the graphitic films separate cleanly at the air-liquid interface due to an oxide interlayer. We characterize this separation layer and compare the quality of graphene transferred from both sides onto target glass and polymer substrates. The results of optical microscopy, confocal Raman spectroscopy, atomic force microscopy (AFM), and electronic transport measurements suggest that the quality of the multilayer graphene on the “non-preferred” side does not differ significantly from that of the “preferred” side. This method will allow more efficient and cost-effective use of graphene by doubling the usable graphene per area of growth substrate, and by eliminating the need for intermediate sacrificial transfer substrates such as poly(methyl methacrylate), PMMA.

F.NM03.09.114
Late News: A Thin, Flexible, Highly Sensitive Ultrasonic Sensor Based on Polydopamine@Hybrid Carbon Nanofillers/Polyvinylidene Fluoride Nanocomposites Zengsheng Weng and Fangxin Zou; Hong Kong Polytechnic University, Hong Kong

Sensors that are thin and flexible and are yet highly sensitive to small deformations have become considerably crucial to a number of high-value-added applications such as wearable electronics, human machine interface, and condition monitoring of high-stake engineering structures. In recent years, these sensors have been undergoing rapid advancement owing to the development of low-dimensional nanomaterials. In particular, by optimizing the synthesis process, it is even possible to fabricate nanocomposite strain sensors that can be used to probe high-frequency, microscopic vibrations generated by ultrasonic waves. In fact, ultrasonic wave is one of the most widely used diagnostic means for *in situ* assessments of structural integrity.
The tunnelling effect and the piezoresistive effect are the main physics principles that allow nanocomposite strain sensors to acquire ultrasonic waves. When a sensor is impinged by ultrasonic waves, the conductive nanofillers inside the sensor will undergo high-frequency micro-vibrations. Such vibrations will cause the inherent electrical resistances of the nanofillers to fluctuate and the distances between adjacent nanofillers to vary, eventually resulting in changes in the overall electrical resistance of the sensor. However, the sensitivity of the existing nanocomposite strain sensors to ultrasonic waves is still far from satisfactory.
There are two main reasons behind the limited sensitivity. One is that the agglomeration of nanofillers or the poor capacitive compatibility between nanofillers and polymer matrices results in poor dispersion of nanofillers inside nanocomposite structures. The other is the lack of effective tunnelling nodes who is not conducive to the tunneling effect.

In this work, we fabricated a highly sensitive nanocomposite sensor for acquiring high-frequency micro-vibrations generated by ultrasonic waves, from polydopamine(PDA)-coated hybrid carbon nanofillers. First, multi-walled carbon nanotubes (MWCNTs) were coated by 10s nm thick viscous PDA to improve their compatibility with polyvinylidene fluoride (PVDF) substrates. The PDA nanolayers on MWCNTs do not only act as a dispersed phase that reduces the entanglement of MWCNTs, but also serves as the buffer layers between MWCNTs and PVDF matrices, helping to improve the responsiveness of the sensors to ultrasonic waves. Compared to uncoated MWCNTs, the use of 15 wt.% PDA-coated MWCNTs led to a 40% increase in sensitivity. Then, one-dimensional PDA@MWCNTs were mixed with two-dimensional single-layer graphene to enhance the geometric contact between nanofillers. Compared with the use of nanofillers of a single dimensionality, the mixing of nanofillers of different dimensionalities can effectively increase the number of tunneling nodes within a unit volume in a nanostructure. As the mass fraction of graphene within the hybrid nanofillers expanded from 33% to 66%, the sensitivity of the proposed sensor improved by approximately 120%, surpassing that of pure graphene sensors, which had been reported to possess the highest sensitivity to ultrasonic waves. The superior sensitivity of the proposed sensor, which actually utilizes a lower graphene content, was shown to be derived from the synergy between the two types of nanofillers which are of different dimensionalities.
Overall, we put forward new strategy for optimizing the sensitivity of nanocomposite strain sensors to high-frequency micro-vibrations. The feasibility of the idea has been validated by a series of experiments that encompass both material characterizations and measurements of ultrasonic signals.

Late News: Enhanced Heavy Metals Removal Using a New Buckypaper Membrane Containing MWCNTs and Two Biopolymers—Chitosan and Carrageenan Sara S. Alnasser, Afnan Alharbi, Ahmed Alshahrani and Bandar alOtaibi; KACST, Saudi Arabia

Due to the current global water crisis, wastewater treatment requires considerable attention and development. Dissolved heavy metals in water trigger serious alerts and can have lethal effects on various components of the environment including water resources, soil, plants, animals, and can also be threatening the health of human beings. In this study, we addressed the issue by introducing novel Buckypaper membranes that were fabricated using a combination of biopolymers (i.e., chitosan and carrageenan) and multi-walled carbon nanotubes (MWCNTs). Three dispersions of MWCNTs with chitosan, carrageenan, and chitosan-carrageenan with 0.1% v/w were prepared using vacuum filtration. The removal of six heavy metals (i.e., cobalt, nickel, copper, cadmium, barium, and lead) was investigated in this study. The water permeability and the removal of heavy metals were evaluated using a dead-end (DE) filtration system. Heavy metals removal was studied at pH 7 and under a range of varying applied pressures (1 to 6 bar). At an applied pressure of 1 bar, the removal of lead and copper by the MWCNTs/carrageenan membrane reached 99% and 88%, respectively. However, MWCNTs/carrageenan membrane was found to be fragile. Nevertheless, adding chitosan to carrageenan had significantly improved the mechanical strength of the membrane while sustain the excellent removal properties of the heavy metals. That is, MWCNT/chitosan-carrageenan membrane significantly exceeds MWCNTs/carrageenan membrane in tensile strength, tensile strain and young's modules by 400%, 17%, and 6%, respectively. On the other hand, the MWCNTs/chitosan membrane showed a high water permeate flux that reached up to 200 $L/h.m^2$. Also, the electrical conductivity of all membranes varied from 37 S/CM to 57 S/CM. Additional characterization techniques on the three membranes were conducted in this study as well.

F.NM03.09.127
Late News: Oil Fly Ash-Derived Carbon Nanostructures for Flexible Supercapacitors Nuha A. Alhebshi[1], Haneen S. Alshaikheid[1], Numan Salah[1] and Husam Alshareef[2]; [1]King Abdulaziz University, Saudi Arabia; [2]King Abdullah University of Science and Technology (KAUST), Saudi Arabia

A variety of innovative designs of wearable electronics require to be powered by energy storage devices such as supercapacitors based on flexible electrodes. One of the current challenges that would delay the implementations of supercapacitors is the high cost of the electrode materials. In this research, Abundant oil fly ash is obtained from a power plant in Jeddah, Saudi Arabia, as a source for the synthesis of carbon nanostructures by sonication (JSON) and carbon nanotubes (CNTs) by chemical vapor deposition [1,2]. These CNTs have diameters around 30-40 nm, few micrometers lengths, and clear zigzagged structures, which are mostly different than the commercial CNTs, as characterized by high resolution transmission electron microscope. To utilize the promising properties of CNTs in a practical application, flexible supercapacitor electrodes of CNTs have been fabricated on carbon cloth as a current collector in addition to H_2SO_4 electrolyte, then tested and compared with JSON electrode in terms of cyclic voltammetry, galvanostatic charging-discharging and electrochemical impedance spectroscopy. Interestingly, CNTs electrode exhibits maximum areal and gravimetric capacitances of 77 mF/cm^2 and 55 F/g, respectively, which are one order of magnitude higher than those of JSON electrode. This improvement can be attributed to the smaller size and hence the larger surface area of CNTs than JSON.

Moreover, CNTs electrode shows exceedingly small equivalent series resistance and charge transfer resistance ascribing to the good contact of the electrode active materials within the carbon cloth substrate and the electrolyte. In addition, the vertical impedance line in the low frequency range of Nyquist plots indicates an excellent electrolyte ion diffusion into the electrode due to the porosity of CNTs. The successful fabrication of such flexible supercapacitors based on affordable and scalable CNTs would facilitate their cost-effective manufacturing.

ACKNOWLEDGMENT

This joint project was co-funded by King Abdulaziz University (KAU), Jeddah, and King Abdullah University of Science and Technology (KAUST), Thuwal, under grant number "JP-19-002". The authors, therefore, acknowledge with thanks KAU & KAUST for their technical and financial support.

Late News: Multifunctional MoS2-Supported Nanocomposites for Water Decontamination Kfir Shapira and Ines Zucker; Tel-Aviv University, Israel

Pollution of drinking water sources by a variety of inorganic compounds has created a need to develop more efficacious removal technologies to ensure contaminant-free and clean water. Conventional methods for water decontamination involve physicochemical separation and chemical oxidation. Yet, physicochemical separation lacks pollutant selectivity and produces toxic waste streams,[1] while chemical oxidation requires intensive energy and chemical inputs and may form transformation byproducts.[2]

Nanotechnology-based approaches are increasingly explored as an alternative for decontamination methods. Many new technologies leverage the reactive and tunable properties of nanomaterials for increased cost-efficiency, selectivity toward priority pollutants and energy/chemical sustainability.[3] Through manipulation of material size, morphology, and chemical structure, nanomaterials can have exceptional adsorptive and catalytic properties for water decontamination.

Molybdenum disulfide (MoS_2) nanosheets stand out as a promising advanced-material for water decontamination. MoS_2 act as an efficient and selective adsorbent for the removal of heavy metal ions (e.g., Hg^{2+} and Ag^{+}) through strong Lewis acid and base soft−soft interactions with sulfur atoms in MoS_2. Affixing MoS_2 nanosheets onto a platform is essential minimize risk of nanomaterial release into the environment. In the context of nano-assisted water treatment technologies, affixing nanomaterials onto *active* platforms such as granular activated carbon media may enable multifunctional decontamination. Activated carbon is the predominant adsorbent used widely in water treatment today, due to its high affinity for organic pollutant adsorption, but lack affinity to inorganics. MoS_2 affixed onto activated carbon, enhances overall decontamination performance by enabling simultaneous adsorption of organic and inorganic pollutants.

In this research, we examined the tunable water decontamination capabilities of MoS_2 nanosheets grown on activated carbon (MoS_2@AC) in a hydrothermal method for the adsorption of organic (methylene blue) and inorganic (mercury) contamination from water. In a batch experiments, we demonstrated the high mercuric adsorption potential of MoS_2@AC (~2000 mg Hg/g MoS_2) in the absence and presence methylene blue. Furthermore, methylene blue was removed in similar rates by MoS_2@AC and pristine AC. These results suggest that while MoS_2 is active and enable the removal of mercury, its presence does not interrupt the activated carbon activity. Moreover, we will investigate the practical application of this nanocomposite by evaluating the effect of background ions on the mercuric adsorption capacity. We also assess the nanomaterial leaching during operation in various conditions to demonstrate the reuse capabilities and to assure safe and durable use. Overall, results from this study provide a proof-of-concept for water treatment enhancement by 2D nanomaterials.

Late News: Ethylene Glycol Removal Characteristics of 2D Nanoporous h-BN Sheets —Computational Predictions Nirmalay Barua[1], Ingrid Padilla Espinosa[2,1] and Ram Mohan[1]; [1]North Carolina A&T State University, United

States; [2]University of California, Merced, United States

Hexagonal boron nitride (h-BN) is a new material with potential for applications in electronic devices, tribology, and separation membranes. Limited theoretical and experimental researches have been conducted to explore their efficiency as a desalination membrane. With the recent advancement of their controlled synthesis, researchers have become more interested in exploiting their interaction with organic materials. The purpose of this work is to explore the efficiency and potential of porous h-BN as a separation membrane for ethylene glycol (EG) removal from water. Very few experiments have been previously conducted to assess the capability of porous h-BN for EG or other organic pollutants removal. However, no prior theoretical or computational work that studies the molecular interactions between EG and h-BN has been reported. In this work, a methodological approach to simulate the atomic interactions of h-BN and EG in different pore configurations is proposed and investigated using classical molecular dynamics. Our results exhibit that nanometer-scale pores in single layer h-BN can effectively reject approximately 90% of EG from EG contaminated water. We also report the removal performance of the freestanding porous h-BN sheet as a function of pore diameter and applied pressure.

Late News: Ionicity-Dependent Separation Property of Graphene Oxide Membrane Mutsuki Oikawa[1], Haruka Takeuchi[2], Zheng-Ming Wang[3] and Setsuko Koura[1]; [1]Chiba Institute of Technology, Japan; [2]Kyoto University, Japan; [3]AIST, Japan

Graphene oxide membrane(GO-M) has recently attracted a great interest because of its potential applications for desalination and for removal of organic matter. The carbon-based GO-M is excellent in chemical resistance, anti-fouling effect, low cost, and so forth as compared to polymer or ceramics membranes. It is known that GO has polar oxygen functional groups and is negatively charged in water, which makes it possible to remove ionic species in water. It has been reported that GO-M shows selective separability toward some neutral solvent molecules. However, its ionicity-based separation property has not yet been sufficiently understood. In this research, we focused on surface charging property of GO-M and examined its separation behaviors toward inorganic ions and organic dyes of different charging properties. It was found that the separation or permeation of inorganic cations by GO-M is dependent on the ionic type and charge number. The rejection ratio can be accounted for by the strength of their electrostatic interaction with the GO surface. GO-M shows good rejection toward anionic dyes but great adsorption toward neutral and cationic dyes, resulting in the blockade of membrane path.

Late News: Atomistic Study of the Influence of Oxide Shell Layers on the Material Properties of Aluminum Nanowires Hoang Thien Luu[1], Yudi Rosandi[2], Herbert M. Urbassek[3] and Nina Gunkelmann[1]; [1]Clausthal University of Technology, Germany; [2]Universitas Padjadjaran, Indonesia; [3]University of Kaiserslautern, Germany

For materials with high oxygen affinity, oxide layers will significantly change the material properties. At aluminum surfaces, an oxide layer may form in seconds, even under vacuum conditions. Recent studies show that thin amorphous oxide shell layers on aluminum surfaces significantly change the responses of the material. However, the relations between the thickness of the oxidized layer, the temperature and the mechanical response of nanowires have not been investigated intensively. In this study, we use a ReaxFF potential to analyze the influences of oxide shell layers on the material responses of the nanowires under uniaxial loading at different strain rates. We conduct simulations within a wide range of strain rates and temperatures varying between 10K and 500K. The Al-O interface leads to an increased defect nucleation rate at the oxide interface preventing localized deformation.

Transparent, Transferrable and Flexible Pseudocapacitors from Ternary PEDOT/V_2O_5/ Graphene with Record Durability in Organic Electrolytes Sanju Gupta[1,2]; [1]CCNY-CUNY, United States; [2]WKU, United States

Transparent conductive electrodes (TCEs) are of enormous significance to the continued growth of optoelectronic devices and the emergence of flexible and wearable electronics in the foreseeable future. Versatile and tunable TCEs, featuring not only high optical transmittance but also intriguing features of electrochemical energy-storage capability, flexibility, and transferability, remain a significant challenge. Here we strategically develop a graphene-conjugated V2O5/poly(3,4-ethylene dioxythiophene (from hereon, V2O5/PEDOT) hybrid, serving as an easily transferable, transparent, capacitive active electrode films. The constructed electrodes exhibit a high areal capacitance of 50-60 mF cm−2 at optical transparency of > 60 percent with a record durability over thousands of cycles. As demonstrated by experimental results, both the kinetic blocking of the PEDOT layer and the anchoring capability of graphene upon soluble vanadium ions from V2O5 nanoribbons/nanotubes contribute synergistically to the unusual electrochemical stability and electroactivity shown using scanning electrochemical microscopy. Transparent symmetric and asymmetric solid-state supercapacitors made of the as-fabricated pseudocapacitive TCEs deliver a broad voltage window of 1.4 V or higher under two different electrolytes (aqueous LiCl and organic gel made from LiCl and polyvinyl alcohol) demonstrate highest power and energy density that outperforms all the previously reported transparent devices (< 0.1 microWatt h cm^-2).

F.NM03.09.07
Thermal Diode Based on Polyethylene Nanofiber Xiao Luo and Sheng Shen; Carnegie Mellon University, United States

Thermal diode is a two-terminal device which rectifies heat flow. For its non-linear nature, interest in thermal diode has been growing for more than 15 years. Thermal diodes have been numerically and experimentally realized with bulk as well as nanomaterial. Among them, phase transition material can realize high rectification with relatively narrower temperature bias. Current optimization studies of phase transition junction thermal diode consider phase transition as a step function of temperature, while in some cases phase transition could happen in a temperature range in the same magnitude with temperature bias. In this study we simulated and optimized the thermal diode based on our recently experimentally realized phase transition of polyethylene nanofiber with a finite temperature range of phase transition.

There is a phase transition within polyethylene nanofiber with high degree of crystallinity: crystalline structure shifts from orthorhombic to hexagonal cell with a sharp decrease of thermal conductivity within about 5K temperature range at around 430 ~ 450K[1]. E-beam irradiation can alter the phase transition behavior. Phase transition retains with a lower critical temperature if irradiation is weak, while phase transition disappears if irradiation is strong[2]. Thus, heavily-irradiated-pristine (HI-P) and lightly-irradiated-pristine (LI-P) junction diode can be fabricated by partially irradiating the PE nanofiber with different exposure time. HI-P junction can rectify heat flow in one certain direction, while LI-P junction can rectify heat flow in both directions under different working temperature.

Calculation based on finite temperature range of phase transition shows a smooth heat flow curve with a better match with experimental data. Calculation based on step-function phase transition gives a limit of rectification value but tends to overestimate the rectification performance under small temperature bias. Optimization formula derived from step-function model can still be used for estimating optimized length fraction of e-beam irradiation despite the range of temperature bias, as maximum rectification value always occurs when interface temperature difference is zero. Specifically, a proper value of thermal conductance value is required for LI-P junction such that rectification performances in both directions can be optimized with one single length fraction of irradiation.

A GFET Nitrile Sensor Using a Graphene-Binding Fusion Protein Abubaker A. Mohamed[1,1], Mirano Tsukiiwa[2], Hironaga Noguchi[2], Takumi Komikawa[2], Chen Chen[2], Qadri E. Mubarak[1], Rachel Heath[1,1], Masayoshi Tanaka[2], Mina Okuchi[2], Samuel de Visser[1,1], Yuhei Hayamizu[2] and Christopher F. Blanford[1,1]; [1]University of Manchester, United Kingdom; [2]Tokyo Institute of Technology, Japan

A bottleneck in the development of enzyme-based graphene field effect transistors is the protein immobilization method used. Non-specific adsorption of protein on graphene is undesirable as it hinder access to the enzyme's active site whilst also changing the natural conformation of proteins by having surface residues bind to the graphene surface. Proteins require specific 3D conformation to be functional and so label-free immobilisation methods is preferred as it increases sensing capabilities of biosensors by maintaining proteins catalytic activity upon immobilization.

Here, a bi-functional self-assembling and graphene-binding peptide was fused to a QueF nitrile reductase protein to create a fusion protein for nitrile detection. The peptide was derived from silk protein fibroin and is capable of forming stable antiparallel β-sheet structure on graphene (1) and so is used to guide protein immobilization. Incorporating this tag into various proteins for enhancing biosensing applications offers a new and effective platform for enzyme-based graphene field effect transistors.

QueF nitrile reductase was chosen because it is the only known enzyme capable of NADPH-mediate nitrile to amine reduction (2). Surface topology of the fusion protein functionalized graphene was observed by atomic force microscopy and showed that both oligopeptide and the fusion protein incorporating it formed a monolayer with six-fold symmetry.

The QueF fusion protein sensing capabilities was first assessed on its natural nitrile substrate which upon immobilisation on graphene field effect transistor showed a 1.4-fold increase in binding affinity compared the wild-type protein which did not incorporate the peptide tag.
Fusion protein was also used to create an agricultural biosensor through the detection on benzyl cyanide. Benzyl cyanide is a chemical distress signal produced by plants and detection of this compound could therefore be used to provide means for crop monitoring and pesticide administration. The fusion protein showed a 3.3-fold increase in response to benzyl cyanide when compared to the wild-type protein. Work here provides a novel immobaliastion method for enzyme based graphene field effect transistor biosensing.

Fullerene C_{76}—An Plored Superior Electrode Material with Wide Operating Potential Window for High Performance Supercapacitors Nageh K. Allam, Basant A. Ali and Ahmed Biby; American University in Cairo, Egypt

Carbon materials have widely been used to enhance the performance of a plethora of supercapacitor electrode materials. In this regard, it is crucial to identify carbon materials that function over a wide pH range while enjoying a wide potential window. Herein, the DFT calculations were used to elucidate the electronic performance of C_{76} and the C_{76}/electrolyte interface. The electronic investigation revealed the nature of the conductivity and charge storage mechanism of C_{76} based on the bandgap and quantum capacitance calculations. Also, the electrochemical and electronic properties of fullerene C_{76} have been extensively investigated over a wide pH range; acidic H_2SO_4, basic KOH, and neutral Na_2SO_4. The results showed a promising performance in the three electrolytes. Moreover, C_{76} electrodes exhibited a potential window of 1.9 V in Na_2SO_4 electrolyte, resulting in capacitances of 171 F/g and 142 F/g at a scan rate of 1 mV/s in the positive and negative potential windows, respectively. The material showed a pseudocapacitance performance of 65% in Na_2SO_4 electrolyte in the positive potential window. We believe higher fullerenes provide a new class of materials for developing versatile supercapacitor devices for efficient energy storage

***In Situ* Formation of Graphene Stabilizes Zero-Valent Copper Nanoparticles and Significantly Enhances the Efficiency of Photocatalytic Water Splitting** Nageh K. Allam; American University in Cairo, Egypt

There is a growing need for new techniques to synthesize metallic copper nanoparticles due to their remarkable use in many advanced technologies. Herein, a novel method to synthesize stable and non-agglomerated zero-valent copper nanoparticles (ZVCNPs) via the in-situ formation of reduced graphene oxide (rGO) during the electrospinning process in the presence of polyvinylpyrrolidone (PVP) as a carbon source is presented. X-ray diffraction (XRD), Raman spectroscopy, electron paramagnetic resonance (EPR), transmission electron microscopy (TEM), and x-ray photoelectron spectroscopy (XPS) techniques were used to investigate the morphology, structure, and composition of the fabricated materials. The synthesized ZVCNPs were coupled with TiO2 nanofibers and rGO to form an efficient photoactive material to photocatalytically produce hydrogen via water splitting, resulting in 344% increase in the hydrogen yield compared to that of TiO2 nanofibers. The density functional theory (DFT) calculations showed that the ZVCNPs enhance the charge transfer and lower the energy needed for photocatalytic water splitting. This study suggests a novel method for metallic copper stabilization and illustrates

the effect of metallic copper as a catalyst for the in-situ formation of rGO.

Topology Influence of Hydroxyl and Epoxide Functional Groups on the Mechanical and Fracture Behavior of Graphene Domain Akarsh Verma[1] and Avinash Parashar[2]; [1]University of Petroleum and Energy Studies, India; [2]Indian Institute of Technology Roorkee, India

Aim of this article is to study the effects of hydroxyl functional group with different coverage percentages on the mechanical strength and fracture toughness of graphene. The hydroxyl functional group forms the backbone of intrinsic atomic structure of graphene oxide (GO).

Molecular dynamics based simulations were performed in conjunction with reactive force field (ReaxFF) parameters to capture the mechanical properties and Mode-I fracture toughness of functionalized graphene. Moreover, these simulations helped in concluding that spatial distribution and concentration of hydroxyl functional group significantly affects the fracture morphology of graphene nanosheet. Room temperature (300 K) was used for the simulations and virial stress components were evaluated for predicting the stress tensor.

In contrast to literature investigations, here the atomistic simulations have predicted a transition in the failure morphology of hydroxyl functionalised graphene from brittle to ductile as a function of its spatial distribution on graphene sheet. This transition in failure morphology from brittle to ductile was gradual in nature and was observed at lower percentage coverage of graphene in the range of 25-50%. Failure morphologies depict that hydroxyl groups tend to boost the ductility through atomic chains and elongated rings formation at lower percentage coverage.

As the graphene nanosheet is highly brittle in nature, so the authors have evaluated the fracture toughness of graphene with the help of Griffith's criteria. We then functionalized the graphene sheet (with an pre-crack) with epoxide functional group and observed that a chemical epoxide-to-ether chemical transformation enhanced the fracture toughness value by 25%, as compared to the pristine graphene.

From this investigation, we concluded that spatial distribution and concentration of functional groups significantly affects the mechanical and fracture behavior of oxide functionalized graphene nanosheet.

F.NM03.09.16
Anomalous Characteristics of Functionalized Grain Boundaries in Graphene—A Nano-Mechanics Study Akarsh Verma[1] and Avinash Parashar[2]; [1]University of Petroleum and Energy Studies, India; [2]Indian Institute of Technology Roorkee, India

Enduring an ultrahigh mechanical strength and thermal conductivity, pristine two-dimensional graphene is still a hypothetical concept in the scientific community. Fabrication techniques for this quantum confined two-dimensional nanomaterial in the experimental environment induce various defects in its polycrystalline domain such as the atomic level grain boundaries (GB). Various computational techniques such as the molecular dynamics and density functional theory have unravelled complex mechanisms operating in the presence of these boundary phases to tune graphene's mechanical, fracture and thermal properties.

Molecular dynamics-based simulations were performed in conjunction with reactive force field (ReaxFF) parameters to capture the mechanical properties of functionalized GB in graphene. Room temperature (300 K) was used for the simulations and virial stress components were evaluated for predicting the stress tensor.

Herein this article, the authors have predicted certain spatial configurations of epoxide functionalized bicrystalline graphene, which could dilute its catastrophic brittle nature and transform it into stable ductile behavior. Altering of failure path and epoxide-to-ether chemical transformations were the chief mechanisms behind the enhanced plasticity for functionalized graphene. Due to brittle nature of graphene, it was expected that failure of graphene would tend to take place from the GB, but in contrast, we found that the failure started from the interior of crystal. This tailoring of failure path induced plasticity in the domain and acted as an energy dissipation mechanism.

The present work provided new insights into the mechanical behavior of bicrystalline GO and predicts plasticity in epoxide functionalized sandwich structure. This persisting ductility of epoxide rich configurations would enable GO to absorb more energy prior to failure and amplified toughness as well, leading to improved structural integrity.

Atomistic Simulations to Explore the Water Interaction Mechanism Through a Defective 2D h-BN Nanosheet—Reactive Forcefield Development and Molecular Dynamics Study Akarsh Verma[1,2], Weiwei Zhang[1] and Adri v. Duin[1]; [1]The Pennsylvania State University, United States; [2]University of Petroleum and Energy Studies, India

Desalination corresponds to supplying of potable water from oceans and seas, which can dissolve the water scarcity problem for human consumption, agriculture use and energy needs. Conversion of earth's 97% salty water into a fresh source is still an ambiguous challenge for the research community. Moreover, conducting costly and time consuming commercial experimental techniques such as reverse osmosis and thermal desalination have consistently proved to be a brain storming challenge for the scientists. So, in order to rectify this problem, herein the authors have performed molecular dynamics simulations to investigate the transport of water molecules through artificially created pores on the honeycomb lattice domain of two-dimensional hexagonal Boron Nitride (h-BN) nanosheet. Initially, a reactive force field (ReaxFF) was developed that had water parameters in conjunction with vacancy defects data for monolayer h-BN derived from the density functional theory incorporated in it. We then checked the structural stability of an h-BN monolayer (both pristine and defected) at different temperatures (300, 500 and 800 K) and ensembles (NVT and NPT); thus, predicting that the developed ReaxFF showed a minimal out-of-plane displacement. From the interaction point of view, we revealed that the water molecules tend to accumulate (droplet formation) and form sharp contact angles (hydrophobic nature) with h-BN. Furthermore, on compressing water molecules by applying external pressure on h-BN nanosheet the water molecules tend to arrange themselves in a layered structure. Finally, we investigated the water dissociation mechanism on a defected h-BN nanosheet, and noticed that the water molecule dissociates into hydroxyl group and hydrogen atom thereby getting attached to boron and nitrogen vacancy edge atoms, respectively (Relative energy barriers with respect to initial configurations were 0.395 and -2.18 eV). These outcomes on h-BN nanosheet may prove to be valuable for designing of 2D nanodevices/nanomembranes for water desalination purpose.

F.NM03.09.19

Synthesis and Functionalization of Carbon Nanospheres in One Step by APCVD Gerardo Patiño Guillén[1], Alan Arceta Lozano[1], Jessica A. Falcón Montes[1], Esmeralda García Díaz[2], Jorge Noé Díaz de León[3], Rafael Vázquez Duhalt[3], Miguel A. Méndez Rojas[1] and Jessica R. Campos Delgado[1]; [1]Universidad de las Américas Puebla, Mexico; [2]Benemérita Universidad Autónoma de Puebla, Mexico; [3]Universidad Nacional Autónoma de México, Mexico

A one-step synthesis/functionalization of carbon nanospheres (CNS) is presented. The synthesis was carried out *vía* the APCVD method using toluene and ethanol (0wt%- 5wt% ethanol) as precursors. Different weight percentages of ethanol were implemented in order to evaluate their effect on the CNS's solubility in water, size distribution, morphology, surface area and surface chemistry. Since this method is a one-step *in situ* functionalization (with oxygen-containing groups), there's no need of a post-treatment to functionalize the sample or the use aggressive chemical reactants that could significantly modify the nanomaterial. Characterization techniques implemented for this study included FT-IR, SEM, EDX, XPS, Raman spectroscopy, BET and solubility tests. Results indicated that CNS possess higher water solubility when a 3 wt% ethanol solution is implemented for the synthesis. It was also demonstrated that higher ethanol concentrations decrease CNS's diameter and induce polydispersion. Finally the increased solubility and stability of the functionalized CNS are highlighted, envisaging applications in the biomedical field were hydrophilicity and availability of functional groups are mandatory.

F.NM03.09.21

Precision Defect Engineering of Graphene for Applications Using Electron-Beam Chemistry with Radiolyzed Water Michael A. Susner[1,2], Ahmad Islam[1], Rahul Rao[1], Jennifer Carpena-Núñez[1,2], San-Hui Chi[1,2] and Benji Maruyama[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States

Defect engineering of graphene is attractive for a wide range of applications. Here, we present a mask-less, resist-free, and fully reversible process to engineer defects in graphene using electron-beam (e-beam) chemistry with radiolyzed water. This process was performed inside a variable pressure scanning electron microscope by generating radiolysis products using reactions between the e-beam and water vapor, which in turn reacted with the graphene at the location of the probe. These reactions enabled controlled chemistry on the graphene surface at a resolution of ~ 60 nm and hence created defects in precise locations defined by the e-beam. Detailed characterization and theoretical analyses suggested the presence of sp^3-type defects, the density of which was tuned by varying the e-beam dose. In addition, these sp^3-type defects were cycled in and out of graphene by alternating e-beam chemistry and thermal annealing. We present initial results showing the ability to manipulate the plasmonic response in graphene though the creation of quickly patterned nanoribbons.

F.NM03.09.23

Synthesis, Reversible Insulator-Metal Transition as Well as High Conductivity and Ampacity of Cobalt Oxide Based Misfit Nanotubes Kankona S. Roy; Indian Institute of Technology Bombay, India

Misfit layered compounds (MLCs) are consist of two alternating sub-lattices with different lattice constants at least in one of the directions. One can selectively alter one of the sub-lattices without affecting the other that can tune both the physical and electronic properties. Among them, calcium cobaltite ($Ca_3Co_4O_9$, CCO)[1] and strontium cobaltite ($Sr_3Co_4O_9$, SCO)[2] are gained interest as potential thermoelectric materials. Bringing them to low-dimensions could further enhance their thermoelectric properties. However, synthesizing them in a one-dimensional structure is extremely difficult. Recently, we have synthesized calcium deficient cobalt oxide-based misfit nanotube[3,4] from the bulk starting material. However, the yield of these nanotubes is rather low. Besides, the physical and electrical properties of these nanotubes have not been explored yet. Here, we present the synthesis of 1D nanotubes (NT) from oxide misfit compounds with a very high yield (80%) by a combination of solid-state and solution-based synthesis. We have also studied their electrical properties on individual nanotube level by patterning with electron beam lithography.

All the synthesized nanotubes are thoroughly characterized by a combination of X-ray diffraction pattern (XRD), scanning electron microscope (SEM,) high-resolution scanning transmission electron microscopy (HRSTEM), electron diffraction (ED) and X-ray photoelectron spectroscopy (XPS). It is found that the crystal structure varies in the case of nanotubes from the bulk starting material. Absorption studies show the bandgap of 2.7 eV and 1.7 eV in case of CCO and SCO NTs, respectively. We have fabricated source-drain channels on individual nanotubes by electron beam lithography to find out their electronic properties. In the case of CCO nanotubes, it is found that the nanotubes are of p-type semiconductor with a high charge carrier concentration of $7.05*10^{19}$ per cm^3, which suggest that these NTs are promising conducting materials. The current-carrying capacity of these nanotubes is around $6.5*10^5$ A/cm^2 (for an individual nanotube). But surprisingly, in the case of SCO nanotube, it shows a very high current carrying capacity of $0.88*10^8$ A/cm^2 for a single NT. These values are close to the reported WS_2 NTs having the highest current carrying capacity (ampacity) of $2.4*10^8$ A/cm^2 among the inorganic nanotubes.[5] Temperature dependent resistivity measurements show that both the nanotubes are semiconducting in nature. However, we have observed a voltage-induced semiconductor to metal transition in the case of SCO NTs. We have observed the four-probe resistance for the SCO nanotube to be 10 kΩ which is lowest among the existing oxide-based inorganic nanotubes. We believe electronic properties can be further tuned by changing the chemical composition between Ca/Co and Sr/Co. These results demonstrate that the high conductivity of these nanotubes could be a potential building block for future thermoelectric devices and interconnects.

Getting Pristine Graphene-Like Behaving rGO—What Really Matters Mohammed Sedki[1], Pegah S. Mirabedini[1], Kenta Nakama[2], Garrett Stephens[3], Michael Groves[3], Mahesh R. Neupane[4] and Ashok Mulchandani[1]; [1]University of California, Riverside, United States; [2]Tokyo University of Agriculture and Technology, Japan; [3]California State University, Fullerton, United States; [4]U. S. Army Research Laboratory, United States

Chemically synthesized graphene or reduced graphene oxide (rGO) is very promising for many applications from coatings and fillers to electronics, as it is economic, easy to prepare and scale up, and has unique properties. Despite the huge expansion of GO/rGO market, there is a clear lack of experimental and computational studies on getting high quality GO and rGO nanosheets/thin films. This caused a huge variation in the reported properties of GO/rGO, with a majority of low quality and low competency in electronic applications. In this work, a detailed experimental study of the factors affecting GO/rGO properties, supported by Density Functional Theory (DFT) calculations, is introduced to help prepare pristine graphene-like rGO. In addition, the impact of lateral sheet size on GO/rGO properties, as one of the factors addressed in this work, was studied using DFT calculations and experimental measurements for the first time, to the best of our knowledge. Field-effect transistor (FET) was used to study and optimize rGO. The optimized rGO-FET device showed the lowest resistance (200±20 Ω) and the highest charge carrier mobilities (53279 and 39891 cm^2/V.s for holes and electrons, respectively) reported.

Furthermore, FET characteristic curve of rGO-FET showed the ambipolar behavior of high-quality graphene, with Dirac point around zero. In addition, the optical band gap of rGO nanosheets (0.4 eV) prepared in this work is the smallest reported, so far. These results highlight the importance of this study for both researchers and companies aiming at using rGO as an alternative for graphene obtained by liquid phase exfoliation or chemical vapor deposition.

Electronic Functionality Encoded Laser-Induced Graphene for Paper Electronics Hyunjin Park, Minsu Kim, Byoung Gak Kim and Yun Ho Kim; Korea Research Institute of Chemical Technology, Korea (the Republic of)

Laser-induced graphene (LIG) has been utilized as a non-metallic conductor for the development of various electronics due to its facile, direct, and scalable synthesis process. Here, the graphitization degree of LIG is simply controlled by adjusting the lasing conditions to encode different electronic functionalities such as resistance and capacitance on commercially available papers. The effect of lasing conditions including the number of lasing scans and the lasing power on the graphitization degree of paper-derived LIG is systematically investigated by evaluating the optical, chemical, and electrical properties. The paper-derived LIG with various lasing conditions exhibits a relatively wide sheet resistance range of 61.5 to 9140 Ω sq^{-1}. The corresponding LIG is used to fabricate resistors and capacitors, and the different electronic functionality encoding is successfully demonstrated by monolithically fabricating non-volatile read-only memory and resistor-capacitor circuits and verifying the electrical performance of the fabricated devices. This work presents a practical approach to develop paper electronics for cost-effective and environmentally-friendly manufacturing.

F.NM03.09.27
Robust Microscale Superlubricity Under Airborne Contaminants Kunqi Wang; Tsinghua University, China

Structural superlubricity, which results from the incommensurability of directly contacted crystalline surfaces, achieves ultralow friction and inspires disruptive innovations in applications across length scales. It is a common belief that this phenomenon requires the contact interface being ultra-clean, ensured by either a clean environment or self-cleaning of the contact. However, in this paper, the observation of robust superlubricity with a contaminant-rich interface is reported. After intentionally introducing airborne contaminants into microscale superlubric graphite contacts, we surprisingly find that two important features of structural superlubricity are well preserved: the nearly-zero friction coefficient and the drastic commensurate/incommensurate anisotropy of frictional force. Moreover, contaminants are found to reduce the friction of a commensurate contact, but increase the friction of an incommensurate contact, which leads to the decrease of anisotropy ratio in friction as the contaminant concentration increases. Molecular dynamics simulations reveal the different roles of the third bodies in commensurate and incommensurate contacts. Our results encourage explorations of structural superlubricity in contaminant-rich environments that practical devices could be facing.

Revealing Structure–Activity Links in Hydrazine Oxidation—Doping and Nanostructure in Carbide–Carbon Electrocatalysts Tomer Burshtein[1], Eliyahu Farber[1], Kasinath Ojha[2] and David Eisenberg[1]; [1]Technion–Israel Institute of Technology, Israel; [2]Leiden University, Netherlands

The oxidation of hydrazine (N_2H_4) is an important challenge in electrocatalysis, with applications in direct hydrazine fuel cells and in medical and environmental sensing. Interest in alternative, nitrogen-based fuels for fuel cells was rekindled by recent advances in alkaline membranes, and by the surfacing of challenges in the transportation of hydrogen. Direct hydrazine fuel cells promise high theoretical voltage (1.56 V with O_2), clean emissions, and improved fuel transportability. We now report a multi-doped carbide–carbon composite with excellent hydrazine electro-oxidation (HzOR) activity in alkaline pH. While iron carbide containing materials are well known catalysts for several applications (e.g. oxygen reduction), our N-doped, Fe_3C-embedded carbons provide the first examples of a carbide-based HzOR catalyst. Multi-doping was thought to enhance reactivity (possibly through cooperation of M=Cu/ Zn, Fe, and edge N atoms), possibly by pore-etching, layers exfoliation or graphitization promotion, thus modulating surface area, mass transfer and conductivity.
To prepare the composites, we designed tunable multi-doped precursors: an organometallic structure combining iron with either copper, zinc, or iron, to investigate the effect of molybdenum-doping reported earlier. Pyrolysis and washing of the fore mentioned precursors yielded HzOR-active composites of Fe_3C nanoparticles and a hierarchically porous, partially graphitic N-doped carbon (NC). Thorough characterization by voltammetry and by a broad range of spectroscopic and microscopic methods revealed that the activity is ordered as: Cu-derived NC > Zn-derived NC > Fe-derived NC. While the catalysts had similar compositions, their nanostructure varied: both Zn- and Cu-doping induced the formation of micropores and small mesopores (5–13 nm diameter). The dopant-induced active site exposure (affecting micropore volume) and improved material flow (linked to mesopore volume) contributed to enhanced HzOR electroactivity. Furthermore, the

intimate mixing of the metals in the precursor is hypothesized to homogenize and enhance the doping effect, as the structure enhancing metal ions (Zn^{2+} or Cu^{2+}) exposed the nearby catalytic Fe_3C sites. Acid washing of the pyrolyzed carbon was crucial for producing microporosity in the Cu-based carbon, but had little effect on the Zn-derived one. This revealed the importance of micropores and small mesopores for HzOR electrocatalysis, and the different nanostructuring mechanisms of the two dopants: while $Zn_{(g)}$ boils during pyrolysis and thus etches micropores into the carbon, $Cu_{(s)}$ diffuses and spreads throughout, making exfoliation by acid reaction more efficient. Further work in our group is dedicated to the catalytic activity of pure phase Fe_3C, and its modification by other dopants.

Synthesis of Flexible 3D Electrodes of TiN Nanotube Arrays Using Atomic Layer Deposition Seokjung Yun[1], Sang-Joon Kim[2], Jaesung Youn[1], Hoon Kim[1], Jeongjae Ryu[1], Changdeuck Bae[3], Kwangsoo No[1] and Seungbum Hong[1,4]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Research Institute of Chemical Technology, Korea (the Republic of); [3]Sungkyunkwan University, Korea (the Republic of); [4]KAIST Institute for NanoCentury (KINC), Korea (the Republic of)

Flexible nanoscale electrode can be used in many applications such as electrochemical energy storage, electrocatalysts and solid memory devices by providing higher density faradaic reaction sites. Although many processing techniques have been used to produce nano-structured electrodes on flexible substrates, prior ones lack the mechanical stability. Here, the mechanical properties and flexibility of the TiN nanotube array on the Pt substrate were improved using a Ti interlayer as an adhesion promoter. Highly aligned TiN nanotube array was fabricated on a Pt substrate using an anodized aluminum oxide (AAO) template and atomic layer deposition (ALD) system. We show that with the use of a Ti interlayer as adhesion promoter between the TiN nanotube arrays and Pt substrate, the TiN nanotube arrays could perfectly attach to the Pt substrate without delamination and faceted phenomena. Peeling was not observed even when the bending test was performed at a high curvature (radius of curvature, ~2 mm). In addition, reliable and uniform contact the nanotube and the substrate evidenced by conducting atomic force microscopy (C-AFM) analysis proved the excellent local transport properties of our electrodes. Furthermore, the mechanical bending test results attest to the excellent flexibility for use in flexible electronic devices. We envision that our 3D electrodes will be implemented as embedded electrodes in semiconductors as well as flexible plastic substrates.

Single Step Reduction and PEGylation of Nanographene Oxide for Drug Delivery and Photothermal Cancer Therapy Raquel Costa-Almeida[1,2], Diana Bogas[3], Cristiana Couto[3], Licínia Timochenco[3], Filipa A. Silva[1,2], José R. Fernandes[4], Inês C. Gonçalves[1,2], Fernão D. Magalhães[3] and Artur Moreira Pinto[1,2,3]; [1]Instituto de Investigação e Inovação em Saúde, Universidade do Porto, Portugal; [2]INEB - Instituto de Engenharia Biomédica, Portugal; [3]LEPABE, Faculdade de Engenharia, Universidade do Porto, Portugal; [4]CQVR – Centro de Química Vila Real, Universidade de Trás-os-Montes e Alto Douro, Portugal

Cancer is the second leading cause of death worldwide. Current treatments frequently rely on surgical resection, radiotherapy, and high-dose chemotherapy, with unsatisfactory outcomes and side effects. Thus, there is a great need for novel and more effective strategies. Photothermal therapy (PTT), a non-invasive alternative based on near-infrared (NIR) light energy conversion into heat, results in hyperthermia (39-47 °C) and induces higher nanoparticle/drug uptake due to increased membrane permeability and tumor cell apoptosis. Nanomaterials, like graphene-based materials (GBM), hold potential as photothermal absorbers to enhance PTT selectivity within the target tumor tissue toward achieving therapeutic temperatures using less total light energy, minimizing damage to the healthy surrounding tissue [1]. This study explored GBM and GBM loaded with 5-fluorouracil (5-FU), an anti-cancer drug, as platforms for combined chemo-photothermal therapy. Nanographene oxide (GOn) was produced through the modified Hummer's method [2] followed by ultrasonication in a custom-built industrial grade system. Following a one-step procedure, GOn was thermally reduced and non-covalent functionalized with poly(ethylene) glycol (PEG) to obtain stable aqueous dispersions (rGOn-PEG) [3]. GOn and rGOn-PEG (0.25 mg/mL) were mixed with 5-FU at a drug concentration varying between 0.25-5 mg/mL. GBM aqueous dispersions were irradiated with a LED source of 812.8±29.9nm (150 mW/cm2) and temperature recorded using a thermocouple. The effect of GBM and NIR irradiation was evaluated by resazurin cell viability assay using a human skin carcinoma cell line (A431 cells, ATCC).
Reduction and PEGlyation of GOn were confirmed by chemical characterization through FTIR, XPS and UV-vis spectroscopy, as well as thermal analysis by TGA. GOn and rGOn-PEG were obtained with mean lateral dimensions of 287 nm and 521 nm, respectively as determined by TEM. GOn and rGOn-PEG dispersions showed colloidal stability with zeta potential values around -25.6±0.8 mV and -10.2±0.3 mV (pH=7), respectively. Loading capacity of 5-FU on GBM reached

5.8±0.8 mg 5-FU/mg GOn and 3.6±1.2 mg 5-FU/mg rGOn-PEG by simple molecular physisorption. NIR irradiation increased rGOn-PEG temperature to 47 °C after 30 min, which is within temperature ranges of hyperthermia. rGOn-PEG in combination with NIR reduced A431 cells viability, in opposition to rGOn-PEG alone.
This study demonstrated the successful non-covalent functionalization and reduction of nanographene oxide, rendering a material with potential to be further explored for combined chemotherapy and PTT for cancer treatment.

Investigation of a Catalyst Ink Dispersion and Three-Dimensional Analysis of Catalyst Layer in Polymer Electrolyte Membrane Fuel Cells Dan Wu, Samindi M. Jayawickrama and Tsuyohiko Fujigaya; Kyushu University, Japan

Carbon-based supports have been widely used to support Pt catalysts in polymer electrolyte fuel cells (PEMFCs) [1]. In our group, we developed polybenzimidazole (PBI)-wrapping onto carbon support that successfully achieved higher cell performance [2].
In this study, we present a dispersion investigation of the catalyst ink using PBI-wrapped catalyst (CB/PBI/Pt) and non-wrapped (CB/Pt) catalyst with a wide range of ionomer: carbon ratio (I/C). The effects of ink parameters, which include carbon black structure, and ionomer concentration, on the ink microstructure of catalyst ink were studied using visual study in combination with dynamic light scattering (DLS). Heterogeneous porous structure of the catalyst layer in PEMFCs is a significantly important parameter because it strongly determines the gas diffusion properties of the catalyst layer. And the connectivity of the network structure is largely depended on the structure of the catalyst agglomerations as well as the homogeneity of the ionomer on the carbon supporting materials. Therefore, we used scanning electron microscopy combined with focused ion beam (FIB-SEM) to visualize the nano-scale pore structure of the catalyst layer. Post-processing of a series of two-dimensional images reconstructed the three-dimensional pore-space of the catalyst layer.
We found that the catalyst ink of CB/PBI/Pt remained as a very stable dispersion in the range of I/C = 0.2~1.4, whereas for CB/Pt, the catalyst ink easily forms aggregation at high I/C (>0.6). The FIB-SEM images of CB/Pt catalyst layer with optimum I/C = 0.6 and CB/PBI/Pt catalyst layer with optimum I/C = 0.2 was analyzed. It is found that the CB/Pt catalyst layer has isolated large pores with the porosity of 0.55, while CB/PBI/Pt catalyst layer shows a uniform porous structure with the porosity of 0.7. It is reported that the presence of isolated pores increases the O_2 transport resistance in the catalyst layer, resulting in lower fuel cell performance [3,4]. Therefore, we concluded that the dispersion stability of catalyst ink is enhanced by PBI wrapping onto the CB surface, thus ensuring a better porous structure of the catalyst layer in PEMFCs. Furthermore, the particle-particle interactions in catalyst ink will be discussed in the presentation.

Monitoring of Adsorption Behavior of Serum Albumin onto the Fatty Acid-Modified Single-Walled Carbon

Nanotube Kenta Nakamura, Yoshiaki Niidome, Yukiko Nagai, Tanaka Naoki, Tomohiro Shiraki, Takeshi Mori, Yoshiki Katayama and Tsuyohiko Fujigaya; Kyushu University, Japan

Single-walled carbon nanotube (SWNT) are attracting increasing attentions in biological applications because of their unique thermal, physical and optical properties. To use SWNT for in vivo applications, SWNT need to be biocompatible. Up to date, coating of SWNT with biocompatible materials especially polyethylene glycol (PEG) has been investigated due to its stealth property. However, it was pointed that the PEG-modified materials are rapidly excreted from the blood due to an immune reaction when they are repeatedly administered, which is known as accelerated blood clearance (ABC) phenomenon. To avoid such a problem, serum albumin (SA) attracts recent attention as an alternative material of PEG since SA is a blood protein derived from a living body. However, since the adsorption coefficient of SA onto SWNT surface is lower than that of the other proteins, the increase of the adsorption to avoid the risk of the replacement might be necessary. Therefore, in this study, we introduced fatty acid onto the surface of SWNT to improve the binding of SA by utilizing the strong binding between SA and fatty acid , where the introduction of the fatty acid was carried out by the radical grafting of the fatty acid derivative onto the SWNT sidewall. Here, the adsorption behavior was monitored by monitoring of the unique red-shifted and brighter photoemission (PL) generated from the grafting site compared to that of the non-functionalized SWNT.

A Novel Route for Controlling and Improving the Texture of Porous Structures Through Dual Growth of Alumina Nanoparticles and Carbon Nanotubes Using Explosion Process of Solid Fuel Osama Saber and Adil Alshoaibi; King Faisal University, Saudi Arabia

Micro- and meso-porous structures of alumina have attracted attention for their potential use in different applications. In this research, a novel and facile route was introduced for dual growth of alumina nanoparticles and carbon nanotubes together to fabricate nanocomposites at low temperature 250°C through explosive processes of solid fuel. In this trend, series of alumina species with and without carbon nanotubes were prepared and characterized by X-ray diffraction, Raman spectra and transmission electron microscopy. The surface properties of the alumina-CNT nanocomposites were characterized and compared with the prepared nanoparticles of alumina by adsorption–desorption system. The specific surface area of the prepared alumina-CNT nanocomposites was increased from257.9 to 307.7 m2/g and 314.8 m2/g with growing CNTs inside the porous structure of alumina. These increments were observed because of the dual growth of nanoparticles and nanotubes by which new micropores inside their nanocomposites were created. When the source of CNTs was changed from ethanol to methanol, pure mesoporous structure with narrow pore size distribution was observed for the alumina-CNT nanocomposite. In addition, the surface area and the total pore volume increased to be 324.9 m2/g and 0.673 cm3/g; respectively. The detonation technique of an explosive solid has been used for the first time to improve and control the porous structure of alumina through dual growth of CNTs and alumina at low temperature to meet the special requirements of the markets of catalysis and water purification.

Failure Behavior and Mechanisms in Dense Highly Aligned Brittle Nanowire Structures Rebecca Gallivan and Julia R. Greer; California Institute of Technology, United States

Nanowires have become an increasingly prevalent nanomaterials in composites and devices. In both surface coatings and mechanically coupled sensing applications, arrays and other complex geometries provide numerous design advantages, such as pixel like features. However, little investigation has been done regarding the mechanical behavior of these micron sized structures. With contact and load bearing applications, both the failure behavior and the underlying failure mechanisms are critical for robust device design. Though in-situ microcompression experiments on highly aligned dense bundles of single crystalline zinc oxide (ZnO) nanowires we investigate these types of structures to build a model for better understanding structural failure.

The ZnO nanowires are formed through hydrothermal growth from an aqueous zinc nitrate solution with hexamethylenetetramine (HMTA) and electrolysis conditions to promote fast growing high aspect ratio nanowires. 2μm and 4μm diameter bundles with individual nanowires of approximately 300nm in diameter and 4μm tall were investigated. These structures provides a range of 10-130 nanowires per bundle and thus probes an order of magnitude in scale. Experiments show two regimes of failure in the nanowire bundles: localized non-catastrophic events and global structural failure. No size dependence is observed in either regime and failure stress ranges from 0.3-1.3GPa and 0.83-2.20GPa respectively. Localized failure corresponds to interfacial splitting between nanowires and can be modeled using a mode I double cantilever beam tests. Analysis of this mechanism provides insight to the flaw size and failure initiation in the structures. Ultimate global failure can be modeled by coupling the accumulation of local failure from interfacial splitting to specific failure parameters of

the nanowire material. Utilizing Weibull statistics and experimental results, we demonstrate the validity of this technique for analyzing flaw distribution and predicting the expected failure stress range of the bundle structures. The technique shows the sensitivity of failure behavior to degree of alignment, flaw size, interfacial interactions of constituents, and structural surface effects. Through analysis of behavior in this specific system, we develop insight to broader fundamental mechanisms for local failure and statistical techniques for assessing and predicting failure behavior of highly aligned structures.

Relationship Between the Dispersibility of Carbon Nanotubes and the Properties of Their Polymer Nanocomposites Taiyo Shimizu, Ryoichi Kishi, Kazufumi Kobashi, Takahiro Morimoto, Toshiya Okazaki, Takeo Yamada and Kenji Hata; National Institute of Advanced Industrial Science and Technology (AIST), Japan

Polymer materials with superior properties have been more and more widely used in our daily life. As compared to metals, light weight and good-processability are particularly beneficial properties of polymer materials. However, there are also several properties of polymers which are required to be improved, e.g. mechanical, electrical and thermal properties, and thus a plenty of research to improve these properties have been conducted so far. Improving these properties can realize the extension of applicable fields of polymer materials.
In order to improve objective properties of polymers, incorporation of appropriate kinds of fillers into polymer matrix is frequently adopted. For instance, carbon nanotubes (CNTs) are one of the most prominent fillers with superior properties such as high mechanical strength and electrical conductivities. Nanocomposite materials with CNTs have been widely explored and various kinds of nanocomposites possessing improved properties have been fabricated so far. However, addition of substantial amount of nanofillers, not limited to CNTs, is required in most cases, and thus the inherent properties of polymer matrix, such as good-processability, tend to be degraded. These kinds of nanofillers are basically aggregated in a pristine form, and are required to be dispersed properly in their nanocomposites, in order to extract their potential as a filler. In this presentation, we will describe the relationship between the dispersibility of CNTs and the resultant properties of their nanocomposites. As an example, the thermal stability of CNT nanocomposite will be focused on. We successfully fabricated the CNT/silicone rubber nanocomposites with high thermal stability achieved by well-dispersed single-walled CNTs. The temperature at 5 % weight loss ($T_{d,5\,\%}$) of silicone rubber, obtained from thermogravimetric analysis, was increased by incorporation of low amount of CNTs. Remarkably, we found that the degree of increase in the $T_{d,5\,\%}$ depends on the dispersion process of CNTs, and appropriate dispersion process can realize higher increase in the temperature than that of the CNT dispersion process only by stirring. This phenomenon is considered to be originated from the homogeneity in the distributions of CNTs in nanocomposites, which has been ascertained by analytical techniques. We also confirmed that the CNT/silicone rubber nanocomposites fabricated by appropriate dispersion process can retain rubbery elasticity after a thermal aging test, while pristine silicone rubber was embrittled soon after the onset of the test. These results indicate that appropriately dispersed CNTs can impart thermal stability in both short- and long-term to silicone matrix only by small amount of loading. Our findings indicate that appropriate dispersion of CNTs can enhance the effectiveness of incorporation of CNT to matrix, and we believe that these kinds of approach can be applicable to a broad range of matrix, not limited to polymers.

Elucidation of Adsorption Behavior of Polybenzimidazole on Carbon Material Surface by Adsorption Isotherm Measurement Nana Kayo[1] and Tsuyohiko Fujigaya[1,2,1]; [1]Kyushu University, Japan; [2]WPI-I2CNER, Japan

In polymer electrolyte fuel cells (PEFC), a composite of carbon black (CB) with platinum particles (Pt) is widely used as an electrode catalyst after mixing with acidic electrolyte. However, low platinum utilization efficiency because of the uneven distribution of acid electrolyte on the CB surface that caused the insufficient protons transport was the issue [1]. We reported that improvement of platinum utilization efficiency and power density by coating of polybenzimidazole (PBI) onto CB surface prior to the platinum loading [2], in which the distribution of the electrolyte become uniform by the coating of PBI. However, it coating homogeneity of PBI onto CB has not been clarified yet.
In this study, the adsorption state of PBI on CB was studied by estimating the adsorption isotherm and the interaction acting between the carbon materials and PBI was investigated.
From the adsorption isotherm of PBI on CB, it was revealed that PBI adsorption reached adsorption equilibrium from a low concentration, suggesting that PBI was adsorbed in a monolayer on the carbon materials efficiently. In addition, the PBI coverage at the coating concentration of 0.50 mg /mL, used for coating, calculated from the Langmuir equation showed as high as 99.9%. Therefore, we concluded PBI uniformly coats CB. Also, based on the calculation of thermodynamic parameters, it was found that ΔH and ΔS were 14 kJ/mol, and 0.11 kJ/mol, respectively. The temperature dependence of the isotherm revealed that this adsorption process was entropy driven since the PBI adsorption amount increased with increasing the temperature. The adsorption behavior and interaction of PBI with other carbon materials will be discussed in the

presentation.

Combined Theoretical and Experimental Study of All-Carbon Transistors Ali D. Özdemir, Artem Fediai, Feliks Pyatkov, Pramit Barua, Ralph Krupke and Wolfgang Wenzel; Institute of Nanotechnology, Karlsruhe Institute of Technology, Germany

Low-dimensional all-carbon nanostructures are promising candidates for future flexible and transparent transistors, as well as light-emitters [Pyatkov *et al*, Nature Photonics 10 , 420–427 (2016)]. Carbon nanotube field-effect transistors with graphene electrodes offer high thermal stability and allow for ultra-flat devices able to carry high current densities. Understanding quantum transport in such systems is essential for device manufacturing. However, conventional simulation methods are limited to local contacts with an overlap width of only a few angstroms, and first-principle quantum transport calculations in systems with realistic contact geometries remained unfeasible. Simulation methods for extended CNT/metal contacts were presented in prior theoretical studies [Fediai *et al*, Nanoscale, 8, 10240 (2016)]. Here, we report quantum transport calculations based on the non-equilibrium Green function formalism and density functional theory, which are capable of treating ~100nm long CNT/graphene overlap regions and electrostatic gating at a pure ab-initio level. These calculations are compared with experiments where graphene electrodes were fabricated and dielectrophoretically bridged with single semiconducting CNTs followed by an electrical characterization over a wide temperature range. The simulation results are in agreement with the experimental data and the fabricated devices exhibit ambipolar behavior, consistent with the theory. Due to large CNT/graphene spacing and small CNT/graphene overlap, only a fraction of the quantum conductance can be achieved for the on-state conductivity. A remarkable feature of the all-carbon transistor with graphene electrodes is electrostatically induced doping of the carbon-system in the contact regions caused by the gate electrode. This is made possible by the low density of states in graphene near the K-point. We hope that this newly developed and verified simulation approach will accelerate progress in fabrication as well as the understanding of advanced all-carbon devices.

Plasma Treated Single-Walled Carbon Nanotubes Decorated by RuO_x Nanoparticles for High Performance Hydrogen Evolution Reaction Fedor Fedorov[1], Daniel Settipani[2], Marthe Buan[2], Jani Sainio[2], Farhan S.M. Ali[2], Daniil Ilatovskii[1], Tanja M. Kallio[2] and Albert Nasibulin[1,2]; [1]Skolkovo Institute of Science and Technology, Russian Federation; [2]Aalto University, Finland

The constant and growing need in new catalysts for hydrogen evolution reaction is triggered by increasing energy demands and promises of its eco-friendliness combined with large gravimetrical storage capacity. Carbon nanotubes are also known to be quite promising for hydrogen (and oxygen) evolution reaction and are characterized by large specific surface area, excellent conductivity, and rather good durability.

We report a cathode material based on plasma-treated single-walled carbon nanotubes decorated by RuO_x nanoparticles using atomic layer deposition (ALD). We have examined cathode performance towards hydrogen evolution reaction by tailoring material wettability, conductivity yielded by plasma-treatment, and the catalyst loading [1]. We discuss that nucleation of particles is facilitated by the appearance of carboxylic and hydroxyl groups triggered by oxygen plasma action. The best performance is associated with samples containing RuO_x particles of 4-5 nm, which show hydrogen evolution onset potential to be about -5 mV (*vs.* RHE) in 0.5 M H_2SO_4 measured at a current density of -1 mA cm^{-2} and Tafel slope of 47.5 mV/dec. The material possesses stable performance at -10 mA cm^{-2} with a potential of about - 160 mV.

The reported study was funded by RFBR, project number 20-03-00804

F.NM03.09.44

Synthesis of Cu_xS/Graphene Aerogel for Photocatalytic Reduction of CO_2 Feng Wang and Liejin Guo; Xi'an Jiaotong University, China

Using solar energy to convert CO_2 into hydrocarbon fuel is a promising technique for harvesting solar energy storage and reducing carbon dioxide. Recently, Graphene-based semiconductor composites have been a topic of great interest, especially in the field of photocatalysis. Graphene has the advantages of high surface area, excellent conductivity, and anticorrosion capacity, which can overcome the limitations of traditional photocatalysts. Thus, graphene-based material can be a feasible photocatalyst for photocatalytic CO_2 reduction. Besides, as an environment-friendly and earth abundant material, Cu_xS has considered as a good candidate for photocatalytic reactions, due to its unique optical, electronic, physical and chemical properties. Herein, we report the photocatalytic reduction of CO_2 using Cu_xS/graphene aerogel as the photocatalyst, which was prepared by hydrothermal method. The as prepared Cu_xS/graphene aerogel exhibited pretty good activity for photocatalytic reduction of CO_2. C_2 products (ethanol, acetate) are main products. In this composite photocatalyst, graphene aerogel not only serves as a 3 dimensional support for Cu_xS, but also transfers the photo generated charges. Moreover, density functional theory calculations were performed to reveal the chemical reactions and the charge transfer between Cu_xS and graphene. Also, the study of Cu_xS/graphene aerogels photocatalyst presents useful information for efficient photocatalytic CO_2 reduction without noble-metals.

F.NM03.09.45

Graphene Encapsulated Nanoscale Vacuum Channel Transistors Girish Rughoobur and Akintunde I. Akinwande; Massachusetts Institute of Technology, United States

There is a growing need for devices that operate at THz frequencies, and with the end Moore's device scaling law approaching, alternatives to solid-state transistors need to be explored. The inherent limitation of solid-state transistors such as the metal-oxide semiconductor field-effect transistor (MOSFET) is the semiconductor channel, which not only causes carrier scattering, velocity saturation of carriers due to optical phonon scattering, but is also susceptible to high temperature and radiation effects. Current research attempts to mitigate these negative effects focus on using wide bandgap semiconductor channels. In contrast, the use of 'empty-space', which can be regarded as the ultimate wide bandgap material, as the device channel could overcome these limitations. This is because in vacuum, there is no carrier scattering (ballistic transport), avalanche breakdown or thermal generation. The absence of any atoms further enhances the tolerance to high temperature as the channel retains its properties. Nanotechnology and nanofabrication has enabled the realization of nanoscale vacuum channel transistors (NVCTs) that could potentially surpass solid state devices of equivalent channel length owing to ballistic transport of electrons, shorter transit time and higher intrinsic breakdown field. Hence, transistors with a vacuum channels could have very high Johnson figure of merit ($J_{FoM} = E_{BD}v_{sat}/2\pi$) of ~$10^{14}$ V/s, even exceeding ultra-wide bandgap materials such as AlGaN and diamond.

We report the demonstration of NVCTs based on gated vertical silicon field emission arrays with two self-aligned gates. The two gates are separated by an oxide with thickness of 350 nm. A first gate with aperture diameter of 360 nm is used to extract electrons from a sharp emitter tip (radius < 7 nm) and the second gate, with aperture diameter of 570 nm, is used to focus the electron in to a vacuum channel. The emitter tips density is 10^8 emitters/cm^2. NVCTs with such electron sources are highly sensitive to barrier variations caused by surface adsorption of molecules on the tip in poor vacuum environment. Here we demonstrate the nano-encapsulation of the electron source for operation in poor vacuum, using several layers of graphene, which are transparent to electrons but impermeable to the larger gas atoms in a poor vacuum.This device architecture with two self-aligned gates also enables the application of a different voltage bias on the graphene and hence controlling the energy of the electrons in the channel, while reducing the encapsulation volume significantly. We demonstrate turn-on voltages below 10 V and operation in poor vacuum and at atmospheric pressure. This device architecture is highly promising to realize empty space electronics capable of functioning at higher power and harsher conditions (high radiation and high temperature, such as in space and in nuclear reactors) transcending the performance of solid state electronics.

F.NM03.09.46

Oil Dynamic Shell Surrounding Fullerenes Aaron Morelos-Gomez[1], Kunio Kondo[2], Hiroshi Ushiyama[3], Kazuhiro Omori[2], Ryuji Monden[2], Yu Gao[2], Masumi Kuritani[2], Taiki Yokokawa[1], Rodolfo Cruz-Silva[1], Syogo Tejima[3], Mauricio Terrones[4] and Morinobu Endo[1]; [1]Shinshu University, Japan; [2]Showa Denko K.K., Japan; [3]Research Organization for Information Science & Technology, Japan; [4]The Pennsylvania State University, United States

Given the increase in technology development the need for more energy efficient devices is required. In mechanical systems a large amount of energy is lost due to friction between sliding surfaces. For this reason, the creation of effective lubricants is needed. Transition metal disulfides such as WS_2 and MoS_2 fulleroids have been used as oil additives. However, disulfides are prone to oxidation and release of sulphide compounds under heat and may corrode metal surfaces creating metal sulphides. Carbon materials can exhibit higher chemical inertness and therefore exhibit longer lubrication lifetime under heat than transition metal disulfides. Among carbon materials; graphene, carbon nanotubes and fullerenes have been added into oil to

decrease friction between two metal surfaces. Unfortunately, the molecular interaction between carbon nanomaterials and lubricants has not been fully understood. We studied the molecular interactions between fullerenes and mineral oil, known as "nano oil", by ultraviolet Raman spectroscopy and molecular dynamics simulations. The results indicate that aromatic molecules help to disperse individual $C_{60/70}$ molecules from aggregates whereas the alkane molecules help to stabilize fullerenes by forming a dynamic shell structure around them. Our findings demonstrate that fullerenes can be used as high-performance additives for effective lubrication.

F.NM03.09.51

Computational Geometry-Centric Evaluation for Electrical Conductivity Variation of Thin-Film Conducting Nanocomposites Jungmin Lee[1], Yesol Yun[2], Sang Hyun Lee[2] and Jinyoung Hwang[1]; [1]Korea Aerospace University, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

Hybrid carbon nanotube (CNT) composites consisting of multiple types of fillers have been developed to provide enhanced characteristics as compared to CNT single-filler composites. The incorporation of secondary fillers, such as silica, $CaCo_3$, and $BaSO_4$, yields remarkably improved mechanical strength and stiffness of the CNT composite and electrical conductivity of the hybrid composite network under the control based on geometry and content of the constituent particulate fillers. In particular, higher electrical conductivity can be attained with the addition of micro-scale secondary fillers to the CNT composite network, while the addition of nano-scale particulate fillers incurs lowering the electrical conductivity of the nanocomposite network. Such electrical conductivity transition is attributed to distinct variations in the network topology caused by the excluded volume originating from the loading of secondary fillers with different scales. Micro-silica composites result in dense clusters of CNTs, thereby forming CNT conducting paths, while densely-dispersed nano-size fillers cause severely twisted CNTs, reducing forming a conducting network.
In this work, Monte-Carlo simulation is first conducted for the estimation of the electrical conductivity of the CNT network of hybrid composites. To obtain a realistic model, flexible CNTs are modeled as long thin cylindrical objects with many joints interconnected in a row. In addition, to take the resistance of the conducting CNTs into account, individual joints are considered to be tiny lumped resistor elements. A computational characterization approach based on numerical linear algebra technique is applied under various size and concentration configurations of composite components, and the corresponding electrical conductivity of the network is derived. The computational results exhibit that the ratio of the average diameter of the particulate filler to the nanotube length governs the tendency of the electrical conductivity variation, as compared to the change of filler contents only affecting the degree of the conductivity change. As the ratio of the silica diameter to the CNT length increases, the ratio of the conductivity without (σ_0) and with (σ) the secondary particulate fillers, i.e. σ/σ_0, increases from the value less than one to the value more than one. This indicates that the impact of the second fillers on the electrical conductivity of the composites shows a transition. By contrast, if the geometric configuration of the fillers is almost fixed, the degree of the conductivity variation increases as the silica content increases, while decreasing for the increasing CNT content. The electrical behaviors of hybrid composites can be simply characterized by the combination of computational geometry centric notions such as Voronoi tessellations and Swiss cheese model along with their associated percolation theory. In the developed model, the CNT dispersed around particulate fillers indicating effective conducting paths can be classified with tessellations from Voronoi cells. The conductance of each effective path is designated by local conductance determined from the density of CNTs in the local region. The reliability of the model is validated based on comparison with the numerical results obtained from the MC simulation. The developed approach achieves, as compared to the MC simulation, remarkable computing cost reduction. Therefore, the combined computational framework enables to provides a novel strategy to estimate for the electrical conductivity of the hybrid composites under the external deformation such as bending, stretching, and patterning, and it is a viable model for the design of the hybrid composites at hand.

Investigation of the Growth Mechanism for Hierarchical Polymer/Carbon Nanotube Nanohybrid Shish-Kebab Structures to Enable High-Performance Printable Thin-Film Transistors Kevin Schnittker and Joseph B. Andrews; University of Wisconsin-Madison, United States

Aerosol jet printing has gained a considerable amount of attention as a method to additively fabricate electronic device. In part, this is due to the compatibility with a wide range of ink viscosities (1-1000 cps) and the ability to print on non-planar surfaces. One elusive material for aerosol jet printed active electronics is a high-performance semiconducting ink with low-variability. One potential promising ink would be a combination of high-mobility carbon nanotubes (CNTs) with highly uniform semiconducting polymers. However, CNTs fully encapsulated by semiconducting polymers have not shown noteworthy improvement. One method to capture both positive attributes of CNTs and semiconducting polymers is through a hierarchical nanostructured composite. The conjugated polymer regioregular poly(3-hexylthiophene) (P3HT) has the ability to self-assemble and form periodic crystals on CNTs due to π-π interactions. These structures, coined nano-hybrid shish

kababs (NHSKs), may directly improves charge carrier transport in printed thin-film electronic devices.
The objective of this project is to fabricate a novel semiconducting ink that consists of P3HT/CNT NHSKs. In developing this ink, we investigated the P3HT shish kabab crystallization and kinetic growth on (6,5) chirality SWNTs. This was done by manipulating the P3HT-SWNT concentrations, the solvent concentration, and crystallization temperature. The P3HT fibril shape, size, and period were found to be correlated to the above parameters. The morphology and purity/concentration were measured using atomic force microscopy (AFM) and ultra-violet/visible spectroscopy.
NHSKs were fabricated via a 6:1 P3HT to SWNT mass concentration solution mixed in 70°C anisole solution. The P3HT supramolecular structures were found to be 32±3.7 nm wide and 269±11.4 nm long. At higher mass ratios (40:1 P3HT to SWNT), full encapsulation was observed with little periodicity. In conclusion, this work investigates the growth mechanisms of P3HT polymer crystals on single chirality CNTs for semiconducting ink applications. Next steps include the manipulation of the solution to increase printability and the fabrication of NHSK-based thin-film transistors.

F.NM03.09.54
Enhanced Heat Transfer of Functionalized Graphene Nanoplatelets in Nanofluids for Energy Conversion and Storage of Solar Power Plants Michael Wilhelm[1], Tim Ludwig[1], Thomas Fischer[1], Dileep Singh[2] and Sanjay Mathur[1]; [1]University of Cologne, Germany; [2]Argonne National Laboratory, United States

The unique thermal conductivity of graphene makes it one of the most promising materials for next generation heat transfer applications that, given the increasing demand for energy supply from sustainable energy sources such as concentrated solar power, has emerged as key technology. The incorporation of graphene and graphene-like nanomaterials into conventional heat transfer fluids has been shown to significantly improve their thermal transport properties. Due to their cost-efficient carbon-based starting material, its high surface area and sheet-like structure, graphene nanoplatelets (GNPs) are suitable for colloidal thermal conductive fluids demonstrating enhanced heat transfer efficiencies.
In this work, hydrophobic graphene nanoplatelets were used as starting material and surface functionalized by acid treatments to synthesize highly stable, exfoliated, surfactant-free and highly concentrated (4 wt.%) graphene nanofluids maintaining high thermal conductivity. Characterization by SEM, XPS, XRD, Raman and FT-IR spectroscopy revealed a significant influence of shape, reaction period, acid volume and temperature on the resulting thermal conductivity values of the nanofluids relative to the carrier fluid. After 14h of measurement in a dormant system, thermal conductivities up to 0.586 W/m*K (base fluid: 0.391 W/m*K) were measured. In combination with a low viscosity of 6.39 cP the overall efficiency of the functionalized particles could be increased to 77 % in comparison to the base fluid. The combination of both low viscosity and high thermal conductivity, even after 14h in a standing system, demonstrate the extraordinary properties of surface functionalized graphene nanoplatelets prepared in this work in comparison to other nanofluidic systems.

F.NM03.09.57
Modeling the Effective Electrical Conductivity of Nanocarbon-Metal Composites Made by the Electrocharging Assisted Process Christopher Klingshirn[1], Andrew Palughi[2], Xiaoxiao Ge[1], Madeline Morales[1], Jessica Ye[1], Christopher Shumeyko[3], Tahir Cagin[2] and Lourdes G. Salamanca-Riba[1]; [1]University of Maryland, United States; [2]Texas A&M University, United States; [3]U.S. Army Research Laboratory, United States

Robust materials with high conductivity are essential to electronic devices and systems. Nanocarbon-metal composites have the potential to improve upon the electrical conductivity of established metals and alloys such as Al and Cu by incorporating carbon nanostructures known for their superior electrical properties. During the fabrication of novel nanocarbon-metal composites called covetics, direct electric current applied to a metal melt containing a dispersion of carbon source material is believed to ionize carbon atoms and lead to the formation of nanoscale graphitic ribbons and chains that ultimately incorporate within the metal lattice upon solidification. The electrical conductivity of the resulting composites is consistently greater than the original alloy, but the magnitude of conductivity enhancement varies significantly from sample to sample, and the theoretical upper limit of conductivity enhancement in these systems remains unclear.

This work combines fundamental assumptions about the nature of covetics, specifically a tightly bound metal-carbon interface, with a simple effective-medium model to estimate the bulk conductivity of ideal Al and Cu covetics with randomly distributed graphene nanoribbons (GNRs). Density-functional theory estimates of charge transfer at the graphene-metal interface, local electrical conductivity measurements, and transmission electron microscopy investigation of the interface region provide inputs to the model. The implications of quantum confinement in narrow GNRs are also explored. We use the model to project a range of performance-enhancement goals for the covetics fabrication community and find the potential for conductivity improvements on the order of 10% under ideal conditions, however fabrication challenges remain before these gains may be realized on an industrial scale.

This work is supported by the U.S. Department of Energy under Award No. DE-EE0008313.

Carbon Nanotube Embedded Vertical Aligned PVDF Membraned with High Mechanical Properties for PRO Membrane Application Juran Noh, Mehdi Habibollahzadeh, Choongho Yu and Ahmed Abdel-Wahab; Texas A&M University at Qatar, Qatar

Water desalination has been a critical issue for reserving the freshwater for human survival, further civilization, industry development. Pressure retarded osmosis (PRO) is desalination technology emerging from the osmosis phenomenon; water flux through the membrane, excluding undesired macromolecules or ions with applying pressure. Thus, a high water permittable membrane with stronger mechanical strength to bear in high water pressure should be developed for a high-performance PRO desalination process. High mechanical strength and water permittivity could be a trade-off relationship based on thickness and porosity. Thus, vertical oriented polyvinylidene fluoride (PVDF) membrane with 3D connected carbon nanotube (CNT) is presented. Vertical pores made of hydrophobic polyvinyl fluoride (PVDF) and hydrophilic metal-organic framework (MOF) decorated on the surface improve their water permeability and salt rejection. The CNT embedded structure in the vertically aligned membrane improves mechanical strength along the in-plane direction. This work presents CNT additives can significantly improve the mechanical properties of water desalination membranes by smartly designing the morphology of the substrate and properly inserting functional materials in the active layer.

F.NM03.09.61
Isopropanol-Assisted Hot Lamination for Facile Synthesis of Large-Area Atomically Thin Graphene Membranes Peifu Cheng[1], Nicole K. Moehring[1], Andrew Naclerio[1], Mattigan Kelly[1], Dahsong Lee[1], Juan C. Idrobo[2] and Piran Ravichandran Kidambi[1]; [1]Vanderbilt University, United States; [2]Oak Ridge National Laboratory, United States

Atomically thin graphene membrane has been considered as an ideal candidate for next-generation membrane-based technologies. While catalytic chemical vapor deposition (CVD) has been demonstrated to be an economical and versatile way of enabling the commercial production of high-quality graphene, CVD graphene has to be transferred from the growth substrate onto a porous support substrate to provide mechanical stability for membrane applications. However, commonly used polymer scaffold methods typically leave polymer residues detrimental to membrane performance, while transfers without sacrificial polymers suffer from low transfer yield leading to high membrane leakage. Hence, high-yield transfer of clean large-area graphene onto appropriately porous supports using scalable processes for membrane applications remains elusive. In this work, we systematically investigate the factors influencing the transfer of CVD graphene from a Cu foil onto a model polycarbonate track etch (PCTE) support for fabricating large-area atomically thin membranes via manual compression, mechanical press and scalable lamination approaches. Particularly, we report on a novel roll-to-roll manufacturing compatible isopropanol-assisted hot lamination that allows for facile, clean and scalable transfer of centimeter-scale graphene onto model PCTE supports with coverage ≥ 99.2% without compromising support porosity, which is one of the best values reported to this date for centimeter-scale atomically thin membranes. The remaining 0.8% of leakage is attributed to defects (>50 nm) primarily along wrinkles formed during CVD growth. Furthermore, water-assisted oxidation effectively detaches CVD graphene from the Cu foil and helps graphene transfer, but significantly damages (~10%) graphene along wrinkles. Finally, fully functional centimeter-scale atomically thin membranes are demonstrated. Our work provides a facile and effective method for the fabrication of atomically thin graphene membranes and can help on the progress towards the practical application of graphene membrane technologies relevant to gas separation, nanofiltration, desalination, ionic/molecular transport, energy and biomedical fields and beyond.

F.NM03.09.63
Effect of Orientation of Graphene Upon Dielectric and Electrical Characteristics of PBAT-PLA-Graphene Composites Radha Perumal Ramasamy[1], Xianghao Zuo[2], Yiwei Fang[2] and Miriam H. Rafailovich[2]; [1]Anna University, India; [2]Stony Brook University, United States

Graphene has several fascinating characteristics such as high thermal and electrical conductivity. Graphene polymer composites is usually made using molding. To enhance the application of graphene in nanocomposites controlling its alignment is important as graphene has different conductivity along and perpendicular to its surface. The orientation of graphene in polymeric materials is a challenging task. Recently 3D printing has been used for aligning graphene in composites. In this research varying amounts of graphene (grade H5 – XG Sciences) was mixed with PBAT-PLA mixture and molded. Also 3D printed PBAT-PLA-graphene composites were made. The dielectric measurements were made by

placing the composites between two brass electrodes of diameter 1cm. The dielectric measurements were made using Wayne-kerr- 6500p LCR meter. The frequency was varied from 100 to 10^6 Hz. The measurements were made at room temperature (22 °C). The samples had cuboid shapes. The measurements were made along height and depth of the samples. The height corresponded to the direction of application of pressure during molding and the depth corresponded to the direction perpendicular to the direction of application of pressure and parallel the surface of the samples. The following observations were made. (A) The dielectric constant for 3D printed samples (along height) was less than dielectric constant for 3D printed samples (along depth) which was less than dielectric constant for molded samples (along height). (B) The dielectric constant for molded samples (along depth) was less than dielectric constant for molded samples (along height). (C) Along depth, for molded samples the dielectric constant becomes negative for 20% graphene containing samples indicating percolation. (D) The electrical conductivity for 3D printed samples (along height) was less than conductivity for molded samples (along height) and (E) Electrical conductivity for 3D printed samples (along depth) was less than electrical conductivity for molded samples (along depth). The observed variations in dielectric and electrical characteristics are attributed to the orientation of graphene in the composites.

F.NM03.08.66
Why Aren't Nano Carbon Based Composites Rise Up to Their Theoretical Potential and How Can We Get Them Closer? Noa Lachman; Tel Aviv University, Israel

Carbon Nanotubes (CNT) and graphene are considered highly promising nanomaterials for composite reinforcement. The nanoscale dimensions of the carbon structures provide ultra-high surface-to-volume ratio, nearly defect-free structure, and their exceptional properties: mechanical (1TPa – five times the value for steel), thermal conductivity (2000-6000 Wm-1K-1 – four to ten times the value for silver) and electrical conductivity (roughly equivalent to copper) makes them highly useful in very many applications. However, these same scale and properties complicate the processing and fabrication of polymer based nanocomposites: high surface-to-volume means that even in small filler concentrations composite process-affecting properties as melt viscosity, heat transfer and other characteristics will drastically change. Morphology control, and thus post-processing behavior prediction, are also challenging – as dispersion and orientation are applied indirectly in the process, and different mechanisms are dominant at different length-scales. Therefore, transferring the exquisite properties of the CNT and graphene to the composite level have been proven less than ideal, as the measured mechanical, electrical and thermal properties of the nanocomposites are usually lower than predicted by rule-of-mixture calculations.
In this talk, various approaches for carbon nanocomposite fabrications, both “top-down” and “bottom-up”, will be presented in case-studies. A few of the major issues inhibiting nanocarbon based composites from achieving their true potential will be highlighted. Effects of different fabrication techniques, including 3D printing, on the morphology of nanocomposites and the resultant behavior will be discussed, and possible solutions to the aforementioned issues will be presented. The new methods can provide better control for improved planning and designing of nano carbon based composites.

Flexible Devices Based on Poliurethane and Reduced Graphene Oxide Composites for Applications in Tactile Sensing Flavio A. Borges[1], Monica A. Cotta[1], Cecília d. Silva[2], Talita Mazon[3], Joao H. Clerici[1] and Daniel M. Ugarte[1]; [1]University of Campinas, Brazil; [2]MackGraphe – Graphene and Nanomaterials Research Center, Brazil; [3]Institute of Information Technology Renato Archer, Brazil

New opportunities have been created along with the advances of the wearable device technology. For pressure sensing and transduction in soft objects like human skin, direct contact between sensor and target area is necessary; therefore, sensor flexibility is a very important parameter for the viability of the sensing device.
In this work, we report on the development of a sensing system that translates the electric signals of low cost composites based on polyurethane (PU) and reduced graphene oxide (r-GO) fabricated in-house. The graphene oxide (GO) is deposited by dispersion in PU foam. The GO reduction is carried out by immersion in ascorbic acid. Different commercial foams were tested and sample heights could be reduced to 1mm with electrical resistance range of 1-100 kΩ for a 90% compression. Electrical resistances were measured in function of the applied force and an exponential character was identified. With the force range which the foams endure and the calibration curve obtained for the samples, a rigid device was developed by integrating an Arduino system to the sensors so that responses could be obtained via a graphical interface, adapted to visual feedback.
The foam shows great conformity with surfaces; flexible contacts, printed in Kapton film using conductive paint, are used to obtain the flexible device. We thus expect to have a flexible sensor integrated to a functioning system fully prepared to neurological rehabilitation applications.

Transition Metal Chalcogenide Nanostructures for High Energy Density Supercapacitors Harish Singh and Manashi Nath; Missouri University of Science and Technology, United States

Electrochemical capacitors (ECs) or supercapacitors (SCs) are considered to be most promising energy storage devices and have received great attention because of their excellent electrochemical performance with high output power, short discharging time and long-term cycle stability. Transition metal chalcogenides (especially selenides and tellurides) have recently attracted considerable attention for electrochemical applications mainly due to better electronic conductivity, facile charge transfer, redox tunability, and chemical stability. In the current project, transition metal telluride-based nanostructure composites were studied for supercapacitor applications. The nickel telluride nanostructures were grown directly on Nickel foam by hydrothermal method as well as electrodeposition process without addition of any binder to the catalyst. The capacitor performance was measured in a three-electrode system with the nickel-telluride electrode as the anode. A specific capacitance of 1826 F/g was achieved at a current density of 1 A/g. The composite electrode maintained cyclic stability of more than 90 % at a higher current density of 10 A/g after 1000 cycles. Also, more than 80 % current density retention achieved at higher current density of 20 A/g. Moreover, doping effect on the transition metal site on the supercapacitor performance was also illustrated in this work. Doping in the transition metal site had a positive influence on the supercapacitor activity since, it led to lattice distortion, electronic structure modification as well as helped to tune the surface redox behavior. Also, combining different carbon-based materials (carbon nanotubes, activated carbons and graphene) with the active nickel telluride nanostructures enhanced specific capacitance and overall cyclic stability by increasing the active surface area and porosity of the composite. In this presentation we will discuss the supercapacitor performance of these telluride nanostructures as well as the effect of transition metal doping and carbon nanostructure additives, and explain how the chemistry of transition metal chalcogenides influences their electrochemical functionality and potential as future energy storage devices.

Nanopores in Multilayer Hexagonal Boron Nitride Mehmet Dogan[1,2], S. Matt Gilbert[1,2,3], Thang Pham[1,2,3], Brian Shevitski[1,2,3], Peter Ercius[2], Shaul Aloni[2], Alex Zettl[1,2,3] and Marvin L. Cohen[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Kavli Energy NanoScience Institute, United States

Controlling the size and shape of nanopores in two-dimensional materials is a key challenge in applications such as DNA sequencing, sieving, and quantum emission in artificial atoms. In single-layer hexagonal boron nitride (*h*-BN), under a high-energy electron beam with certain properties, triangular pores are formed whose edges are entirely made up of nitrogen atoms. This allows fabrication of triangular pores at will with matching orientation throughout the two-dimensional material. However, in multilayer *h*-BN, which is usually in the AA′ stacking, neighboring sheets are rotated by 60° with respect to each other, which causes triangular pores in consecutive layers to be misaligned. Here, we investigate experimentally and theoretically triangular vacancies in (unconventional) Bernal-stacked *h*-BN (AB-*h*-BN) formed using a high-energy electron beam. Due to the geometric configuration of AB-*h*-BN, triangular pores in different layers are aligned, and their sizes are controlled by the duration of the electron irradiation. Interlayer covalent bonding at the edge of the pore is not favored, as opposed to what occurs in the more common AA′-stacked BN. A variety of monolayer, concentric and bilayer pores in bilayer AB-*h*-BN are observed in high-resolution transmission electron microscopy and characterized using *ab initio* simulations. Bilayer pores in AB-*h*-BN are commonly formed, and grow without breaking the bilayer character. Nanopores in AB-*h*-BN exhibit a wide range of electronic properties, ranging from half-metallic to non-magnetic and magnetic semiconducting. Therefore, because of the controllability of the pore size, the electronic structure is also highly controllable in these systems, and can potentially be tuned for particular applications.

F.NM03.09.72
Enhanced Mechanical Properties of Polymer-Matrix Nanocomposites Reinforced with Graphene Synthesized in

Atmospheric Plasmas Albert Dato, Jacob Knego, Nicole Subler, Taylor Sloop, Chance Bisquera and Kevin Nakahara; Harvey Mudd College, United States

Graphene can be synthesized in the gas phase using atmospheric plasmas. Gas-phase-synthesized graphene (GSG) is pure and highly ordered. Additionally, GSG contains graphitic nanocrystals that provide the two-dimensional material with significant mechanical stability and enable GSG sheets to resist deformation. GSG is also more environmentally friendly to produce than graphene that is obtained from graphite. These unique features make GSG a promising filler material for fabricating high-strength multifunctional nanocomposites that have a wide range of applications, such as automobiles, aircraft, and wind turbines.

Here we present the results of an investigation into epoxy-matrix nanocomposites reinforced with GSG. We show that as-synthesized GSG effectively disperses in epoxy resins and resists aggregation indefinitely. We report that incorporating a relatively low loading of GSG into epoxy (0.1 wt%) results in nanocomposites that exhibit significant increases in both strength and strain at break. In contrast, epoxy-matrix nanocomposites that were filled with 0.1 wt% graphene nanoplatelets had enhanced strength but diminished strain at break. Scanning electron microscopy images of nanocomposite fracture surfaces will be presented, which indicate much higher matrix reinforcement by GSG relative to graphene nanoplatelets. These results indicate that (1) GSG could overcome the challenges of contemporary graphene-based nanocomposites and (2) unique strengthening mechanisms exist in polymers reinforced with GSG.

F.NM03.09.73
Metal-Free, Highly Conductive Protein Carbon Nanotube Dispersions and Their Films for Biological Applications Ankarao Kalluri and Vijaya Kumar Challa; University of Connecticut, United States

A simple and facile method to produce highly concentrated (> 5 mg/ml) and high-quality multi-walled carbon nanotube (MWCNT) dispersions by ordinary benchtop magnetic stirrer is reported here. Exfoliation and debundling of the MWCNTs were possible by stirring in the presence of a protein, driving the adsorption of the protein onto the nanotube surfaces. High concentrations of the debundled nanotubes were obtained (6 mg/ml) after stirring for 5 days, and these are much higher than other reports in the literature. The bioCNT aqueous dispersions are stable up to 6 months, which is important for storage and practical applications. We also fabricated the facile, inexpensive, highly conductive and flexible CNT paper (Bucky paper) by vacuum filtration of the dispersion through an ordinary filter, which composed of self-assembled, randomly oriented, and highly packed CNTs. These metal-free CNT films were flexible and showed a high electrical conductivity of > 1000 S/cm than expected. These biological CNT dispersions used as conductive ink on cellulose paper, which can be used in printed and flexible electronics, bio-electrochemical sensors, bio-supercapacitor electrode applications. Therefore, inexpensive, highly concentrated biological CNT dispersions prepared by a simple method of stirring provides new opportunities for a wider range of CNT applications.

F.NM03.09.74
Sub-Nanometer Carbon-Nanotube Membranes with Anomalously Enhanced Water-Vapor Flux Da-Chi Yang[1], Richard Castellano[1], Melinda Jue[2], Ricardo P. Silvy[3], Robert F. Praino[3], Francesco Fornasiero[2] and Jerry Shan[1]; [1]Rutgers, The State University of New Jersey, United States; [2]Lawrence Livermore National Laboratory, United States; [3]Chasm Advanced Materials, Inc., United States

Fluid transport through the inner cores of carbon nanotubes (CNTs) is known to occur at extraordinary rates, exceeding classical predictions by several orders of magnitude, especially for very-small-diameter nanotubes. However, macroscopic, vertically aligned- (VA-) CNT membranes with sub-nanometer pores have not been previously fabricated due to the difficulty in growing aligned forests of such small CNTs. Here, we report the scalable, solution-based fabrication of the first macroscopic membranes with VA-CNTs of sub-nanometer diameter, and the first water-vapor transport measurements for such membranes. Membranes were fabricated from CNT powder using electric-field alignment and electrophoretic concentration of suspended nanotubes, followed by solvent replacement with a liquid prepolymer and UV curing. The single-wall nanotubes are grown in bulk by chemical-vapor deposition with a specialized catalyst, tuned to produce long, 0.8 nm diameter CNTs. After etching to open CNT pores, the membranes filter out dye solution and demonstrate sublinear conductance scaling with salt concentration at low concentrations. These observations indicate that our fabrication process produces defect-free membranes with CNT pores as the primary trans-membrane pathway. Based on KCl-conductance estimates for the total open pore area in the membranes, the concentration-driven water-vapor permeability is enhanced by many orders of magnitude, well above values reported in literature for larger-diameter VA-CNT membranes. Interestingly, the enhancement in concentration-driven water-vapor transport appears to considerably exceed the enhancement present in the pressure-driven flux of dry nitrogen gas in the pores. Additionally, due to the size of the CNT pores, and the charge

present on carboxyl groups at the CNT tips, the membranes demonstrate cation selectivity in KCl solution. Coupled with the enhanced flux of liquid water, such membranes could increase the energy efficiency of membrane-based desalination techniques. These findings present new opportunities to scalably fabricate VA-CNT membranes with sub-nanometer pores and study their fundamental transport properties, with possible applications in breathable and protective garments as well as desalination technologies.

F.NM03.09.75
Growth Pressure Dependence of Graphene Direct Growth on A-Plane Sapphire Using Metal-Catalyst-Free Low-Pressure CVD Yuki Ueda, Takahiro Maruyama and Shigeya Naritsuka; Meijo University, Japan

Graphene direct growth on sapphire by metal-catalyst-free chemical vapor deposition (CVD) has attracted much attention as the method to avoid the transfer process [1]. The transfer process not only damages but also deteriorates the graphene. Recently, we reported a graphene direct growth on r-plane sapphire using metal-catalyst-free low-pressure CVD where the graphene grows very fast and quite uniformly comparing to that on c-plane sapphire [2]. However, there are many unknown parts in the growth mechanism. In this report, we focused on a-plane sapphire as a substrate, which is often used in horizontally-aligned growth of carbon nanotubes [3]. The growth pressure was systematically changed in metal-catalyst-free low-pressure CVD to reveal the growth mechanism.
Graphene was directly grown on a-plane sapphire using low-pressure CVD without using a metal catalyst. A mixture gas of N_2, H_2, and 3-Hexyne was flown in a reaction chamber at a constant flow rate of 1000 sccm. The growth temperature, H_2, and 3-Hexyne partial pressures were fixed at 1250 ^{o}C, 500 Pa, and 0.3 Pa while the growth pressure was systematically changed from 5 kPa to 50 kPa.
Raman measurements show that graphene was only grown below 17 kPa and all the grown graphene was smooth and uniform with mono-layer-thick. At the same time, the D/G ratio decreased with decreasing the growth pressure. To investigate the reason, the early stages of growth were studied between 5 kPa and 15 kPa. Consequently, AFM study showed that the density of graphene islands on the sample grown at 5 kPa was approximately 3 times lower than that of the sample grown at 15 kPa. On the contrary, the growth rate of graphene at 5 kPa was much faster than that at 15 kPa. A high growth rate usually means a high supersaturation, and, therefore, a high nucleation rate. In our case, however, the nucleation rate was slow at low growth pressure. This inconsistency suggests the existence of a special mechanism, which controls the nucleation. From the AFM study, the most graphene islands were found at the step edges of the sapphire substrate. At a low growth pressure, the thermal decomposition of the sapphire surface is enhanced and nucleation sites, in other words, surface steps are destroyed at the same time. This brings the difficulty to the graphene nucleation at the step edges even with a higher supersaturation at a low pressure. Consequently, excellent smooth monolayer graphene with a small D/G ratio of less than 0.2 was successfully obtained on a-plane sapphire at 5 kPa with forming larger grains.

Partially Reduced Graphene Oxide Enhancement of Thrombin Activation of Fibrinogen Clots Rebecca Isseroff[1], Juyi Li[1], Jonathan Lederer[2], Nava Schein[1], Abraham Balsam[1] and Miriam H. Rafailovich[1]; [1]Stony Brook University, The State University of New York, United States; [2]Columbia University, United States

Partially reduced graphene oxide (pRGO) has been found to enhance the enzymatic activity of microbial transglutaminase on the cross-linking of gelatin. To determine if this is a more general phenomenon in modification of enzymatic activity, we tested whether it has an effect on thrombin's ability to clot fibrinogen, an easily quantifiable effect to measure.

Three ml of 10 mg/ml fibrinogen solution in PBS were tested with 8 μ thrombin/ml as a control. Upon adding thrombin, rheometry was used to measure the clotting time as well as the clot modulus. Sharp increases in modulus, shorter clotting times, and stronger clots would indicate enhancement of thrombin, whereas slow increases in modulus, longer clotting time, and weaker clots would indicate inhibition of the enzyme. Test samples included 0.5 ml of 1 mg GO/ml PBS in the fibrinogen mixture, and 0.5 ml of 1 mg pRGO/ml PBS added to the fibrinogen. The pRGO solution produced a clot with an elastic modulus four times greater than the control, and 1.5 times greater than the clot with GO. Different concentrations of

pRGO in PBS were then added to fibrinogen solutions and tested. Increasing pRGO concentrations increased the maximum elastic modulus and decreased the clotting time. The elastic moduli were found to be logarithmic, as the logarithmic trendlines had relatively high R^2 values. Higher concentrations of pRGO had higher coefficients, indicating shorter clotting times. Results suggest further future study of partially reduced graphene oxide as a modifier of enzymatic activity.

F.NM03.09.77
Interactions Between Graphene Oxide and Pyrrole Towards Understanding the Electro-Polymerized Substrates—A Molecular Dynamics Study Todd M. Richards and Isaac Macwan; Fairfield University, United States

Graphene Oxide, an oxidized form of graphene, a carbon allotrope, has many applications including the formation of conductive films for use in flexible electronics and chemical sensors, nanofiltration membranes, and even as a replacement for tin-oxide in batteries. One of the pressing issues with carbon allotropes in general and graphene oxide in particular, however, is that they cannot form freestanding films on their own, instead they rely on a secondary reactant to help aid in the synthesis of such films. To synthesize such nanocomposite substrates, cyclic voltammetry is a very commonly used technique, where an electrolyte containing a monomer to be electro – polymerized is used along with the nanoparticles. Electro-polymerized substrates consisting of GO and Polypyrrole (Ppy), an organic polymer created by polymerizing pyrrole, have drawn much attention owing to their applications in solid state supercapacitors, biosensing, tissue engineering, and artificial muscle studies. It has been proven theoretically and experimentally that Ppy and GO do interact and exhibit improvement in conductivity and thermal stability compared to pure Ppy and GO, but there is still very little information on the interactions at the molecular level between GO and pyrrole monomers especially during the synthesis of such nanocomposites. This work deals with the study of interactions at the interface of GO and pyrrole in order to better understand the evolution of polypyrrole over the surface of graphene oxide during the formation of these films. The system is modeled using Visual Molecular Dynamics (VMD) and all – atom simulations are carried out using Nanoscale Molecular Dynamics (NAMD) at ten different temperatures based on the peak currents and scan – rate through the Randles – Sevcik equation. Each simulation is carried out for 100ns, thereby looking into a total of one microsecond long window of interactions between GO and 50 pyrrole monomers as the polypyrrole film is evolved over the surface of GO. Stability of the GO/ Ppy nanocomposite is quantified through RMSD (Root Mean Square Deviation), conformational energies and center of mass deviations. Interaction energies are calculated to understand the role of non – bonding interactions such as Van der Waals and electrostatics between the monomers and between monomers and GO. It is anticipated that pyrrole monomers form dimers in the bulk of the solution, trimers when near the surface of GO, and tetramers when adsorbed on the surface of the GO. Based on these results, a potential mechanism is proposed on the way monomers interact with the nanoparticles during electro – polymerization and the role of such interactions in synthesizing carbon – based free – standing films.

Development of Planar-Type Thermoelectric Device Using Carbon Nanotube Sheet for Wearable Application Tsuyohiko Fujigaya[1,2,3], Ryohei Yamaguchi[1] and Naoki Tanaka[1]; [1]Kyushu University, Japan; [2]Center for Molecular System, Kyushu University, Japan; [3]International Institute for Carbon-Neutral Energy Research, Kyushu University, Japan

Single-walled carbon nanotube (SWNT) is ideal materials for thermoelectric conversion because of their high Seebeck coefficient and electrical conductivity. Development of the wearable thermoelectric device using SWNTs is now investigated by taking advantage of their film toughness and flexibility. Up to date, π-shape structure has been proposed for the SWNT thermoelectric sheet. However, this structure needs to attach on a skin vertically and not preferable for the wearable application. Therefore, we proposed a new planar-type structure, in which the sheet can attach on the skin surface and preferable as a wearable device. Since sequential repeating of p-type and n-type properties are necessary for the devices, in this study, we investigated the patterned doping of p-type SWNT sheet into n-type. We found that the deposition of benzimidazole derivatives successfully turned un-masked area into n-type, giving a repeating of p and n-type structure. Detail characterization of the n-doping were carried out by Raman spectroscopy, X-ray photoelectron spectroscopy and Seebeck Coefficient measurements. Devise performance of the thermoelectric sheet will be introduced in the presentation.

Fabrication and Characterization of $PbTiO_3$ Multi-Layered Truss Structure Hyunji Kim, Kisun Kim, Hoon Kim, Seokjung Yun, Gun Park, Seokwoo Jeon and Seungbum Hong; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Future society will enjoy augmented reality, haptic displays, intelligent cars, and robots in everyday life. Those devices

require tactile enhancement which would be improved by high piezoelectric coefficient and strain limit. $PbTiO_3$ is one of the piezoelectric materials which has high piezoelectric coefficient, low price and wide application but at the expense of low elastic strain limit. In this work, we applied nanoscale truss structure to enhance the elastic stress limit while maintaining the high piezoelectric coefficient of $PbTiO_3$. Fabricating $PbTiO_3$ in multi-layered truss structure around 20~30 nm, we expect to improve both piezoelectric coefficient and strain limit up to 300% respectively. We deposited 8 nm $PbTiO_3$ layer 3 times on the Nickel template and after deposition of multilayers, Nickel template was removed. Each layer of $PbTiO_3$ was formed by depositing TiO_2 using atomic layered deposition (ALD) and PbO gas reaction in the tube furnace. The crystallinity of each $PbTiO_3$ layer was confirmed by XRD. We expect multi-layered $PbTiO_3$ to show 100% higher piezoelectric coefficient than single-layered $PbTiO_3$ showing better crystallinity. [1] After measuring the crystallinity, thickness was measured by TEM. By measuring the deposition thickness according to the distance, we will set thickness of single-layered $PbTiO_3$ to 8 nm. This will be a significant experiment in that it stacks nano layers of targeted thickness. Also, our approach will provide insight into making piezoelectric materials that have both high piezoelectric coefficient and strain limit, and realize various tactile applications.

Layer-by-Layer Self-Assembly PEI/MWCNT-COOH Nano-Porous Coating for Enhanced Heat Transfer Characteristics of Heat Dissipation Devices Jaemin Lee, Daehyeon Kyeong, Ji heon Kim and Wonjoon Choi; Korea University, Korea (the Republic of)

With the development of AI, 5G, and autonomous vehicles, higher performance electronic devices are required for more data collection and data processing. In addition, as electronic devices are gradually downsized and thinned, the amount of heat generated per unit area also increases exponentially, so conventional heat dissipation devices (e.g. Heat sink, Heat pipe and Vapor chamber) cannot satisfy these heat generation and electronic device manufacturing conditions. In order to improve the performance of these heat dissipating devices, many studies have improved heat transfer performance through various coating methods such as CVD, PVD, ALD and Spray coating. However, these coating methods are not suitable for heat sinks with complex shapes or heat pipes with a thin tube structure because they require special process conditions such as high temperature or vacuum, and the process cost is large or greatly affected by the shape and size of substrate.

The Layer-by-Layer (LbL) coating method is a solution-based technique which is a self-assembled coating using electrostatic force through the difference in zeta potential between positive and negative solution. Since the LbL coating method is based on a solution-based processing, it can be coated to the complex structures regardless of the size or shape of the substrate. This characteristic enables the direct applications to a heat sink within fin structures or a tubular heat pipe within an inner micro porous structure.

Herein, we present multi-functional LbL PEI/MWCNT-COOH nano-porous coatings based on a solution processing to improve the heat transfer characteristics of heat sinks and heat pipes. To investigate the direct correlation of the nano-porous coatings and the heat transfer characteristics, the LbL PEI/MWCNT coatings were prepared as bare, 10-bi, 20-bi, and 30-bi layers. The change in thickness and surface morphologies of LbL coatings was precisely analyzed through FIB and SEM image analysis, while the surface area and pore size distribution according to the number of LbL coatings was examined using BET surface area analysis. Furthermore, the wettability of the PEI/MWCNT coating was measured to confirm the capillary rise, which is one of the important factors to determine the heat transfer performances of the devices.

Through the natural convection test of the LbL coated heat sinks, it was confirmed that the enhanced thermal performances could be obtained due to increasing the porosity and surface area of the LbL coating. As the porosity and surface area was optimized in the number of coatings, the overall thermal performances including heat transfer coefficients were significantly improved up to 11% for 30 bi-layers coated heat sink due to the increase in the surface area, in comparison with that of the bare heat sink. Furthermore, the LbL functional coating layers could highly improve the heat transfer characteristics of the heat pipes, as well. Because a nano-micro sized bi-porous structure appeared in the microporous-sintered heat pipe with the LbL coating layers, such bi-porous structure could strengthen capillary wicking, fluid transportation, and superhydrophilicity as well as increasing surface area, thereby improving heat transfer efficiency and thermal resistance up to 14.3% in a 10 bi-layers coated heat pipe.

The PEI/MWCNT LbL nano-porous coating, which was used for the heat dissipation devices (i.e. heat sink and heat pipe) could show the enhanced heat transfer characteristics, while the fabricate process was based on the only simple and low-cost

LbL coating technology. This multi-functional and thin PEI/MWCNT LbL nano-porous coating not only improved the performance of the conventional heat dissipation device, but also is expected the design trend of miniaturization, thinning, and lightweight electronic equipment.

Dielectrophoresis (DEP)-Aligned Semiconducting Carbon Nanotubes for Fabricating Electronic Devices Abram Jones, Lauren Williams, Brandon Whitaker, Rodricka Miller, Jhamaree Elam, Qunying Yuan and Zhigang Xiao; Alabama A&M University, United States

We report the deposition and alignment of semiconducting carbon nanotubes with the alternating electric field-directed dielectrophoresis (DEP) method and the fabrication of carbon nanotube-based electronic devices with the DEP-aligned semiconducting carbon nanotubes (CNTs). Semiconducting carbon nanotubes, which were dispersed ultrasonically in the n-methyl pyrrolidone (NMP) solution, were deposited and aligned onto a pair of gold electrodes using the dielectrophoresis method. The excellent alignment of carbon nanotubes was achieved by optimizing the AC voltage, frequency, and deposition time of the applied AC signal. The DEP-aligned tubes were further fabricated into carbon nanotube field-transistors (CNTFETs) and CNTFET-based electronic devices such as CNT-based inverters using the microfabrication techniques. Plasma-enhanced atomic layer deposition (PE-ALD) was used to grow hafnium dioxide ($HfO_{2)}$ as the high-k gate oxide in the fabrication of CNTFETs. The aligned carbon nanotubes and fabricated devices were imaged using the scanning electron microscope (SEM), and the electrical properties were measured from the fabricated devices using the semiconductor analyzer. About 70% yield was obtained from the semiconducting carbon nanotube-based CNTFETs, and the fabricated CNTFETs and CNT-based inverters demonstrated excellent current (I) – voltage (V) curves and transfer characteristics.

F.NM03.09.82
Inertial Sensor Based on Energy Harvesting Carbon Nanotube Yarn Ji Hwan Moon and Seon Jeong Kim; Hanyang University, Korea (the Republic of)

Inertial sensors are devices that can monitor inertial movements like linear acceleration and angular motions, in various applications such as industrial and human monitoring. For wearable and portable applications, inertial sensors are better to be self-powered and miniaturized. Here, we developed a self-powered inertial sensor with various applications having high accuracy based on carbon nanotube (CNT) yarn. Our inertial sensor can sense and monitor inertial movements without any external power by harvesting the mechanical energy to electric energy by the coiled CNT yarn. For applications, the sensor can monitor practical kinds of inertial movements, such as impact energy, vibrations, tilting, and body motions such as walking, running, jump and squatting motions. These results suggest that the self-powered inertial sensor shows the advantages of portable and wearable application in industrial and human motion monitoring system.

Formation of Nanosheets via Unfurling of Vanadate Nanoscrolls from Bulk Vanadium Oxide Md Shahidul Islam Khan[1] and John B. Wiley[1,2]; [1]The University of New Orleans, United States; [2]Advanced Materials Research Institute, United States

Vanadium oxide materials are renowned for their catalytic properties, super-capacitance, chemical sensing, and high energy density cathodic properties. A two-step synthesis method was applied to obtain 2D structures of vanadium oxide (V_2O_5) or vanadate ($V_{2-x}O_{5-x}$) nanosheets from bulk V_2O_5 where the first step involved the formation of vanadate nanoscrolls, 1D structures, that resulted from the dissociation of layered vanadium oxide. In the second step, the nanoscrolls were unfurled to obtain nanosheets, 2D materials. This latter step can be performed using a wet chemical process or annealing treatment. During the wet chemical process, vanadate nanoscrolls turn into thin-layered vanadate nanosheets, and with the annealing process, thin-layered vanadium oxide nanosheets are produced. The formation of these different types of nanosheets was confirmed by X-ray diffraction. Nanosheets obtained from the wet process showed the presence of organic groups that were detected using FTIR and Raman spectroscopy. Both the vanadate and vanadium oxide nanosheets were single or multilayered but only the latter one possesses irregular hexagonal shape which was confirmed through TEM.

Self-Assembly of Tetra-Peptides on Surfaces of Two-Dimensional Materials Wei Luo, CHEN CHEN and Yuhei Hayamizu; Tokyo Institute of Technology, Japan

As the novel “bottom-up” strategy for fabricating nanomaterials, molecular self-assembly has attracted considerable attention worldwide. On one hand, two-dimensional (2D) materials such as graphite and molybdenum disulfide (MoS_2) have been demonstrated as the platform for this self-assembly due to their unique electrical, optical properties, and atomically flat surfaces, etc. [1,2]. On the other hand, amphiphilic peptides with both of the hydrophobic and hydrophilic nature also have already been used as ideal building blocks for forming various sophisticated self-assembling materials with certain applications. Therefore, in order to functionalize the 2D material surface by peptides self-assembly, it is necessary for a deliberate understanding of the interaction between biomolecules and 2D substrate materials [3].
Molecular dynamics (MD) simulation provides insight into the molecular-scale structure detail of interface. Several works have been done on solid surface to understand the role of peptides, like on Au (111) for self-assembly [4] or on calcite for biomineralization [5]. More recently, peptides on graphene [6] or MoS_2 [7] have been studied because of the atomically flat surface and some progress in experiments exhibiting the molecular resolution morphology. From these, aromatic amino and charged amino acids are considered to have a meaningful interaction with those surfaces. Although the peptide-peptide interaction is also important for surface self-assembly of peptides, the understanding for both interpeptides and peptide-surface interactions are still limited.
In this work, we aim to utilize computational approaches to understand the molecular mechanism. For this purpose, we started with a tetrapeptide consisting of aromatic and charged amino acids, where these amino acids may play a role for the self-assembly. We performed the molecular dynamics simulation (MD) starting with single tetrapeptide on graphene surface. From this calculation, we obtained the most stable tetrapeptide structure on graphene surface. Analyses of center-of-mass distance between peptide and graphene surface, angle change of aromatic rings, and free energy distribution revealed that the balance between interpeptide and peptide-surface is a key to have a well assembled peptides on surface. Furthermore, information about binding process for tetrapeptide on 2D surface was also obtained. This work can be a foundation for building a conformation-property relation of amphiphilic tetrapeptide self-assembly on 2D material surfaces.

Formation of Various Cross-Linked Gel Layer Around Single-Walled Carbon Nanotubes Tsuyohiko Fujigaya[1,2,3] and Yukiko Nagai[1]; [1]Kyushu University, Japan; [2]Center for Molecular System, Kyushu University, Japan; [3]International Institute for Carbon-Neutral Energy Research, Kyushu University, Japan

Single-walled carbon nanotubes (SWNTs) have unique near-infrared (NIR) absorption and NIR photoemission that are attractive for in vivo biological applications such as photothermal cancer treatment and imaging. Therefore, a smart functionalization strategy for SWNTs to create biocompatible surfaces and introduce various ligands to target cancer cells without losing their unique optical properties of the SWNTs is strongly required. We developed novel coating technique of SWNTs inspired by emulsion polymerization method, in which the micelle dispersion of SWNT was used for free radical polymerization. In the dispersion, polymerization takes place in the surfactant micelle having SWNT in the core. Thus the SWNTs were coated by polymer layer. When the cross-linker was added, the SWNTs were coated by gel layer, offering the highly stable coating of SWNT
We have revealed the requirement for the formation of the thin cross-linked polymer-wrapped SWNTs, in which the use of monomers that can undergo polymerization inside the micelles was important. In our study, such hybrids were formed when using various monomers in aqueous SDS dispersions of the SWNTs in the presence of APS and BIS as the initiator and cross-linker, respectively in high yeild (>75%) except acryl amide and hydroxymethyl methacrylate. The present study provides useful insight into preparing many polymer-SWNT hybrids with designed functions due to the wide availability of the monomers.

Investigation of Electrocharging-Assisted Fabrication Parameters for Nanocarbon-Al Composites with Improved Electrical Conductivity and Tensile Strength Madeline Morales[1,2], Xiaoxiao Ge[1], Christopher Klingshirn[1], Christopher Shumeyko[2], Daniel P. Cole[3] and Lourdes G. Salamanca-Riba[1]; [1]University of Maryland, United States; [2]US CCDC Army Research Laboratory, Vehicle Technology Directorate, United States; [3]US CCDC Army Research Laboratory, Army

Research Office, United States

Nanocarbon-metal composites are sought after for their excellent mechanical, electrical and thermal properties. Electrocharging-assisted processing of a novel class of materials, called “covetics,” presents a practical option for macroscale production of nanocarbon-metal composites. This process incorporates carbon on the order of several weight percent in metals such as Al and Cu where carbon solubility is in the low ppm range. Increased tensile strength and electrical conductivity have been measured in Al covetics; however, there is limited understanding of the electrocharging-assisted process and subsequently high variability in measured properties among trials. It has been found that under the influence of a high direct current applied to the molten metal, the activated carbon precursor is converted to sp^2 graphitic carbon with increased crystallite size, as measured by the Tuinstra-Koenig relation for Raman spectra. Electrical conductivity is also enhanced in areas that show increased graphitic carbon crystallite size. A series of experiments varying applied current have been carried out to understand the effect of current density on carbon crystallization rate and size of reaction volume within the Al-1350 melt where carbon crystallization occurs. Local electromechanical behavior is measured by nanoindentation and AFM to gain insight into the structure-property relationship at the nanoscale, which can be used to further inform optimization of the electrocharging-assisted process.

F.NM03.09.87
Direct *In Situ* Observation of Toughening and Fatigue Behavior in Alumina/Graphene Nanocomposites Qizhong Wang[1], Cristina Ramirez[2] and Nitin Padture[1]; [1]Brown University, United States; [2]Instituto de Cerámica y Vidrio, Spain

There is growing interest in using 2D graphene-related reinforcements to toughen brittle ceramics in nanocomposites. However, there is a lack of fundamental understanding of the toughening mechanisms and microstructural effects in such nanocomposites. To address this paucity, fully-dense nanocomposites of aluminum oxide (Al_2O_3) matrix and reduced graphene-oxide (rGO) reinforcements (~5 vol%) of different average-thicknesses and orientations are fabricated and characterized. The interactions between stably propagating cracks and rGO in the Al_2O_3/rGO nanocomposites are observed *in situ* inside a scanning electron microscope (SEM). Toughening by pullout of thick rGO in the crack-tip wake in the cross-section orientation is found to be the most effective, which is consistent with the highest fracture toughness (K_{IC} ~6.7 $MPa.m^{0.5}$) measured in those Al_2O_3/rGO nanocomposites. Interestingly, while achieving stable crack growth for flat punch compression of notched samples, we found that upon unloading and reloading, the intact rGO crack-bridges appear to crinkle and uncrinkle without a remnant crease, respectively, which is a unique deformation property of multi-layer graphene-like materials. Information extracted accompanied by the Raman spectroscopy studies has permitted to have a deeper understanding of the fatigue resistance mechanisms in this novel material. This is unlike conventional ceramic composites toughened by fibers or whiskers which have poor cyclic fatigue resistance due to the degradation of the crack-wake bridging and pointing to a possible new cyclic-fatigue resistance mechanism in the nanocomposites. The results from this study have implications for the creation of high-toughness, fatigue-resistant, and wear-resistant graphene-reinforced ceramic nanocomposites of the future.

F.NM03.09.89
Effects of Electrical Image Forces on Salt Dissolved in Water Jeffrey B. Sokoloff[1,2] and Andy Lau[2]; [1]Northeastern University, United States; [2]Florida Atlantic University, United States

Onsager and Samara have shown that electrical image charge forces acting on ions dissolved in water can explain the observed increase of the surface tension due to the presence of dissolved ions. Electrical image charge forces at the interface of a salt solution and air are repulsive, but at the interface between the salt solution and a dielectric of higher dielectric constant than that of the solution or a metal, in contrast, the force is attractive. It has also recently been shown that electrical image forces may play a role in the attraction of ions to the electrodes in capacitive desalination, and to play an important role in the freezing of a confined room temperature ionic liquid. Here, the effect of electrical image forces on the distribution of salt ions in a solution that is in contact with a metallic or dielectric surface is considered. It is shown that in the case of either a metallic or dielectric surface, the salt ion concentration near the surface can be very large, raising the possibility that this could result in precipitation of the salt. In fact, solidification of ionic liquids near a metallic surface with which they are in contact has been observed. Concentration of ions near a metallic surface could be used to desalinate salt water by pushing the salt water between an array of parallel plates of a conducting material. Graphene would be an excellent coating for these plates because the friction between flowing water and graphene is known to be extremely small. In order to support our prediction of a high ionic concentration near metallic and dielectric surfaces, we have performed a variational calculation of

the grand canonical partition function to lowest order in the ion density, which is the Debye-Huckel approximation. This calculation supports our conclusion. Our calculation also confirms the concentration dependence of the surface tension found by Onsager and Samarasa in the small salt concentration limit.

F.NM03.09.90

Detection of Limonene Using Graphene Field Effect Transistor Modified by Self-Assembling Peptide Chishu Homma[1], Hironaga Noguchi[1], Yoshiaki Sugizaki[2], Atsunobu Isobayashi[2] and Yuhei Hayamizu[1]; [1]Tokyo Institute of Technology, Japan; [2]Toshiba Corporation, Japan

Graphene, a representative two-dimensional material, has excellent electronic properties due to its high mobility and specific surface area. Biosensors based on graphene field-effect transistor (GFET) are expected to be applied in various fields such as medical diagnosis, environmental monitoring, and security management. A number of studies on biosensors using GFET have been carried out so far. The surface functionalization with probe molecules is crucial, which gives a high affinity to the target molecule. In this process, covalent bonding and π-π interaction have been used to immobilize probe molecules to the surface. However, there are two disadvantages with these detection methods. Firstly, chemical modifications may degrade inherent electronic properties of graphene. Secondly, random adsorption of probe molecules on the surface may result in loss of the probe activity. These lead to a decrease in sensitivity as a sensor.
So far, there have been various demonstration of GFET biosensors reported. The target of the biosensors have been living cells, virus, DNA, and proteins. There is a still challenge here to detect relatively small molecules. These small molecules have low molecular weight and generally do not have a polarization. GFET-based biosensors have a drawback for these small molecules, because the detection mechanism depends on the Coulombic interaction between trapped molecules and graphene. In addition, most of the small molecules are volatile and insoluble. Therefore, in aqueous solutions, it is very difficult to detect volatile molecules dissolved in small amounts. This is also one of the challenges for biosensors.
To solve these problems, we suggest an alternative surface modification method using peptide self-assembly. Peptides are known to recognize crystalline structures of inorganic material surfaces and form uniform structures through interactions among molecules [1]. These peptides are physically adsorbed to the surface. Thus, the surface can be modified without losing their intrinsic electronic properties. These self-assembly of peptides has been demonstrated on gold, boron nitride (BN), transition metal chalcogenides, and graphene in previous studies. The self-assembly of peptides have potential as a scaffold domain for biosensors [2]. In this study, we aimed to develop a new technique to detect an odor molecule, which is relatively small and volatile. For this sake, we utilized rationally designed peptides as a molecular scaffold [3] and probe peptides on graphene surface. Then, we performed odor sensing with limonene, a representative molecule for the smell of lemons. We successfully detected limonene with high sensitivity. We also found that the sensitivity to limonene was altered by the amino acid sequence of the probe domain.
This work was supported by the Cabinet Office (CAO), Cross-ministerial Strategic Innovation Promotion Program (SIP), “An intelligent knowledge processing infrastructure, integrating physical and virtual domains” (funding agency: NEDO).

Direct Measurements of Tensile Properties and Current-Carrying Capacity of 14 cm-Tall Few-Walled CNT Forest Tatsuhiro Hayashi[1], Takayuki Nakano[1], Hisashi Sugime[2], Suguru Noda[2,2] and Yoku Inoue[1]; [1]Shizuoka University, Japan; [2]Waseda University, Japan

We have clarified the tensile properties and electron transport capacity properties of macro-sized continuous crystal few-walled CNT forests, which have a height of 14 cm. The present CNT is the highest forest ever reported. The CNT was grown by a CVD method using a Fe-Gd catalyst on Al oxide support [1]. The crystal structures of CNT were evaluated by SEM, TEM, and Raman measurements. Then, the bundle taken out from the CNT forest was converted to a cylindrical structure to define a cross-sectional area and weight density. The cylindrical specimens were tailored by passing through a pinhole with a diameter of 30-100 μm. The reshaped CNT bundle enables to measure tensile tests and electrical measurements by the conventional methods for macroscale specimen. From tensile measurements, it was found that the nominal tensile strength and Young's modulus of the individual CNT were 0.59 GPa and 48 GPa, respectively. This nominal tensile property was obtained by using the entire cross-sectional area, including the inner hole space of the tubular structure for calculation. These results are comparable with reported values, which were measured on various types of CNT by the microscopic methods, and it is lower than theoretical values. The difference between the theoretical and the experimental results is because the present extremely long bundle includes a large number of crystal defects. Also, bundling of millions of CNTs induces further

weakening of tensile properties compared to those of micro-sized single CNTs. As for the electrical properties, conductivity and the current-carrying capacity, ampacity, were 140 S/cm and 6700 A/cm^2, respectively. These properties were improved significantly by heat treatment at 2800°C in Ar, up to 340 S/cm and 8800 A/cm^2, respectively. These results correspond to the specific conductivity of 1560 S*cm^2/g and ampacity per CNT of 5.2×10^4 A/cm^2. The ampacity of our CNT was as high as that of commercially available Cu wire (5.8×10^4 A/cm^2).

Copper Oxide Nanocrystals Catalyzed Growth of Nanospheres, Solid and Hollow Carbon Spheres in Thermally Stressed Jet A-1 Pooja Sharma Parihar; Indian Institute of Science, India

Aviation turbine fuel, Jet A-1 contains trace metals that catalyze carbonaceous nanostructures formation and their transformation to carbon spheres in the liquid phase at low temperature (190 ^{0}C) by flask tests. Thermal stressing of Jet A-1 produced nanospheres, solid and hollow carbon spheres in this work, which is consistent and continuation of a previous study [1]. Focus of the current study is to identify the trace metallic compounds that catalyze the growth of spherical nanoparticles and carbon spheres in thermally stressed Jet A-1. In the previous study [1], however, the formation of carbon spheres by self-assembly was observed, and their characterization was conducted. Heteroatoms and trace metals are precursors to the deposit formation in the thermally stressed jet fuel [2, 3]. The presence of trace metals and heteroatoms in the Jet A-1 deposits is validated by transmission electron microscopy (TEM), energy dispersive x-ray spectroscopy (EDS), scanning transmission electron microscopy (STEM) and high-angle annular dark-field (HAADF), and high-resolution transmission electron microscopic (HRTEM) micrographs. Heteroatomic species were also recorded by Fourier transform infrared (FTIR) spectroscopy. Trace metal copper oxide nanocrystals (CuO and Cu_2O) were identified by HRTEM and selected area electron diffraction (SAED) analysis. TEM EDS spectra provided the ratio of Cu and O; Cu to O ratio approximately 1:1 and 2:1. Indexing of the polycrystalline SAED pattern generated the d-values corresponding with copper oxides nanoparticles. Copper oxides nanocrystals as constituents of spherical particles were confirmed by comparing the measured d-values and calculated Miller indices (h k l) for copper oxides with i) ICSD database and, ii) simulated diffraction pattern of the Cu_2O, CuO by Crystal Maker software. Furthermore, structure elucidation of Fe and S nanocrystals is in progress and can suggest the effect of trace metal catalysts on the spherical nanoparticles, and carbon spheres formation in the thermally stressed kerosene type fuel.

Structural Analyses of Single Walled Carbon Nanotubes Obtained by Highdensity Plasma Chemical Vapor Deposition Ronaldo D. Mansano and Ana Paula M. Mansano; University of São Paolo, Brazil

Carbon nanotubes have been an important subject of many recent studies owing to their possible potential applications in nano-scale technologies. Carbon nanotubes can be described as fiber like structures consisting of concentric graphite sheets nested along their long axis and extending to several micrometers. Single-walled carbon nanotubes (SWNTs) can be either metallic or semiconductors depending on the diameter and chirality . All the synthetic methods can be roughly categorized into three groups: the carbon arc-discharge method, laser vaporization of a graphite electrode and chemical methods . In this work, carbon nanotubes were obtained by chemical vapor deposition using high-density plasma processes. Structural studies of carbon nanotubes have relied heavily on Raman spectroscopy. Raman spectroscopy is an analytical technique largely used for characterization of different carbon based materials, either graphite-like or diamond-like. The great versatility of carbon materials rises from the strong dependence of their physical properties on the ratio of sp^2 (graphite-like) to sp^3 (diamond-like bonds). Raman spectroscopy of carbon nanotubes has attracted a lot of attention in recent years, both theoretically and experimentally. Theoretically, it is possible to predict morphological characteristics such as the diameter of the tubes or their conductance properties, especially of single wall carbon nanotubes. Experimentally, it is a powerful method for determining

the degree of structural ordering or presence of contaminants [3]. In the Raman spectra of graphite and SWCNTs, there are many features that can be identified with specific phonon modes and with specific Raman scattering processes that contribute to each feature. The Raman spectra of SWCNTs can be provide us much information about the exceptional 1D properties of carbon materials, such as their phonon structure and their electronic structure, as well as information about sample imperfections (defects). Raman spectra provide much general information about the structure and properties of SWNTs. The Radial Breathing Mode (RBM) is a unique phonon mode, appearing only in carbon nanotubes and its observation in the Raman spectrum provides direct evidence that a sample contains SWNTs. The RBM is a bond-stretching out-of-plane phonon mode for which all the carbon atoms move coherently in the radial direction, and whose frequency w_{RBM} is about 100-500 cm^{-1} .
The results obtained with the Raman spectroscopy have been compared with the results obtained by Fourier Transformed Infrared (FTIR) spectroscopy, and by Scanning Electronic Microscopy (SEM) . The results obtained by these technical analyzes confirm the deposition of single-walled carbon nantotubes with metallic features by high-density plasma chemical vapor deposition.
The results obtained in this work, show the possibility to obtain higher aligned single-walled carbon nanotubes deposited at room temperature by HDPCVD. In this way, it was necessary the increase of the surface energy, that promotes the nano-structuration of the carbon materials, using diamond powder as a seed. It was observed the presence of carbon nanotubes and other kinds of nano-structures of carbon. The results obtained by SEM, Raman spectroscopy and Fourier Transformed Infrared spectroscopy FTIR, comproved the carbon nanotubes bundles and “islands” of amorphous carbon materials and, due the different of surface energy promoted by the precursor.

Hydrophobic Properties of Nano-Structured Carbon Films Obtained with Alumina Ceramic Powder Ronaldo D. Mansano, Ana Paula M. Mansano and Nelson Ordonez; University of São Paulo, Brazil

In this work, we have obtained nano-structured carbon films using ceramic powder (alumina) as seed and pure methane plasmas. The nano-structured carbon films were obtained using a high density plasma chemical vapour deposition system. The present study demonstrates the creation of hydrophobic surface using the nano-scale roughness inherent in high-aligned carbon nanotubes forest, when we used alumina as precursor material. The hydrophobic properties of the nano-structured carbon films were analyzed by Atomic Force Microscope (AFM), Scanning Electron Microscope (SEM) and Contact Angle Measurements (drop shape method), and the structural properties of the nano-films were analyzed by Far-FTIR.
The high-density plasma chemical vapour deposition (HDPCVD) system uses a new conception on plasma generation: a planar coil coupled in a RF system and an electrostatic shield for plasma densification. In this mode, are obtained high-density plasmas and for the ion acceleration we have used another RF system on planar configuration. The substrates used to deposit the films were 75 mm diameter silicon wafers, 380 μm thick and orientation (100). They were submitted to a Piranha clean, followed by a diluted HF dip, before the modification of the surface. The alumina ceramic powder presence promotes the increase of the surface energy of the silicon wafers. In this case, nano-structures are formed. Before the films deposition, alumina ceramic powder was deposited on the silicon wafers by spinner (1000 rpm, 30 sec.). The alumina powder dispersion was made in acid solution. We have used different final deposition times (30 min, 1h, 2h, 3h, 4h and 5h). After preparation of the sample, the DLC films were deposited. The parameters of the DLC films depositions were: 15 mTorr, 250 W (coil power, RF, 13.56 MHz, remote plasma), 40 sccm (methane).
The hydrophobic properties of the nano-structured carbon films were analyzed by Atomic Force Microscope (AFM), Scanning Electron Microscope (SEM) and Contact Angle Measurements (drop shape method), and the structural properties of the nano-films were analyzed by Far-FTIR. High-density plasma is quite for the growth of good quality nano-structured carbon films. But the properties of these films are largely dependent on the deposition conditions. The roughness of the nano-structured carbon films is important, in this situation, because it is affected by surface topography and the hydrophobic properties of these nano-materials.
The surface morphologies of the nano-structured carbon films obtained with alumina powder varied with the final time of deposition process. When the final time is increased, the atoms fill the holes and are accumulated around the islands (formed by the filled holes) and the roughness decreases. This effect promotes the reduction of the surface energy and the hydrophobicity of these films increases too. For longer deposition time, the atoms cover every nano-islands and the spaces between one island and another, forming a continuous film (for deposition time of 4 hours, the roughness was 40 nm). In this way, we noticed that the contact angle measurements showed that nano-structured carbon films obtained using alumina as precursor materials obtained for longer deposition time, showed more super hydrophobicity effect

F.NM03.09.95
Self-Assembled Peptides for Suppression of Non-Specific Binding of Biomolecules on Graphene Mirano Tsukiiwa,

Yasuaki Nakata, Hironaga Noguchi, Chishu Homma and Yuhei Hayamizu; Tokyo Institute of Technology, Japan

Graphene is suitable for an active layer for biosensors with high-sensitivity because of their fascinating electrical properties with atomically-flat surface and high specific surface area. Biomolecular immobilization on the active layer of biosensing devices is of vital importance for the functionality, such as sensing with biomolecular probes and protecting from unnecessary unspecific adsorption of biomolecules. However, the immobilization by chemical bonding will introduce atomic defects for graphene, which influences its intrinsic properties to some extent. Self-assembled peptide can be a good candidate. Specific peptides spontaneously form ordered structures through non-covalent intermolecular interactions on the surface of graphene without losing the intrinsic electrical properties of the materials.[1][2][3] On the other hand, non-specific adsorption of biomolecule causes a background noise and decrease the sensing ability of a bio-probe. Therefore, the suppression of nonspecific adsorption is an important issue for the realization of high-performance biosensors. To solve these problems, in this research, we designed new self-assembled peptides and evaluated their performance, aiming at construction of surfaces with the anti-fouling property. The designed peptides consisted of three main domains. (1) antifouling domain: hydrophilic and zwitterionic, which is effective in reducing protein non-specific adsorption. The hydrophilic groups are known to form a hydration layer and create a physical energy barrier that prevents adsorption. (2) Peptide-to-peptide interaction domain: inspired by fibroin, a protein of silk thread. The repetitive sequences of glycine (G) and alanine (A) are introduced. Here we expect the formation of a strong and stable peptide monolayer derived from the β-sheet structure.[2] (3) Anchoring domain: electrons in tyrosine are expected to help to have a stacking of the aromatic ring with the surface of two-dimensional materials. The aqueous solution was placed on the surface of graphite to form a self-assembled film of peptides. The surface structure of these samples was characterized using atomic force microscopy (AFM). We found that peptides had a tendency coverage with increasing concentration. The peptide structure had a six-fold symmetry, which is same as one of underlying graphene lattice. The hydrophilic properties of the peptide film were characterized using contact angle measurements. Furthermore, the antifouling performance was evaluated by AFM and graphene field effect transistors (GFETs). It showed that the adsorption of proteins was greatly inhibited. The peptide offer to be a new molecular scaffold for sensitive graphene biosensors.

Nonlocal and Nonlinear Optical Response in Guided Nanoribbon Plasmons Alvaro Rodriguez Echarri[1], Javier Garcia de Abajo[1,2] and Joel Cox[3,4]; [1]ICFO - The institute of Photonic Sciences, Spain; [2]ICREA – Institució Catalana de Recerca i Estudis Avançats, Spain; [3]Center for Nano Optics, University of Southern Denmark, Denmark; [4]Danish Institute for Advanced Study, University of Southern Denmark, Denmark

Electrically-doped graphene supports highly-confined and actively-tunable plasmons that exhibit lower losses than their conventional noble metal counterparts, positioning the atomically-thin carbon layer as an ideal active ingredient in nanophotonic devices. These appealing properties are maintained in nanostructured graphene, which is emerging as a promising candidate for the excitation and guiding of propagating plasmons in future optoelectronic circuitry. Here we employ realistic quantum-mechanical simulations to describe the nonlocal optical response associated with highly-confined propagating plasmons in graphene nanoribbons, accounting for quantum finite-size and edge-termination effects in their electronic band structure. In addition to strong nonlocal effects manifesting in the linear dynamics of plasmons moving in the direction of transverse symmetry, we observe a stronger dependence on quantum finite-size effects in the nonlinear optical response, which involves additional transitions among the quantized electronic Bloch states. We further explore the breaking of inversion symmetry that occurs for optical excitation with large in-plane optical momenta along the transverse direction of the ribbon and reveal that even-ordered nonlinear optical processes such as a second-harmonic generation can occur with remarkably-high efficiency when enhanced by plasmonic resonances. These findings suggest possibilities to exploit the active tunability of graphene to engineer interactions among individual quantized propagating plasmons supported by 1-D nanoribbons.

Single-Walled Carbon Nanotube Growth from Ir Catalysts by Alcohol Gas Source Method Takahiro Maruyama, Takuya Okada, Takahiro Saida and Shigeya Naritsuka; Meijo University, Japan

Single-walled carbon nanotubes (SWCNTs) have been anticipated for applications in a lot of future nanodevices. However, there still remain several problems for realizing the SWCNT devices, and one of the most significant issues is high-yield growth of semiconducting SWCNTs. So far, to grow SWCNTs with high-yield, Al_2O_3 buffer layers are widely used, because they prevent migration of catalysts on the substrate surface at growth temperature and aggregation of catalyst particles are suppressed [1]. In this study, we attempted to grow SWCNTs using Ir catalysts without Al_2O_3 buffer layers, which have never been used as catalysts in SWCNT growth.
After deposition of Ir catalysts on SiO_2/Si substrates, SWCNT growth was carried out using alcohol gas source method in a high vacuum [2]. Growth Temperature and growth time were set at 800°C and 1 h, respectively. The ethanol pressure was varied between 1×10^{-3} and 1×10^{-1} Pa. The grown SWCNTs were characterized by FE-SEM, TEM and Raman spectroscopy. SEM and Raman results showed that, as the ethanol pressure increased, the SWCNT yield became higher and the SWCNT diameter became narrower. When the ethanol pressure was 1×10^{-1} Pa, high-density vertically aligned SWCNTs were grown, whose lengths were about 2 μm. Raman measurement showed that SWCNT diameter were distributed between 0.8 and 1.1 nm. Our results indicated that Ir catalysts are effective to obtain high-density vertically aligned and small diameter SWCNTs using no Al_2O_3 buffer layers.

F.NM03.09.105
Organophilicity of Graphene Oxide for Enhanced Wettability of ZnO Nanowires Pavan Emani[1], Hisham A. Maddah[1], Arjun Rangoonwala[1], Songwei Che[1], Dieter Gruen[2], Vikas Berry[1] and Sanjay K. Behura[1]; [1]University of Illinois at Chicago, United States; [2]Dimerond Technologies, United States

Interfacing two-dimensional graphene oxide (2D GO) platelets with one-dimensional zinc oxide nanowires (1D ZnO) would create mixed-dimensional heterostructures suitable for modern optoelectronic devices. However, there remains a lack in understanding of interfacial chemistry and wettability in GO-on-ZnO heterostructures. Here, we propose a hydroxyl-based dissociation-exchange mechanism to understand interfacial interactions responsible for GO adsorption onto ZnO hydrophobic substrates. The proposed mechanism would allow us to overcome the poor wettability of the super-hydrophobic ZnO surface (with contact angle 140.5°) to GO, from the dispersion of GO suspension with various organic media prior to drop-casting of GO on the ZnO. The addition of different classes of organics into the relatively high pH GO suspension with a volumetric ratio of 1:3 (organic-to-GO) is believed to introduce free radicals (OH and COOH), which consequently result in enhancing adhesion (chemisorption) between ZnO nanowires and GO platelets. The wettability study shows as high as 75% reduction in contact angle ($\theta = 35.5°$) when the GO suspension is mixed with alcohols (e.g. ethanol) prior to interfacing ZnO nanowires. The proposed method brings forth a scalable tool for developing graphene-coated-ZnO heterojunctions for photovoltaics, photocatalysis, biosensors, and UV detectors.

Late News: Application of Starch-Derived Graphene Quantum Dot Embedded Carbon Aerogel as Efficient Catalyst in Proton Exchange Membrane Fuel Cell Eric J. Kim and Sunil Sharma; Stony Brook University, The State University of New York, United States

Proton Exchange Membrane Fuel Cells (PEMFC) are considered to be one of the most promising clean energy sources to mitigate the global crisis of climate change and air pollution. However, its dependence on expensive catalyst materials with low durability, such as platinum, prevent this technology from being widely commercialized. In this study, we present the application of a metal-free starch-derived graphene quantum dot (GQD) supported on highly porous carbon aerogel (GQD/CA) in PEMFC to overcome these technical barriers. Structural, morphological, and crystalline features of GQDs and GQD/CA are analyzed using HRTEM, TEM, AFM, and XRD. Further electrochemical characteristics are investigated using cyclic voltammetry (CV), CO-stripping, ORR polarization, and fuel cell testing. Additionally, the durability of the catalyst is measured using the DOE2020 accelerated stress test (AST). The TEM imaging shows the small size and uniformity of GQDs, which allows for an even distribution of GQDs onto the support and a higher electrochemical surface area (ECSA). The presence of functional groups on GQD is shown to improve ORR performance by up to 10 times compared to platinum. In addition, the structural integrity of both GQD and CA create a synergistic effect to prevent the agglomeration of particles during AST. As a result, compared to a commercial standard catalyst, platinum supported on carbon black (Pt/CB), GQD/CA shows significantly higher electrocatalytic activity, with up to 220% increase in ECSA and 1432% increase in peak power density. After 30,000 cycles of AST testing, GQD/CA is shown to retain 92.9% of its ECSA, 97.1 % of its specific activity,

and 98.4% of its mass activity. Thus, GQD/CA is demonstrated to be a highly efficient, durable, and economical catalyst for PEMFCs to mitigate the ever-present effects of climate change and air pollution.

Late News: A Green Graphene-Based Ink for Artworks—Toward a Green Chemistry in Synthesis of Graphene Sepidar Sayyar, Jo Law, Agnieszka Golda, Helen McGregor, Aaron Burton and Gordon Wallace; University of Wollongong, Australia

Climate change is a major threat to the future of our planet and its inhabitants, and there is no doubt that human activities have been the dominant contributor. Scientists can play an important role in mitigating these contributing factors by utilising green approaches in manufacturing and developing eco-friendly materials in different fields. This work presents how our interdisciplinary collaborative research team, consisting of contemporary artists, a materials scientist, and a climate scientist, promote environmental sustainability through the development of 'green' materials and techniques. The aim of the project is to develop a graphene-based ink through a green chemistry/engineering approach and use the ink to create conductive screen-printed e-texitle artworks that communicate climate science. Graphene is a unique two-dimensional carbon structure with excellent electrical, thermal and mechanical properties that make it ideal candidate for a variety of applications1,2. However, converting graphene to a processable material involves hazardous chemical reactions using toxic materials3. We developed a graphene-based ink without using any hazardous or toxic chemicals through a facile mechanical exfoliation method. The viscosity of the ink is easily tunable owing to its thermos-sensitive nature, which makes it a suitable material for screen-printing. The ink is used to screen-print electrically conductive patterns for the e-textile art works. The results of the phase 1 of the project were exhibited at the Museum of Applied Arts and Science in Sydney and attracted over 26,000 visitors. Preliminary experiments demonstrated that this material is a suitable candidate for developing sustainable sewable smart electronics.

Late News: Multibit Optoelectronic Memory Using Graphene/Diamond (carbon sp^2-sp^3) Heterojunctions Kenji Ueda, Y. Mizuno and Y. Ito; Nagoya University, Japan

Recently, interfaces between graphene and diamond (carbon sp^2-sp^3 interfaces) has attracted much attention because the carbon sp^2-sp^3 interfaces become sources of various interesting physical phenomena and novel functions. Although there are many interesting theoretical predictions on the interfaces, experimental results regarding the electronic properties of such interfaces have rarely been reported. More recently, we found that vertically aligned graphene (carbon nanowalls: CNW)/diamond heterojunctions, that is, C sp^2-sp^3 interfaces became photo-controllable memristors [1], which are optically controllable memory-resistors with nonvolatile memory and switching functions. One of the most important application of the photo-controllable memristors is thought to be optoelectronic memory, which possess both photo-sensing and data storage function.
In this study, we show the CNW/diamond heterojunctions can be used as multibit optoelectronic memories, where light information stores as multilevel resistance in nonvolatile manner [2].
CNW were formed on B-doped diamond semiconductors in-situ by using microwave plasma CVD apparatus [1, 3]. Junctions using the CNW/diamond heterostructures were fabricated (area: 40-160 μm φ) and their current-voltage (*I-V*) characteristics were measured at room temperature in air, with or without photo-irradiation by using visible LED.
In the Raman spectrum of the CNW on diamond, four major peaks, which are characteristic of vertically aligned graphene, were observed: G, 2D, D' and D peaks, in addition to the diamond related peak (Dia.) at 1332 cm^{-1}. A SEM image of the CNW/diamond surface showed numerous wall-like structures, which also suggested formation of CNW on diamond. The transmission electron microscope (TEM) image of the interface of the CNW/diamond bilayers indicates that CNW with good crystallinity and clear interfaces were formed on the diamond semiconductors. These Raman, SEM and TEM results suggest CNW/diamond heterostructures with sharp interfaces were successfully formed. The CNW/diamond junctions exhibited hysteretic I-V behaviors. The resistance of the junctions was changed to low or high resistance states by the light irradiation with bias voltage application and the resistance states was maintained in nonvolatile manner. The mechanism for the photoconductive change is considered to be originated from oxidation-reduction of the CNW and/or CNW-diamond interfaces through the movement of oxygen ions by bias with photo-irradiation. The CNW/diamond junctions also show apparent response to optical pulses. The output current, that is, conductivity was increased (or decreased) step-by-step in proportion to the number of optical pulses under positive (or negative) bias. The numer of levels and heights of the current steps can be controlled by changing optical pulse intensity, pulse width, bias voltage, etc. To determine the relationship between output current and applied pulse numbers precisely, multiple (~10) optical pulses (38 $\mu W/cm^2$, 30 ms, 1 Hz) were applied to the junctions. The output current, that is, conductance increased linearly from 2 nA to 142 nA in response to the total optical pulse numbers from 1 to 10. The linear relationship between the number of optical pulses (*n*) and the output

current [$I(n)$ (nA)] can be expressed as "$I(n)= 14.26*n + 2.27$". Application of one optical pulse induces current increase of ~14 nA. This means that the junctions are also used as optical computing-memory devices with arithmetic functions such as counting, addition, and subtraction. These results indicate the CNW/diamond heterojunctions are capable of multibit optoelectronic devices, where light information is stored as multilevel resistance in nonvolatile manner and the stored information is processed immediately.

Late News: Preparation of Large Surface Area Nanocarbon from Cellulose Nanocrystals and Its Carbonization Mechanism Jung-Eun Lee, Hyejin Ju, Min Jeong Kim, Ga-Hyeun Lee and Han Gi Chae; Ulsan National Institute of Science and Technology, Korea (the Republic of)

In the recent time, the biomass-derived carbon materials have attracted attention for application to energy storage and battery devices based on the abundant resources, low cost, and sustainability of precursors. Among them, cellulose nanocrystal (CNC), which can be obtained from the removation of amorphous region of cellulose materials by acid hydrolysis, is regarded as promising carbon precursor. Its high crystallinity (54-88%) compared to other conventional cellulose causes high mechanical integrity, high thermal stability, and the formation of more developed carbon crystallites after carbonization. Although it is prerequisite to thoroughly define the carbonization mechanism of CNC for use in a variety of applications, however, there is still an insufficient research. In particular, only speculations have been reported about the interesting phenomenon that the CNC often shows a graphitic phase at a low carbonization temperature of 1000 °C, unlike carbonized cellulose. Therefore, in the current study, we dried the CNCs by spray-freeze-drying method and carbonized them in the range of 1000-2500 °C. They showed interconnected fibrillar morphology and large surface area of 265.2 m^2/g after carbonization at 2500 °C, which is favorable to use as a carbon nanofiller, purification, or catalyst support. In addition, the different behavior between amorphous and crystalline region of cellulose materials was thoroughly analyzed based on HRTEM, Raman, WAXD, and MD simulation results. The current study will not only open the new application of CNC-based nanocarbons but provide in-depth mechanism of carbonization of cellulosic materials.

F.NM03.09.113
Late News: Effect of Cellulose Nanocrystal(CNC) on Polyacrylonitrile(PAN) Polymer Chain Structure in the PAN/CNC Fibers Prepared Through an *In Situ* Polymerization Hyejin Ju, Jung-Eun Lee, Min Jeong Kim and Han Gi Chae; Ulsan National Institute of Science and Technology, Korea (the Republic of)

In-situ polymerization of polyacrylonitrile (PAN) polymer in the presence of cellulose nanocrystal (CNC) is conducted to produce CNC reinforced PAN nanocomposite fibers for high-performance carbon fiber. Cellulose is the most abundant organic material available on earth, therefore it can be an environmentally sustainable resource for producing carbon materials and carbon fiber. Also, CNC is useful for the reinforcing agent in nanocomposite materials due to its excellent properties such as high crystallinity and mechanical properties.
In the current study, there are two main effects 1) CNC into the nanocomposite fiber and 2) the impact of in-situ polymerization. We have conducted the thorough characterizations of CNC dispersion and radical polymerization of PAN polymer in the presence of about 1.5 wt% CNC. In-situ PAN/CNC nanocomposite fiber was produced by the dry-jet wet spinning method right after the polymerization was terminated.
From the mechanical and crystal orientation measurement, CNC is able to affect improving polymer chain orientation through interaction between PAN and hydroxyl groups of CNC. Furthermore, as the in-situ PAN/CNC nanocomposite solution is used directly without any removing PAN polymer with low molecular weight, it is supposed that they can act as plasticizers during the fiber spinning and affect the polymer chain structure transition during the heat-treatment process. Besides, using thermal analyses, the heat treatment conditions of precursor fiber have been set for manufacturing CNC reinforced high-performance carbon fiber. And the evolution of the structure from polymer chain to the graphite form during the stabilization and carbonization in the presence of CNC has been investigated.

F.NM03.09.114
Late News: A Thin, Flexible, Highly Sensitive Ultrasonic Sensor Based on Polydopamine@Hybrid Carbon Nanofillers/Polyvinylidene Fluoride Nanocomposites Zengsheng Weng and Fangxin Zou; Hong Kong Polytechnic University, Hong Kong

Sensors that are thin and flexible and are yet highly sensitive to small deformations have become considerably crucial to a number of high-value-added applications such as wearable electronics, human machine interface, and condition monitoring of high-stake engineering structures. In recent years, these sensors have been undergoing rapid advancement owing to the development of low-dimensional nanomaterials. In particular, by optimizing the synthesis process, it is even possible to fabricate nanocomposite strain sensors that can be used to probe high-frequency, microscopic vibrations generated by ultrasonic waves. In fact, ultrasonic wave is one of the most widely used diagnostic means for *in situ* assessments of structural integrity.

The tunnelling effect and the piezoresistive effect are the main physics principles that allow nanocomposite strain sensors to acquire ultrasonic waves. When a sensor is impinged by ultrasonic waves, the conductive nanofillers inside the sensor will undergo high-frequency micro-vibrations. Such vibrations will cause the inherent electrical resistances of the nanofillers to fluctuate and the distances between adjacent nanofillers to vary, eventually resulting in changes in the overall electrical resistance of the sensor. However, the sensitivity of the existing nanocomposite strain sensors to ultrasonic waves is still far from satisfactory.

There are two main reasons behind the limited sensitivity. One is that the agglomeration of nanofillers or the poor capacitive compatibility between nanofillers and polymer matrices results in poor dispersion of nanofillers inside nanocomposite structures. The other is the lack of effective tunnelling nodes who is not conducive to the tunneling effect.

In this work, we fabricated a highly sensitive nanocomposite sensor for acquiring high-frequency micro-vibrations generated by ultrasonic waves, from polydopamine(PDA)-coated hybrid carbon nanofillers. First, multi-walled carbon nanotubes (MWCNTs) were coated by 10s nm thick viscous PDA to improve their compatibility with polyvinylidene fluoride (PVDF) substrates. The PDA nanolayers on MWCNTs do not only act as a dispersed phase that reduces the entanglement of MWCNTs, but also serves as the buffer layers between MWCNTs and PVDF matrices, helping to improve the responsiveness of the sensors to ultrasonic waves. Compared to uncoated MWCNTs, the use of 15 wt.% PDA-coated MWCNTs led to a 40% increase in sensitivity. Then, one-dimensional PDA@MWCNTs were mixed with two-dimensional single-layer graphene to enhance the geometric contact between nanofillers. Compared with the use of nanofillers of a single dimensionality, the mixing of nanofillers of different dimensionalities can effectively increase the number of tunneling nodes within a unit volume in a nanostructure. As the mass fraction of graphene within the hybrid nanofillers expanded from 33% to 66%, the sensitivity of the proposed sensor improved by approximately 120%, surpassing that of pure graphene sensors, which had been reported to possess the highest sensitivity to ultrasonic waves. The superior sensitivity of the proposed sensor, which actually utilizes a lower graphene content, was shown to be derived from the synergy between the two types of nanofillers which are of different dimensionalities.

Overall, we put forward new strategy for optimizing the sensitivity of nanocomposite strain sensors to high-frequency micro-vibrations. The feasibility of the idea has been validated by a series of experiments that encompass both material characterizations and measurements of ultrasonic signals.

F.NM03.09.115

Late News: Enhanced Heavy Metals Removal Using a New Buckypaper Membrane Containing MWCNTs and Two Biopolymers—Chitosan and Carrageenan Sara S. Alnasser, Afnan Alharbi, Ahmed Alshahrani and Bandar alOtaibi; KACST, Saudi Arabia

Due to the current global water crisis, wastewater treatment requires considerable attention and development. Dissolved heavy metals in water trigger serious alerts and can have lethal effects on various components of the environment including water resources, soil, plants, animals, and can also be threatening the health of human beings. In this study, we addressed the issue by introducing novel Buckypaper membranes that were fabricated using a combination of biopolymers (i.e., chitosan and carrageenan) and multi-walled carbon nanotubes (MWCNTs). Three dispersions of MWCNTs with chitosan, carrageenan, and chitosan-carrageenan with 0.1% v/w were prepared using vacuum filtration. The removal of six heavy metals (i.e., cobalt, nickel, copper, cadmium, barium, and lead) was investigated in this study. The water permeability and the removal of heavy metals were evaluated using a dead-end (DE) filtration system. Heavy metals removal was studied at pH 7 and under a range of varying applied pressures (1 to 6 bar). At an applied pressure of 1 bar, the removal of lead and copper by the MWCNTs/carrageenan membrane reached 99% and 88%, respectively. However, MWCNTs/carrageenan membrane was found to be fragile. Nevertheless, adding chitosan to carrageenan had significantly improved the mechanical strength of the membrane while sustain the excellent removal properties of the heavy metals. That is, MWCNT/chitosan-carrageenan membrane significantly exceeds MWCNTs/carrageenan membrane in tensile strength, tensile strain and young's modules by 400%, 17%, and 6%, respectively. On the other hand, the MWCNTs/chitosan membrane showed a high water permeate flux that reached up to 200 $L/h.m^2$. Also, the electrical conductivity of all membranes varied from 37 S/CM to 57 S/CM. Additional characterization techniques on the three membranes were conducted in this study as well.

F.NM03.09.116

Late News: Multifunctional MoS2-Supported Nanocomposites for Water Decontamination Kfir Shapira and Ines Zucker; Tel-Aviv University, Israel

Pollution of drinking water sources by a variety of inorganic compounds has created a need to develop more efficacious removal technologies to ensure contaminant-free and clean water. Conventional methods for water decontamination involve physicochemical separation and chemical oxidation. Yet, physicochemical separation lacks pollutant selectivity and produces toxic waste streams,[1] while chemical oxidation requires intensive energy and chemical inputs and may form transformation byproducts.[2]

Nanotechnology-based approaches are increasingly explored as an alternative for decontamination methods. Many new technologies leverage the reactive and tunable properties of nanomaterials for increased cost-efficiency, selectivity toward priority pollutants and energy/chemical sustainability.[3] Through manipulation of material size, morphology, and chemical structure, nanomaterials can have exceptional adsorptive and catalytic properties for water decontamination.

Molybdenum disulfide (MoS_2) nanosheets stand out as a promising advanced-material for water decontamination. MoS_2 act as an efficient and selective adsorbent for the removal of heavy metal ions (e.g., Hg^{2+} and Ag^{+}) through strong Lewis acid and base soft−soft interactions with sulfur atoms in MoS_2. Affixing MoS_2 nanosheets onto a platform is essential minimize risk of nanomaterial release into the environment. In the context of nano-assisted water treatment technologies, affixing nanomaterials onto *active* platforms such as granular activated carbon media may enable multifunctional decontamination. Activated carbon is the predominant adsorbent used widely in water treatment today, due to its high affinity for organic pollutant adsorption, but lack affinity to inorganics. MoS_2 affixed onto activated carbon, enhances overall decontamination performance by enabling simultaneous adsorption of organic and inorganic pollutants.

In this research, we examined the tunable water decontamination capabilities of MoS_2 nanosheets grown on activated carbon (MoS_2@AC) in a hydrothermal method for the adsorption of organic (methylene blue) and inorganic (mercury) contamination from water. In a batch experiments, we demonstrated the high mercuric adsorption potential of MoS_2@AC (~2000 mg Hg/g MoS_2) in the absence and presence methylene blue. Furthermore, methylene blue was removed in similar rates by MoS_2@AC and pristine AC. These results suggest that while MoS_2 is active and enable the removal of mercury, its presence does not interrupt the activated carbon activity. Moreover, we will investigate the practical application of this nanocomposite by evaluating the effect of background ions on the mercuric adsorption capacity. We also assess the nanomaterial leaching during operation in various conditions to demonstrate the reuse capabilities and to assure safe and durable use. Overall, results from this study provide a proof-of-concept for water treatment enhancement by 2D nanomaterials.

Late News: Carbon Nanotube Field-Effect Transistor Model for a Wide Temperature Range Junsung Park and Michael Shur; Rensselaer Polytechnic Institute, United States

The carbon nanotube field-effect transistor (CNT FET) has been intensively studied due to the high mobility and large current carrying capacity, thus considered as a promising material for nano-scale electronics. For the commercialization of the CNT FETs, the accurate and reliable model is an essential requirement. Especially, transport characteristics of the CNT FETs at high temperature (>300K) is crucially important since the CNT FETs typically operate at elevated temperature. We now report on an improved compact model of the CNT FET. The model is based on the unified charge control model (UCCM) suitable for implementation in standard computer-aided design (CAD) environment such as SPICE. The model accurately describes the current-voltage characteristics for all operation regimes over a wide range of temperatures from 295 to 523K. The model accounts for the temperature and bias effects on the threshold voltage and mobility as the key metrics impacting the CNT FET's performance. It reproduces the mobility, subthreshold swing, on- and off-state current, and threshold voltage behavior as functions of the operating temperature. The model is validated by comparison with the experimental data for the CNT FET reported earlier. The model applications include the device design, characterization, large scale simulation, and parameter extraction of the CNT-based devices and integrated circuits.

Late News: Laser Peening Enhances Tribological Resistance of Electrodeposited Cr Coatings Reinforced with Yttria Stabilized Zirconia and Carbon Nanotubes Pragya Tripathi, Kantesh Balani and Janakarajan Ramkumar; Indian Institute of Technology, India

Laser shock peening is performed on chromium based electrochemical coatings consisting of 3 mol% yttria stabilized zirconia nanoparticles (YSZ) and carbon nanotubes (CNT) as reinforcements, deposited on steel substrate as a suitable strategy to further enhance mechanical and tribological properties of protective coatings. Coated Cr has shown an increased hardness after laser peening from ~8 GPa to ~9.4 GPa, whereas, upto 26 GPa hardness is obtained for Cr-YSZ-CNT coating. Increased hardness might be accredited to high compressive stresses, ranging up to ~1757 MPa, induced as a result of laser peening. Synergistically reinforced with YSZ and CNT after laser peening treatment, minimum wear rate of $\sim 1.8\times10^{-5}$ mm^3/Nm by fretting wear test is recorded in the Cr matrix, which is concomitant with maximum dislocation density of $\sim 3.0\times10^{16}$ m^{-2}. An overall improvement in mechanical and tribological properties i.e. low wear constant of the order of 10^{-6} is achieved, out of which Cr-YSZ-CNT outperformed the other coating systems. Addition of YSZ strengthens the Cr matrix, whereas, multi-functionality of CNT provides with lubrication along with matrix strengthening as well as bridging effect to crack propagation. Therefore, synergistic effect of two reinforcements (YSZ, CNT) in Cr matrix combined with the laser peening treatment lead to superior properties of the coating (Cr-YSZ-CNT) capable enough of limiting the problems of wear and erosion.

F.NM03.09.120

Late News: Graphene-Protein Adhesion Interactions are Influenced by Substrate Properties Eleanor L. Brightbill, Katherine Young, Hilena F. Gezahagne, Decarle S. Jin, Bryce Hitchcock and Eric M. Vogel; Georgia Institute of Technology, United States

A wealth of studies utilizing graphene to sense biomolecules (such as glucose, DNA, Concanavalin A) across different sensing modalities (such as surface plasmon resonance, redox, field effect transistor) have been published due to graphene's unique properties including high surface area and conductivity. However, in any sensor device where graphene interacts with a biofluid, the graphene must be supported by some underlying substrate. Moreover, previous studies indicate that the substrate can influence graphene's properties, where substrate hydrophilicity can affect graphene's water contact angle and substrate polarity can affect the success of epitaxial growth through a graphene layer. Despite this, little to no work has been completed describing how the substrate support effects the graphene-biological solution interaction.

In this study, e*x situ* protein adsorption is measured via ellipsometry and X-ray photoelectron spectroscopy (XPS) of model small (Lysozyme), medium (Bovine Serum Albumin, BSA), and large (Fibrinogen) proteins on substrates with a variety of hydrophobicity and surface polarity with and without a transferred graphene monolayer. Additionally, we investigate the *in situ* adhesion of lysozyme on Si and Au substrates with and without transferred graphene via quartz crystal microbalance with dissipation (QCM-D) to monitor kinetic differences in attachment. Fully coalesced graphene was synthesized via Chemical Vapor Deposition and transferred onto various substrates using a wet transfer process and PMMA scaffold.

Ex-situ ellipsometry and XPS results reveal that the impact of the substrate on protein attachment to graphene depends on the protein studied. The largest model protein, Fibrinogen, shows a similar level of attachment across all 4 substrates regardless of the presence of graphene. Lysozyme, the smallest model protein, shows a difference in adsorption only when a graphene monolayer is added to non-polar substrates. The adsorption of BSA, the intermediate size protein, is influenced strongly by substrate hydrophilicity, where less adsorption is observed on more hydrophilic substrates with or without the presence of graphene. Overall, a more hydrophobic substrate leads to a larger amount of adsorption to graphene.

In-situ QCM-D results show that not only the equilibrium attachment, but also the kinetics of interaction, can be affected by the substrate. Modeling the attachment of lysozyme to graphene on Au and Si substrates indicates that the appropriate kinetic model may be determined by the substrate even in cases where differences in absolute adsorption are observed, further indicating that support substrates have a significant effect on protein adsorption behavior to graphene.

This work indicates that the substrate of a graphene-based biosensor is an important but currently overlooked parameter when understanding and optimizing the performance of the device. The *ex-situ* ellipsometry and XPS analysis of protein attachment indicates that the substrate can have a profound impact on protein-graphene interactions, to the extent that twice the BSA attachment to graphene is observed when graphene is supported by TaN rather than Si. The level of non-selective protein adsorption on graphene can be independently engineered through modifying the support substrate without directly modifying the graphene itself.

F.NM03.09.121
Late News: Electrochemical Cathodic Exfoliation of Graphite into Graphene in Aqueous Solutions of Alkali Metal Salts Md Habibullah Dalal, Chong-Yong Lee and Gordon Wallace; University Wollongong, Australia

Electrochemical exfoliation has emerged as a green, effective and scalable route to mass production of graphene.[1] The use of reductive cathodic exfoliation of graphite, offers a direct production of high quality and low defect graphene.[2] However, cathodic exfoliation protocols reported to date use organic solvents in which often requires extended intercalation time, and post-treatment to further exfoliate the intercalated graphene layers.[3] In contrast, the employment of environmentally friendly aqueous-based electrolytes, coupling with a shorter exfoliation period would be attractive features of any new protocol. Here, we demonstrate for the first time, efficient cathodic electrochemical exfoliation of graphite to graphene in aqueous electrolytes using common and inexpensive alkali-metal salts such as KCl. The key to exfoliate graphite successfully in aqueous electrolyte is applying a sufficiently high voltage, and a high salt concentration which facilitates hydrated cationic intercalation, and promotes hydrogen evolution to exfoliate the graphene. The cathodic exfoliated graphene produced using KCl electrolyte exhibits a low defect density (I_D/I_G of 0.06, a C/O ratio of 57.8), high graphite exfoliation yield (>80%) in short time (< 10 mins for 1 cm^2 electrodes) and the highly conductive 6 to 7 layers graphene sheets served as an excellent support materials for electrocatalytic reactions. This environment-benign aqueous-based cathodic electrochemical graphite exfoliation approach opens a new opportunity in large-scale and low cost production of high quality graphene.

Late News: Nanoporous Free-Standing SWCNT Films Radovan Kukobat, Dragana Stevic and Katsumi Kaneko; Shinshu University, Japan

Nanoporous free-standing SWCNT films are essential for understanding porosity of these films which should be promising for catalyst supports and supercapacitors. The SWCNTs form networks of randomly distributed SWCNTs, giving materials such as transparent thin films and free-standing films. The transparent thin films of SWCNTs form two dimensional porous networks of randomly oriented SWCNTs whose pore sizes vary from micropores to mesopores, according to the SEM and TEM observation. On the other hand, porosity of the free-standing SWCNT films is not straightforward because the micropores and mesopores are hidden in the three-dimensional structures of these films. We use nitrogen adsorption at 77 K to characterize porosity of the free-standing SWCNT films. The nitrogen adsorption isotherm shows a prominent hysteresis loop over the wide relative pressure range of ~10^{-3} to ~1, which we assigned to the presence of ultramicropores of < 0.7 nm. These ultramicropores were open during ultrasonication treatment of the SWCNTs prior to the free-standing film fabrication. The ultramicropores are evidenced as defects on SWCNTs using Raman spectroscopy. The D- and G-band ratio increases from pristine SWCNTs of 0.04 to SWCNTs of free-standing films of 0.11. The surface area increases from pristine SWCNTs of 320 and 280 m^2/g (BET and αs) to free-standing SWCNT film of 605 and 590 m^2/g (BET and αs). Micropore volume increases from pristine SWCNTs to free-standing SWCNT film from 0.06 to 0.18 cm^3/g, respectively. High surface area of the free-standing SWCNT films is assigned to the ultramicropores. Also, the free-standing SWCNT film is composed of mesopores created by entangling of SWCNTs in the network as observed with SEM and TEM. Understanding porosity of the free-standing SWCNT films is important for developing the SWCNT electrodes of desired porosity and surface area for the electrochemical applications.

F.NM03.09.123
Late News: Effects of Water and Different Solutes on Carbon-Nanotube Low-Voltage Field-Effect Transistors Raphael Pfattner[1,2], Amir M. Foudeh[1], Shiheng Lu[1,3], Nicola S. Kubzdela[1], Theodore Gao[1], Ting Lei[1,4] and Zhenan Bao[1]; [1]Stanford University, United States; [2]Materials Science Institute of Barcelona (ICMAB-CSIC), Spain; [3]Duke University, United States; [4]Peking University, China

Semiconducting single-walled carbon nanotubes (swCNTs) are a promising class of materials for emerging applications. In particular, they are demonstrated to possess excellent biosensing capabilities, and are poised to address existing challenges in sensor reliability, sensitivity, and selectivity.[1,2] Functionalized and pristine individual CNTs have shown high sensitivity and

selectivity down to the single molecule level.[3,4] However, single CNT devices are challenging to make and characterize compared to CNT networks which add further complexity due to inter-CNT contacts. Such systems may not be as sensitive or selective compared to single CNT devices, but may be a cost-effective alternative for particular environments.
Here, we report on the characteristics of single-walled carbon nanotube (swCNT) networks exposed directly to aqueous solutions containing different solutes.[1] This was made possible by employing a solid-state dielectric poly(vinylidene fluoride-co-hexafluoropropylene) (ePVDF-HFP), which has been demonstrated to be compatible with swCNTs and also enables low-voltage field-effect transistor (FET) operation.[5,6]
These devices exhibit small device-to-device variation as well as high current output at low voltages (<0.5 V), making them compatible with most physiological liquids. Using this platform, the swCNT devices are directly exposed to aqueous solutions containing different solutes to characterize their effects on FET current–voltage (FET I–V) characteristics. Clear deviation from ideal characteristics is observed when swCNTs are directly contacted by water.
Such changes are attributed to strong interactions between water molecules and sp^2 -hybridized carbon structures. Selective response to Hg^{2+} is discussed along with reversible pH effect using two distinct device geometries. Additionally, the influence of aqueous ammonium/ammonia in direct contact with the swCNTs is investigated. Understanding the FET I–V characteristics of low-voltage swCNT FETs may provide insights for future development of stable, reliable, and selective biosensor systems.

F.NM03.09.124

Late News: Bifacial Float Transfer of Multilayer Graphene Joseph Andrade[1], Jan Folkson[1], Mohamed Boukhicha[2], Amanda Carr[1] and Matthew Eisaman[1]; [1]Stony Brook University, The State University of New York, United States; [2]Brookhaven National Laboratory, United States

We present a method for graphene transfer we refer to as “bifacial transfer” that allows transfer of multilayer chemical vapor deposition (CVD) graphene from both sides of a native metal substrate, such as an as-received nickel catalyst. In traditional transfer methods, the graphene on the “non-preferred” side, i.e. the bottom of the substrate, is removed with oxygen plasma before removal of the metal catalyst in etchant solution. Although this treatment prevents undesired aggregation of the graphene films, it fails to utilize both sides of CVD-grown graphene. Our bifacial transfer method reduces the cost of multilayer graphene by allowing the transfer of graphene from both sides of the substrate. After hot-press lamination to a polymer film and a temporary metal etching step, the graphitic films separate cleanly at the air-liquid interface due to an oxide interlayer. We characterize this separation layer and compare the quality of graphene transferred from both sides onto target glass and polymer substrates. The results of optical microscopy, confocal Raman spectroscopy, atomic force microscopy (AFM), and electronic transport measurements suggest that the quality of the multilayer graphene on the “non-preferred” side does not differ significantly from that of the “preferred” side. This method will allow more efficient and cost-effective use of graphene by doubling the usable graphene per area of growth substrate, and by eliminating the need for intermediate sacrificial transfer substrates such as poly(methyl methacrylate), PMMA.

F.NM03.09.127

Late News: Oil Fly Ash-Derived Carbon Nanostructures for Flexible Supercapacitors Nuha A. Alhebshi[1], Haneen S. Alshaikheid[1], Numan Salah[1] and Husam Alshareef[2]; [1]King Abdulaziz University, Saudi Arabia; [2]King Abdullah University of Science and Technology (KAUST), Saudi Arabia

A variety of innovative designs of wearable electronics require to be powered by energy storage devices such as supercapacitors based on flexible electrodes. One of the current challenges that would delay the implementations of supercapacitors is the high cost of the electrode materials. In this research, Abundant oil fly ash is obtained from a power plant in Jeddah, Saudi Arabia, as a source for the synthesis of carbon nanostructures by sonication (JSON) and carbon nanotubes (CNTs) by chemical vapor deposition [1,2]. These CNTs have diameters around 30-40 nm, few micrometers lengths, and clear zigzagged structures, which are mostly different than the commercial CNTs, as characterized by high

resolution transmission electron microscope. To utilize the promising properties of CNTs in a practical application, flexible supercapacitor electrodes of CNTs have been fabricated on carbon cloth as a current collector in addition to H_2SO_4 electrolyte, then tested and compared with JSON electrode in terms of cyclic voltammetry, galvanostatic charging-discharging and electrochemical impedance spectroscopy. Interestingly, CNTs electrode exhibits maximum areal and gravimetric capacitances of 77 mF/cm^2 and 55 F/g, respectively, which are one order of magnitude higher than those of JSON electrode. This improvement can be attributed to the smaller size and hence the larger surface area of CNTs than JSON. Moreover, CNTs electrode shows exceedingly small equivalent series resistance and charge transfer resistance ascribing to the good contact of the electrode active materials within the carbon cloth substrate and the electrolyte. In addition, the vertical impedance line in the low frequency range of Nyquist plots indicates an excellent electrolyte ion diffusion into the electrode due to the porosity of CNTs. The successful fabrication of such flexible supercapacitors based on affordable and scalable CNTs would facilitate their cost-effective manufacturing.

ACKNOWLEDGMENT

This joint project was co-funded by King Abdulaziz University (KAU), Jeddah, and King Abdullah University of Science and Technology (KAUST), Thuwal, under grant number "JP-19-002". The authors, therefore, acknowledge with thanks KAU & KAUST for their technical and financial support.

Late News: Ethylene Glycol Removal Characteristics of 2D Nanoporous h-BN Sheets —Computational Predictions Nirmalay Barua[1], Ingrid Padilla Espinosa[2,1] and Ram Mohan[1]; [1]North Carolina A&T State University, United States; [2]University of California, Merced, United States

Hexagonal boron nitride (h-BN) is a new material with potential for applications in electronic devices, tribology, and separation membranes. Limited theoretical and experimental researches have been conducted to explore their efficiency as a desalination membrane. With the recent advancement of their controlled synthesis, researchers have become more interested in exploiting their interaction with organic materials. The purpose of this work is to explore the efficiency and potential of porous h-BN as a separation membrane for ethylene glycol (EG) removal from water. Very few experiments have been previously conducted to assess the capability of porous h-BN for EG or other organic pollutants removal. However, no prior theoretical or computational work that studies the molecular interactions between EG and h-BN has been reported. In this work, a methodological approach to simulate the atomic interactions of h-BN and EG in different pore configurations is proposed and investigated using classical molecular dynamics. Our results exhibit that nanometer-scale pores in single layer h-BN can effectively reject approximately 90% of EG from EG contaminated water. We also report the removal performance of the freestanding porous h-BN sheet as a function of pore diameter and applied pressure.

Late News: Ionicity-Dependent Separation Property of Graphene Oxide Membrane Mutsuki Oikawa[1], Haruka Takeuchi[2], Zheng-Ming Wang[3] and Setsuko Koura[1]; [1]Chiba Institute of Technology, Japan; [2]Kyoto University, Japan; [3]AIST, Japan

Graphene oxide membrane(GO-M) has recently attracted a great interest because of its potential applications for desalination and for removal of organic matter. The carbon-based GO-M is excellent in chemical resistance, anti-fouling effect, low cost, and so forth as compared to polymer or ceramics membranes. It is known that GO has polar oxygen functional groups and is negatively charged in water, which makes it possible to remove ionic species in water. It has been reported that GO-M shows selective separability toward some neutral solvent molecules. However, its ionicity-based separation property has not yet been sufficiently understood. In this research, we focused on surface charging property of GO-M and examined its separation behaviors toward inorganic ions and organic dyes of different charging properties. It was found that the separation or permeation of inorganic cations by GO-M is dependent on the ionic type and charge number. The rejection ratio can be accounted for by the strength of their electrostatic interaction with the GO surface. GO-M shows good rejection toward anionic dyes but great adsorption toward neutral and cationic dyes, resulting in the blockade of membrane path.

F.NM03.09.131

Late News: Atomistic Study of the Influence of Oxide Shell Layers on the Material Properties of Aluminum Nanowires Hoang Thien Luu[1], Yudi Rosandi[2], Herbert M. Urbassek[3] and Nina Gunkelmann[1]; [1]Clausthal University of Technology, Germany; [2]Universitas Padjadjaran, Indonesia; [3]University of Kaiserslautern, Germany

For materials with high oxygen affinity, oxide layers will significantly change the material properties. At aluminum surfaces, an oxide layer may form in seconds, even under vacuum conditions. Recent studies show that thin amorphous oxide shell layers on aluminum surfaces significantly change the responses of the material. However, the relations between the thickness of the oxidized layer, the temperature and the mechanical response of nanowires have not been investigated intensively. In this study, we use a ReaxFF potential to analyze the influences of oxide shell layers on the material responses of the nanowires under uniaxial loading at different strain rates. We conduct simulations within a wide range of strain rates and temperatures varying between 10K and 500K. The Al-O interface leads to an increased defect nucleation rate at the oxide interface preventing localized deformation.

6:30 PM INTRODUCTION AND ANNOUNCEMENTS

6:35 PM *F.NM04.01.03
Skyrmions in Thin-Film Heterostructures Kang L. Wang[1], Hao Wu[1], Ying Ying Wu[1], Arvin Razavi[1] and Alexander Grutter[2]; [1]University of California, Los Angeles, United States; [2]National Institute of Standards and Technology, United States

Magnetic skyrmions are swirling topological spin textures in either non-centrosymmetric magnetic bulk compounds or thin films resulted from broken inversion symmetry. Their presence is the result of the balance among the Dzyaloshinskii–Moriya interaction, the Heisenberg exchange interaction, magnetic anisotropy, and the Zeeman energy and was first demonstrated in cryogenic temperatures. Skyrmions behave as particles, which can be created, annihilated, and manipulated and can be as small as a few nanometers by careful design of material structures. The study of skyrmions is of great interest as they may be a strong candidate for high density and energy-efficient information storage and processing. In this talk, we will briefly review the requirements for the presence and the establishment of the phase diagram of skyrmions in various thin films. Particularly we will discuss the room-temperature skyrmion phase diagram as affected by DMI, anisotropy, and the Zeeman energy. Because of the interest in applications in logics and memories, there is an increased interest in using electric means, current or voltage, to create and manipulate skyrmions in ferromagnetic and antiferromagnetic thin-film materials platforms. For room-temperature skyrmions, nonuniform current in geometric restrictions was used to create and move skyrmions. We will describe the use of magneto-transport and the Kerr effect to study and image skyrmions, followed by the discussion on the use of neutron scattering, X-ray magnetic dichroism, and others to study the interface magnetism of heterostructures and to understand their creation and annihilation by torques of different origins. The materials platforms to be discussed include

ferromagnetic and antiferromagnetic (AFM) materials. The use of metallic CoFeB/MgO/heavy metal (Ta, W, etc.) was used to demonstrate and image skyrmions. Other examples include topological insulator/AFM (MnTe) heterostructures, which will be described to show the use of the induced exchange bias via interface proximity effect for controlling the topological charge number via field cooling. Structures consisting of antiferromagnetic (AFM) and ferri-magnetic materials (FRM) offer the speed advantage to THz for information propagation in the form of spin and skyrmion current. In this area, we will discuss the exchange coupling of the two sub-lattices of FRM and AFM as revealed from x-ray dichroism and neutron scattering. In particular, the use of insulator heterostructures will be discussed, which have the advantage of having no electrical charge current. The voltage control of perpendicular anisotropy will be discussed to show the creation and annihilation of skyrmions and their dynamics without the use of an applied magnetic field. Lastly, we will discuss the recent progress of 2D materials for skyrmionics and in general for spintronics as 2D materials make possible a wider choice of materials available to experiments. In addition, the 2-D van der Waals gap may offer different interaction characteristics for their presence as well as creation and manipulations under current and voltage drives. The study of skyrmions and anti-skyrmions in analogy with the creation and annihilation of particles and antiparticle may provide a condensed matter platform for studying the particle counterparts.

Supported by ARO, NSF, and DOE.

7:25 PM BREAK

7:30 PM *F.NM04.01.01
Microwave Resonances of Magnetic Skyrmions in Multilayers Christos Panagopoulos; Nanyang Technological University, Singapore

We report a magnetic resonance study of the chiral multilayer Ir/Fe/Co/Pt hosting Néel skyrmions at room temperature. Employing in-plane ac fields, experiments reveal two distinct resonances of the skyrmion phase with frequencies between 6-12 GHz. Complementary micromagnetic simulations indicate that both resonances exhibit a counterclockwise rotation of the net magnetic dipole moment. Whereas the magnon probability distribution for the lower-frequency resonance is well localized to the skyrmion core, it extends over the inter-skyrmion area for the resonance with higher frequency. The properties of both modes depend sensitively on the interlayer distance due to the dipolar coupling between ferromagnetic layers. Our work reveals the tunability of the resonance response of skyrmions in magnetic architectures over a broadband frequency range, a promising avenue towards tailored microwave applications based on room temperature topological spintronics.

7:55 PM *F.NM04.02.06
Structures and Dynamics of Spin Textures with Boundaries Naoto Nagaosa[1,2], Wataru Koshibae[2] and Jan Masell[2]; [1]University of Tokyo, Japan; [2]RIKEN Center for Emergent Matter Science (CEMS), Japan

Structures and dynamics of spin textures in magnets are the subject of extensive studies, which is a crucial issue also for applications. The structures and their motion in the bulk are rather well understood, but the influence of the boundaries is less studied. In this talk I would focus on the effects of boundaries such as surfaces and edges as revealed by theoretical analysis. It includes (i) the skyrmion string in a thin film with associated topological defects, and (ii) the helix with boundaries. In the former case with an out-of-plane magnetic field, a step edge on the thin film substantially affects the motion of a skyrmion string, leading to its splitting and annihilation. These processes are understood by introducing two types of topological indices, i.e., the bulk monopole number and the surface skyrmion number. For an in-plane magnetic field, on the other hand, several kinds of topological defects are found to appear, which is consistent with the experimental observations. Recently, the helix structure was proposed to show inductance under an ac current. Therefore, the nonlinear dynamics of the helix are an important issue, which we have investigated both by numerical simulations and analytical calculations. It turns out that the role of the boundary is crucial to determine the direction of the wavevector of the helix: There is a 90° difference between periodic boundary condition and open boundary condition, revealing the vital role of the boundary.

8:20 PM CLOSING SUMMARY

SESSION F.NM04.05: Live Keynote II: Material Systems for Manipulating and Controlling Magnetic Skyrmions
Session Chairs: Markus Garst and Oleg Tretiakov

11:30 AM INTRODUCTION AND ANNOUNCEMENTS

11:35 AM *F.NM04.02.05
Chiral Non Collinear Spin Textures Stuart S. Parkin; Max Planck Institute of Microstructure Physics, Germany

Magnetic non-collinear spin textures that have chiral structures are of great current interest. The same type of Dzyaloshinskii-Moriya (DMI) vector exchange interactions that stabilize chiral Néel domain walls in magnetic multilayers [1-3] results in the formation of topological spin textures in bulk compounds. We recently discovered magnetic *antiskyrmions* in a tetragonal inverse Heusler compound $Mn_{1.4}Pt_{0.9}Pd_{0.1}Sn$ using Lorentz transmission electron microscopy (LTEM)[4]. Unlike skyrmions in B20 compounds, that have been extensively studied, the size of the anti-skyrmion can be tuned by varying the thickness of the host material allowing for sizes varying from nanometer to microns in the same material[5]. This is due to long range magneto-dipole interactions that are important in this compound that has a complex DMI interaction with a symmetry that follows the D_{2d} symmetry of its crystalline structure. The same symmetry ensures that anti-skyrmions are robust to temperature and magnetic field[6]. The magnetic dipole-dipole interactions also allow for the formation of metastable "elliptical skyrmions" in this same material[7]. These have Bloch-like boundaries that we can directly observe using LTEM. Finally, we discuss our recent discovery of novel Néel like skyrmions in a metallic compound that exist almost to room temperature and that are also tunable in size[8]. Chiral spin textures in ferro-, ferri- and anti-ferrimagnetic materials and thin film heterostructures are of fundamental interest with potential for spintronic applications especially Racetrack Memory.

12:00 PM *F.NM04.01.02
Skyrmions in Chiral Magnetic Multilayers Katharina Zeissler[1], Simone Finizio[2], Kowsar Shahbazi[1], Jamie Massey[1], Fatma Al Ma'mari[1], Alexandra Huxtable[1], David Bracher[2], Armin Kleibert[2], Sebastian Wintz[2], Sina Mayr[2], Teresa Weßels[3], Alexandr Sadovnikov[4], Mark Rosamond[1], Edmund Linfield[1], Thomas Moore[1], Joerg Raabe[2], Gavin Burnell[1] and Christopher Marrows[1]; [1]University of Leeds, United Kingdom; [2]Paul Scherrer Institut, Switzerland; [3]Forschungszentrum Jülich GmbH, Germany; [4]Saratov State University, Russian Federation

Magnetic skyrmions are topologically-nontrivial spin textures with particle-like properties [1]. Their size, topological stability, and mobility suggest their use in future generations of spintronic devices, the prototype of which is the skyrmion racetrack [2]. To realise a racetrack requires three basic operations: the nucleation (writing), propagation (manipulation), and detection (reading) of a skyrmion, all by electrical means. Here we show that all three are experimental feasible at room temperature in Pt/Co/Ir or Pt/CoB/Ir multilayers in which the different heavy metals above and below the magnetic layer break inversion symmetry and induce chirality by means of the Dzyaloshinskii-Moriya interaction, defining the structure of Néel skyrmion spin textures [3]. We show deterministic nucleation on nanosecond timescales using an electrical point contact on top of the multilayer [4] , current-driven propagation along a wire in which the skyrmions are channelled by defects in the multilayer [5], and their detection by means of the Hall effect that reveals an unexpectedly large contribution to the Hall signal that correlates with the topological winding number [6].

Magnetic Skyrmions and Hopfions in Three-Dimensional Chiral Magnets Jiadong Zang; University of New Hampshire, United States

In this talk, various three-dimensional (3D) topological spin textures in magnets without inversion symmetry will be introduced. The first part of the talk features the recent observation of target skyrmions in chiral magnet nanodisks through theory-experiment collaborations. Two types of zero-field target skyrmions are confirmed, and Bloch points are identified during topological transition between different types of target skyrmions. The spectrum of collective spin wave modes in target skyrmions also reveal the 3D nature of spin excitations.

Second part of the talk introduces a very recent work on hopfions in chiral magnetic nanodisk. This is one of the first experimentally feasible prediction on magnetic hopfions. The hopfion in this setup is confirmed by analyzing the linking between any two equal-spin loops and calculating the Hopf invariant. Another topological configuration, the pairing between monopole and anti-monopole, is also identified in the same system. Transition from this state to hopfion, being identical to sphere-torus topological deformation, can be achieved by an external magnetic field. Dynamics of hopfions will also be discussed.

Skyrmions—A Playground for Non-Conventional Computing and Phase Transitions in 2D Mathias Klaeui; Johannes Gutenberg University Mainz, Germany

In our information-everywhere society IT is a major player for energy consumption. Novel spintronic devices can play a role in the quest for GreenIT if they are stable and can transport and manipulate spin with low power. Devices have been proposed, where switching by energy-efficient approaches, such as spin-polarized currents is used [1],
Firstly, to obtain ultimate stability of states, topological spin structures that emerge due to the Dzyaloshinskii-Moriya interaction (DMI) at structurally asymmetric interfaces, such as chiral domain walls and skyrmions with enhanced topological protection can be used [2-5]. We have investigated in detail their dynamics and find that it is governed by the topology of their spin structures [2]. By designing the materials, we can even obtain a skyrmion lattice phase as the ground state [3].
Secondly, for ultimately efficient spin manipulation, we use spin-orbit torques, that can transfer more than 1hbar per electron by transferring not only spin but also orbital angular momentum. We combine ultimately stable skyrmions with spin orbit torques into a skyrmion racetrack device [3-5], where the real time imaging of the trajectories allows us to quantify the novel skyrmion Hall effect [5,6].
Beyond conventional memory, we furthermore use spin-orbit torque induced skyrmion dynamics for non-conventional stochastic computing applications, where we have developed a skyrmion reshuffler device [6]. Here we use thermal skyrmion motion to implement a key component for stochastic computing [6]. Such thermal skyrmion diffusion can also be controlled by symmetry breaking [7] and this is useful for token – based Brownian computing.
Finally the thermal dynamics of skyrmion quasi-particles lends itself to exploiting this system for the study of phases and phase transitions in 2D. We have studied the transition of skyrmion arrangements from the liquid phase across the hexatic phase unique to 2D systems into the solid phase [8]. These transitions occur in a wide range of skyrmions systems [8,9], thus showing that skyrmions have evolved from an object of study themselves and are now being understood controlled sufficiently well for use as model systems to study exciting statistical physics in 2D.

Microwave Resonances of Magnetic Skyrmions in Multilayers Christos Panagopoulos; Nanyang Technological University, Singapore

We report a magnetic resonance study of the chiral multilayer Ir/Fe/Co/Pt hosting Néel skyrmions at room temperature. Employing in-plane ac fields, experiments reveal two distinct resonances of the skyrmion phase with frequencies between 6-12 GHz. Complementary micromagnetic simulations indicate that both resonances exhibit a counterclockwise rotation of the net magnetic dipole moment. Whereas the magnon probability distribution for the lower-frequency resonance is well localized to the skyrmion core, it extends over the inter-skyrmion area for the resonance with higher frequency. The properties of both modes depend sensitively on the interlayer distance due to the dipolar coupling between ferromagnetic layers. Our work reveals the tunability of the resonance response of skyrmions in magnetic architectures over a broadband frequency range, a promising avenue towards tailored microwave applications based on room temperature topological spintronics.

Skyrmions in Thin-Film Heterostructures Kang L. Wang[1], Hao Wu[1], Ying Ying Wu[1], Arvin Razavi[1] and Alexander

Grutter[2]; [1]University of California, Los Angeles, United States; [2]National Institute of Standards and Technology, United States

Magnetic skyrmions are swirling topological spin textures in either non-centrosymmetric magnetic bulk compounds or thin films resulted from broken inversion symmetry. Their presence is the result of the balance among the Dzyaloshinskii–Moriya interaction, the Heisenberg exchange interaction, magnetic anisotropy, and the Zeeman energy and was first demonstrated in cryogenic temperatures. Skyrmions behave as particles, which can be created, annihilated, and manipulated and can be as small as a few nanometers by careful design of material structures. The study of skyrmions is of great interest as they may be a strong candidate for high density and energy-efficient information storage and processing. In this talk, we will briefly review the requirements for the presence and the establishment of the phase diagram of skyrmions in various thin films. Particularly we will discuss the room-temperature skyrmion phase diagram as affected by DMI, anisotropy, and the Zeeman energy. Because of the interest in applications in logics and memories, there is an increased interest in using electric means, current or voltage, to create and manipulate skyrmions in ferromagnetic and antiferromagnetic thin-film materials platforms. For room-temperature skyrmions, nonuniform current in geometric restrictions was used to create and move skyrmions. We will describe the use of magneto-transport and the Kerr effect to study and image skyrmions, followed by the discussion on the use of neutron scattering, X-ray magnetic dichroism, and others to study the interface magnetism of heterostructures and to understand their creation and annihilation by torques of different origins. The materials platforms to be discussed include ferromagnetic and antiferromagnetic (AFM) materials. The use of metallic CoFeB/MgO/heavy metal (Ta, W, etc.) was used to demonstrate and image skyrmions. Other examples include topological insulator/AFM (MnTe) heterostructures, which will be described to show the use of the induced exchange bias via interface proximity effect for controlling the topological charge number via field cooling. Structures consisting of antiferromagnetic (AFM) and ferri-magnetic materials (FRM) offer the speed advantage to THz for information propagation in the form of spin and skyrmion current. In this area, we will discuss the exchange coupling of the two sub-lattices of FRM and AFM as revealed from x-ray dichroism and neutron scattering. In particular, the use of insulator heterostructures will be discussed, which have the advantage of having no electrical charge current. The voltage control of perpendicular anisotropy will be discussed to show the creation and annihilation of skyrmions and their dynamics without the use of an applied magnetic field. Lastly, we will discuss the recent progress of 2D materials for skyrmionics and in general for spintronics as 2D materials make possible a wider choice of materials available to experiments. In addition, the 2-D van der Waals gap may offer different interaction characteristics for their presence as well as creation and manipulations under current and voltage drives. The study of skyrmions and anti-skyrmions in analogy with the creation and annihilation of particles and antiparticle may provide a condensed matter platform for studying the particle counterparts.

Magnetic Spin Textures in Thin-Film Heterostructures Suzanne G. te Velthuis; Argonne National Laboratory, United States

Topologically protected chiral spin textures, such as magnetic skyrmions, that exhibit quasi-particle like behavior have been envisioned to enable low-power information technologies, and consequently have engaged considerable the interest of the scientific community in recent years [1]. To this end, inversion asymmetric multilayers consisting of ferromagnetic and heavy metal layers have been explored and have been shown to host chiral domain walls and stabilize magnetic skyrmions due to interfacial Dzyaloshinskii-Moriya interactions. The controlled generation and manipulation of these spin structures is key to harnessing their potential in applications. We have shown that diverging electric charge currents can locally generate skyrmions. The diverging currents can be created by making use of geometric constrictions [2,3], and from nonmagnetic conducting point contacts [4]. Due to spin orbit torques at the interfaces, the spin textures can also be manipulated by charge currents. Magnetic skyrmions have been shown to exhibit a transverse motion relative to the current direction, i.e., the skyrmion Hall effect [5]. This effect arises due to the non-trivial topological charge of the skyrmions and is the analogue of the ordinary Hall effect for electrical charges in the presence of a magnetic field. The skyrmion Hall effect should vanish for antiferromagnetic skyrmions because of the cancelation of opposite topological charges and likewise for ferrimagnets at the compensation temperature. To explore this idea, have investigated the current driven motion in artificially ferrimagnetic multilayers consisting of Co and Gd. We have studied the temperature dependence of the motion from room temperature down to temperatures below the compensation point of around 100 K and find a dependency of the skyrmion Hall angle and domain wall speed on the applied temperature.

Manipulation of Magnetic Skyrmion for Future Electronic Application Joonyeon Chang[1], Kyung Mee Song[1] and Seonghoon Woo[2]; [1]KIST, United States; [2]IBM T.J. Watson Research Center, United States

Most magnetic materials show collinear magnetic ordering due to the large exchange interaction between neighbouring magnetic moments. If provided the Dzyaloshinskii-Moriya interaction (DMI) is strong enough to overcome the exchange interaction, magnetic spins tend to align in a non-collinear manner with fixed homochirality. In any structures where the broken inversion symmetry leads to sufficiently large DMI, non-trivial small cylindrical swirling spin structures, called magnetic skyrmions can be energetically stable. Magnetic skyrmions are topologically protected spin textures that have nanoscale dimensions and can be manipulated by an electric current. These properties make the structures potential information carriers in data storage, processing and transmission devices.
The room temperature stabilization of magnetic skyrmions and their current pulse-induced displacement on nano-tracks has been reported in magnetic heterostructures. While such current controlled skyrmion motion is applicable to an actual device scheme, the deterministic writng and deleting of a single isolated magnetic skyrmion is required for fully functional skyrmionic devices.
In order to utilize skyrmion for any electrical electronic devices, we have studied current driven dynamics of skyrmions and inhibition of the skyrmion Hall effect which is detrimental to application. [1~3] We have shown that the current-induced creation, motion, detection and deletion of skyrmions at room temperature can be used to store information as well as to mimic the potentiation and depression behaviours of biological synapses. In particular, the accumulation and dissipation of magnetic skyrmions in ferrimagnetic multilayers can be controlled with electrical pulses to represent the variations in the synaptic weights. [4]
In this talk, I will briefly introduce current induced dynamics of skyrmions and discuss about future application of skyrmions in terms of non-volatile memory and synapse devices for neuromorphic computing.

Controlling Dzyaloshinskii-Moriya Interaction in Ferrimagnetic GdCo—A First Principles Calculation Md Golam Morshed[1], Khoong Hong Khoo[2], Yassine Quessab[3], Robert Laskowski[2], Prasanna Balachandran[1,1], Andrew D. Kent[3] and Avik W. Ghosh[1,1]; [1]University of Virginia, United States; [2]Institute of High Performance Computing, Agency for Science, Technology and Research, Singapore; [3]New York University, United States

Magnetic skyrmions are topological spin textures with potential applications in next-generation memory and logic. Controlling the inversion symmetry breaking interfacial Dzyaloshinskii-Moriya Interaction (DMI) is the key to stabilizing skyrmions in magnetic multilayers. We investigate the DMI of compensated ferrimagnetic GdCo alloy using Density Functional Theory (DFT), and explain the impact of Tungsten (W) alloying in a $Pt/GdCo/Pt_{1-x}W_x$ structure. We find that a small amount of W (~10%) is sufficient to give rise to a non-zero DMI by breaking the inversion symmetry of Pt/GdCo/Pt. We also find that the DMI increases as a function of W composition (x), but saturates at higher W composition, in agreement with experiment. We show that the vanishing of spin-orbit coupling (SOC) energy to the adjacent metal layers of the top interface and the simultaneous constancy of the bottom interface is responsible for such saturating behavior of the DMI. Additionally, we investigate Pt/GdCo/X, where X = Ta, W, Ir to demonstrate the effect of capping layer heavy metals on the DMI. Our results predict that W in the capping layer favors a higher value of the DMI than Ta and Ir. Our results open up exciting combinatorial possibilities for controlling the DMI in ferrimagnets to nucleate and manipulate ultrasmall high-speed skyrmions.

6:25 AM F.NM04.01.07
Experimental Observation of Exchange-Driven Chiral Effects in Parabolic Nanostripes Oleksii M. Volkov, Denys Makarov and Jürgen Fassbender; Helmholtz-Zentrum Dresden-Rossendorf, Germany

Broken magnetic symmetry is a key aspect in condensed matter physics and in particular in magnetism. It results in the appearance of chiral effects, e.g. topological Hall effect [1] and non-collinear magnetic textures including chiral domain walls and skyrmions [2,3]. These chiral structures are in the heart of novel concepts for magnonics [4], antiferromagnetic spintronics [5], spin-orbitronics [6] and oxitronics [7].
The main origin of the chiral symmetry breaking and thus for the magnetochiral effects in magnetic materials is associated to an antisymmetric exchange interaction, the intrinsic Dzaloshinskii-Moriya interaction (DMI). At present, tailoring of DMI is done rather conventionally by optimizing materials, either doping a bulk single crystal or adjusting interface properties of

thin films and multilayers. A viable alternative to the conventional material screening approach can be the exploration of the interplay between geometry and topology. This interplay is of fundamental interest throughout many disciplines in condensed matter physics, including thin layers of superconductors [8] and superfluids [9], nematic liquid crystals [10], cell membranes [11], semiconductors [12]. In the emergent field of curvilinear magnetism chiral effects are associated to the geometrically broken inversion symmetries [13]. Those appear in curvilinear architectures of even conventional materials. There are numerous exciting theoretical predictions of exchange and magnetostatically-driven curvature effects, which do not rely on any specific modification of the intrinsic magnetic properties, but allow to create non-collinear magnetic textures in a controlled manner by tailoring local curvatures and shapes [14,15]. Until now the predicted chiral effects due to curvatures remained a neat theoretical abstraction.
Here, we demonstrate the very first experimental confirmation of the existence of the curvature-induced chiral interaction with exchange origin in a conventional soft ferromagnetic material [16]. It is experimentally explored the theoretical predictions, that the magnetisation reversal of flat parabolic stripes shows a two step process. At the first switching event, a domain wall pinned by the curvature induced exchange-driven DMI is expelled leading to a magnetisation state homogeneous along the parabola's long axis. Measuring the depinning field enables to quantify the effective exchange-driven DMI interaction constant. The magnitude of the effect can be tuned by the parabola's curvature. It is found that the strength of the exchange-induced DMI interaction for the experimentally realised geometries is remarkably strong, namely ≈ 0.4 mJ/m^2 , compared the surface induced DMI. The presented study legitimates the predictive power of full-scale micromagnetic simulations to design the properties of ferromagnets through their geometry, thus stabilising chiral textures.

Design of Giant DMI and Its Microscopic Origin in Magnetic Bilayers Priyamvada Jadaun, Leonard Register and Sanjay Banerjee; UT Austin, United States

Magnetic skyrmions are compact spin textures that show remarkably unique, particle-like properties. They are widely regarded as promising candidates for emergent magnetic devices as they are small in size and easily maneuverable. The Dzyaloshinskii-Moriya interaction (DMI) is often critical to the generation and manipulation of skyrmions. However, there has been a fundamental lack of understanding of the microscopic origin of DMI or the mechanisms by which DMI stabilizes skyrmions in magnetic bilayers. Little has been known of the material parameters that determine the value of DMI. This knowledge is critical for rational design of skyrmion-hosting materials and further development of skyrmion technology. Here we investigate DMI in a series of magnetic bilayers using first principles methods. We present a new theoretical model that explains the microscopic origin of DMI in magnetic bilayers. We demonstrate that the value of DMI depends on two material parameters, interfacial hybridization and orbital contributions of the heavy metal. Using these parameters, we explain experimentally observed DMI trends. We also report four new materials systems predicted to have giant DMI and can be expected to outperform the best materials known so far, and new designs for magnetic multilayers. Our results provide a new understanding of DMI, discover highly promising materials and suggest pathways for the controlled generation of skyrmions.

5:00 AM *F.NM04.02.01
Advances in X-Ray Spectromicroscopies to Study Novel Topological Spin Textures Peter Fischer[1,2]; [1]Lawrence Berkeley National Lab, United States; [2]University of California, Santa Cruz, United States

Microscopic spin textures and their dynamics are key to understand and control the properties, behavior and functionalities of novel magnetic materials. Of particular interest are topological systems, as they hold the promise to improve speed, size and energy efficiency of future spin driven technologies. Advanced characterization tools that provide magnetic sensitivity to spin textures at high spatial resolution, ultimately at buried interfaces and in all three dimensions [1], and at high temporal resolution to capture the spin dynamics across scales, are therefore of large scientific interest.
Magnetic soft X-ray spectro-microscopies [2] provide unique characterization opportunities to study the statics and dynamics of spin textures in magnetic materials combining X-ray magnetic circular dichroism (X-MCD) as element specific, quantifiable magnetic contrast mechanism with spatial and temporal resolutions down to fundamental magnetic length, time, and energy scales.
Current developments of x-ray sources aim to increase dramatically the coherence of x-rays opening the path to new approaches and characterization tools, such as ptychography [3] or x-ray photo-correlation spectroscopy (XPCS) [4] that allow unprecedented studies of nanoscale heterogeneity, complexity, and fluctuations.
I will review recent results studying the static properties and dynamic behavior of magnetic skyrmion [5,6] textures with potential application to novel magnetic logic and storage devices, as well as first results from target skyrmions that are seen as precursors for hopfions [7]. An unexpected and drastic change of the correlation times in nanoscale spin fluctuations near phase boundaries, i.e., in the skyrmion phase, and near the boundary with the stripe phase of a multilayered Fe/Gd system [4] was observed in an XPCS study at LCLS with a novel 2-pulse scheme.

Three-Dimensional Skyrmionic Networks in Chiral Magnets and Liquid Crystals Andrey Leonov; Hiroshima University, Japan

Chiral skyrmions [1] are particle-like topological solitons with complex non-coplanar spin structures stabilized in noncentrosymmetric magnetic materials by specific Dzyaloshinskii-Moriya interaction (DMI). Being surrounded by the homogeneously magnetized state, skyrmions represent ensembles of weakly ***repulsive axisymmetric particles*** [2] oriented along the field. With the onset of the conical phase, skyrmions become non-axisymmetric and due to the attractive interaction tend to produce multi-skyrmion bound states - clusters [3]. Both types of skyrmions were observed experimentally in PdFe/Ir(111) bilayers with induced DMI [2] and in thin (≈70 nm) single-crystal samples of Cu_2OSeO_3 [3]. Moreover, the attracting skyrmions were predicted to underlie precursor phenomena (e.g., A-phase in B20 magnets) and to have prospects of being used in spintronics as *an effective alternative* to the common axisymmetric skyrmions [4]. Prototypes of spintronic devices based on the crossover of skyrmion-skyrmion interaction and low spin currents required to set skyrmions into motion were suggested in Ref. [4]. Note that the cross-section of isolated skyrmions within the conical phase has the typical structure of bimerons introduced in Ref. [5] and shown to develop an anisotropic character of skyrmion-skyrmion interaction in lacunar spinels GaV_4Se_8 with the C_{3v} symmetry and easy-plane uniaxial anisotropy.
Skyrmions may also become oblique with respect to the field. In particular, in Cu_2OSeO_3 due to the competing exchange and

cubic anisotropies [6], the conical phase tilts away from the field direction and thus underlies the deviation of skyrmions. As a result, attracting oblique skyrmions may potentially form ***extended networks*** in which their axes are not parallel to each other as in previously reported skyrmion clusters. Skyrmion networks with ***mutually orthogonal isolated skyrmions*** [7] were directly visualized in thin layers of chiral liquid crystals. We used chiral nematics as a model system for probing the skyrmion behavior due to the similarity of phenomenological models for both condensed-matter systems, chiral magnets and liquid crystals.
Thus, in the present abstract ***by experimental and theoretical means,*** I will introduce different classes of oblique non-axisymmetric skyrmions and elucidate the principles of their meshing into a large diversity of extended three-dimensional ***skyrmionic networks*** in chiral magnets and liquid crystals.

Magnetic Skyrmions and Hopfions in Three-Dimensional Chiral Magnets Jiadong Zang; University of New Hampshire, United States

In this talk, various three-dimensional (3D) topological spin textures in magnets without inversion symmetry will be introduced. The first part of the talk features the recent observation of target skyrmions in chiral magnet nanodisks through theory-experiment collaborations. Two types of zero-field target skyrmions are confirmed, and Bloch points are identified during topological transition between different types of target skyrmions. The spectrum of collective spin wave modes in target skyrmions also reveal the 3D nature of spin excitations.

Second part of the talk introduces a very recent work on hopfions in chiral magnetic nanodisk. This is one of the first experimentally feasible prediction on magnetic hopfions. The hopfion in this setup is confirmed by analyzing the linking between any two equal-spin loops and calculating the Hopf invariant. Another topological configuration, the pairing between monopole and anti-monopole, is also identified in the same system. Transition from this state to hopfion, being identical to sphere-torus topological deformation, can be achieved by an external magnetic field. Dynamics of hopfions will also be discussed.

This work is supported by the U.S. Department of Energy (DOE), Office of Science, Basic Energy Sciences (BES) under Award No. de-sc0020221.

Chiral Non Collinear Spin Textures Stuart S. Parkin; Max Planck Institute of Microstructure Physics, Germany

Magnetic non-collinear spin textures that have chiral structures are of great current interest. The same type of Dzyaloshinskii-Moriya (DMI) vector exchange interactions that stabilize chiral Néel domain walls in magnetic multilayers [1-3] results in the formation of topological spin textures in bulk compounds. We recently discovered magnetic *antiskyrmions* in a tetragonal inverse Heusler compound $Mn_{1.4}Pt_{0.9}Pd_{0.1}Sn$ using Lorentz transmission electron microscopy (LTEM)[4]. Unlike skyrmions in B20 compounds, that have been extensively studied, the size of the anti-skyrmion can be tuned by varying the thickness of the host material allowing for sizes varying from nanometer to microns in the same material[5]. This is due to long range magneto-dipole interactions that are important in this compound that has a complex DMI interaction with a symmetry that follows the D_{2d} symmetry of its crystalline structure. The same symmetry ensures that anti-skyrmions are robust to temperature and magnetic field[6]. The magnetic dipole-dipole interactions also allow for the formation of metastable "elliptical skyrmions" in this same material[7]. These have Bloch-like boundaries that we can directly observe using LTEM. Finally, we discuss our recent discovery of novel Néel like skyrmions in a metallic compound that exist almost to room temperature and that are also tunable in size[8]. Chiral spin textures in ferro-, ferri- and anti-ferrimagnetic materials and thin film heterostructures are of fundamental interest with potential for spintronic applications especially Racetrack Memory.

Structures and Dynamics of Spin Textures with Boundaries Naoto Nagaosa[1,2], Wataru Koshibae[2] and Jan Masell[2]; [1]University of Tokyo, Japan; [2]RIKEN Center for Emergent Matter Science (CEMS), Japan

Structures and dynamics of spin textures in magnets are the subject of extensive studies, which is a crucial issue also for applications. The structures and their motion in the bulk are rather well understood, but the influence of the boundaries is less studied. In this talk I would focus on the effects of boundaries such as surfaces and edges as revealed by theoretical analysis. It includes (i) the skyrmion string in a thin film with associated topological defects, and (ii) the helix with boundaries. In the former case with an out-of-plane magnetic field, a step edge on the thin film substantially affects the motion of a skyrmion string, leading to its splitting and annihilation. These processes are understood by introducing two types of topological indices, i.e., the bulk monopole number and the surface skyrmion number. For an in-plane magnetic field, on the other hand, several kinds of topological defects are found to appear, which is consistent with the experimental observations. Recently, the helix structure was proposed to show inductance under an ac current. Therefore, the nonlinear dynamics of the helix are an important issue, which we have investigated both by numerical simulations and analytical calculations. It turns out that the role of the boundary is crucial to determine the direction of the wavevector of the helix: There is a 90° difference between periodic boundary condition and open boundary condition, revealing the vital role of the boundary.

The lamellar morphology of chiral spin textures is analogous to liquid crystals and biological systems. Analogous to cholesteric liquid crystals, chiral magnets possess a periodic layered structure and form a wide variety different types of non-trivial topological defects. Using magnetic force microscopy (MFM) on the near-room temperature helimagnet FeGe we resolve 1D and 2D topological defects, including disclinations and dislocations with nonzero topological winding number, as well as three fundamental types of helimagnetic domain walls. Interestingly, in addition to their non-trivial structure, all topological defects in FeGe exhibit an unusual magnetic response in MFM, which is not observed in regions with perfect lamellar-like order. This magnetic signature is reminiscent of the so-called “lines of flare” in cholesteric liquid crystals, suggesting local variations in magnetic susceptibility. We investigate the origin of the magnetic signature of the topological defects and discuss the possibilities to utilize the local MFM response as read-out signal in spintronics devices.

Topological Half-Skyrmions and Bimerons in an Antiferromagnetic Insulator at Room Temperature Hariom Jani[1], Jheng-Cyuan Lin[2], Jiahao Chen[2], Jack Harrison[2], Francesco Maccherozzi[3], Jonathon Schad[4], Saurav Prakash[1], CHANG-BEOM EOM[4,4], Ariando Ariando[1], T. Venky Venkatesan[1] and Paolo G Radaelli[2]; [1]National University of Singapore, Singapore; [2]University of Oxford, United Kingdom; [3]Diamond Light Source, United Kingdom; [4]University of Wisconsin–Madison, United States

In the quest for post-CMOS technologies, ferromagnetic domain walls and topological skyrmions have shown great promise as elements in spintronic racetrack devices. Recently, attention has been shifted to antiferromagnetic (AFM) analogues, as they are anticipated to demonstrate relativistic dynamics, fast motion without transverse deflection and size scaling. Despite this, experimental implementations in natural antiferromagnetic systems at room temperature are yet to emerge. Here, we

demonstrate a family of topological antiferromagnetic spin-textures in α-Fe_2O_3 – an earth-abundant oxide insulator – capped with a Pt over-layer. By varying temperature and doping, we stabilize exotic AFM merons-antimerons (half-skyrmions), and AFM bimerons, which can be erased by magnetic fields and re-generated by temperature cycling. Controlled by current-based spin-torques from the heavy-metal over-layer, these AFM textures could emerge as prime candidates for low-energy antiferromagnetic spintronics.

Skyrmions in Centrosymmetric Magnets Shinichiro Seki; The University of Tokyo, Japan

Magnetic skyrmion, i.e., a topologically stable swirling spin configuration, has recently attracted attention as a particle-like object potentially suitable for the design of high-density information bits. Previous observations of skyrmions have mostly focused on noncentrosymmetric systems, where Dzyaloshinskii-Moriya interaction plays an important role[1,2]. On the other hand, recent theoretical studies suggest that skyrmions can be stabilized even in centrosymmetric systems by considering different microscopic mechanisms. For example, geometrical frustration of short-range exchange interactions on triangular lattice is predicted to stabilize a hexagonal lattice of skyrmions[3]. Another potential mechanism is the RKKY and four-spin interactions mediated by itinerant electrons, which is expected to favor a skyrmion lattice state for highly-symmetric (such as hexagonal or tetragonal) crystal lattice systems[4].
In this talk, I overview the recent experimental discovery of skyrmions in centrosymmetric systems[5-7]. In particular, we focus on the case of centrosymmetric tetragonal magnet $GdRu_2Si_2$, where the square lattice of skyrmions with extremely small diameter (1.9nm, i.e. the smallest value ever reported for single-component bulk materials) has been observed[7]. Our results demonstrate that skyrmions can be stabilized even without geometrically frustrated lattice nor inversion symmetry breaking, and suggest that rare-earth intermetallics with highly-symmetric crystal lattice may ubiquitously host nanometric skyrmions of exotic origins.

Skyrmions—A Playground for Non-Conventional Computing and Phase Transitions in 2D Mathias Klaeui; Johannes Gutenberg University Mainz, Germany

In our information-everywhere society IT is a major player for energy consumption. Novel spintronic devices can play a role in the quest for GreenIT if they are stable and can transport and manipulate spin with low power. Devices have been proposed, where switching by energy-efficient approaches, such as spin-polarized currents is used [1],
Firstly, to obtain ultimate stability of states, topological spin structures that emerge due to the Dzyaloshinskii-Moriya interaction (DMI) at structurally asymmetric interfaces, such as chiral domain walls and skyrmions with enhanced topological protection can be used [2-5]. We have investigated in detail their dynamics and find that it is governed by the topology of their spin structures [2]. By designing the materials, we can even obtain a skyrmion lattice phase as the ground state [3].
Secondly, for ultimately efficient spin manipulation, we use spin-orbit torques, that can transfer more than 1hbar per electron by transferring not only spin but also orbital angular momentum. We combine ultimately stable skyrmions with spin orbit torques into a skyrmion racetrack device [3-5], where the real time imaging of the trajectories allows us to quantify the novel skyrmion Hall effect [5,6].
Beyond conventional memory, we furthermore use spin-orbit torque induced skyrmion dynamics for non-conventional stochastic computing applications, where we have developed a skyrmion reshuffler device [6]. Here we use thermal skyrmion

motion to implement a key component for stochastic computing [6]. Such thermal skyrmion diffusion can also be controlled by symmetry breaking [7] and this is useful for token – based Brownian computing.
Finally the thermal dynamics of skyrmion quasi-particles lends itself to exploiting this system for the study of phases and phase transitions in 2D. We have studied the transition of skyrmion arrangements from the liquid phase across the hexatic phase unique to 2D systems into the solid phase [8]. These transitions occur in a wide range of skyrmions systems [8,9], thus showing that skyrmions have evolved from an object of study themselves and are now being understood controlled sufficiently well for use as model systems to study exciting statistical physics in 2D.

Detection and Transformation of Confined Magnetic Skyrmions in Metal Silicide and Germanide Nanostructures Song Jin; University of Wisconsin--Madison, United States

Skyrmions are novel topologically stable spin vortices that show promise for next-generation magnetic storage due to their nanoscale domains to enable high information storage density and their low threshold for current-driven motion to enable ultralow energy consumption. One-dimensional (1D) nanowires are ideal hosts for skyrmions since they not only serve as a natural platform for magnetic racetrack memory devices but also can stabilize skyrmions. We have developed synthetic methods for nanowires (and nanoplates) of non-centrosymmetic cubic B20 monosilicides (MnSi, FeSi, CoSi) and monogermanides (FeGe) and their alloys (such as $Fe_xCo_{1-x}Si$ and $Fe_{1-x}Co_xGe$), many of which display exotic helimagnetic and skyrmion magnetic phases with domain sizes from 10 to 230 nm. Collaborating with several groups, we have used Lorentz TEM, off-axis electron holography (EH), magnetotransport measurements to confirm that magnetic skyrmion phases are stable over a larger magnetic field-temperature range in these nanostructures compared to bulk crystals and thin films. Magnetoresistance (MR) measurements revealed the critical magnetic fields for the transitions between different magnetic spin structures at different temperatures. Topological Hall effect (THE) measurements of MnSi nanowires and $Fe_{1-x}Co_xGe$ ($x<0.1$) nanoplates further confirmed the extended skyrmion stability, for example, in FeGe nanowires and $Fe_{1-x}Co_xGe$ ($x<0.1$) nanoplates with skyrmions stabile up to about 280 K. We have further demonstrated the current-driven motion of skyrmions in this extended skyrmion phase region in MnSi nanowires. Correlating real space magnetic imaging with the magnetotransport measurements reveals previously unexplored transformation of skyrmion strings and other magnetic ordering due to nanoscale confinements. These results open up the exploration of nanowires as an attractive platform for investigating skyrmion physics in 1D systems and exploiting skyrmions in magnetic storage concepts.

5:45 AM *F.NM04.03.04
Thermal Effects on the Skyrmion Dynamics Wanjun Jiang; Tsinghua University, China

Skyrmions are particle-like topological spin textures stabilized by the Dzyaloshinskii-Moriya interaction, which have recently stimulated great interests in spintronics community. The dynamics of which have been frequently studied via using magnetic fields and current-induced spin torques. On the other hand, a comprehensive understanding of thermal effects, including random thermal fluctuation and directional thermal currents, on the dynamics of skyrmions are not fully established yet.

In this talk, I will first discuss our recent experimental observation of the thermal fluctuation-induced random walk of a single isolated Néel-type magnetic skyrmion in an interfacially asymmetric Ta/CoFeB/TaO_x multilayer. In particular, an intriguing topology dependent Brownian gyromotion behavior of skyrmions has been identified. The onset of Brownian gyromotion of a single skyrmion induced by the thermal effects, including a nonlinear temperature-dependent diffusion coefficient and topology-dependent gyromotion are further formulated based on the stochastic Thiele equation.

Subsequently, I will discuss the thermal generation, manipulation and detection of nanoscale skyrmions, which were made in microstructured devices made of different multilayers – $[Ta/CoFeB/MgO]_{15}$, $[Pt/CoFeB/MgO/Ta]_{15}$ and

[Pt/Co/Ta]$_{15}$ integrated with on-chip heaters, by using a full-field soft X-ray microscopy. In particular, the thermal generation of densely packed skyrmions at the device edge, together with the unidirectional diffusion of skyrmions from the hot region towards the cold region were experimentally observed. These thermally generated skyrmions can be further electrically detected by measuring the accompanied anomalous Nernst voltages. These results could open another exciting avenue for enabling skyrmionics, and promote interdisciplinary studies among spin caloritronics, magnonics and skyrmionics.

Stabilization of Skyrmion States by a Gradient of Curvature in Ferromagnetic Shells Oleksandr Pylypovskyi[1,2], Denys Makarov[1], Volodymyr Kravchuk[3,4], Avadh Saxena[5] and Denis Sheka[2]; [1]Helmholtz-Zentrum Dresden-Rossendorf e.V., Ukraine; [2]Taras Shevchenko National University of Kyiv, Ukraine; [3]Karlsruhe Institute of Technology, Germany; [4]Bogolyubov Institute for Theoretical Physics of National Academy of Sciences of Ukraine, Ukraine; [5]Los Alamos National Laboratory, United States

Skyrmions represent a class of chiral magnetic textures with unique properties relevant for spintronic and spin-orbitronic applications [1]. Geometrical curvature can be used as an efficient mean to tailor chiral and anisotropic responses of thin ferromagnetic shells [2-4]. This was recently confirmed by quantifying the strength of the Dzyaloshinskii-Moriya interaction (DMI) in curved nanostripes [5]. Furthermore, there are numerous predictions of the stabilization of curvature-driven of small-radius skyrmions in spherical shells [6] and an appearance of skyrmion lattices as the ground state in intrinsically chiral curvilinear thin films [7].

Here, we demonstrate a new pathway of stabilizing Neel skyrmion and skyrmionium states relying on the gradient of curvature using a magnetic thin film hosting a circular nanoindentation [8]. These skyrmion states can be formed in a material even without an intrinsic DMI. We propose a physical picture of this effect, which is related to the pinning of a chiral magnetic domain wall at the bend of a nanoindentation. Geometry of the film is described by two principal curvatures k1(r), describing film geometry in radial direction, and k2(r) inversely proportional to the distance from origin. In this respect, the spatial inhomogeneity of the curvature-induced DMI governing by k1(r) is responsible for the stabilization of the skyrmion state. The lateral dimensions of the stabilized chiral magnetic textures are varied in a broad range by engineering the size of the nanoindentation. We describe the stability condition of skyrmion states. Furthermore, on the fundamental side, we put forth a general analytical framework allowing us to map a complex problem of the description of a magnetic texture at a surface of revolution to a standard planar problem with modified constants of DMI and magnetic anisotropy. In this respect, our model predicts a new mechanism of pinning of magnetic domain walls in planar ferromagnetic films with intrinsic DMI on inhomogeneities of the DMI.

Topological Transformation of Magnetic Skyrmion Strings in Nanostructures of Cubic B20 Materials Nitish Mathur[1], Fehmi Yasin[2], Matthew J. Stolt[1], Wensen Wei[3], Haifeng Du[3], Mingliang Tian[3], Xiuzhen Yu[2] and Song Jin[1]; [1]University of Wisconsin-Madison, United States; [2]RIKEN Center for Emergent Matter Science, Japan; [3]High Magnetic Field Laboratory, Chinese Academy of Science, China

Magnetic skyrmions are topological spin textures that have shown promise due to their potential applications in high density

and energy efficient memory nanodevices. Chiral helimagnets with the non-centrosymmetric cubic B20 crystal structure host Bloch-type skyrmions due to the antisymmetric spin exchange interaction known as the Dzyaloshinskii-Moriya interaction (DMI). Although magnetic skyrmions are depicted as two-dimensional spin texture in bulk crystals, in reality, they possess a three-dimensional structure of skyrmions that looks like elongated strings extending throughout the thickness of the sample. In geometrically confined nanostructures, such as FeGe nanowires or nanoplates, these skyrmion strings (SkS) are stabilized over large range of temperature and magnetic field. We have developed "bottom-up" chemical vapor deposition (CVD) synthetic techniques to synthesize single-crystal FeGe nanowires and $Fe_{1-x}Co_xGe$ ($x<0.1$) nanoplates. We have observed increased sensitivity of magnetotransport measurements towards magnetic phase transitions in FeGe nanostructures when the applied magnetic field is parallel to the current, which could be mapped to the transformations of conical and helimagnetic spin textures to/from SkS. We further implemented Lorentz TEM imaging technique on nanostructures with applied magnetic field perpendicular to the observation direction to visualize the topological transformations of SkS to helical/conical spin states in real space. These Lorentz TEM imaging in correlation with the magnetotransport measurements reveal previously unexplored transformation of skyrmion strings due to nanoscale confinements.

Mechanism of Structural and Chemical Control Over Skyrmion Phases in Lacunar Spinels Daniil A. Kitchaev, Emily C. Schueller and Anton Van der Ven; University of California, Santa Barbara, United States

The formation of magnetic skyrmions is intrinsically controlled by the coupling between magnetic interactions and the underlying crystal structure, meaning that skyrmion phase stability is particularly sensitive to chemical variations, structural transitions and mechanical deformation. The GaM_4X_8 (M=V/Mo, X=S/Se) lacunar spinels are a versatile class of model materials for studying these couplings as they exhibit a variety of skyrmionic phase diagrams across several structures and chemistries. First, we use electronic-structure calculations and generalized cluster expansions to derive a universal magnetic phase diagram for materials in this space, and argue that reported variations in skyrmion stability are quantitatively explained by structurally- and chemically-induced changes to magnetocrystalline anisotropy[1]. In particular, skyrmion stability across all temperatures below T_c reported in some of these materials is a direct consequence of minimal uniaxial anisotropy. Second, we combine experimental and first-principles computational analysis to demonstrate that subtle variations in the structural evolution of $GaMo_4Se_8$ lead to dramatic changes in magnetic behavior, switching from skyrmion host to ferromagnet[2] and corresponding to a giant effective magnetostructural coupling. Our results reveal specific materials design strategies for engineering robust skyrmion-host materials, and controlling skyrmion behavior through mechanical means.

Andreev Bound States and Majorana Fermions in Helical 1D Systems Jelena Klinovaja; University of Basel, Switzerland

In my talk, I will discuss low-dimensional condensed matter systems, in which topological properties could be engineered per demand. Majorana fermions can emerge in hybrid systems with proximity-induced superconducting pairing. I will present our numerical and analytical studies of such geometries with proximity effects [1-3]. In the second part of the talk, I will discuss an analytical model of a Rashba nanowire that is partially covered by and coupled to a thin superconducting layer, where the uncovered region of the nanowire forms a quantum dot [4,5]. Even if there is no topological superconducting phase possible, there is a trivial Andreev bound state that becomes pinned exponentially close to zero energy as a function of magnetic field strength when the length of the quantum dot is tuned with respect to its spin-orbit length such that a resonance condition of Fabry-Perot type is satisfied. In this case, the Andreev bound state remains pinned near zero energy for Zeeman energies that exceed the characteristic spacing between Andreev bound state levels but that are smaller than the spin-orbit energy of the quantum dot. Importantly, as the pinning of the Andreev bound state depends only on properties of the quantum dot, this behavior is unrelated to topological superconductivity.

12:00 PM *F.NM05.04.03
Materials Considerations for Majorana Based Quantum Computations Jay Sau; University of Maryland, United States

Majorana modes are one of the most promising candidates for the creation of topological qubits in the long term. While evidence for Majorana modes has been obtained for Majorana modes in several systems such as semiconductor nanowires, semiconductor 2DEGs, iron-based superconductors, topological insulators as well as iron atom chains to name a few, evidence for a qubit degree of freedom is elusive. I will begin by reviewing what it means experimentally to observe a qubit. Following this we will discuss the central device challenge in this regard i.e. quasiparticle poisoning. I will then describe potential material dependence of this phenomena as well as how quasiparticle poisoning can manifest in various experiments related to topological superconductivity. Specifically, we will discuss how the observation of quantized conductance into a zero-bias conductance peak associated with a Majorana over a range of tunneling provides some bounds on quasiparticle poisoning times. The measurement of Coulomb blockade transport, which has been observed only for a limited number of superconductors can provide more precise information on such bounds.

12:30 PM *F.NM05.04.05
Topological Superconductivity in Superconductor–Semiconductor Heterostructures Roman Lutchyn; University of California, Santa Barbara, United States

Superconductor–semiconductor heterostructures represent a versatile platform for realizing Majorana zero-energy modes. In this talk, I will explain how to engineer topological superconductivity at the interface of a conventional (s-wave) superconductor and a semiconductor with spin-orbit interaction. I will discuss state-of-the-art numerical approaches for modeling realistic devices which take into account proximity-induced superconductivity, orbital and Zeeman effect of an applied magnetic field, spin-orbit coupling as well as the electrostatic environment on equal footing. Finally, I will review recent materials science progress in growing superconductor–semiconductor heterostructures and discuss promising new directions.

Materials Science, Physics and Engineering of Topological Quantum Circuits Sergey Frolov; University of Pittsburgh, United States

With Quantum Supremacy upon us, and with major tech companies investing in quantum computing, one may wonder how

much room is left there for academic research? The answer is: more than ever! Our existing qubits are great, but it is difficult to see them carrying us beyond the modern era of noisy intermediate-scale quantum processors, and ushering in the truly scalable, fault tolerant and commercially viable computers. Most likely, a qubit and its couplings, gates will once more need to be re-thought from the ground up - from the atomic first-principles level to the device architecture level. At the same time, the progress we made in quantum control and engineering is so huge that these methods have themselves become mature tools of science. They can be applied beyond quantum computing - to understand the basic questions of quantum dynamics and to probe exotic matter.

One solution may come from studying topological superconductivity. This is an interesting state most notable for spurring Majorana zero modes. Those modes can be both investigated as some of the first non-Abelian excitations, and they can be used in quantum circuits for storing and protecting quantum information. Majorana research has posed many basic materials questions of how to engineer the precise structures that possess intrinsic fault tolerance through topological protection. In my work I have developed new materials and devices for unambiguous observation of robust Majorana modes. I have worked on establishing clear criteria (signatures) of Majorana modes and how to tell them apart from other excitations that may be present in the same devices. It is exciting to apply modern quantum probes, developed based on transmon and spin qubits, to these systems in search for new exotic quantum matter. And perhaps solving some of the big challenges facing quantum computing at the same time.

Atomic Qubits in Silicon Michelle Y. Simmons[1,2]; [1]University of New South Wales, Australia; [2]Silicon Quantum Computing Pty Ltd, Australia

Atom qubits in silicon have demonstrated extremely long electron and nuclear spin coherence times [1,2] making silicon a promising semiconductor material for spin-based quantum information. The two-level spin state of single electrons bound to shallow phosphorus donors in silicon provide well defined, reproducible qubits [3] with low gate densities. An important challenge in these systems is the realisation of an architecture, where we can position donors within a crystalline environment with <20nm separation, individually address each donor, manipulate the electron spins using ESR techniques, read-out their spin states and perform both single and two qubit gates.

We have pioneered a unique strategy to build a scalable quantum computer in silicon atom by atom. We use scanning tunneling microscope lithography and ultra-high vacuum crystal growth to precisely position individual P donors in Si [4] aligned with nanoscale precision to local control gates [5] necessary to initialize, manipulate, and read-out the spin states [6-8].

During this talk I will focus on demonstrating fast, high fidelity single-shot spin read-out [9], ESR control of precisely-positioned P donors in Si [10] and our recent results of demonstrating a fast (~ns) two-qubit SWAP gate [11,12]. We have also published a 3D architecture for implementation of error corrrection using the surface code [13]. With important advances in control at the atomic-scale, I will attempt to highlight the benefits of single atom qubits in silicon.

Effects of Coulomb Interactions in Silicon Quantum Dots Susan Coppersmith[1,2]; [1]University of New South Wales, Australia; [2]University of Wisconsin–Madison, United States

Silicon is an attractive materials platform for developing large-scale quantum computers because of its compatibility with classical silicon electronics and its potential for scalability. Recent progress towards quantum computing in silicon has been impressive, but better understanding of the materials will enable improved controllability and predictability of qubit devices.

This talk will discuss some of the fundamental physics and materials science challenges that arise, focussing on the nontrivial interplay between Coulomb interactions and the valley degree of freedom in silicon quantum dots containing more than one electron. Prospects for further development will also be discussed.

8:48 AM *F.NM05.06.04
Exchange Control of Three Spins in Si Triple Quantum Dots Seigo Tarucha; RIKEN, Japan

High-fidelity quantum operations of single and two spins as well as readout and initialization have recently been demonstrated for Si quantum dots. Among them exchange control between spins is an ingredient of quantum entanglement for implementing quantum algorithms, but the demonstration of entanglement has been limited to two-qubit entanglement mainly due to difficulties in controlling exchange couplings in a multi-qubit array. We use a triple quantum dot equipped with a micro-magnet to control exchange couplings in two or three spin systems. We first measure the single qubit fidelity for three spins in the (1,1,1) charge state and obtain the values of 99.4 to 99.9 % for three spins. Then we use two spins to study exchange control of two qubits or singlet-triplet qubit drive. We use a resonant drive technique of the exchange interaction at the qubit frequency and obtained the fidelity of 99.6% thanks to the symmetric operation and a large micro-magnet Zeeman field gradient. Finally we use three spins to implement three-qubit entanglement. We precisely control exchange couplings between three spins and generate GHZ state. The GHZ state generation protocol will be useful to encode and decode a logical state for the bit-flip quantum error correction code.

Quantum Computing with Semiconductors—Spins Inside Lieven Vandersypen; TU Delft, Netherlands

Quantum computation has captivated the minds of many for almost two decades. For much of that time, it was seen mostly as an extremely interesting scientific problem. In the last few years, we have entered a new phase as the belief has grown that a large-scale quantum computer can actually be built. Quantum bits encoded in the spin state of individual electrons in silicon quantum dot arrays, have emerged as a highly promising direction [1]. In this talk, I will present our vision of a large-scale spin-based quantum processor, and ongoing work to realize this vision.

First, we created local registers of spin qubits with sufficient control that we can program arbitrary sequences of operations. We show the creation of each of the Bell states with fidelities of 85-90% and the implementation of the four instances of the Deutsch-Jozsa and the Grover algorithms on two qubits [2].

Second, we have explored coherent coupling of spin qubits at a distance via two routes. In the first approach, the electron spins remain in place and our coupled via an intermediary degree of freedom. After showing this principle with an ancillary quantum dot as a coupler [3], we recently observed strong coupling of a single spin to a single microwave photon in a superconducting resonator [4]. In the second approach, spins are shuttled along a quantum dot array, preserving both the spin projection [5] and spin phase [6].

Third, in close collaboration with Intel, we have fabricated and measured quantum dots using all-optical lithography on 300 mm wafer, using industry-standard processing [7]. Qubit measurements are now underway. We expect that this industrial approach to nanofabrication will be critical for achieving the extremely high yield necessary for devices containing hundreds or thousands of qubits. Furthermore, we anticipate that the device stability and charge noise levels will eventually outperform those of devices made in university-style cleanrooms.

When combined, the progress along these various fronts can lead the way to scalable networks of high-fidelity spin qubit registers for computation and simulation.

Si/SiGe Heterostructures for Quantum Information Science Clayton A. Jackson; HRL Laboratories, United States

Quantum information and computing are at the forefront of computer science, but their implementation relies on the identification and development of a suitable materials system. One such candidate is Si/SiGe. Much progress has been made in Si/SiGe heterostructures grown on metamorphic SiGe substrates as hosts to lithographically defined quantum dots. In this presentation we focus on the general structure and requirements of SiGe quantum dot heterostructures, the demands imposed by necessary dot performance, and advances in characterization methods for these materials.

Engineering Semiconductors for Spin-Based Quantum Technologies Christopher Anderson, Alexandre Bourassa, Kevin Miao and David Awschalom; University of Chicago, United States

Silicon carbide (SiC) is a technologically mature semiconductor material that is host to a variety of different solid-state spin defects. These spin qubits not only boast long coherences but also a natural spin-photon interface that can mediate entanglement at a distance. However, as for any solid-state quantum technology, issues of charge noise and magnetic fluctuations are prevalent. In this talk, we present recent advances in minimizing and controlling these sources of noise.

We first discuss our ability to mitigate charge noise in commercial SiC electronic devices [1]. Surprisingly, the integration of single spins into these devices results in THz-scale tunability of a single divacancy spin's optical interface while simultaneously eliminating spectral diffusion and blinking. This results in an electrically-tunable single photon source that can be tuned over 40,000 linewidths, constituting a near-ideal spin-photon interface at wafers scales near the telecommunications band.

We then describe the control and optimization of the nuclear spin environment for these spin qubits [2]. In general, nuclear spins are both a cause of decoherence and a valuable resource for electron spins in the solid-state. While isotopic purification

removes noise, it also reduces the availability of nuclear spin quantum memories that are vital to many quantum technologies. Guided by *ab-initio* theory, we strike this balance and find an optimal isotopic concentration that maximizes the number of available quantum memories. Experimentally, we demonstrate extended coherences and the first entanglement and control of single nuclear spins in silicon carbide through isotopic engineering.

The elimination of electrical noise combined with finely tuning the nuclear environment results in a material platform for quantum technology that combines a stable spin-photon interface with an electron spin that can leverage entanglement with local nuclear spin qubit clusters. We show that this electron spin state has long coherence times (T_2>2.3 ms, T_2*>370 μs), state-of-the-art control fidelities (>99.984%), and displays readout and initialization contrast exceeding 99%, providing an exciting pathway toward scalable quantum information technologies in the solid-state.

This work was done in collaboration with Mykyta Onizhuk, He Ma, Gary Wolfowicz, Peter Mintun, Alex Crook, Hiroshi Abe, Jawad Ul Hassan, Nguyen Son, Takeshi Ohshima and Giulia Galli.

2:15 PM *F.NM05.02.03
Scalable Quantum Networks with Artificial Atoms Dirk R. Englund; Massachusetts Institute of Technology, United States

The central challenge in building quantum computers and long-range quantum networks is distributing entanglement across multiple individually-controllable quantum memories. While proof-of-concept experiments are possible with today's optical components, scaling these systems to tens, hundreds, or thousands of individually controllable quantum memories requires very-large-scale integration of electronic and photonic circuits.
Diamond color centers (CC) have emerged as leading solid state "artificial atom" qubits, having recently surpassed the entanglement-to-decoherence threshold for deterministic delivery of quantum entanglement[1] as well as the first demonstration of "useful" quantum-memory-enhanced communication beating any direct-transmission optical channel[2]. A central challenge now lies in the development of quantum information processing architectures to improve entanglement rates, reduce decoherence, and to scale systems for applications ranging from quantum repeaters to general-purpose quantum computers.
To answer this challenge, we are developing photonic integrated circuits (PICs) with integrated quantum memories based on diamond CCs. In particular, this talk discusses our recent demonstration of a PIC with 128 waveguide-integrated silicon vacancy (SiV) and germanium vacancy (GeV) color centers[3].
Secondly, this talk will review recent advances on spin and optical properties of recently discovered tin-vacancy (SnV) CCs which have significantly larger ground state orbital splitting than the lighter Group IV-vacancy complexes. We observe that even at modest temperatures near ~ 4K, the SnV possesses the essential attributes for a spin-photon interface: optical transitions approaching the lifetime limit and a long-lived electronic spin state[4].
The talk will finish with an outlook on resource-performance analyses for large-scale quantum repeaters [3,5,6], modular quantum computers[7,8], and coherent interfaces to phonons and microwave photons[9].

Coherent Control of a Hybrid Superconducting Circuit Made with van der Waals Heterostructures William Oliver and I-Jan Wang; Massachusetts Institute of Technology, United States

In this talk, we present the demonstration of a superconducting transmon qubit realized using a graphene-based weak-link junction. The graphene is encapsulated by hexagonal Boron Nitride (hBN), forming a van der Waals heterostructure. Applying a voltage to a backgate in proximity to the weak-link junction enables voltage tunability of the qubit frequency. We present the coherent control of this qubit, and discuss the promise and the challenges if building superconducting qubits with such van der Waals heterostructures.

3:15 PM *F.NM05.03.01
Quantum Computing with Superconducting Circuits Ryan T. Gordon; IBM Research, United States

Quantum computing has made tremendous progress in recent years, including both experimental advances and hardware developments. Quantum processors have scaled significantly in size, as measured by the number of quantum bits (qubits) connected on a chip, with devices incorporating 10's of qubits available today. An example of a publicly available quantum system is the IBM Q Experience (www.research.ibm.com/ibm-q). While the goal of fault-tolerant universal quantum computing is still some time away, early applications and demonstrations can be implemented on smaller scale near-term quantum systems. Among the different hardware implementations, Josephson-junction-based superconducting quantum circuits are a promising technology to scale quantum processors. Together with increasing the number of qubits, other metrics need to evolve and improve as well, such as qubit quality, hardware integration, and system level performance. In this talk, I will review the current status and discuss some of the remaining challenges.

A Multiscale Model of the Reaction Pathway for P-Type Doping Using Diborane on Si(100)-2x1 Quinn Campbell, Jeffrey A. Ivie, Scott W. Schmucker, Andrew Baczewski and Shashank Misra; Sandia National Laboratories, United States

Diborane (B_2H_6) is a promising precursor molecule for atomic precision p-type doping of silicon that has recently been experimentally demonstrated on the Si (100) surface [Škeren, et al., 2019]. We use first principles density functional theory (DFT) calculations to determine the reaction pathway of diborane dissociating into incorporated boron at the silicon surface. We show that diborane must overcome an energy barrier to even adsorb onto the bare silicon surface, explaining the low sticking coefficient seen in previous studies. Heating can be used to increase the initial adsorption rate. From there, the diborane has a roughly half chance of splitting into two BH_3 particles or merely losing hydrogen to form a boron dimer such as B_2H_4. Dimers of boron are likely electrically inactive, thus making it crucial that the diborane split for final incorporation of an electrically active acceptor. The dissociation process proceeds with high energy barriers, necessitating the use of high temperatures for incorporation. Using the barriers calculated from DFT, we parameterize a Kinetic Monte Carlo model, predicting incorporation statistics of diborane as a function of initial depassivation geometry, dose pressure, and anneal temperature. Finally, we present a theoretical comparison of diborane to other potential acceptor precursor molecules.

5:25 AM F.NM05.01.03
Low-Temperature Processing for Atomically Precise Dopant Incorporation with CMOS Integration Scott W. Schmucker, Evan M. Anderson, Esther Frederick, Jeffrey A. Ivie, Ezra Bussman, DeAnna Campbell, Lisa A. Tracy, Tzu-Ming Lu, Ping Lu, George Wang, Daniel Ward and Shashank Misra; Sandia National Laboratories, United States

Scanning tunneling microscopy and hydrogen depassivation lithography (HDL) have enabled tip-defined placement of dopant atoms in Si for Atomic Precision Advanced Manufacturing (APAM) [1-2] of conventional and quantum electronic devices. Although it affords greater placement accuracy than ion implantation, APAM has historically required high-temperature processing incompatible with microelectronics fabrication workflows. Recent process developments have reduced the thermal budget for APAM sample prep, the highest temperature step of the process, to temperatures comparable to activation for ion implantation. Reduced temperature prep opens the door to integrating APAM near the end of front-end-of-line (FEOL) fabrication thereby integrating atomic-scale dopant placement with conventional microelectronic processes. Further reducing the thermal budget for key parts of the APAM process flow – sample preparation, hydrogen termination, dopant incorporation, and silicon capping – may open the door to adding dopants during back-end-of-line (BEOL) fabrication for the first time.

Here, we discuss techniques for FEOL and BEOL APAM integration of donor and acceptor dopants in Silicon. We demonstrate room-temperature Si(100) hydrogen passivation without compromising HDL and reduced-temperature Si encapsulation without significantly compromising electron transport. In an effort to reduce surface preparation temperatures and achieve BEOL CMOS compatibility, we explore both wet chemical and ion beam processes for low-temperature Si(100) 2×1 preparation and discuss the limitations of each. Thermal budget considerations explored here are one of the key challenges which must be addressed to enable APAM integration. We conclude that hydrogen passivation, HDL, dopant

introduction, and Si encapsulation can be made compatible with BEOL integration. Future challenges remain for sample cleaning, but preliminary results are encouraging and suggest, with continued development, the possibility of APAM BEOL CMOS integration.

5:35 AM F.NM05.01.04
Atomically Precise *P*-Type Doping Using Alanes Wiley P. Kirk[1,2], Eduardo Maldonado[1], Jeffery Murphy[1,2] and Jean-Francois Veyan[3]; [1]3D Epitaxial Technologies, United States; [2]The University of Texas at Arlington, United States; [3]The University of Texas at Dallas, United States

Recently, new devices for future classical and quantum computation technologies have been demonstrated using scanning tunneling microscopy (STM) and hydrogen depassivation lithography (HDL) to position phosphorous or arsenic atoms as donors in silicon with atomic-scale precision.[1,2] Although precursors such as phosphine (PH_3) and arsine (AsH_3) serve satisfactorily as gaseous sources for donors, the potential counterpart acceptor precursors such as diborane (B_2H_6) and alane (aluminum hydride, AlH_3) as sources have proven to be more challenging when combined with the aforesaid atomic-scale STM-HDL technology. In particular, alanes are energetically stable only at temperatures $T \leq 120$ K. On the other hand, recent DFT calculations [3] show a stable route exists for AlH_3 dissociation and Al incorporation (following selective surface hydrogen desorption by STM). Moreover, the DFT results show the overall process of AlH_3 surface interactions on Si parallels PH_3; hence, atomically precise acceptor doping should be possible using alanes. With these constraints in mind, we have developed a new type of low-temperature alane precursor source that provides *p*-type dopants that are compatible with atomic-scale fabrication techniques. Specifically, infrared data from fast Fourier transform spectroscopy, examining alane formation and specie type, will be presented as a function of temperature. In addition, electronic transport characteristics from van der Pauw and Hall effect measurements as a function of temperature are planned for presentation.

Solving the Puzzle of Al Atom Density on Delta-Doped Si (100) Ke Tang[1,2], Hyun Soo Kim[1,2], Aruna Ramanayaka[1] and Joshua M. Pomeroy[1]; [1]National Institute of Standards and Technology, United States; [2]University of Maryland, United States

Efforts to grow Si (100) with a supersaturated Al delta layer in pursuit of a superconducting phase are hampered by an ambiguity in the surface Al atom density as measured by STM (scanning tunneling microscopy). An apparent consensus for decades has been that Al tends to form surface dimers, which can appear as single sphere in positive bias, in 2 x 2 structure at low temperature and saturates at 0.5 monolayer (3.4×10^{14} cm^{-2}) before Al cluster formation (monolayer is in reference to Si(100) site density). However, our recent SIMS (secondary ion mass spectroscopy) analysis shows that the 2D number density of Al on Si (100) is actually 0.25 monolayer (1.7×10^{14} cm^{-2}), half of the prior STM density, indicating the possibility of another Al phase on Si (100) surface. In addition, mesa etched hall bar devices fabricated find p-type carriers with consistent densities $\approx 1.5 \times 10^{14}$ cm^{-2} and mobility of ≈ 20 cm^2/V s. Developing a complete phase diagram of the surface doping will enable optimal Al dosing above the expected superconducting critical density of 4 at. % with a minimum number of mixed Al clusters in the doped lattice.

Triethyl Aluminium—A Precursor for Atomically-Precise Acceptor Dopant Placement James H. Owen, Robin Santini and John Randall; Zyvex Labs, United States

The fabrication of n-type dopant-based devices such as the 'single atom transistor' [1] and 2D Quantum Metamaterials[2] uses STM lithography to create patterns of reactive Si dangling bonds with a background of passive H-terminated Si. Phosphine (PH3) is used as a precursor molecule for the P dopant atoms adsorbing extremely selectively onto the bare Si atoms which make up the device pattern. For p-type dopants, the Group III equivalents of phosphine, the alanes, are thought to react on the surface in a similar way [3], but are not stable at room temperature. Diborane has a very low sticking coefficient onto bare Si, forcing the use of very large doses to achieve a good density of B dopants[4]. Here we are exploring alkyl dopant sources, including Trimethyl Al, Triethyl Al and Tri-isobutyl Al, which are widely used in III-V CVD reactors. Recently, we have focused on Triethyl Al, as it has a much higher sticking coefficient than Tri-isobutyl Al and is preferred over Trimethyl Al for lower carbon contamination of the grown films. On Si, ethylene is known to desorb from the clean Si surface at about 400°C, which promises a lower carbon incorporation rate.
We have conducted adsorption and selectivity experiments with Triethyl Al on bare and H-terminated Si(001) surfaces. At room temperature, we find that the sticking coefficient of the molecule is low even on the bare Si(001) surface. There is no apparent adsorption on the H-terminated surface. However, we find that patterns drawn on the H-terminated surface after a TEAl dose will slowly fill with adsorbates over time, indicating the presence on the surface of mobile molecules, which are weakly bound and invisible to the STM. By performing the adsorption at elevated temperatures, we were able to remove these mobile molecules, and at the same time, the reaction of the bare surface to these molecules was greatly increased. After adsorption, the ethyl groups were driven off the surface, and the Al atoms incorporated into the surface, using a high-temperature anneal to around 400°C. This recipe was used to create delta layers of Al, which were then buried using the same process as used to bury P delta layers [1]. SIMS data of these delta layers show good confinement of Al to the delta layer. We continue to refine the adsorption and annealing process to increase the peak concentration of the Al in the delta layer, minimise segregation into the overgrowth, as well as to further reduce the amount of carbon trapped at the delta layer. Considering the bigger picture, if a suitable process can be found for Triethyl Al, this process is likely to be compatible with other standard CVD dopant precursors, such as TriEthyl Ga, and similar precursors for other elements, such as Zn or Er, which would greatly broaden the applicability of the atomically-precise dopant placement process.

Feedback Controlled Lithography for Atomically Perfect Quantum Devices and Materials in Si Jonathan Wyrick[1], Xiqiao Wang[1], Ranjit Kashid[1], Pradeep Namboodiri[1], Fan Fei[2,2] and Richard Silver[1]; [1]National Institute of Standards and Technology, United States; [2]University of Maryland, United States

In recent years it has become possible to construct near-atomically perfect phosphorus-based structures, 2D materials and quantum devices, embedded in silicon using STM bottom-up fabrication. If this technology can be developed to a sufficient degree of accuracy and reproducibility, it will have very clear applications for quantum computing and quantum information architectures in addition to realizing the promise of scaling electronics to the atomic limit. In the current implementation of the bottom-up fabrication technique, the STM is used to generate regions of clean silicon by selective removal of H atoms from a hydrogen terminated Si (100) surface. This is followed by introduction of phosphine (PH3) gas which chemically bonds only to depassivated sites. Subsequent thermal processing allows for reactions to take place in which P atoms substitutionally replace Si surface atoms so that spacings between electronic components (defined by P) are controlled to within a few lattice sites. Individual components can be scaled down to the point that they are composed of few P atom clusters. However, to date, deterministic control over the number of P atoms incorporated at a site has not been achieved in a reliable manner. Results from previous studies have found that for targeted single-atom sites, there is approximately a 20% chance of failure to incorporate any atoms (i.e. the site is left empty).

In this talk, we detail our progress towards achieving true single atom per site control. We write patterns intended for single P atom incorporation using feedback controlled lithography (FCL) so that adsorption sites are atomically identical. In a subset of patterned sites, we investigate STM-based manipulation of the deposited phosphine species. These results are combined with a density functional theory analysis in which precise adsorption configurations and reaction products can be identified via STM image simulation to gain insights into the chemistry of phosphine adsorption at FCL-tailored sites. We find that for

perfectly patterned structures, sub-nanometer precision in placement of individual P atoms is achieved and that there is evidence of the presence of the P atoms after the thermal processing step in which P is incorporated. While technically demanding, these results suggest a path to fabricate devices with absolute certainty in the number of P atoms comprising key components, enabling precision control over their electronic structure and, therefore, quantum properties.

6:15 AM F.NM05.01.08
Quantum Transport and Hubbard Physics in a 3×3 Artificial Lattice of Few-Donor Quantum Dots Xiqiao Wang[1,2], Fan Fei[1,2], Jonathan Wyrick[1], Ranjit Kashid[1], Pradeep Namboodiri[1], Emily Townsend[1], Albert Rigosi[1], Garnett Bryant[1] and Richard Silver[1]; [1]National Institute of Standards and Technology, United States; [2]University of Maryland, United States

Donor-based quantum materials in silicon are a promising candidate for scalable solid-state quantum computing and analog quantum simulation. Central to the scalability and performance of this quantum materials system is the precision control and physical understanding of materials properties at the atomic scale. Recent advances in atomically precise fabrication in silicon using scanning tunneling microscopy (STM) have demonstrated success in atomic-scale control of tunneling and atom-by-atom construction of single and few-donor quantum devices, enabling donor-based quantum meta-materials and high-fidelity two-qubit gates. In this presentation, we demonstrate the construction of a 3×3 artificial square lattice using precision patterned few-donor quantum dots. We probe the resonant quantum transport and Hubbard properties of the donor-array towards the possibilities of using the donor-based artificial lattice as a Hubbard quantum simulator.

The Hubbard model has been one of the primary models for capturing the essential physics and materials properties in condensed matter and emerging quantum systems. Due to its natural long-range Coulomb interactions, accessible low-temperatures, and atomic-scale nature, an artificial lattice of donor clusters made of one or multiple donor atoms in silicon is advantageous in simulating Hubbard many-body problems, especially in strong interaction regimes. In this presentation, we focus on the atomic-scale fabrication and low-temperature transport characterization of an STM-patterned 3×3 array of few-donor quantum dots. By embedding the dot-array system in the electrostatic environment of the real transport device and solving the extended Hubbard model, we analyze the Coulomb blockade and quantum transport features through the donor array. We estimate the microscopic structure and tunnel coupling of individual quantum dots at each artificial lattice site by measuring single-electron tunneling spectroscopy through single and few-donor quantum dots with atomically defined tunnel gaps. Combining experimental and simulated results, we evaluate the potential impact of disorder and atomic-scale imperfection in the donor array on single-electron transport and the possibility of using quantum transport as a sensitive probe for understanding Hubbard physics in donor-based quantum materials systems.

B- and Al-Doped Delta Layers in Si Using Halogen-Based Precursors Sungha Baek[1], Azadeh Farzandeh[1], Matthew S. Radue[2], Quinn Campbell[3], Kevin J. Dwyer[1], Andrew Baczewski[3], Yifei Mo[1], Shashank Misra[3] and Robert E. Butera[1,2]; [1]University of Maryland, United States; [2]Laboratory for Physical Sciences, United States; [3]Sandia National Laboratories, United States

The technology required to fabricate atomic-scale quantum devices in silicon has advanced significantly over the past decade to produce a variety of dopant-based devices, including qubits, atomic wires, tunnel junctions, and single electron transistors. Nearly all such devices made to date have been phosphorous-based and achieved through the careful control of the reaction PH_3 with the silicon surface. While the PH_3/Si system has been well studied, little progress has been made towards the realization of analogous acceptor-based devices. With the promise of hole-based qubits with extremely long coherence times and strong coupling to electric fields, along with the potential to achieve superconductivity in Si, there are tremendous opportunities to advance Si-based quantum computing upon the identification of an ideal gaseous precursor. Here, we present results on the use of BCl_3 and $AlCl_3$ as dopant precursors for the formation of acceptor-doped, delta layers in silicon. Surface reactions were studied with scanning tunneling microscopy (STM), X-ray photoelectron spectroscopy (XPS), secondary ion mass spectroscopy (SIMS), and density functional theory (DFT) calculations to elucidate the reaction pathways for B and Al dopants leading towards dopant incorporation into the Si surface. SIMS measurements confirm B and Al concentrations in excess of 10^{20} cm^{-3}. These results provide a major step in the further development of atomic-scale quantum devices in Si. SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

Engineering Semiconductors for Spin-Based Quantum Technologies Christopher Anderson, Alexandre Bourassa, Kevin Miao and David Awschalom; University of Chicago, United States

Silicon carbide (SiC) is a technologically mature semiconductor material that is host to a variety of different solid-state spin defects. These spin qubits not only boast long coherences but also a natural spin-photon interface that can mediate entanglement at a distance. However, as for any solid-state quantum technology, issues of charge noise and magnetic fluctuations are prevalent. In this talk, we present recent advances in minimizing and controlling these sources of noise.

We first discuss our ability to mitigate charge noise in commercial SiC electronic devices [1]. Surprisingly, the integration of single spins into these devices results in THz-scale tunability of a single divacancy spin's optical interface while simultaneously eliminating spectral diffusion and blinking. This results in an electrically-tunable single photon source that can be tuned over 40,000 linewidths, constituting a near-ideal spin-photon interface at wafers scales near the telecommunications band.

We then describe the control and optimization of the nuclear spin environment for these spin qubits [2]. In general, nuclear spins are both a cause of decoherence and a valuable resource for electron spins in the solid-state. While isotopic purification removes noise, it also reduces the availability of nuclear spin quantum memories that are vital to many quantum technologies. Guided by *ab-initio* theory, we strike this balance and find an optimal isotopic concentration that maximizes the number of available quantum memories. Experimentally, we demonstrate extended coherences and the first entanglement and control of single nuclear spins in silicon carbide through isotopic engineering.

The elimination of electrical noise combined with finely tuning the nuclear environment results in a material platform for quantum technology that combines a stable spin-photon interface with an electron spin that can leverage entanglement with local nuclear spin qubit clusters. We show that this electron spin state has long coherence times (T_2>2.3 ms, T_2*>370 μs), state-of-the-art control fidelities (>99.984%), and displays readout and initialization contrast exceeding 99%, providing an exciting pathway toward scalable quantum information technologies in the solid-state.

This work was done in collaboration with Mykyta Onizhuk, He Ma, Gary Wolfowicz, Peter Mintun, Alex Crook, Hiroshi Abe, Jawad Ul Hassan, Nguyen Son, Takeshi Ohshima and Giulia Galli.

Correlating Surface Spectroscopy with Qubit Measurements to Systematically Eliminate Sources of Noise Nathalie P. de Leon; Princeton University, United States

The nitrogen vacancy (NV) center in diamond exhibits spin-dependent fluorescence and long spin coherence times under ambient conditions, enabling applications in quantum information processing and sensing. NV centers near the surface can have strong interactions with external materials and spins, enabling new forms of nanoscale spectroscopy. However, NV spin coherence degrades within 100 nanometers of the surface, suggesting that diamond surfaces are plagued with ubiquitous defects. Prior work on characterizing near-surface noise has primarily relied on using NV centers themselves as probes; while this has the advantage of exquisite sensitivity, it provides only indirect information about the origin of the noise. I will describe our recent efforts to use X-ray and photoelectron spectroscopies, diffraction techniques, and morphology characterization to understand sources of noise at the diamond surface. By correlating this spectroscopic data with single spin measurements, we have been able to devise new surface processing and termination techniques to stabilize shallow NV centers within 5 nm of the surface with coherence times exceeding 100 ms [1]. Specifically, we are able to demonstrate reversible and reproducible control over the top layer of atoms. These highly coherent, shallow NV centers will provide a

platform for sensing and imaging down to the scale of single atoms.

In fact, many platforms for quantum technologies are limited by noise and loss arising from uncontrolled defects at surfaces and interfaces, including superconducting qubits, trapped ions, and semiconductor quantum dots. Our approach for correlating surface spectroscopy techniques with single qubit measurements to realize directed improvements is generally applicable to many systems, and I will describe our recent efforts to tackle noise and microwave losses in superconducting qubits. Building large, useful quantum systems based on transmon qubits will require significant improvements in qubit relaxation and coherence times, which are orders of magnitude shorter than limits imposed by bulk properties of the constituent materials. This indicates that relaxation likely originates from uncontrolled surfaces, interfaces, and contaminants. Previous efforts to improve qubit lifetimes have focused primarily on designs that minimize contributions from surfaces. However, significant improvements in the lifetime of two-dimensional transmon qubits have remained elusive for several years. We have fabricated two-dimensional transmon qubits that have both lifetimes and coherence times with dynamical decoupling exceeding 0.3 milliseconds by replacing niobium with tantalum in the device [2]. We have observed increased lifetimes for many devices, indicating that these material improvements are robust, paving the way for higher gate fidelities in multi-qubit processors.

Scalable Quantum Networks with Artificial Atoms Dirk R. Englund; Massachusetts Institute of Technology, United States

The central challenge in building quantum computers and long-range quantum networks is distributing entanglement across multiple individually-controllable quantum memories. While proof-of-concept experiments are possible with today's optical components, scaling these systems to tens, hundreds, or thousands of individually controllable quantum memories requires very-large-scale integration of electronic and photonic circuits.
Diamond color centers (CC) have emerged as leading solid state "artificial atom" qubits, having recently surpassed the entanglement-to-decoherence threshold for deterministic delivery of quantum entanglement[1] as well as the first demonstration of "useful" quantum-memory-enhanced communication beating any direct-transmission optical channel[2]. A central challenge now lies in the development of quantum information processing architectures to improve entanglement rates, reduce decoherence, and to scale systems for applications ranging from quantum repeaters to general-purpose quantum computers.
To answer this challenge, we are developing photonic integrated circuits (PICs) with integrated quantum memories based on diamond CCs. In particular, this talk discusses our recent demonstration of a PIC with 128 waveguide-integrated silicon vacancy (SiV) and germanium vacancy (GeV) color centers[3].
Secondly, this talk will review recent advances on spin and optical properties of recently discovered tin-vacancy (SnV) CCs which have significantly larger ground state orbital splitting than the lighter Group IV-vacancy complexes. We observe that even at modest temperatures near ~ 4K, the SnV possesses the essential attributes for a spin-photon interface: optical transitions approaching the lifetime limit and a long-lived electronic spin state[4].
The talk will finish with an outlook on resource-performance analyses for large-scale quantum repeaters [3,5,6], modular quantum computers[7,8], and coherent interfaces to phonons and microwave photons[9].

Hybridized Defects in 2D Materials as Artificial Molecules Derek Wang[1], Christopher J. Ciccarino[1], Johannes Flick[2] and Prineha Narang[1]; [1]Harvard University, United States; [2]Flatiron Institute, United States

The optical and electronic properties of defects in solid-state materials can be tuned with external fields, as well as with sculpted electromagnetic environments, such as cavities and waveguides. Here, we add to this toolbox by computationally demonstrating that defects, often described as "artificial atoms," become "artificial molecules" when placed within a few unit cells of each other. Specifically in monolayer hexagonal boron nitride, we observe dissociation curves and hybridization of defect orbitals into bonding and antibonding orbitals, as well as changes in frequency and intensity of dipole-allowed transitions. We calculate the energetics of *cis* and *trans* analogs of paired out-of-plane defects and find that paired in-plane defects interact more strongly than out-of-plane ones. We envision leveraging this chemical degree of freedom to more precisely engineer defects as quantum memories and quantum emitters for quantum information applications.

5:55 AM F.NM05.02.06
Growth and Direct Observation of SiV Centers in Ultrasmall Nanodiamonds Shuo Li[1,2], Daniel Angell[2], Hye Ryoung Lee[2,1] and Nicholas Melosh[1,2]; [1]SLAC National Accelerator Laboratory, United States; [2]Stanford University, United States

Single photon emitters (SPEs) in solids have emerged as promising candidates for various applications such as quantum technology, nanophotonics and biological imaging. Silicon-vacancy color centers in diamond exhibit high-brightness, stable photo-stability and room-temperature quantum emission, but the precise localization, controllable formation, and direct observation of SiV centers within nanometer scale still remain elusive. Here, we use grow ultrasmall high-quality nanodiamonds using plasma-enhanced vapor deposition (PECVD) from molecular diamondoids as seedings, and incorporated SiV centers during growth. We directly observe SiV emission from 20 nm nanodiamond particles using a combination of cathodoluminescence (CL) and cryogenic transmission electron diffraction (cryo-TEM). Our results provide the controlled growth and direct observation of stable SiV emission in nanometer-scale CVD grown nanodiamonds. These findings are important for fundamental understanding of color center formation mechanism and stability in nanoscale, and are promising for the realization of precise localization of color centers for various quantum applications.

6:05 AM F.NM05.02.07
Strong Spin-Orbit Quenching in Group IV Neutral Defects in Diamond via the Product Jahn-Teller Effect Christopher J. Ciccarino[1], Johannes Flick[2], Isaac Harris[1,3], Matthew Trusheim[1], Dirk R. Englund[3] and Prineha Narang[1]; [1]Harvard University, United States; [2]Flatiron Institute, United States; [3]Massachusetts Institute of Technology, United States

Defects in diamond are leading solid-state candidates for a range of quantum technologies. Recent research has focused on identifying new color centers with properties that reach beyond the limitations of the well-known nitrogen-vacancy (NV^-) center. Group IV-vacancy centers have been a primary focus due to their symmetry-protected optical transitions and long-lived spin degree of freedom. A detailed understanding of the electronic structure of these emitters is paramount to their use in spin-photon systems. Here we detail the ground- and excited-state properties of the neutral group IV color centers using first principles methods. In particular, we capture the product Jahn-Teller (pJT) effect [1] resulting from the simultaneous Jahn-Teller interactions in two defect orbitals. The significant pJT effects found suggest the excited state is a coupled electron-phonon (vibronic) system, which can have important implications on electronic observables. In particular, we present a nonperturbative approach to capturing the effective spin-orbit splitting [2], which we find to be significantly quenched as a result of this pJT interaction. The lowest optically-active ^3E_u states are weakly spin-split into ms-resolved states. Our spin-resolved level structure predictions will be useful in understanding the finer details of the SiV^0 as well as provide additional fingerprints for experimental identification of the other group IV neutral emitters.

6:15 AM F.NM05.02.09
Late News: Dangling Bonds in Hexagonal Boron Nitride for Quantum Information Science Mark Turiansky[1], Audrius Alkauskas[2], Lee Bassett[3] and Chris G. Van de Walle[1]; [1]University of California, Santa Barbara, United States; [2]Center for

Physical Sciences and Technology (FTMC), Lithuania; [3]University of Pennsylvania, United States

Hexagonal boron nitride has been found to host single-photon emitters across a range of energies. Among the observed emitters is a group in the visible spectrum, known as the 2 eV emitters, that are notoriously heterogeneous. Extensive experimental efforts have uncovered a wealth of interesting properties; most notably, the 2 eV emitters are highly desirable for quantum information applications, having minimal coupling to phonons and spin-dependent transitions. Despite these efforts, the microscopic origin of the emitters is the subject of intense debate. We propose that boron dangling bonds are the source of the observed emission. We apply first-principles calculations, based on density functional theory with a hybrid functional, to characterize the properties of these dangling bonds and demonstrate that they provide a consistent understanding of the experimental observations. In the negative charge state, the boron dangling bond is occupied with two electrons. Excitation of one electron into a localized p_z state results in optical emission with a zero-phonon line of 2.06 eV. The transition is linearly polarized, and the coupling to phonons is characterized by a Huang-Rhys factor of 2.3. Proximity of the states to the conduction band allows for an indirect excitation mechanism for sufficiently large energies. This unique feature explains the misalignment of the absorptive and emissive dipole observed in experiment. While the ground state is a singlet state, we predict the existence of a metastable triplet state, which allows for spin-dependent transitions. All of these features are in line with experimental observations, indicating that boron dangling bonds are the likely origin of the observed emission.

SESSION F.NM05.03: Materials for Superconducting Quantum Systems

5:00 AM *F.NM05.03.01
Quantum Computing with Superconducting Circuits Ryan T. Gordon; IBM Research, United States

Quantum computing has made tremendous progress in recent years, including both experimental advances and hardware developments. Quantum processors have scaled significantly in size, as measured by the number of quantum bits (qubits) connected on a chip, with devices incorporating 10's of qubits available today. An example of a publicly available quantum system is the IBM Q Experience (www.research.ibm.com/ibm-q). While the goal of fault-tolerant universal quantum computing is still some time away, early applications and demonstrations can be implemented on smaller scale near-term quantum systems. Among the different hardware implementations, Josephson-junction-based superconducting quantum circuits are a promising technology to scale quantum processors. Together with increasing the number of qubits, other metrics need to evolve and improve as well, such as qubit quality, hardware integration, and system level performance. In this talk, I will review the current status and discuss some of the remaining challenges.

5:15 AM *F.NM05.03.03
Materials Loss Measurements Using Superconducting Microwave Resonators Corey Rae McRae[1] and Josh Mutus[2]; [1]University of Colorado Boulder, United States; [2]Google, United States

Two level system (TLS) loss in dielectric materials and interfaces remains at the forefront of materials research in quantum information science. The identification of low loss fabrication techniques, materials, and thin film dielectrics is critical to achieving scalable architectures for superconducting quantum computing. Superconducting microwave resonators provide a convenient qubit proxy for assessing loss performance and studying loss mechanisms such as TLS loss, non-equilibrium quasiparticles, and magnetic flux vortices. In this talk, an overview of design considerations for accurate resonator loss measurements will be given, summarizing techniques that have been evolving for over two decades, and will conclude with recommendations for future measurements in this field.

5:30 AM *F.NM05.03.04
Coherent Control of a Hybrid Superconducting Circuit Made with van der Waals Heterostructures William Oliver and I-Jan Wang; Massachusetts Institute of Technology, United States

In this talk, we present the demonstration of a superconducting transmon qubit realized using a graphene-based weak-link junction. The graphene is encapsulated by hexagonal Boron Nitride (hBN), forming a van der Waals heterostructure.

Applying a voltage to a backgate in proximity to the weak-link junction enables voltage tunability of the qubit frequency. We present the coherent control of this qubit, and discuss the promise and the challenges if building superconducting qubits with such van der Waals heterostructures.

5:45 AM F.NM05.03.05
Characterization of the Structure and Superconducting Properties of Plasma Assisted Molecular Beam Epitaxy Grown $Nb_xTi_{1-x}N$ Alloy Thin Films Austin Thomas[1,2], Alan Kramer[1] and Christopher Richardson[1,2]; [1]Laboratory for Physical Sciences, United States; [2]University of Maryland, United States

Several niobium titanium nitride ternary superconducting alloys were grown to assess the superconducting properties of an alloy which can be tuned to grow pseudomorphically with an insulating layer. The goal is to engineer a superconductor that may decrease charge noise and has improved critical current across the interface of a Josephson junction. This alloy can be paired with wide-bandgap nitrides to create an oxygen-free heterostructure. $Nb_xTi_{1-x}N$ thin films were grown using plasma assisted molecular beam epitaxy on C-plane sapphire substrates, across the compositional range $0 \leq x \leq 1$. Sample topography is verified using reflection high energy electron diffraction and ex-situ atomic force microscopy. The surface exhibits a river-rock-type topography across the compositional range with RMS roughness values under one nanometer. The structure is analyzed using x-ray diffraction and Rutherford backscattering spectroscopy, which shows the change in composition causes a corresponding change in lattice constants. All films are completely relaxed, and consistent with an abrupt metamorphic growth mode. Variations in the alloy phase and corresponding superconducting properties will be discussed.

Synthesis and Characterization of AlN and TiN for All Nitride Josephson Junctions Alan R. Kramer, Ashish Alexander, Austin M. Thomas and Christopher Richardson; University of Maryland, United States

The non-linear building blocks of superconducting qubits are Josephson Junctions (JJs). The current state-of-the-art is qubits fabricated with JJs that are made from Al/AlOx/Al using the double-angle evaporation and oxidation method. The need to fabricate higher quality, lower loss, and more uniform superconducting devices motivates this work to focus on making epitaxial Josephson junction heterostructures using transition metal nitride superconductors and a wide-bandgap nitride dielectric on a low-loss substrate.

Aluminum nitride and Titanium nitride are two foundation materials in the construction of an all nitride JJ. We use plasma assisted molecular beam epitaxy (PAMBE) with varying metal-nitrogen growth flux ratios from nitrogen rich to metal rich growth conditions. The optimization of both epitaxial materials is guided by characterization of the bulk by x-ray diffraction (XRD), chemical profile using energy dispersive x-ray spectroscopy (EDX), 'near' surface structure using electron backscatter diffraction (EBSD) and surface topography via atomic force microscopy (AFM).

Superconducting TiN epitaxial growth parameters and their correlation to structure are reported along with temperature dependent resistivity and critical temperature. Superconducting microwave loss is a key parameter for quantum information applications, and will be explored for all films and correlated to structure using coplanar waveguide resonators.

6:05 AM F.NM05.03.08
Improved Surface Quality of *A*-Axis $YBa_2Cu_3O_{7-\delta}$ Thin Films Y. Eren Suyolcu[1], Jiaxan Sun[1], Jürgen Schubert[2] and Darrell Schlom[1,3]; [1]Cornell University, United States; [2]Peter Gruenberg Institute (PGI-9) and JARA-Fundamentals of Future Information Technology, Germany; [3]Kavli Institute at Cornell for Nanoscale Science, United States

Due to the significantly longer superconducting coherence length along the *a*-axis of $YBa_2Cu_3O_{7-\delta}$ (YBCO) than along the *c*-axis, the growth of *a*-axis YBCO films is important for Josephson junctions, provided they can be made sufficiently smooth.[1] The necessity for smoothness is so Josephson junctions, regardless of their position on the wafer, have the same thickness of the tunnel barrier.[2,3] With the goal of making smoother *a*-axis YBCO films, we utilize ozone-assisted molecular beam epitaxy (MBE) to grow *a*-axis YBCO films and perform comprehensive structural, morphological, and electrical characterization. The *a*-axis films are grown on (100) $LaAlO_3$ substrates. The structural quality and *a*-axis content of the samples is examined using four-circle x-ray diffraction (XRD). The morphology of the film surfaces is assessed by atomic force microscopy (AFM). Leveraging a new temperature-ramping model, we achieve high structural quality and improved surface roughness of *a*-axis YBCO films. *In-situ* reflection high-energy electron diffraction (RHEED) substantiates the gradually improved crystallinity during the temperature ramping. *Ex-situ* XRD measurements prove the films to have >99% *a*-axis content, while AFM measurements reveal improved surface quality with a root-mean-square (rms) roughness of < 2 nm. Resistivity vs. temperature measurements exhibit the onset of the superconducting transition at $T_c \sim 87$ K.

Influence of Al Thickness on Tunneling Spectra of Nb/Al Based N/I/S Tunnel Junction Zachary Barcikowski[1,2] and J.M. Pomeroy[2]; [1]University of Maryland, United States; [2]National Institute of Standards and Technology, United States

A metallic bilayer system can behave like two materials when thick, but in the thin film limit may exhibit properties that are a hybrid of the individual layers or dominated by one. As an example, the Nb/Al bilayer, in conjunction with AlOx, is a widely utilized material stack for quantum computing, where in the thin film limit (<100 nm) the Al superconducting properties are strongly perturbed by the proximity of the Nb. Each metal individually has liabilities: when used separately in tunnel junction devices, Al's lower Tc requires lower operation temperatures but Nb oxides introduce a range of problematic features including magnetic scattering and dissipation. By choosing an appropriate Al thin film thickness on Nb, it may be possible to mitigate both to get 1) the higher Nb Tc and 2) better AlOx tunnel barrier. We have fabricated a series of Nb/Al/AlOx/normal metal tunnel junctions while varying the Al thin film thickness in order to investigate the tunnel junction properties with changing Al thickness. The normalized sub-gap conductance in tunneling spectra is found to strongly vary as a function of Al thickness, with sub-gap conductance exceeding normal state conductance in some cases, which is typically attributed to Andreev reflection. Tunnel junction spectra are well modeled within the Blonder-Tinkham-Klapwijk (BTK) theory and we discuss trends between BTK barrier strength Z and the apparent superconducting gap as the Al thin film thickness varies. Additionally, we will present temperature dependent tunneling spectra measured between 4 K and , and discuss the analysis of the data within the BTK theory.

Compound Semiconductor Nanowire Networks Anna Fontcuberta i Morral; EPFL, Switzerland

Nanowires are filamentary crystals with a tailored diameter ranging from few to ~100 nm. The reduced dimensions and longitudinal morophology of these nanowires results in interesting optical and electrical properties and provides a great potential for many applications, including sensing, quantum computing and all those that involve photonics [1].
In all these potential applications, the deterministic positioning of nanowires and associated branches on a substrate is key. In this talk we will present our strategy to obtain III-V nanowire networks in an organized fashion on a device substrate. We will consider different shapes of the nanostructure connections as well as strate-gies to increase the carrier mobility in views of ballistic 1D transport. We will address the growth and the optical and electronic properties as well as perspectives for quantum technology applications [2-4].

Andreev Bound States and Majorana Fermions in Helical 1D Systems Jelena Klinovaja; University of Basel, Switzerland

In my talk, I will discuss low-dimensional condensed matter systems, in which topological properties could be engineered per demand. Majorana fermions can emerge in hybrid systems with proximity-induced superconducting pairing. I will present our numerical and analytical studies of such geometries with proximity effects [1-3]. In the second part of the talk, I will discuss an analytical model of a Rashba nanowire that is partially covered by and coupled to a thin superconducting layer, where the uncovered region of the nanowire forms a quantum dot [4,5]. Even if there is no topological superconducting phase possible, there is a trivial Andreev bound state that becomes pinned exponentially close to zero energy as a function of magnetic field strength when the length of the quantum dot is tuned with respect to its spin-orbit length such that a resonance condition of Fabry-Perot type is satisfied. In this case, the Andreev bound state remains pinned near zero energy for Zeeman energies that exceed the characteristic spacing between Andreev bound state levels but that are smaller than the spin-orbit energy of the quantum dot. Importantly, as the pinning of the Andreev bound state depends only on properties of the quantum dot, this behavior is unrelated to topological superconductivity.

5:30 AM *F.NM05.04.03
Materials Considerations for Majorana Based Quantum Computations Jay Sau; University of Maryland, United States

Majorana modes are one of the most promising candidates for the creation of topological qubits in the long term. While evidence for Majorana modes has been obtained for Majorana modes in several systems such as semiconductor nanowires, semiconductor 2DEGs, iron-based superconductors, topological insulators as well as iron atom chains to name a few, evidence for a qubit degree of freedom is elusive. I will begin by reviewing what it means experimentally to observe a qubit. Following this we will discuss the central device challenge in this regard i.e. quasiparticle poisoning. I will then describe potential material dependence of this phenomena as well as how quasiparticle poisoning can manifest in various experiments related to topological superconductivity. Specifically, we will discuss how the observation of quantized conductance into a zero-bias conductance peak associated with a Majorana over a range of tunneling provides some bounds on quasiparticle poisoning times. The measurement of Coulomb blockade transport, which has been observed only for a limited number of superconductors can provide more precise information on such bounds.

Materials Science, Physics and Engineering of Topological Quantum Circuits Sergey Frolov; University of Pittsburgh, United States

With Quantum Supremacy upon us, and with major tech companies investing in quantum computing, one may wonder how much room is left there for academic research? The answer is: more than ever! Our existing qubits are great, but it is difficult to see them carrying us beyond the modern era of noisy intermediate-scale quantum processors, and ushering in the truly scalable, fault tolerant and commercially viable computers. Most likely, a qubit and its couplings, gates will once more need to be re-thought from the ground up - from the atomic first-principles level to the device architecture level. At the same time, the progress we made in quantum control and engineering is so huge that these methods have themselves become mature tools of science. They can be applied beyond quantum computing - to understand the basic questions of quantum dynamics and to probe exotic matter.

One solution may come from studying topological superconductivity. This is an interesting state most notable for spurring Majorana zero modes. Those modes can be both investigated as some of the first non-Abelian excitations, and they can be used in quantum circuits for storing and protecting quantum information. Majorana research has posed many basic materials questions of how to engineer the precise structures that possess intrinsic fault tolerance through topological protection. In my work I have developed new materials and devices for unambiguous observation of robust Majorana modes. I have worked on establishing clear criteria (signatures) of Majorana modes and how to tell them apart from other excitations that may be present in the same devices. It is exciting to apply modern quantum probes, developed based on transmon and spin qubits, to these systems in search for new exotic quantum matter. And perhaps solving some of the big challenges facing quantum computing at the same time.

Topological Superconductivity in Superconductor–Semiconductor Heterostructures Roman Lutchyn; University of California, Santa Barbara, United States

Superconductor–semiconductor heterostructures represent a versatile platform for realizing Majorana zero-energy modes. In this talk, I will explain how to engineer topological superconductivity at the interface of a conventional (s-wave) superconductor and a semiconductor with spin-orbit interaction. I will discuss state-of-the-art numerical approaches for modeling realistic devices which take into account proximity-induced superconductivity, orbital and Zeeman effect of an applied magnetic field, spin-orbit coupling as well as the electrostatic environment on equal footing. Finally, I will review recent materials science progress in growing superconductor–semiconductor heterostructures and discuss promising new directions.

6:15 AM F.NM05.04.06
Synthesis and Size Effects on Resistivity of Topological Metal MoP Nanostructures Hyeuk Jin Han, David Hynek, Zishan Wu, Lei Wang, Pengzi Liu, Joshua Pondick, Sajad Yazdani, John Woods, Milad Yarali, Yujun Xie, Hailiang Wang and Judy Cha; Yale University, United States

Nanoscale topological materials can enhance the contributions of the topologically protected surface states to transport signals by increasing their surface to volume ratios. For potential applications in quantum computing, and low-power electronics that exploit the topological properties, fundamental studies of electronic phases of nanoscale topological materials are critical. Recently, molybdenum phosphide (MoP) was discovered as a triple-point topological semi-metal with excellent transport properties of bulk resistivity of 8.2 μΩ*cm and carrier density of 1.1×10^{23} cm^{-3} at room temperature (Kumar et al., Nat.comm., 2019). Due to the topological protection predicted to suppress electron scattering at the surface, MoP may preserve its low resistivity values at the nanoscale, which may rival the line resistance of current Cu interconnects.
Here, we report the synthesis and transport properties of MoP nanostructures, which were obtained by the direct conversion of MoO_3 nanostructures. We observe that the initial size of the MoO_3 nanostructure critically determines the crystalline quality of the converted MoP nanostructures. Large MoO_3 flakes lead to porous MoP flakes, while narrow MoO_3 nanowires lead to MoP nanowires without pores. The size-dependent porosity observed in the MoP nanostructures is attributed to volume changes during the conversion reaction and nanoscale confinement effects. Notably, MoO_3 nanowires with diameters less than 10 nm were converted to single-crystalline MoP nanowires. Because of their porous nature, the resistivity values of the MoP nanoflake were higher than the reported values of MoP bulk crystals. However, despite the high porosity, the residual resistance ratio was ~ 2, and the temperature-dependent resistivity curves did not show any strong surface or grain-boundary scattering. The simple synthesis strategy opens opportunities to study the nature of topological surface states in MoP, which could be sensitive to the overall morphology and dimensions of the nanostructure, and to explore their feasibility as nanoscale interconnects.

6:25 AM F.NM05.04.08
Remote Doping of InGaAs Nanowire Branches Didem Dede[1], Martin Friedl[1], Kristopher Cerveny[2], Chunyi Huang[3], Nicholas P. Morgan[1], Wonjong Kim[1], Lucas Guniat[1], Akshay Balgarkashi[1], Jean-Baptiste leran[1], Valerio Piazza[1], Mohammad Samani[2], Megan Hill[3], Jaime Segura[4], Lincoln J. Lauhon[3], Dominik Zumbuhl[2] and Anna Fontcuberta i Morral[1]; [1]École Polytechnique Fédérale de Lausanne, Switzerland; [2]Universität Basel, Switzerland; [3]Northwestern University, United States; [4]European Synchrotron Radiation Facility, France

III-V semiconductor nanowires (NWs) have been the building blocks of many different research areas including photonics, solar cells, energy storage, and recently, quantum computing.[1,2] In particular, the fast-growing field of topological quantum computing has brought great attention to In-based NWs, thanks to the core properties of these materials including high electron mobility, large Landé g-factor, and high spin-orbit coupling. The most common growth technique for these NWs results in the formation of free-standing, vertical structures which require transfer onto a host substrate for further characterization, and this hinders their scalability for industrial applications. To overcome this limitation and to achieve high-quality NW junctions, selected area epitaxy (SAE) of horizontal NW networks has been proposed as a more scalable approach. Recently, SAE of InAs NWs has been demonstrated on GaAs substrates.[3,4] To decrease the number of detrimental defects, nanomembranes or buffer layers have been used as templates. Thanks to the defect-free nature of these GaAs nanomembranes, NWs with high crystal-quality have been obtained. However, the attempt to grow pure InAs NWs on (111)B GaAs membranes resulted in the formation of intermixed InGaAs NWs with low In content (~20%).[4] Even though these NWs were shown to have quasi-1D transport, their electrical and transport properties were insufficient for quantum applications, leaving much room for improvement.

Herein, we present remotely doped InGaAs NW branches to enhance the properties of these structures.[5] Remote doping, or so-called modulation doping, has been commonly used in different material platforms to enhance mobility by suppressing ionized impurity scattering. In our growths, silicon dopants are introduced close to the interface during the membrane growth stage. The location of these dopants was later confirmed by atom-probe tomography. By using this information in our finite element analysis, we demonstrate that the electrons are localized in the wire segment thanks to the band alignment of GaAs and InGaAs. Moreover, by investigating the InAs growth window while changing In and As flux, we achieved In concentrations of up to 50% in our NWs. Finally, transport and electrical properties of these Y-junctions are characterized under magnetic field at low temperatures. Together with reduced donor scattering, the increase in the In content results in enhanced mobility and large electron mean free paths. Additionally, these NWs exhibit weak anti-localization, which is the hallmark of strong spin-orbit interaction. All these improvements make these NWs promising for future applications in topological quantum computing.

Hybrid-Interfaces in Topological Quantum Materials Panchapakesan Ganesh and Anh Pham; Oak Ridge National Laboratory, United States

Two dimensional magnetic topological materials, such as magnetic topological insulators and magnetic Weyl semimetals, represent a novel platform exhibiting the quantum anomalous Hall effect (QAHE). To realize the quantum anomalous Hall state, the material system needs to break time reversal symmetry while maintaining a nontrivial 2D bulk gap protected by a nonzero Chern number. One pathway is to realize *hybrid-interfaces* between different quantum materials to achieve this synergy. The scientific objective is the rational design of quantum materials and control over their properties by exploiting low dimensionality at heterointerfaces.

In this talk, I will focus on our recent works[1,2,3], employing a combination of density functional Theory (DFT) and k.p model Hamiltonian calculations, to design synthesizable hybrid-interfaces where QAHE can potentially be realized. By systematically investigating such magnetically doped topological insulating materials, we reveal that interfaces between Cr-doped Sb_2Te_3 and the anitferromagnetic insulator Cr_2O_3 are ideal for realizing functional QAHE since the system consists of a large bulk insulating gap with the Fermi level pinned inside a bulk gap due to a type-I band offset, while the dopants at the interface of the TI layer exhibit robust ferromagnetism. We also screened viable vdW-bonded hybrid-interfaces, and discovered that exploiting the unique 'buried' topology in CrI_3 is a good strategy, which can be achieve by interfacing it with elemental layers of antimonene, so as to induce a semimetallic transition in CrI_3 through a charge transfer process. Progress in our ongoing effort in simulating topological heterogeneities, such as step-edges, at interfaces of intrinsic magnetic topological materials, such as $MnBi_2Te_4$, using real-space DFT-methods that allow few-thousand electrons, will also be presented.

Exploring Quantum Systems via Scanning Transmission Electron Microscopy—Machine Learning and Artificial Intelligence Based Workflows Sergei V. Kalinin, Ondrej Dyck, Stephen Jesse, Rama Vasudevan, Christopher Nelson, Matthew Chisholm, Andrew Lupini and Maxim Ziatdinov; Oak Ridge National Laboratory, United States

The emergence of quantum information systems necessitates the development of the tools and workflows capable of probing quantum functionalities on the atomic scale and connecting them to the local structures. Recent advances in Scanning Transmission Electron Microscopy have allowed the direct visualization of materials structures with picometer-scale precision, as well as collection of high-veracity information on local electronic, plasmonic, and vibrational properties via Electron Energy Loss Spectroscopy (EELS). However, the interpretation of these data sets even on the exploratory level of identification of the repeatable units, site symmetries, and outliers remains largely driven by human operator and limited to a priori defined models. Notably, the nature of the STEM data sets, as affected by observational biases and limited to small number of materials, limits the applicability of the classical correlation-based machine learning methods. However, the analysis of such data can be performed assuming the parsimony of structural descriptors and generative mechanisms and adopting the Bayesian analysis frameworks. In this presentation, I will illustrate several applications of the machine learning based workflows based on rotationally invariant and conditional variational autoencoders for the elucidation of the local structures and structure-breaking distortions in 2D materials and ferroelectric oxides. The Bayesian nature of these methods can also be used to extend these to the analysis of the causal relationships between the physical and chemical degrees of freedom. Ultimately, we seek to answer the questions such as whether electronic instability due to the average Fermi level guides the development of the local atomic structure, or frozen atomic disorder drives the emergence of the local structural distortions, whether the nucleation spot of phase transition can be predicted based on observations before the transition, and what is the driving forces controlling the emergence of unique functionalities of morphotropic materials and ferroelectric relaxors. The unique aspect of Bayesian methods is their potential to quantify uncertainty, and harnessing this for automated experimentation is discussed on example of ferroelectric domain patterning and atomic fabrication via electron beams.

5:30 AM F.NM05.05.05
Electric-Field Manipulation of Spins in Dilute Magnetic Ferroelectrics Katherine Inzani[1], Weichaun Huang[2], Junjie Liu[3], Sujit Das[2], Valentin V. Laguta[4], Ruchira Chatterjee[1], Evan Sheridan[1], Arzhang Ardavan[3], Ramamoorthy Ramesh[2,1] and Sinead Griffin[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]University of Oxford, United Kingdom; [4]The Czech Academy of Sciences, Czechia

As a pathway to quantum computing, spins in multiferroic materials offer novel routes of manipulation due to their coupled electrical and magnetic properties. In order to control individual spins as in defect-based qubits, we explore ferroelectric materials with magnetic dopants. Using Fe^{3+}-doped $PbTiO_3$ as a model system, we present a combined first-principles and electron paramagnetic resonance study of the spin-orbit coupling effect in dilute magnetic ferroelectrics. We show that the spins in the Fe^{3+} ion are strongly aligned perpendicular to the ferroelectric polar axis and follow manipulation by an electric field. First principles modelling indicates the atomic scale effects of lattice modification on qubit switching parameters by way of strain and defect complexes, in excellent agreement with experimental observations. These results demonstrate the manipulation of spins by electric field and the possibility to tailor spin control by the atomic environment.

5:40 AM F.NM05.05.07
Uncovering Electron Scattering in Goniopolar Metal NaSn2As2 from First Principles Yaxian Wang and Prineha Narang; Harvard University, United States

Electron scattering on a non-trivial Fermi surface topology plays an important role in electron transport, thus giving rise to exotic phenomena such as violation of Wiedemann Franz law, hydrodynamic electron flow, unusual phonon decay etc. Recent experimental discoveries in axis-dependent conduction polarity, or goniopolarity, have observed that the charge carriers can conduct like either electrons or holes depending on the crystallographic direction they travel along in layered compounds such as NaSn2As2 and PdCoO2, the latter of which also features hydrodynamic electron flow.
In this talk, we present an ab initio study of electron scattering in such systems. Taking NaSn2As2 as an example, we study different microscopic scattering mechanisms from ab initio and present the electron-phonon scattering time distribution on its Fermi surface in momentum space, the anisotropy of which is proposed to be the origin of the axis-dependent conduction polarity. Further, we obtain the overall anisotropic lifetime tensors in real space at different electron chemical potentials and temperatures and discuss how they contribute to the macroscopic thermopower. While we find that the contribution of the in-plane and cross plane lifetimes exhibits a similar trend, the concave portion of the Fermi surface alters the electron motion significantly in the presence of a magnetic field, thus flipping the conduction polarity as measured via the Hall effect. Our calculations and analysis of NaSn2As2 also suggests the strong possibility of hydrodynamic electron flow in the system. These results together have implications for electron lifetimes in a broad class of new quantum materials and provide key, general insights into electron scattering on open Fermi surfaces.

5:50 AM F.NM05.05.08
2D-Ordered Nanodomains in Doped Rutile VO2 Driven by Structural Geometric Frustration Jared M. Allred[1], Matthew Davenport[1], Tyra Douglas[1], Top B. Rawot Chhetri[1], Stephan Rosenkranz[2], Ray Osborn[2] and Matthew J. Krogstad[2]; [1]University of Alabama, United States; [2]Argonne National Laboratory, United States

The rutile crystal structure is a classic crystal structure type that is an important platform for potential device application, including solar cells (TiO_2) and ultrafast optical switches (VO_2). Open d-shell systems such as VO_2 usually undergo a structural distortion that is strongly coupled to changes in the electronic properties. Using single crystal total x-ray scattering and the 3D-ΔPDF method, we discovered a new manifestation of structural order in rutile characterized by a loss of displacement coherence in one dimension but not the other two, resulting in the formation of nanoscopically ordered domains of size ~50x50x5 Å. The loss of dimensionality is attributed to geometric frustration of strongly interacting atomic displacements, since the long- and short-range axes are crystallographically equivalent.

6:00 AM F.NM05.05.09
Imaging Phonon-Mediated Hydrodynamic Flow in WTe2 with Cryogenic Quantum Magnetometry Uri Vool[1], Assaf Hamo[1], George Varnavides[1], Yaxian Wang[1], Tony Zhou[1], Nitesh Kumar[2], Johannes Gooth[2], Claudia Felser[2], Prineha Narang[1] and Amir Yacoby[1]; [1]Harvard University, United States; [2]Max Planck institute for chemical physics in solids, Germany

Tungsten ditelluride (WTe2) is a layered semimetal with many unique features. It is a Type-II Weyl semimetal candidate(1), exhibits large magnetoresistance(2), and superconductivity under strain(3). To gain insight into the electron-electron and electron-phonon interactions in WTe2, we study the spatial structure of current flowing through a WTe2 flake. Significant electron-electron scattering can lead to hydrodynamic effects in electron flow(4), which have been imaged in graphene(5,6). We adapt these techniques to study the nature of interactions in WTe2.

We study the current profile in WTe2 by imaging the local magnetic field above it using a nitrogen-vacancy (NV) center in a diamond scanning tip. Using coherent quantum sensing, we obtain magnetic field resolution of ~10nT and spatial resolution of ~100nm. The current pattern we observe differs substantially from the flat profile of a normal metal, and indicates correlated flow through the semimetal. The pattern also shows significant temperature dependence, with hydrodynamic effects increasing as the system is cooled and peaking at ~20 K. At lower temperatures the current profile becomes flatter, likely due to a competition between hydrodynamic and ballistic effects.

We compare our results to an ab initio calculation of electron scattering mechanisms, which are used to extract a current profile using the electronic Boltzman transport equation. These calculations show quantitative agreement with our measurement, capturing the non-monotonic temperature dependence. This comparison allows us to quantitatively extract the strength of electron-electron interactions in our material. Furthermore, this strong interaction cannot be explained by a direct Coulomb effect, and is mostly phonon-mediated electron-electron interaction. This surprising result opens a path for hydrodynamic flow and strong interactions even in high-density materials with significant screening of Coulomb interactions.

Late News: Potential of Rare-Earth Doped Sesquioxide Thin Films Grown by Chemical Vapour Deposition as a Material Platform for Quantum Technologies Nao Harada[1], Alban Ferrier[1], Diana Serrano[1], Emrick Briand[2], Romain Bachelet[3], Ian Vickridge[2], Jean-Jacques Ganem[2], Philippe Goldner[1] and Alexandre Tallaire[1]; [1]IRCP CNRS, France; [2]INSP, France; [3]INL, France

Harnessing rare-earth (RE) ions outstanding optical coherent properties for quantum information technologies has attracted a lot of attention recently, in the race for exploiting emerging solid-state quantum-grade systems. Indeed, REs offer a wide tunability of their ultra-narrow optical transitions, including the useful telecom-band wavelength. While macroscopic bulk oxide crystals (such as Y_2SiO_5) are usually the preferred host material for RE ions, the development of a silicon-compatible thin film platform would greatly facilitate post-processing, up-scalability as well as interfacing with other systems in a hybrid design. In this work, we focus on the synthesis of nanoscale Eu-doped Y_2O_3 thin films on silicon wafers using a modified version of Chemical Vapour Deposition (CVD) based on direct liquid injection (DLI-CVD) of the precursors. This approach improves the control of the composition and purity of the films by alleviating the issue of low volatility of heavy RE elements. We successfully obtained films in the full Eu composition range, with a strong-(111) texture that crystallized in the bixbyite cubic phase. We probed the $^5D_0$ - $^7F_2$ transition lifetime following resonant excitation of the $^7F_0$ - $^5D_2$ level and found values of the order of 1 ms for the lowest Eu concentrations. Inhomogeneous linewidths as narrow as 50 GHz were also measured. Finally, using spectral hole burning (SHB) spectroscopy we successfully burned a spectral hole in a 200 nm-thin film with a 2 % Eu doping with an estimated homogeneous linewidth of 11 MHz. These values are still at least an order of magnitude higher than those reported for bulk single crystals indicating that additional decoherence mechanisms exist in our nanometric films. Further improvements of the crystalline quality and purity of the films is thus desired so that the full potential of such CVD-grown thin films is unleashed for integrated quantum information processing devices.

6:20 AM F.NM05.05.11
Late News: Tuning the Particle Size and Photoluminescence in Phase-Pure CdSe Quantum Dots Synthesized Through Novel Solution-Growth Technique Naveen Narasimhachar Joshi[1,2] and Muttanagoud Kalasad[3]; [1]Indian Institute of Technology Kharagpur, India; [2]Indian Institute of Science, India; [3]Davangere University, India

In the present work, we show that the *in situ* growth of highly oriented cadmium selenide quantum dots can be explored to alter and tune the emission intensity of the particles. As such, the impact of particle size and distribution on the band emission is studied. Monodispersed cadmium selenide quantum dots (CdSe QDs) were prepared through non-coordinating solvent route, using cadmium oxide (CdO) and selenium (Se) as precursor materials and oleic acid as a capping molecule. The as-synthesized particles were found to be highly stable, with narrow size distribution and good homogeneity. No precipitate was observed for several months. X-ray diffraction (XRD) and transmission electron microscopy (TEM) measurements confirm the formation of (Wurtzite structure) phase-pure CdSe QDs with a diameter tunable between 4 and 6 nm. The particle size is controlled by varying the precursor concentration, reaction time and temperature, without the need for post-synthesis heat treatment techniques. This work was performed without the use of pyrophoric precursors and the reported method represents a basic concept for the preparation of small nanoparticles in general [1]. The smaller sized quantum dots exhibit a strong band emission and are more easily tuned because of their larger surface-area-to-volume ratio [2]. Results demonstrate that the emission wavelength of CdSe QDs vary as a function of particle size, exhibiting high photoluminescence quantum yield (QY) (≈ 62%.) This finding reveals the fluorescence property of CdSe QDs that offers new opportunities for future applications of quantum sources as emerging light emitting materials [3].

Late News: *In Situ* Formation and Conductance of Spin 1/2 Coordination Complexes Masha Kamenetska; Boston University, United States

Electronic and spin states in single coordination complexes containing a paramagnetic center are a promising material platform for use in Quantum Information Science (QIS).[1,2] Such molecules can display a high degree of molecular anisotropy that can be tuned synthetically either by the choice of the metal ion center or through the ligand field of the complex, making them attractive as potential qubits. However, metal-containing complexes have recently been observed to fragment on gold surfaces, impeding the use of these molecules for QIS applications.[3] Here, we demonstrate the *in situ* assembly of coordination complexes between the tip and substrate of our scanning tunneling microscope break junction (STMBJ) setup. Our measurements and density functional theory (DFT) calculations point to the formation of an open-shell structure where a single gold atom coordinates to the nitrogen atoms of imidazolate ligands; this structure bridges the metal electrodes with at least ~1.5 eV of binding energy per bond. We measure a reproducible conductance signature of this coordination complex, which suggests that a selective binding mechanism results in repeatable junction geometries.[4] This *in situ* formation of stable spin ½ single molecule junctions with a robust electronic signature at room temperature points to potential applications of these nanoscale materials in QIS.

5:00 AM *F.NM05.06.01
Quantum Computing with Semiconductors—Spins Inside Lieven Vandersypen; TU Delft, Netherlands

Quantum computation has captivated the minds of many for almost two decades. For much of that time, it was seen mostly as an extremely interesting scientific problem. In the last few years, we have entered a new phase as the belief has grown that a large-scale quantum computer can actually be built. Quantum bits encoded in the spin state of individual electrons in silicon quantum dot arrays, have emerged as a highly promising direction [1]. In this talk, I will present our vision of a large-scale spin-based quantum processor, and ongoing work to realize this vision.

First, we created local registers of spin qubits with sufficient control that we can program arbitrary sequences of operations. We show the creation of each of the Bell states with fidelities of 85-90% and the implementation of the four instances of the Deutsch-Jozsa and the Grover algorithms on two qubits [2].

Second, we have explored coherent coupling of spin qubits at a distance via two routes. In the first approach, the electron spins remain in place and our coupled via an intermediary degree of freedom. After showing this principle with an ancillary quantum dot as a coupler [3], we recently observed strong coupling of a single spin to a single microwave photon in a superconducting resonator [4]. In the second approach, spins are shuttled along a quantum dot array, preserving both the spin projection [5] and spin phase [6].

Third, in close collaboration with Intel, we have fabricated and measured quantum dots using all-optical lithography on 300 mm wafer, using industry-standard processing [7]. Qubit measurements are now underway. We expect that this industrial approach to nanofabrication will be critical for achieving the extremely high yield necessary for devices containing hundreds or thousands of qubits. Furthermore, we anticipate that the device stability and charge noise levels will eventually outperform those of devices made in university-style cleanrooms.

When combined, the progress along these various fronts can lead the way to scalable networks of high-fidelity spin qubit registers for computation and simulation.

Si/SiGe Heterostructures for Quantum Information Science Clayton A. Jackson; HRL Laboratories, United States

Quantum information and computing are at the forefront of computer science, but their implementation relies on the identification and development of a suitable materials system. One such candidate is Si/SiGe. Much progress has been made in Si/SiGe heterostructures grown on metamorphic SiGe substrates as hosts to lithographically defined quantum dots. In this presentation we focus on the general structure and requirements of SiGe quantum dot heterostructures, the demands imposed by necessary dot performance, and advances in characterization methods for these materials.

5:30 AM *F.NM05.06.03
Effects of Coulomb Interactions in Silicon Quantum Dots Susan Coppersmith[1,2]; [1]University of New South Wales, Australia; [2]University of Wisconsin–Madison, United States

Silicon is an attractive materials platform for developing large-scale quantum computers because of its compatibility with classical silicon electronics and its potential for scalability. Recent progress towards quantum computing in silicon has been impressive, but better understanding of the materials will enable improved controllability and predictability of qubit devices.

This talk will discuss some of the fundamental physics and materials science challenges that arise, focussing on the nontrivial interplay between Coulomb interactions and the valley degree of freedom in silicon quantum dots containing more than one electron. Prospects for further development will also be discussed.

5:45 AM *F.NM05.06.04
Exchange Control of Three Spins in Si Triple Quantum Dots Seigo Tarucha; RIKEN, Japan

High-fidelity quantum operations of single and two spins as well as readout and initialization have recently been demonstrated for Si quantum dots. Among them exchange control between spins is an ingredient of quantum entanglement for implementing quantum algorithms, but the demonstration of entanglement has been limited to two-qubit entanglement mainly due to difficulties in controlling exchange couplings in a multi-qubit array. We use a triple quantum dot equipped

with a micro-magnet to control exchange couplings in two or three spin systems. We first measure the single qubit fidelity for three spins in the (1,1,1) charge state and obtain the values of 99.4 to 99.9 % for three spins. Then we use two spins to study exchange control of two qubits or singlet-triplet qubit drive. We use a resonant drive technique of the exchange interaction at the qubit frequency and obtained the fidelity of 99.6% thanks to the symmetric operation and a large micro-magnet Zeeman field gradient. Finally we use three spins to implement three-qubit entanglement. We precisely control exchange couplings between three spins and generate GHZ state. The GHZ state generation protocol will be useful to encode and decode a logical state for the bit-flip quantum error correction code.

6:00 AM F.NM05.06.05
Theory of Single-Electron Transistors with Multiple Quantum Dots Maicol A. Ochoa[1,2], Keyi Liu[1,2], Emily Townsend[1,2], Michal Gawelczyk[3], Michal Zielinski[3] and Garnett Bryant[1,2]; [1]National Institute of Standards and Technology, United States; [2]University of Maryland, United States; [3]Nicolaus Copernicus University, Poland

Donor-based quantum devices in silicon, manufactured with atomic precision, are a feasible alternative for the realization of universal quantum computing and analog quantum simulation. Protocols for operation, readout, and active control of these devices require a complete understanding of the quantum confinement effects, many-body interactions, transport characteristics, and response of the system to external fields. We report theoretical calculations on Si:P nanoscale transistors consisting of a single and multiple quantum dots, based on solutions of the Schrödinger-Poisson equations. In particular, we investigate the role of dopant location, dopant-dopant distance, and array orientation in the shape of the potential in different dopant arrays including 2 × n and n × n arrays. We adopt a combined tight-binding description of the electronic properties of the Si:P substrate, and exact diagonalization techniques for electrons in the dopant array. The effect of external gates and source/drain potentials is accounted for by solving the Poisson equation with the finite element method under appropriate boundary conditions. Most importantly, we develop a way to describe transport through multi-electron, multidot quantum devices. Our simulations allow us to rationalize recent experimental measurements in these devices in terms of their stability diagrams, thus demonstrating that our approach provides an accurate description of single-electron transistors with multiple quantum dots.

6:10 AM F.NM05.06.06
Alternative Gate Materials for Silicon Quantum Devices—Defects and Strain Ryan Stein[1] and M. D. Stewart, Jr.[2]; [1]University of Maryland, United States; [2]National Institute of Standards and Technology, United States

Quantum dots (QD) in the silicon MOS system benefit from the use of palladium or platinum for gate materials because the small grain size of these metals compared to aluminum aids in shrinking the gate and dot dimensions. However, it is not clear what differences arise with respect to process-induced defect density and inhomogeneous strain. Here, we present measurements of oxide defect densities (fixed charge and interface trap density) as a function of forming gas anneal temperature for three different gate metals: Al, Ti/Pd, and Ti/Pt. We also investigate the concomitant effect of these anneals on the mechanical properties of the gate material, such as the intrinsic film stress (σ_0) and coefficient of thermal expansion (α). Our results show that Ti/Pd and Ti/Pt result in much higher fixed charge density and higher, though comparable, interface trap densities when compared to Al with all three metals showing a minimum in interface trap density for a 30 minute anneal at 350C. Moreover, we find that α is larger than the bulk value and that both α and σ_0 increase with temperature with $\sigma_0 \approx 1$ GPa at 350 C for Pd. These results demonstrate that the forming gas anneal which minimizes electrical defects (inhomogeneous strain) strongly increases the effects of inhomogeneous strain (electrical defects).

6:20 AM F.NM05.06.07
Tracking Interfacial Disorder in SiGe Qubit Material Luis F. Pena, Justin C. Koepke and Ezra Bussman; Sandia National Laboratories, United States

Nano-scale quantum dot (QD) qubits in SiGe are exhibiting competitive quantum characteristics, e.g. long coherence times, required of future materials platforms for quantum information technologies. Qubits are intimately nested at semiconductor interfaces between Si and SiGe in layered heterostructures. A major challenge in developing the SiGe platform lies in understanding relationships between interface structure and quantum electronic properties. Specifically, atomic steps at Si/SiGe interfaces is theoretically predicted to strongly modulate a critical quantum property, the conduction band valley spitting. This atomic-scale interface structure-to-electronic-function relationship may be a determining factor in manufacturability of SiGe qubits. However, it is difficult to examine the relationship since it’s exceedingly challenging to probe atomic structure at buried interfaces.

We characterize atomic-scale structural disorder at Si/SiGe qubit interfaces by using scanning tunneling microscopy in parallel with molecular beam epitaxial growth. We report a counterintuitive evolution of roughness and step spatial correlations during growth. We find interfaces are completely uncorrelated with Si sample miscut and take-on unique distributions at each interface, stemming from growth kinetics and strain effects. In addition, at the Si qubit interface, there are widely-ranging atomic step arrangements, at all length scales relevant for QDs reported in literature. This indicates that one should expect widely varying valley splittings and suppressed values measured in both QDs, and mesoscale electronic transport devices. Further, our measurements make it clear that sparse transmission electron and atomic force microscopy (AFM) measurements (the standard approach) will not suffice to evaluate these interfaces. For example, the Si qubit interface and other nearby interfaces have completely different structure and can't serve as proxies for one another to allow top-surface AFM to estimate the buried qubit interface structure. These results are meaningful toward elucidating structure-function relationships in SiGe QDs and a pathway to understanding the complex engineering required to leap beyond current device performance.

6:30 AM F.NM05.06.08
Growth of Nearly Atomically-Flat SiGe Layers on Thick SiGe Relaxed Buffers by UHV-CVD for Valley Splitting Enhancement Weiguang Huo and James C. Sturm; Princeton University, United States

Motivation

Spin qubits of electrons in Si are a leading route to implement quantum computing, due to silicon's weak spin-orbit coupling and the existence of stable zero nuclear spin isotopes. However, a fundamental challenge is the degeneracy of the conduction band minima, which is a decoherence source.
For electron qubits, a thin Si layer is typically grown on a $Si_{0.7}Ge_{0.3}$ relaxed buffer for a tensile strain of 1.2%, which will break the cubic symmetry of Si and split its 6-fold degenerate valleys into four in-plane $\triangle_4$ high-energy valleys and two out-of-plane $\triangle_2$ low-energy valleys. This strain-induced valley splitting is a very large ~200 meV. The two degenerate $Si_{0.7}Ge_{0.3}$ $\triangle_2$ valleys are further split by the quantum well confinement potential, estimated to be 1 meV [1], sufficient for QC. However, experimental measurements are 10 times lower than this expectation [2], which seriously hinders the further development of Si-based QC. It is believed that a roughness as small as one atomic step at the SiGe/Si interface could cause this reduction in valley splitting, so that an atomically flat interface is required [1]. The typical roughnesses of relaxed SiGe layers in the literature are in the nm range or more, at least 10X too high. In this paper, we demonstrate the growth of an atomically flat relaxed $Si_{0.7}Ge_{0.3}$ buffer layer, which could be the key to enhance the splitting of the two $\triangle_2$ valleys in a thin Si layer grown on top of the SiGe. We also outline the fundamental mechanisms leading to SiGe roughness that must be suppressed.

Methods

Conventional thick (3-micron) graded relaxed $Si_{0.7}Ge_{0.3}$ relaxed buffers are first grown by CVD on Si (100) substrates. They are rough, so they are then chemically and mechanically polished to a surface roughness less than 0.2 nm. After wet acid cleaning, SiGe and Si layers are grown in a custom-built UHV-CVD system using silane and germane sources. The typical growth rates for Si and SiGe at 600°C are ~1-2 nm/min respectively. Oxygen and carbon contamination in Si and SiGe layers are all below 5×10^{17} cm^{-3}, indicating clean layers. The roughness is characterized by a Bruker Dimension ICON3 Atomic Force Microscope (AFM) in tapping mode with a 5μm×5μm scan size. The noise error is ~0.10 nm RMS.

Results

Important parameters affecting the growth of the SiGe layer are pre-growth "baking" of the polished relaxed SiGe in the UHV CVD chamber before growth and the growth temperature of the SiGe. Unlike the growth of Si on Si in UHV-CVD, we find that for growth on SiGe, baking is necessary to remove surface contamination, and thus layers grown after baking are

initially rough. The surface roughness is smoother as the regrowth interface contamination is reduced, from 3.4 nm RMS for 750°C baking to 0.46 nm RMS for 800°C baking, indicating that the cleanliness of the regrowth interface is important for layer roughness. The smoothest SiGe surface morphology occurs when the growth temperature is around 650°C, and the morphology gets rougher if the growth temperature is either lower or higher than 650°C. Growing SiGe at lower temperatures, adatoms from the gas source may not find minimum energy locations for step flow growth, possibly due to low adatom surface mobility, leading to roughness. At higher temperatures, multiple mechanisms may to contribute to roughness, such as the re-evaporation process and the role of entropy. Silicon layers are consistently smoother than SiGe layers, and a nearly atomically flat relaxed SiGe (roughness = 0.17 nm RMS) is achieved by inserting a thin Si layer into the relaxed SiGe layer.

6:40 AM F.NM05.06.09
Can AlO_x SETs be Integrated with MOS Quantum Devices? Yanxue Hong[1,2], Ryan Stein[1,2], N. M. Zimmerman[2], M. D. Stewart, Jr.[2] and J.M. Pomeroy[2]; [1]University of Maryland, United States; [2]National Institute of Standards and Technology, United States

Plasma oxidation and ultra-high vacuum handling enable the formation of ultra-stable aluminum oxides (AlO_x), demonstrated here using single-electron transistor (SET) measurements and improving prospects for broader implementation in quantum information applications. These devices exhibit remarkably mitigated charge offset drift (best $\Delta Q_0 = 0.13$ e ± 0.01 e over ≈ 7.6 days) in our Al/AlO_x/Al SETs, compared to previous SET results [1-4] with conventional, thermally oxidized tunnel barriers (best $\Delta Q_0 = 0.43$ e ± 0.007 e over ≈ 9 days and most $\Delta Q_0 \geq 1$ e within one day). Slow, linear drift (< 0.025 e/day) accounts for most of the charge offset drift in our devices and $\Delta Q_0^{corr} = 0.07$ e ± 0.01 e over ≈ 7.6 days when the linear background is subtracted. Slow drift, combined with a control voltage feedback loop, allows good charge sensing as long as the control voltage activity does not obscure "real" charge transition events. The charge stability demonstrated here enables these Al/AlO_x/Al SETs to be integrated as persistent charge sensors for projective spin-to-charge readout in qubit devices. For example, a signal-to-noise > 2 can be achieved when the coupling capacitance is > 3.5 aF between an AlO_x SET and a Si MOS quantum dot with a self-capacitance ≈ 50 aF.

F.NM05.07.01
Observation of Strong Electron-Phonon and Electron-Photon Interactions in Topological Weyl Semimetals Kunyan Zhang[1], Tong Wang[2], Xiaoqi Pang[2], Fei Han[3], Nguyen Tuan Hung[2], Ahmad R. Nugraha[2,4], Mingda Li[3], Riichiro Saito[2] and Shengxi Huang[1]; [1]The Pennsylvania State University, United States; [2]Tohoku University, Japan; [3]Massachusetts Institute of Technology, United States; [4]Indonesian Institute of Sciences, Indonesia

Electron-phonon interaction plays an important role in the electronic properties of topological materials by affecting the dispersion and lifetime of phonon and electronic states. For example, Kohn anomaly describes the phonon softening

phenomenon when the dielectric screening from conducting electrons in a metal is disrupted. Another evidence of strong electron-phonon interaction is Fano resonance, the interference between discrete and continuous states, featured by an asymmetric Breit-Wigner-Fano lineshape. In this work, we present the anisotropic Kohn anomaly and Fano resonance in a type-II Weyl semimetal candidate LaAlSi by polarized Raman spectroscopy. The B_1 phonon mode in our Raman spectra shows excitation-wavelength-dependent phonon-softening and lineshape asymmetry. In type-I Weyl semimetal TaP, abnormal symmetry breaking of another B_1 mode in polarized Raman spectroscopy has been observed, attributed to the quantum interference of degenerate carrier pockets with different symmetries. The experimental observations combined with density-functional theory (DFT) calculations provide valuable insights into microscopy scattering pathways and transport properties of the type-II Weyl semimetal candidate LaAlSi and type-I Weyl semimetal TaP.

F.NM05.07.02

1.5 µm Telecom-Wavelength Single Photon Source of InAs/InP Quantum Dot via Strain-Controlled Growth Youngho Ko[1], Mireu Lee[1,2], Hosung Kim[1], Won Seok Han[1], Je-Hyung Kim[2] and Jung Jin Ju[1]; [1]Electronics and Telecommunications Research Institute, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)

Owing to the rapid development of quantum information technology including quantum communication, quantum sensor, and quantum computer, realization of quantum light source, an essential element for the photonic quantum information applications, have been required. There have been numerous efforts to obtain single photon sources as a quantum light source by using various solid-state material platforms including semiconductor quantum dots (QDs), defect-based color centers in diamond and SiC, QDs in two-dimensional material of WS_2 and WSe_2, and etc. III-V semiconductor QDs have been widely considered as a promising platform for the single photon source due to their various advantages of high generation efficiency of single photon, wavelength tunability, and favourable integration with various semiconductor-based photonic circuits. Single photon emission in 1.5 µm telecom-wavelength range was quite important because of compatible with quantum communication and photonic integrated circuits of silicon photonics. However, single photon emission in telecom-wavelength range was still challenge. InAs QDs are normally grown by Stranski–Krastanov growth mode with molecular-beam epitaxy or metal organic chemical vapor deposition (MOCVD). Because the diameter and height of the self-assemble InAs QDs are determined by strain originated from lattice mismatch with host materials, it was difficult to obtain telecom-wavelength single photon emission from InAs/GaAs or InAs/InP QDs. In this study, we obtained 1.5 µm telecom-wavelength single photon emission from InP-based InAs QDs by using strain-controlled layer of InAlGaAs. The single photon source was fabricated with circular bragg grating structure to obtain high collection efficiency of single photon emission. Moreover, we proposed integrated single photon devices to realize integrated quantum light source with photonic integrated circuits. For the strain control during the growth of InAs QDs, tensile-strained InAlGaAs layers as a host material were grown on the InP substrate. The InAs QDs were grown by Stranski–Krastanov growth mode in MOCVD. lattice-mismatched InAlGaAs on InP showed 0.74 % tensile strain with InP, which was characterized by x-ray diffraction measurement. We monitored the structural properties of InAs QDs by atomic force microscopy and transmission electron microscopy with changing the strain-controlled layers of InAlGaAs, InGaAs, and InP and with changing the thickness of strain-controlled layers. To optimize the size and density of the QD, InAs samples were grown with various growth condition including the temperature, growth rate, and the III/V ratio. We found that the size of InAs QDs were strongly dependent on the density and As flow was critical for emission efficiency of QD and wetting layer. Through systematic study, we could obtain low enough density of InAs QD from 10^7 /cm^2 to 10^9 /cm^2 for fabrication of single photon emitter. We carried out the micro-photoluminescence measurement at 3.4 K for optical analysis of QDs. The single QD emission peak was exhibited from 1.5 to 1.6 µm wavelength. The second-order correlation function was measured for single photon analysis through Hanbury-Brown Twiss experiment. We designed circular bragg grating structures with InAs/InAlGaAs QD for collection efficiency and Purcell enhancement of cavity. Optical simulation of the QD in cavity was performed by finite-difference time domain simulation. The collection efficiency of the circular bragg grating structure was more than 80 % to objective lens of NA 0.7. We also designed the integrated single photon source with Si photonic circuit. InAlGaAs waveguide was designed as the nano tapered waveguide and SiO_2 interlayer was adopted to efficiently couple the single photon emission with Si waveguide. The QD-based telecom-wavelength single photon source of high collection efficiency and integrated single photon source could provide a solution for on-chip quantum photonic devices.

Quantum Technologies with Single Spin Defects in Semiconductors Anais Dreau; CNRS - L2C, France

Optically-active spin defects in semiconductors are solid-state artificial atoms that can maintain their quantum properties over very long times, and sometimes up to room-temperature. A review of their appealing properties for quantum applications, such as ultra-sensitive nanoscale quantum sensors and quantum communication networks, will be presented. Current challenges towards large-scale implementation of quantum technologies and the exploration of novel platforms to isolate individual spin defects will be addressed.

Chemical synthesis creates materials that are atomically precise, customizable, and reproducible. By bringing this toolkit to bear on the challenge of creating materials for quantum information science, we can design custom materials, each molecule geared towards a specific purpose. With these "designer qubits" it may be possible to imbue a qubit with water solubility for biological quantum sensing, create quantum memories with the careful placement of nuclear spins, or tune the emission frequency for quantum communication. Results will be presented on creating and understanding molecular qubits, with an emphasis on strategies to create qubits that can be integrated with established read-out approaches.

Molecular Spin Qudits for Quantum Algorithms Mario Ruben; Karlsruhe Institute of Technology, Germany

Metal complexes will be proposed to acting as active quantum units for Quantum Computing (QC). We report on the implementation of metal complexes into nanometre-sized (single-)molecular spintronic devices by a combination of bottom-up self-assembly and top-down lithography techniques. The controlled generation of magnetic molecular nanostructures on conducting surfaces/electrodes will be shown and persistence of their magnetic properties under confinement in Supramolecular Quantum Devices (SMQD) will be proven. The quantum properties (e.g.. superposition entanglement) of the metal complexes will be addressed at the single molecule level[1-9] to finally implement a quantum algorithm on a $TbPc_2$ Qudit performing quantum computing operations.[10]

Sensing and Controlling the Spin Sublattices of an Insulating Antiferromagnet by Electrical Means Anand Bhattacharya; Argonne National Laboratory, United States

A central goal of antiferromagnetic spintronics is the ability to sense and control the magnetic state of an antiferromagnet. While the magnetic state of a metallic antiferromagnet (AF) may be inferred using magnetoresistance measurements, this is not an option for insulating AF materials. The spin Seebeck effect (SSE), where thermal gradients are used to drive magnon spin currents, has proven to be an effective probe [i] of AF order. Substantial spin currents have been measured using the

SSE in AF insulators Cr_2O_3 [ii] and MnF_2 [iii], and even in geometrically frustrated antiferromagnets [iv]. In this talk, I will briefly review the antiferromagnetic spin Seebeck effect and present our latest results on epitaxial Pt/Cr_2O_3 (0001)/Pt heterostructures. In our devices, the spin currents generated by thermal gradients are detected using the inverse spin Hall effect (ISHE) in thin films of Pt, grown both as an epitaxial underlayer beneath and as an overlayer on top of the Cr_2O_3 film. Cr_2O_3 is unique in that the spins on the top and bottom surfaces of the (0001) oriented film are uncompensated, and belong to separate magnetic sublattices, even in the presence of surface roughness. Using the ISHE in both top and bottom Pt layers [v], we find that the SSE is strongly sensitive to the respective sublattice magnetization. As a result, we are able to track the exact orientation of both sublattices upon application of a magnetic field, including during spin-flop processes. Furthermore, Cr_2O_3 is a classic linear magnetoelectric, where an electric field applied in the [0001] direction can be used to tune the net magnetization [vii]. In this context, I will discuss how the application of electric fields in Pt/Cr_2O_3/Pt heterostructures can be used to tune magnon spin currents, generated using thermal gradients [viii].

Driven Spin Systems with Protected Coherence in Commercially Available Silicon Carbide Kevin Miao, Alexandre Bourassa, Christopher Anderson and David Awschalom; University of Chicago, United States

Silicon carbide (SiC) is a host to a variety of robust, optically active quantum systems. Recent studies have shown that basally oriented *kh* divacancy defects in SiC possess a robust optical interface as well as exceptional spin coherence properties even in commercially available, naturally abundant SiC. We show that these excellent intrinsic properties can be further augmented and tuned by applying a periodic drive, giving rise to emergent phenomena unique to non-equilibrium quantum systems.

First, we demonstrate electrically driven coherent quantum interference in the optical transition of single *kh* divacancies [1]. By applying microwave frequency electric fields, we coherently drive the divacancy's excited-state orbitals and induce Landau-Zener-Stückelberg interference fringes in the resonant optical absorption spectrum. This result shows that the optical absorption spectrum of these divacancy defects can be rapidly reconfigured using localized electric field control, and reveals a highly responsive mechanism to potentially coherently interact with other electrically active quantum systems.

We then construct a robust qubit embedded in a decoherence-protected subspace, obtained by hybridizing an applied microwave drive with the ground-state electron spin of the *kh* divacancy [2]. This qubit is protected from magnetic, electric, and temperature fluctuations, which account for nearly all relevant decoherence channels in the solid state. This culminates in an increase of the qubit's inhomogeneous dephasing time by over four orders of magnitude (to >22 milliseconds), while its Hahn-echo coherence time approaches 64 milliseconds. Such an extension of inhomogeneous dephasing time opens up pathways to a vast array of hybrid quantum system applications. Furthermore, since this protocol requires few key platform-independent components, this result suggests that substantial coherence improvements can be achieved in a wide selection of quantum architectures.

Molecular States in the Silicon Vacuum—Deterministic Clusters of Donors and Acceptors in Silicon Jianhua Zhu[1], Wei Wu[1], Nguyen Le[2], Eran Ginossar[2] and Andrew Fisher[1]; [1]UCL (University College London), United Kingdom; [2]University of Surrey, United Kingdom

Advances in localised tip-induced lithography mean that the process of doping a semiconductor need no longer be random: instead, dopant atoms can be located in well-defined positions relative to one another. This has already been demonstrated for donors in silicon [1,2] and may in future be possible for other types of dopant. This opens the possibility of controlling the interactions between the dopants to form new deterministic devices, which in turn elevates the spin degree of freedom from a spectator into an important variable. As well as the established potential for spin-based quantum gates [3] a number of other applications can now be foreseen.

We have computed the excitation spectra of donor pairs and larger clusters [4] in silicon, using a combination of ab initio band-structure simulations and quantum chemistry techniques. The results show strong and characteristic changes in the character of the dominant excitation as a function of separation and spin state, raising the possibility optical detection and initialisation of the multi-donor spin state. We have also studied the application of controlled donor arrays as quantum simulators that can be probed by their transport properties [5]; in particular we have identified topological edge states and shown how their properties vary across the metal-insulator transition [6].

Finally, for acceptor clusters we have studied the consequences of the richer spin-orbit coupling present in the silicon valence band [7]. We find a complex interplay between the relative strengths of hopping and Coulomb interactions, the arrangement of the bond lengths, and the spin-orbit coupling. This can result in the emergence of novel kinds of topological state.

Magnetoelectric Effects in Spin Crossovers and Metal-Organic Frameworks Vivien Zapf; Los Alamos National Laboratory, United States

Magnetoelectric coupling is the coupling between magnetic order and the electric polarization in an insulator. To date it has been largely studied in inorganic oxides that show various types of ferromagnetic or antiferromagnetic order. Metal-organic frameworks and molecular compounds are a new and fertile direction to search for new magnetoelectric coupling mechanisms. I will talk about several recent results in which we couple spin crossovers to structure and electric polarization. I will also highlight multiferroic behavior in metal-organic frameworks. The experimental part of the work takes advantage of pulsed magnetic fields to perform high-sensitivity measurements and reach extended regions of the magnetic field-temperature phase diagram.

Ultrastrong Magnonic Coupling in Canted Antiferromagnets Takuma Makihara, Nicolas Marquez Peraca and Junichiro Kono; Rice University, United States

Light-matter coupling in the so-called ultrastrong coupling (USC) regime [1] has become an important general subject of modern science and technology. Many next-generation quantum technologies that exploit the extremely efficient light-matter interactions in the USC regime have been proposed. Further, a wealth of exotic phenomena has been predicted in the USC regime, such as quantum vacuum radiation or nonclassical ground states known as two-mode squeezed vacuums. The source

of these phenomena is the so-called counter-rotating terms in the Hamiltonian, which are typically negligible compared to the so-called co-rotating terms for weaker coupling strengths. USC has now been achieved in diverse platforms, but the exotic nature of the ground state due to the counter-rotating terms has not been explored. We have recently observed unusual matter-matter USC phenomena in rare-earth orthoferrites. First, we observed cooperative, Dicke-type coupling between a paramagnetic Er^{3+} spin ensemble and a single mode of terahertz magnons of ordered Fe^{3+} spins in $ErFeO_3$ [2]. The data exhibited vacuum Rabi splitting values in the USC regime, indicating that rare-earth orthoferrites provide a rich playground in which to explore USC phenomena without light. Furthermore, we observed that magnons in $YFeO_3$ display USC with a dominant role played by the counter-rotating terms. Our system is described by an unusual Hamiltonian, where: (i) the coupling strengths are tunable, (ii) the counter-rotating interactions dominate the co-rotating interactions, and (iii) the ground state is a magnonic two-mode squeezed vacuum with quantum fluctuation suppression up to 5.9 dB. These observations demonstrate that $YFeO_3$ provides an extraordinary platform for both applied and fundamental studies of USC beyond the reaches of photonic platforms.

Electron and Nuclear Spin Dynamics in Semiconductor Nanosystems Mikhail Glazov; Ioffe Institute, Russian Federation

Recently, the physicists and material scientists have experienced a new wave of interest in spin effects in solid-state systems. On the one hand, semiconductors and semiconductor nanosystems, allow one to perform benchtop studies of quantum and relativistic phenomena. On the other hand, the interest is supported by the prospects of realizing spin-based electronics where the electron or nuclear spins can play the role of quantum or classical information carriers. In my tutorial lecture, I will present the key aspects of multifaceted physics of interacting electron and nuclear spins in semiconductor-based low-dimensional structures. The hyperfine interaction of the charge carrier and nuclear spins increases in nanosystems compared with bulk materials. The enhanced coupling results in the efficient spin exchange between these two systems. It gives rise to beautiful and complex physics occurring in the ensemble of electrons and nuclei in semiconductors.

I will address the hyperfine interaction, nuclear magnetic resonance, dynamical nuclear polarization, spin-Faraday and -Kerr effects, processes of electron spin decoherence and relaxation, effects of electron spin precession mode-locking and frequency focusing, as well as fluctuations of electron and nuclear spins.

11:45 AM *F.NM06.05.03
Suppression of Nuclear Spin Fluctuations in (In,Ga)As/GaAs Quantum Dots Under Pulsed Excitation with GHz Frequency E. Evers[1], N.E. Kopteva[1,2], Dmitri R. Yakovlev[1,3], A. Greilich[1] and Manfred Bayer[1,3]; [1]Technische Universität Dortmund, Germany; [2]St. Petersburg State University, Russian Federation; [3]Russian Academy of Sciences, Russian Federation

One of the possible hybrid realizations of a qubit is the spin of an electron confined in a semiconductor quantum dot (QD), which is interacting with the surrounding nuclear spins. The prominent advantage of QDs is their strong optical dipole moment, which allows efficient coupling of photons to the confined electron spins according to the optical selection rules. The electron, on the other hand, is coupled to the nuclei of the QD crystal matrix by the hyperfine interaction. These couplings allow one to design schemes where the angular momentum of the photon is transferred to the nuclear spins using the electron as an auxiliary spin state. This may have significant advantages, as the electron spin coherence is limited to several microseconds at low temperatures, while the nuclear spin coherence can reach milliseconds.
To test the degree of control between the electron and the nuclear spin system, we present a model system of an ensemble of singly charged QDs. The use of an ensemble is justified in our case by the spectroscopic signal strength, which allows us to observe an averaged and integral response of many electron spins at the same time. It is also of interest for quantum memory applications. On the other hand, such an ensemble is usually strongly inhomogeneous, which leads to a strong variation of the

intrinsic parameters, like optical dipole moments, electron g-factor values, and strength of electron-nuclear spin interactions. This inhomogeneity can, however, be overcome in designed experiments, enabling effects such as spin mode-locking and nuclear-induced frequency focusing.
In previous studies on nuclei-induced frequency focusing in singly charged (In,Ga)As/GaAs QDs multiple precession modes were covered by the ensemble, as the nuclear fluctuations were of the same order as the mode separation in low external fields. Here we explore the degree of possible control of the nuclear surrounding using an inhomogeneous QD ensemble excited with a high repetition laser operated at 1 GHz. The GHz laser repetition frequency allows us to investigate the interaction of nuclear spin polarization and nuclear spin fluctuations with the electrons as the mode separation is an order of magnitude larger than the fluctuating nuclear field. It further allows us to use the effects of the strong electron-nuclear feedback and drive the inhomogeneous ensemble of electron spins to a single frequency precession. Additionally, we demonstrate the discretization of the total magnetic fields seen by the electron ensemble and show the effect of the reduction of the nuclear field fluctuations. While for fields lower than 0.6 T nuclear spin fluctuations inhibit the formation of a significant nuclear polarization, above the nuclear spin relaxation time becomes elongated such that the electron spins precess on the closest preferred frequency over a range of 128 mT. This leads to the observation of plateaus in the precession frequency as a function of the external magnetic field. The nuclear spin bath is constantly tuned, such that the phase synchronization condition is fulfilled while nuclear fluctuations are suppressed.

12:00 PM *F.NM06.06.01
The Physical Origins of Extreme Cross-Polarization Extinction in Confocal Resonant Spectroscopy Khaled Karrai[1], Meryem Benelajla[1,2], Elena Kammann[1] and Bernhard Urbaszek[2,1]; [1]Attocube Systems AG, Germany; [2]Université de Toulouse, INSA-CNRS-UPS, LPCNO, France

In optical spectroscopy experiments, it is crucial to excite an emitter with a laser very close to its transition energy. Experiments under resonant excitation are essential for accessing the intrinsic optical and spin-polarization properties of large class of emitters [1–6].Using linear cross-polarization in a confocal setup has been successfully employed as a dark-field method to carry out resonant fluorescence experiments to suppress scattered laser light, with the added benefit of high spatial resolution. Resonant fluorescence experiments allow crucial insights into light-matter coupling, such as the interaction of a single photon emitter with its environment, with optical cavities and also studying single defects in atomically thin materials such asWSe2. Dark-field confocal techniques allow developing single photon sources with high degrees of photon indistinguishability and longer coherence. In practice dark-field laser suppression is not just a spectroscopy tool, it is also a key part of more matured quantum technology systems. Despite many advances based on experiments in confocal microscopes with cross-polarization laser rejection, the physical mechanisms that make these experiments possible are not understood, hampering further progress in this field. The key figure of merit is the suppression of the excitation laser background by at least six orders of magnitude. Indeed a suppression by a factor of 10^8 up to 10^{11} (this work) have been measured. But this is very surprising as mirrors and beam-splitter in such a system reduce the theoretical extinction limit to the 10^3 to 10^4 range. In this work we explain the physics behind the giant enhancement of the extinction ratio by up to eight orders of magnitude that make microscopy based on dark-field laser suppression possible. The measurements of resonant fluorescence are typically performed in an epifluorescence geometry, for which laser excitation and fluorescence collection are obtained through the same focusing lens. This involves necessarily the use of a beam-splitter orienting the back-reflected light containing the fluorescence towards a detection channel. In our work we identify two key ingredients that explain the giant amplification of the cross-polarization extinction ratio : (i) a reflecting surface (i.e. the beam-splitter) placed between a polarizer and analyzer, and (ii) a confocal arrangement. We demonstrate giant extinction ratios in our experiments for different mirrors (silver, gold, dielectric, beam-splitter cubes) and polarizers (Glan-Taylor, nanoparticle thin films). We demonstrate that behind this general observation lies the intriguing physics of the Imbert-Fedorov effect, which deviates a reflected light beam depending on its polarization helicity. We discover that a confocal arrangement not only amplifies the visibility of the Imbert-Fedorov effect dramatically, taking it from the nanometer to the micrometer scale, but also exploits conveniently the symmetry of the newly observed Imbert-Fedorov modes to insure that the cross-polarized laser beam is not coupled, explaining the near complete suppression of the laser background signal. In other words, we cannot treat the spatial (i.e. modal) and polarization properties of light separately in our dark-field confocal microscope analysis. In addition to new developments in dark-field microscopy our experiments provide powerful tools to understand spin-orbit coupling of light, in the broader context of topological photonics. Single Artificial Atoms in Silicon Emitting at Telecom Wavelengths Anais Dreau; Laboratoire Charles Coulomb, CNRS & University of Montpellier, France

Given its unrivaled potential of integration and scalability, silicon is likely to become a key platform for large-scale quantum technologies. Individual electron-encoded artificial atoms either formed by impurities [1] or quantum dots [2, 3] have emerged as a promising solution for silicon-based integrated quantum circuits. However, single qubits featuring an optical interface needed for large-distance exchange of information [4] have not yet been isolated in such a prevailing semiconductor.
We show the first isolation of single optically-active point defects in a commercial silicon-on-insulator wafer implanted with carbon atoms [5]. These artificial atoms exhibit a bright, linearly polarized single-photon emission at telecom wavelengths suitable for long-distance propagation in optical fibers. Our results demonstrate that despite its small bandgap (~1.1 eV) a priori unfavorable towards such observation [6], silicon can accommodate point defects optically isolable at single scale, like in wide-bandgap semiconductors [7]. This work opens numerous perspectives for silicon-based quantum technologies, from integrated quantum photonics to quantum communications [8] and metrology.

Ultrafast Excitation of Coherent Spin Waves in 2D Antiferromagnets Xiao-Xiao Zhang; University of Florida, United States

The recently discovered atomically-thin magnetic crystals provide a unique playground to develop new approaches to manipulate magnetism. Rapid progresses have been made that demonstrate the potentials of utilizing 2D magnets to construct novel spintronics devices. However, their spin dynamics, which are crucial for microscopic understanding and determine the fundamental limit of spin manipulation, still remain elusive due to the difficulty of characterizing these micron-sized samples with conventional microwave techniques. In this talk, we will show how we can access and probe the collective spin-wave excitations in an antiferromagnetic bilayer CrI_3, which allows us to extract magnetic anisotropy and exchange energy. In particular, we will demonstrate the gate tunability of magnon frequencies, which is unique for the 2D magnet system.

Van der Waals Epitaxy of Transition Metal Dichalcogenides by MBE Application to the Study of the Valley Nernst Effect in WSe_2 Minh-Tuan Dau[1], Celine Vergnaud[1], Alain Marty[1], Frederic Bonell[2], Cyrille Beigne[1], Serge Gambarelli[1], Vincent Maurel[1], Thomas Guillet[1], Timotee Journot[3], Berangere Hyot[3], Benjamin Grevin[2], Hanako Okuno[1] and Matthieu Jamet[1]; [1]CEA Grenoble, France; [2]CNRS, France; [3]CEA-LETI, France

Semiconducting transition metal dichalcogenides (TMDCs) have gained a great attention because of their fascinating electronic and optical properties when downing the thickness to one monolayer. In the monolayer form, due to the breaking of inversion symmetry and strong spin–orbit coupling, the carriers in TMDCs carry a valley index noted K+ or K−. This valley degree of freedom refers to local extrema in the band structure of TMDC monolayers at the K points of the two-dimensional Brillouin zone and it can be exploited to develop novel valleytronic devices. In MX_2 (M = Mo, W and X = S, Se) monolayers, the broken inversion symmetry and strong spin–orbit coupling originating from the d-orbitals of the transition metal atom align the electron spins near opposite valleys K+ and K− to opposite out-of-plane directions thus preserving time reversal symmetry. The broken spatial inversion symmetry also generates large Berry curvatures near the K valleys, the Berry curvatures being opposite at opposite valleys. This effect gives rise to unconventional electronic properties such as the valley

Hall effect. An interesting growing field of investigation consists in coupling the valley physics with thermoelectrics. Several spin/valley-dependent thermoelectric effects have already been predicted theoretically in monolayer TMDCs such as the spin Nernst effect (thermoelectric counterpart of the spin Hall effect) and the valley Nernst effect (VNE). Hence, the experimental demonstration of those effects could give rise to a new field called valley caloritronics (by analogy with spin caloritronics) with the advantage that the coupled valley-spin degree of freedom is more robust than the spin with respect to external magnetic fields due to the large intrinsic spin–orbit coupling.
In this presentation, I will first review our recent results on the MBE growth of transition metal dichalcogenides on various substrates over large areas and explain the mechanisms underlying the van der Waals epitaxy regime [1]. Using this growth technique, we could study the interplay between thermoelectricity and the valley degree of freedom in monolayers of WSe_2. For this purpose, high quality WSe_2 mono and multilayers were grown on epitaxial graphene on SiC. Using millimeter-sized samples, we were able to apply well-defined temperature gradients and demonstrate the very strong Seebeck response of this material. In a second step, we used the ferromagnetic resonance-spin pumping technique (FMR-SP) to (i) apply the temperature gradient by off centering the sample in the radio frequency (RF) cavity and (ii) address a single valley and break time reversal symmetry using the spin pumping through spin-valley coupling. For FMR-SP, we deposited in-situ the $Al/Ni_{81}Fe_{19}/Al$ magnetic stack on top of the WSe_2 layer. The combination of a temperature gradient and the valley polarization lead to the valley Nernst effect in WSe_2 that we could detect electrically in the RF cavity. The Nernst coefficient we measured is in very good quantitative agreement with the predicted value [2]. This effect could be exploited to generate large transverse valley currents for valleytronics applications.

Optical and Microwave Spin Control of Donors in ZnO Kai-Mei Fu; University of Washington, United States

Electrons bound to donors in silicon are electrically-controlled qubits with exceptional spin coherence properties. Here we seek to find analogous donor systems in direct band gap semiconductors which will enable an efficient optical interface to the donor electron spin qubit. We show that ZnO donors, optically coupled to donor-bound excitons, are particularly promising candidates [1]. Due to low spin-orbit coupling, we find donors exhibit longitudinal spin relaxation times up to 0.5 s at 1.5 K with relaxation fundamentally-limited by phonon interactions. Both lambda and near-cycling optical transitions exist which are suitable for optical spin initialization and readout. Spin-echo coherence times, which we determine via both optical and microwave control, are in the tens of microseconds and likely limited by nuclear spins in natural isotopic ZnO. These characteristics are all extracted from measurements on an ensemble of Ga donors in a commercial substrate. We will present ongoing efforts and challenges toward single donor isolation in nanowires, dual optical-microwave control of donors and two-laser coherent spin-spectroscopy in this emerging qubit platform.

Chemistry for the Second Quantum Revolution Daniel Laorenza[1], Michael Wojnar[1], Joseph Zadrozny[2] and Danna E. Freedman[1]; [1]Northwestern University, United States; [2]Colorado State University, United States

Chemical synthesis creates materials that are atomically precise, customizable, and reproducible. By bringing this toolkit to bear on the challenge of creating materials for quantum information science, we can design custom materials, each molecule geared towards a specific purpose. With these "designer qubits" it may be possible to imbue a qubit with water solubility for biological quantum sensing, create quantum memories with the careful placement of nuclear spins, or tune the emission frequency for quantum communication. Results will be presented on creating and understanding molecular qubits, with an emphasis on strategies to create qubits that can be integrated with established read-out approaches.

5:15 AM *F.NM06.01.03
Molecular Spin Qudits for Quantum Algorithms Mario Ruben; Karlsruhe Institute of Technology, Germany

Metal complexes will be proposed to acting as active quantum units for Quantum Computing (QC). We report on the implementation of metal complexes into nanometre-sized (single-)molecular spintronic devices by a combination of bottom-up self-assembly and top-down lithography techniques. The controlled generation of magnetic molecular nanostructures on conducting surfaces/electrodes will be shown and persistence of their magnetic properties under confinement in Supramolecular Quantum Devices (SMQD) will be proven. The quantum properties (e.g.. superposition entanglement) of the metal complexes will be addressed at the single molecule level[1-9] to finally implement a quantum algorithm on a $TbPc_2$ Qudit performing quantum computing operations.[10]

Giant Phonon-Induced Effective Magnetic Fields in 4f Paramagnets Dominik M. Juraschek and Prineha Narang; Harvard University, United States

A common approach to spin-based technologies is to manipulate the magnetic order of materials using ultrashort laser pulses, promising operation speeds that are orders of magnitude faster than in conventional spin-based devices. The electromagnetic field components of the radiation change electronic correlations and induce motions of the atoms that produce effective magnetic fields, which couple to the orbital and spin angular momentum of the electrons. A central challenge is to induce large fields that are able to quantitatively change the magnetic order, and usually they range on the order of a milli to a few tesla [1,2].

Here, we show that the extraordinarily strong spin-phonon coupling in the rare-earth trihalides allows the generation of effective magnetic fields of more than 100 tesla by driving circular lattice vibrations (phonons) in the material [3]. At these fields, the paramagnetic spins polarize, nearly reaching saturation, and the magnetization can be reversed by changing the handedness of circular excitation. Specifically, we use a combination of phenomenological modeling and first-principles calculations to predict the effective magnetic fields generated by the excitation of phonons and the subsequently induced magnetization for experimentally accessible pulse energies and temperatures. The phonon-induced magnetizations potentially enable entirely novel ways of ferroelectric or ferromagnetic switching.

Sensing and Controlling the Spin Sublattices of an Insulating Antiferromagnet by Electrical Means Anand Bhattacharya; Argonne National Laboratory, United States

A central goal of antiferromagnetic spintronics is the ability to sense and control the magnetic state of an antiferromagnet. While the magnetic state of a metallic antiferromagnet (AF) may be inferred using magnetoresistance measurements, this is not an option for insulating AF materials. The spin Seebeck effect (SSE), where thermal gradients are used to drive magnon spin currents, has proven to be an effective probe [i] of AF order. Substantial spin currents have been measured using the SSE in AF insulators Cr_2O_3 [ii] and MnF_2 [iii], and even in geometrically frustrated antiferromagnets [iv]. In this talk, I will briefly review the antiferromagnetic spin Seebeck effect and present our latest results on epitaxial Pt/Cr_2O_3 (0001)/Pt heterostructures. In our devices, the spin currents generated by thermal gradients are detected using the inverse spin Hall effect (ISHE) in thin films of Pt, grown both as an epitaxial underlayer beneath and as an overlayer on top of the Cr_2O_3 film. Cr_2O_3 is unique in that the spins on the top and bottom surfaces of the (0001) oriented film are uncompensated, and belong to separate magnetic sublattices, even in the presence of surface roughness. Using the ISHE in both top and bottom Pt layers [v], we find that the SSE is strongly sensitive to the respective sublattice magnetization. As a result, we are able to track the exact orientation of both sublattices upon application of a magnetic field, including during spin-flop processes. Furthermore, Cr_2O_3 is a classic linear magnetoelectric, where an electric field applied in the [0001] direction can be used to tune the net magnetization [vii]. In this context, I will discuss how the application of electric fields in Pt/Cr_2O_3/Pt heterostructures can be used to tune magnon spin currents, generated using thermal gradients [viii].

Transient Field- and Current-Induced Magneto-Transport in Epitaxial α-Fe_2O_3/Pt Heterostructures Alexandra Churikova[1], Angela Wittmann[1], Norman Birge[1,2], Larry Scipioni[3], Adam Shepard[3], Ty Newhouse-Illige[3], James Greer[3] and Geoffrey Beach[1]; [1]Massachusetts Institute of Technology, United States; [2]Michigan State University, United States; [3]PVD Products, United States

Antiferromagnetic (AF) materials are candidates for next generation spintronic devices due to terahertz AF spin dynamics, high packing densities, and insensitivity to external magnetic fields. In AF insulators (AFIs), long spin diffusion lengths and predicted superfluid transport of spin currents are attractive for low-power device operation. The electrical control of AF domains has been attempted in AFIs with an adjacent heavy metal (HM) as a source of spin-orbit torque (SOT). Electrical detection of AF order via spin Hall magnetoresistance (SMR) has been developed, but due to heating artifacts in the HM, electrical detection methods must be supplemented by direct probing techniques. Hematite (α-Fe_2O_3), an easy-plane AFI with triaxial anisotropy, is at the forefront of this effort, spurring discoveries of magnon-mediated long-distance spin transport, understanding of anisotropy-driven AF phase transitions, and an unambiguous control of the AF order by electrical current. Contrary to ferromagnets, where domain structure is governed by long-range demagnetizing fields, the domain structure in AFMs is controlled by "destressing fields" of magnetoelastic origin. **Here, we demonstrate that the destressing energy, rather than the anisotropy energy, governs the final state of the AF order in a low anisotropy AFI after the application of an external stimulus (applied current or magnetic field). We report the purely transient effect of electrical current and magnetic field application to the rotation of the AF vector in epitaxial α-Fe_2O_3/Pt bilayers. Implementing a combination of angle-dependent SMR and current pulsing methods, we probe, respectively, the full and partial re-orientation of AF domains. The current-induced rotation of the AF order within the α-Fe_2O_3 domains is confirmed with full rotation to a monodomain state via external magnetic field (due to the low spin-flop transition). We find that approximately 20% of the maximal SMR signal is retained after the external magnetic field has been**

turned off and follows the angular symmetry of the saturated SMR (rather than the triaxial anisotropy). Meanwhile, a remanent SMR switching signal (~5% of the expected maximal SMR signal) remains after current pulsing along two of the three easy axes to rotate the AF order along each one. Therefore, a small fraction of the re-oriented domains retains their AF order even after the magnetic field (or, analogously, a current pulse) is turned off and the rest of the domains relax toward an equilibrium state. This finding is crucial to developing and engineering AFIs properties which would prevent such a relaxation following external stimulus—a key limitation to the stability of switched states in spintronic devices.

Prominent Verwey Transition in Three-Dimensional Fe_3O_4 Nanowire at 10 nm Length Scale Azusa Hattori[1], Rupali Rakshit[2], Yasuhisa Naitoh[3], Hisashi Shima[3], Hiroyuki Akinaga[3] and Hidekazu Tanaka[1]; [1]Osaka Univ, Japan; [2]DST Inspire Faculty, India; [3]National Institute of Advanced Industrial Science and Technology, Japan

Nanostructured material is important because of low dimension fundamental physics and device application. The oldest magnetic material, magnetite (Fe_3O_4) undergoes a sharp Verwey transition with an abrupt change in its structure and electrical conductivity at about 120 K. To date, a variety of fabrication technique to realize high-quality nanostructures. However, the thin film and nanostructured configuration of Fe_3O_4 are unable to show bulk−like Verwey transition due to a large number of unavoidable defects in them [1]. Three-dimensional (3D) Fe_3O_4 epitaxial nanowires of 10 nm length scale have been constructed on a 3D-MgO nanotemplate using an original nanofabrication technique [2]. In spite of the high density of inevitable nanoscale defects, the ultrasmall Fe_3O_4 nanowires exhibit a prominent Verwey transition at about 112 K with a maximum relative change in resistance of 9.5, which is six times larger than that of the thin-film configuration. Numerous measurements on a large number of Fe_3O_4 nanowires grown concurrently on the same 3D-MgO nanotemplate reveal a dramatic difference in their electrical transport property with the presence/absence of the Verwey transition. A comparative study of Fe_3O_4 wires of increasing volume and a thin film reveals that a profound change in the Verwey transition is observed only for wires with a volume of 10 nm^3 order. Moreover, a significant decrease in the sharpness of the resistance jump and the transition temperature (T_{MI}) of the Verwey response is noticed with increasing volume of Fe_3O_4. This indicates the potency of the 3D nanofabrication technique in controlling nanoscale defects which is further reconfirmed through magnetoresistance (MR) measurement. A feature of the MR curve identifies the antiphase boundaries as a major source of defects. The occurrence of the smallest MR in the ultrasmall nanowire with the highest T_{MI} and resistance change ratio proves that 3D isotropic spatial confinement into a length scale comparable to the average spacing between two antiphase boundaries enables the favourable control over nanoscale defects. Comparison of the Verwey transition properties of Fe_3O_4 wires with increasing volume and thin film revealed that the efficient isolation of defects is only possible through isotropic 3D nanoconfinement at a length scale comparable to the average distance between two defects and also indicates the dependence of the Verwey response on the defect concentration. A simple statistical model satisfactorily illustrates the dependence of electrical transport properties on the volume of Fe_3O_4 from the macroscale down to the nanoscale. Finally, an ultrasmall nanowire with a low defect concentration allows the estimation of the true coherent length of the fundamental quasiparticle, the trimeron, responsible for the Verwey transition.

A Novel Cubic-Fe/Pd Alloy Film Based Lithographically Patterned Hydrogen Gas Sensor with Enhanced FMR Signal Strength and Faster Response Time Shahbaz Khan, Martin Saunders, Mariusz Martyniuk and Mikhail Kostylev; The University of Western Australia, Australia

The concept of Ferromagnetic resonance (FMR) based hydrogen gas sensing is a potential candidate for future hydrogen gas sensing technology. However, improvements of the FMR signal strength, response time, and stability of the employed sensing medium are required to make this novel concept competitive with established sensing platforms. Here, we proposed a novel cubic phased-Fe/Pd alloy film based hydrogen gas sensor (HGS), fabricated in a microwave waveguide like geometry. The fabricated devices show a superior FMR signal strength and a faster response time in ambient and H_2 environments in comparison with previous HGS based on continuous magnetic films. Moreover, upon annealing, the as sputtered Fe/Pd patterned devices undergo a structural phase transition from a tetragonal to a cubic phase. The transition is confirmed by careful analysis and interpretation of collected XRD and TEM data. Our findings suggest that the cubic phase of the Fe/Pd alloy film is thermally stable and offers high response times when compared to the tetragonal Fe/Pd film-based devices. This progress in the understanding of the fundamental principles behind the sensing process and the achieved enhancement in device performance represents a step forward towards the practical implementation of the FMR based sensing concept.

Reversible Hydrogen-Ion Control of Room Temperature Antiferromagnetic State in α-Fe_2O_3 Hariom Jani and T. Venky Venkatesan; National University of Singapore, Singapore

Antiferromagnetic insulators are a ubiquitous class of magnetic materials, holding the promise of low-dissipation spin-based computing devices that can display ultra-fast switching and are robust against stray fields. However, their imperviousness to magnetic fields also makes them difficult to control in a reversible and scalable manner. Here we demonstrate a novel ionic pathway to drive a 90° spin-reorientation reversibly in the most common antiferromagnetic insulator α-Fe_2O_3 (hematite) – now an emerging spintronic material that has recently been shown to host topological AFM textures (eg: half-skyrmions and bimerons) and long magnon-diffusion lengths. Our low-temperature catalytic-spillover process involves the incorporation (or removal) of hydrogen from α-Fe_2O_3, post-growth, driving pronounced changes in its magnetic anisotropy, Néel-vector orientation and canted magnetism via electron injection and localized strains. We explain these effects with a detailed magnetic anisotropy model and first-principles calculations. Tailoring our work for future applications, we demonstrate control of the spin-state at room-temperature by reversibly doping hydrogen in Rh-substituted α-Fe_2O_3 and suggest pathways to build electric-field-controlled antiferromagnetic devices by deploying ionotronics.

Thickness-Dependent Magnetic and Structural Properties of Epitaxial Fe Films Sangjae Lee[1], Valentina Bisogni[2], Jonathan Pelliciari[2], Frederick Walker[1] and Charles H. Ahn[1]; [1]Yale University, United States; [2]Brookhaven National Laboratory, United States

Manipulating spins in a ferromagnet spin channel using electrical current or voltage has received substantial attention in pursuit of more compact and energy-efficient memory and spintronic devices. As the technology focuses on nanoscale device applications, understanding the relationship between the dimensionality of the magnetic channel and magnetic and structural properties is crucial. We characterize the magnetic and structural properties of ferromagnetic thin films of α-Fe (body-centered cubic, *bcc*) as a function of thickness, which are grown epitaxially on MgO substrates using molecular beam expitaxy (MBE). The out-of-plane dimensions of the Fe layers, measured with x-ray reflectivity, range from sub-nanometer to ~30nm. The MgO capping layer prevents the Fe layer from oxidation, as measured using x-ray absorption spectroscopy, and all films show saturation magnetization of ~2.1u_B/Fe at 100K, consistent with unoxidized bulk Fe. The lattice constant mismatch between the α-Fe and the bulk MgO imposes a 3.7% tensile strain on Fe, resulting in a tetragonal distortion of the films for all thicknesses. Measurements of crystal truncation rods (CTRs) show strain relaxation of thicker Fe thin films while 3 unit cell thick Fe is coherently strained to the substrate. The synchrotron CTR measurements also show an unexpected expansion of the unit cell for ultra-thin Fe films, which does not strongly affect the magnetic properties. This work lays the groundwork for understanding how to control the spin excitations in ferromagnetic systems.

Work at Yale is supported by a grant from the Department of Energy, Basic Energy Sciences under grant number DE-SC0019211. This research used beamline 2-ID of the National Synchrotron Light Source II, a U.S. Department of Energy (DOE) Office of Science User Facility operated for the DOE Office of Science by Brookhaven National Laboratory under Contract No. DE-SC0012704.

5:00 AM F.NM06.03.01
Transport Spin-Polarization of Pt/Magnetic Insulator Bilayers—Evidence for the Magnetic Proximity Effect Michael S. Osofsky[1], Joseph Prestigiacomo[1], C S. Hellberg[1], Peng Li[2], Lauren Riddiford[3] and Yuri Suzuki[3]; [1]U.S. Naval Research Laboratory, United States; [2]Auburn University, United States; [3]Stanford University, United States

The anomalous Hall effect has been observed in non-magnetic metallic films with strong spin-orbit scattering that are in intimate contact with a magnetic insulator [1]. Two mechanisms have been proposed to explain this observation: the magnetic proximity effect (MPE) and a combination of the spin Hall effect and inverse spin Hall effect. Direct measurements of the local magnetization of the non-magnetic metal using spectroscopic techniques that are sensitive to local magnetic moments have been inconclusive. To definitively determine whether there is an MPE, point contact Andreev reflection (PCAR) measurements [2] were used to detect an induced transport spin polarization in Pt films deposited on yttrium iron

garnet and manganese aluminum ferrite films. The results will be compared to density functional theory calculations and can be used in the interpretation of measurements of spin currents.

The authors acknowledge the support of the Basic Research Office of the Assistant Secretary of Defense for Reserch and Engineering under the Vannevar Bush Faculty Fellowship (funded by the Office of Naval Research through grant N00014-15-1-0045).

Driven Spin Systems with Protected Coherence in Commercially Available Silicon Carbide Kevin Miao, Alexandre Bourassa, Christopher Anderson and David Awschalom; University of Chicago, United States

Silicon carbide (SiC) is a host to a variety of robust, optically active quantum systems. Recent studies have shown that basally oriented *kh* divacancy defects in SiC possess a robust optical interface as well as exceptional spin coherence properties even in commercially available, naturally abundant SiC. We show that these excellent intrinsic properties can be further augmented and tuned by applying a periodic drive, giving rise to emergent phenomena unique to non-equilibrium quantum systems.

First, we demonstrate electrically driven coherent quantum interference in the optical transition of single *kh* divacancies [1]. By applying microwave frequency electric fields, we coherently drive the divacancy's excited-state orbitals and induce Landau-Zener-Stückelberg interference fringes in the resonant optical absorption spectrum. This result shows that the optical absorption spectrum of these divacancy defects can be rapidly reconfigured using localized electric field control, and reveals a highly responsive mechanism to potentially coherently interact with other electrically active quantum systems.

We then construct a robust qubit embedded in a decoherence-protected subspace, obtained by hybridizing an applied microwave drive with the ground-state electron spin of the *kh* divacancy [2]. This qubit is protected from magnetic, electric, and temperature fluctuations, which account for nearly all relevant decoherence channels in the solid state. This culminates in an increase of the qubit's inhomogeneous dephasing time by over four orders of magnitude (to >22 milliseconds), while its Hahn-echo coherence time approaches 64 milliseconds. Such an extension of inhomogeneous dephasing time opens up pathways to a vast array of hybrid quantum system applications. Furthermore, since this protocol requires few key platform-independent components, this result suggests that substantial coherence improvements can be achieved in a wide selection of quantum architectures.

Sensing Sub-Thermal Energies Through Low-Field DC Magnetoresistance of Neutral Divacancies in Silicon Carbide Stephen R. McMillan[1] and Michael E. Flatté[1,2]; [1]University of Iowa, United States; [2]Technische Universiteit Eindhoven, Netherlands

The neutral divacancy in 4H-SiC has a spin-1 ground state that is highly sensitive to electrical and mechanical perturbations [1]. The long room temperature coherence times of these deep centers suggest that they are robust candidates for nanoscale quantum sensing [2]. Within the past five years optical readout of single divacancies in SiC has been demonstrated [3]. Electrical readout of single spins typically relies on Boltzmann distributed spin polarizations which necessitate operation at low temperatures and/or high magnetic fields to improve the quality of the single-shot protocol [4]. Recently ambient

electrical readout has been demonstrated on SiC defects using photocurrent detected magnetic resonance [5], relying on optical excitation to generate current. In contrast, we propose a time-averaged projective measurement technique that derives from local influences on the ground state coherent dynamics of the neutral divacancy. This provides resolution of processes corresponding to energy scales far below the thermal noise floor of the system without the need for optical hardware, AC fields, or large DC fields. We calculate the defect mediated current through a spin-polarized contact under a small (~mT) external magnetic field similar to previous calculations done on a spin-1/2 ground state [6]. We predict that measurement of the spin relaxation time is possible from analysis of the zero-field current and that spin-decoherence is discernible from the zero-field width. Magnetoresistive signatures also provide information on local electric and strain fields suggesting a path toward scalable, all-electric, room temperature quantum technology based on SiC. We acknowledge support for this work from DOE BES through grant number DE-SC0016379.

Molecular States in the Silicon Vacuum—Deterministic Clusters of Donors and Acceptors in Silicon Jianhua Zhu[1], Wei Wu[1], Nguyen Le[2], Eran Ginossar[2] and Andrew Fisher[1]; [1]UCL (University College London), United Kingdom; [2]University of Surrey, United Kingdom

Advances in localised tip-induced lithography mean that the process of doping a semiconductor need no longer be random: instead, dopant atoms can be located in well-defined positions relative to one another. This has already been demonstrated for donors in silicon [1,2] and may in future be possible for other types of dopant. This opens the possibility of controlling the interactions between the dopants to form new deterministic devices, which in turn elevates the spin degree of freedom from a spectator into an important variable. As well as the established potential for spin-based quantum gates [3] a number of other applications can now be foreseen.

We have computed the excitation spectra of donor pairs and larger clusters [4] in silicon, using a combination of ab initio band-structure simulations and quantum chemistry techniques. The results show strong and characteristic changes in the character of the dominant excitation as a function of separation and spin state, raising the possibility optical detection and initialisation of the multi-donor spin state. We have also studied the application of controlled donor arrays as quantum simulators that can be probed by their transport properties [5]; in particular we have identified topological edge states and shown how their properties vary across the metal-insulator transition [6].

Finally, for acceptor clusters we have studied the consequences of the richer spin-orbit coupling present in the silicon valence band [7]. We find a complex interplay between the relative strengths of hopping and Coulomb interactions, the arrangement of the bond lengths, and the spin-orbit coupling. This can result in the emergence of novel kinds of topological state.

Magnetoelectric Effects in Spin Crossovers and Metal-Organic Frameworks Vivien Zapf; Los Alamos National Laboratory, United States

Magnetoelectric coupling is the coupling between magnetic order and the electric polarization in an insulator. To date it has been largely studied in inorganic oxides that show various types of ferromagnetic or antiferromagnetic order. Metal-organic frameworks and molecular compounds are a new and fertile direction to search for new magnetoelectric coupling mechanisms. I will talk about several recent results in which we couple spin crossovers to structure and electric polarization. I will also highlight multiferroic behavior in metal-organic frameworks. The experimental part of the work takes advantage of pulsed magnetic fields to perform high-sensitivity measurements and reach extended regions of the magnetic field-temperature phase diagram.

Narrow-Gap Semiconductor Spintronics—Electron G-Tensor Engineering with Multilayer Structures Antonio Ferreira da Silva[1,2], Jhon E. Leon Padilla1[1], Marcelo A. Toloza Sandoval[1] and Jose Fernando D. Chubaci[2]; [1]Federal University of Bahia, Brazil; [2]São Paulo University, Brazil

Among the main trends for spintronic applications, narrow gap semiconductors provide a fertile ground to engineering the electron effective g factor, because of its strong dependency on the energy gap of the bulk material. Furthermore, it is well-known that in semiconductor heterostructures, the mesoscopic confinement also renormalizes the effective g factor by introducing extra anisotropies, transforming scalar g factors into tensors. In particular, for narrow-gap semiconductor layered structures, the electronic g-tensor is expressed as a diagonal matrix, where the diagonal elements correspond to configurations of magnetic-field longitudinal and transversal to the growth direction. Considering bound electrons in both, InAs- and InSb-based multilayer structures, we use an analytical and transparent envelope-function solution based on the Kane model for the bulk, to investigate the effective g tensor and the corresponding anisotropy, i.e., the difference between the longitudinal and transversal components. Following the prescription abovementioned, we 1) study the dependency between the obtained results and the bulk-band parameters, 2) study the fine-tunning of the effective g-factors (longitudinal and transversal) with the structural parameters, i.e., the thicknesses of the active layer and the tunneling barrier, in particular, we 3) explore the strongly interacting regime for thin active layers, for which the structure inversion asymmetry plays a fundamental role by inverting the signal of the g-factor anisotropy. Such results provide a clear understanding of the mechanisms of the g-factor renormalization in semiconductor nanostructures and can be useful in electron g-factor engineering.

Spin Texture and Berry Curvature of Holes Confined in SiGe Quantum Well System Tatsuki Tojo and Kyozaburo Takeda; Waseda University, Japan

The spin-orbit interaction (SOI) is the relativistic correction, caused by the coupling between a spin σ and an effective magnetic field (EMF) of a charged carrier. Despite the necessity of understanding the characteristics in the SOI phenomena for holes as well as for electrons, the complexity of the valence band structure prevents us from our deep understanding of the SOI for holes. The SOIs are generally caused by symmetry breakings, such as the bulk-inversion-asymmetry (BIA) and the structure-inversion-asymmetry (SIA). Dresselhaus has studied intensively the BIA (Dresselhaus) SOI and revealed the characteristics for holes. Rashba has theoretically proposed that an electric field externally applied to quantum systems has potential to cause the SIA (Rashba) SOI.
In this presentation, we apply the Rashba external field to the two-dimensional (2D) SiGe mixed alloy quantum well (QW) system, and then study how the coexistence of the BIA and SIA SOIs influences the spin textures of holes. We particularly focus on the spin texture and Berry curvature of the heavy-mass holes (HHs), because it is our one more purpose how the inter-subband interaction influences them via the strongly anisotropic and non-parabolic eigenstates. Taking into account the in-planar crystal momentum as well as the particle one, we extend the ***kp*** approach including the 2nd-order terms crossing

with those SIA and BIA SOIs and solve the ***kp*** perturbation equation under the virtual crystal approximation. By employing the solved Bloch periodic parts, we calculate the ***k***-distribution of the in-plane spin of HHs.
The SIA-BIA coexistence system changes the symmetry of the present SiGe 2D QW system characteristically. The electric-field application perpendicular to the 2D (001) plane causes the SIA whereas the alternating arrangement of Si and Ge heteroatoms causes the BIA. Eventually, the SIA and BIA SOIs strengthen the axial vectors cooperatively in the first and third quadrants of the Brillouin zone (BZ) whereas they compete and suppress themselves in the second and fourth quadrants. The present SIA and BIA SOIs resolve the spin degeneracy of HHs into the stabilized (HH+) and destabilized (HH-) one. Each spin texture exhibits the inequivalence between the [110] and [-110] directions, and both planes of (110) and (-110) are the mirror plane for an axial-vector spin. For the <110> direction, the HH spin orients to the tangent line of the equi-energy surface. However, except for this direction, the spin does not orient toward the tangential line. HHs basically orient their spins parallel to their own EMF. However, the EMF has a remarkable term to cause the directional discrepancy from the tangential line. In addition to this EMF characteristics, the EMF and spin correlate via the ***ls*** coupling. Consequently, the spin texture shows the characteristic ***k***-distribution, significantly different from that found in 2D electron gas (2DEG).
We further study the Berry curvature B^+ for HH+ and B^- for HH- influenced by the coexistence of SIA and BIA SOIs. HHs are energetically separated from other holes and the pair relation of B^+=-B^- results. The coexistence of SIA and BIA SOIs multiply changes the sign of the Berry curvatures. Furthermore, the strong anisotropy and significant non-parabolicity of HHs distribute the Berry curvatures complicatedly. Nevertheless, the pair relation B^+=-B^- is valid. We carry out the integration of the Berry curvature surrounded by the equi-energy contour E, and estimate the Berry phase $\gamma(E)$ at an energy E. The resulting $\gamma^+(E)$ causes a plateau of a half-integer 1/2 until E~16meV; $\gamma^-(E)$ does that of -1/2. However, it suddenly changes the sign and an opposite plateau of -1/2 (+1/2) results in the higher energy region. This characteristic feature is peculiar to HHs not found in the 2DEG because the sign and ***k***-distribution of the Berry curvature in the integral area are crucial for determining $\gamma(E)$. This feature influences the Chern number and Hall conductivity.

Late News: Zero-Bias Giant Rashba Spin-Orbit Coupling at Complex Oxide Interfaces Ganesh Ji Omar and Ariando Ariando; National University of Singapore, Singapore

Following the second law of thermodynamics, the Landauer's principle dictates a fundamental physical limitation for the switching energy of complementary metal-oxide-semiconductor (CMOS). A primary solution in breaking this limitation is to utilize the spin-orbit coupling (SOC) effect, as it allows easy manipulation of spin currents. However, this SOC effect is often quite weak, especially in the absence of external voltage biases. We report a four-fold SOC enhancement at zero bias voltage and pronounced SOC evolution in correlated $LaAlO_3$-$SrTiO_3$ heterostructures buffered by a carrier modulating $LaFeO_3$ layer. We use an entirely new approach to provide evidence of generating Rashba SOC. Correlating the magnetotransport data with first-principles calculations and high-resolution electron microscopy, we reveal that its origin lies in the asymmetric hybridization of the interfacial wavefunctions. Our results open hitherto unexplored avenues of generating and controlling Rashba coupling to design next-generation two-dimensional electron system based spin-orbitronic devices.

Electron and Nuclear Spin Dynamics in Semiconductor Nanosystems Mikhail Glazov; Ioffe Institute, Russian Federation

Recently, the physicists and material scientists have experienced a new wave of interest in spin effects in solid-state systems. On the one hand, semiconductors and semiconductor nanosystems, allow one to perform benchtop studies of quantum and relativistic phenomena. On the other hand, the interest is supported by the prospects of realizing spin-based electronics where the electron or nuclear spins can play the role of quantum or classical information carriers. In my tutorial lecture, I will present the key aspects of multifaceted physics of interacting electron and nuclear spins in semiconductor-based low-dimensional structures. The hyperfine interaction of the charge carrier and nuclear spins increases in nanosystems compared with bulk materials. The enhanced coupling results in the efficient spin exchange between these two systems. It gives rise to beautiful and complex physics occurring in the ensemble of electrons and nuclei in semiconductors.

I will address the hyperfine interaction, nuclear magnetic resonance, dynamical nuclear polarization, spin-Faraday and -Kerr

effects, processes of electron spin decoherence and relaxation, effects of electron spin precession mode-locking and frequency focusing, as well as fluctuations of electron and nuclear spins.

5:15 AM *F.NM06.05.03
Suppression of Nuclear Spin Fluctuations in (In,Ga)As/GaAs Quantum Dots Under Pulsed Excitation with GHz Frequency E. Evers[1], N.E. Kopteva[1,2], Dmitri R. Yakovlev[1,3], A. Greilich[1] and Manfred Bayer[1,3]; [1]Technische Universität Dortmund, Germany; [2]St. Petersburg State University, Russian Federation; [3]Russian Academy of Sciences, Russian Federation

One of the possible hybrid realizations of a qubit is the spin of an electron confined in a semiconductor quantum dot (QD), which is interacting with the surrounding nuclear spins. The prominent advantage of QDs is their strong optical dipole moment, which allows efficient coupling of photons to the confined electron spins according to the optical selection rules. The electron, on the other hand, is coupled to the nuclei of the QD crystal matrix by the hyperfine interaction. These couplings allow one to design schemes where the angular momentum of the photon is transferred to the nuclear spins using the electron as an auxiliary spin state. This may have significant advantages, as the electron spin coherence is limited to several microseconds at low temperatures, while the nuclear spin coherence can reach milliseconds.
To test the degree of control between the electron and the nuclear spin system, we present a model system of an ensemble of singly charged QDs. The use of an ensemble is justified in our case by the spectroscopic signal strength, which allows us to observe an averaged and integral response of many electron spins at the same time. It is also of interest for quantum memory applications. On the other hand, such an ensemble is usually strongly inhomogeneous, which leads to a strong variation of the intrinsic parameters, like optical dipole moments, electron g-factor values, and strength of electron-nuclear spin interactions. This inhomogeneity can, however, be overcome in designed experiments, enabling effects such as spin mode-locking and nuclear-induced frequency focusing.
In previous studies on nuclei-induced frequency focusing in singly charged (In,Ga)As/GaAs QDs multiple precession modes were covered by the ensemble, as the nuclear fluctuations were of the same order as the mode separation in low external fields. Here we explore the degree of possible control of the nuclear surrounding using an inhomogeneous QD ensemble excited with a high repetition laser operated at 1 GHz. The GHz laser repetition frequency allows us to investigate the interaction of nuclear spin polarization and nuclear spin fluctuations with the electrons as the mode separation is an order of magnitude larger than the fluctuating nuclear field. It further allows us to use the effects of the strong electron-nuclear feedback and drive the inhomogeneous ensemble of electron spins to a single frequency precession. Additionally, we demonstrate the discretization of the total magnetic fields seen by the electron ensemble and show the effect of the reduction of the nuclear field fluctuations. While for fields lower than 0.6 T nuclear spin fluctuations inhibit the formation of a significant nuclear polarization, above the nuclear spin relaxation time becomes elongated such that the electron spins precess on the closest preferred frequency over a range of 128 mT. This leads to the observation of plateaus in the precession frequency as a function of the external magnetic field. The nuclear spin bath is constantly tuned, such that the phase synchronization condition is fulfilled while nuclear fluctuations are suppressed.

5:30 AM F.NM06.05.04
Spin-Phonon Relaxation from a Universal *Ab Initio* Density-Matrix Approach Yuan Ping; University of California Santa Cruz, United States

Designing new quantum materials with long-lived electron spin states urgently requires a general theoretical formalism and computational technique to reliably predict intrinsic spin relaxation times. We present a new, accurate and universal first-principles methodology based on Lindbladian dynamics of density matrices to calculate spin-phonon relaxation time of solids with arbitrary spin mixing and crystal symmetry[1]. This method describes contributions of Elliott-Yafet and D'yakonov-Perel' mechanisms to spin relaxation for systems with and without inversion symmetry on an equal footing. We show that intrinsic spin and momentum relaxation times both decrease with increasing temperature; however, for the D'yakonov-Perel' mechanism, spin relaxation time varies inversely with extrinsic scattering time. We predict large anisotropy of spin lifetime in transition metal dichalcogenides. The excellent agreement with experiments for a broad range of materials underscores the predictive capability of our method for properties critical to quantum information science. [1] J. Xu et al, *Nature Communications* **11**, 2780 (2020)

Magnetocrystalline Anisotropy in Antiferromagnetic Fe_2As—A First-Principles Study Kisung Kang, Kexin Yang, David Cahill and Andre Schleife; University of Illinois at Urbana-Champaign, United States

Antiferromagnetic tetragonal Fe_2As attracts attention due to its easy-plane magnetism which might enable future usage in magnetic memory devices. Moreover, the possibility for electrical switching of the Néel vector is expected because of its metallicity. To understand the mechanism of switching for easy-plane magnetism, it is essential to know the magnetocrystalline anisotropy energy of antiferromagnetic Fe_2As, which acts as an energy barrier. Using first-principles density functional theory, we study the contributions of spin-orbit interaction (SOI) and magnetic dipole-dipole interaction (MDD) to magnetocrystalline anisotropy. The tetragonal structure exhibits out-of-plane and in-plane anisotropy energy terms. The out-of-plane anisotropy, computed as a $|K_1|$ coefficient of 830 kJ/m^3, originates from both SOI and MDD. The contribution of SOI is two times larger than that of MDD, and both show the same two-fold symmetry. Conversely, the in-plane MDD contribution is almost negligible and most of the anisotropy energy comes from SOI, which shows four-fold symmetry and a $|K_{22}|$ coefficient of 280 J/m^3. This closely corresponds to the value of 150 J/m^3, measured using torque magnetometry. Based on the calculated anisotropy energy, antiferromagnetic Fe_2As shows potential for the switching process to occur, however, the results also indicate low thermal stability of the magnetic structure.

Late News: Controlling Magnetic Order by Driving Phonons with Light Ankit S. Disa[1], Michael Fechner[1], Michael Först[1], Paolo G Radaelli[2] and Andrea Cavalleri[1,2]; [1]Max Planck Institute for the Structure and Dynamics of Matter, Germany; [2]University of Oxford, United Kingdom

The ability to strongly and deterministically manipulate magnetic order is crucial for applications ranging from spintronics to information storage. For example, strain engineering enables tuning of magnetic phases in a variety of complex systems. Combining this tunability with optical methods would enable novel optomagnetic technologies operating on ultrafast time scales. In this work, we demonstrate a route to dynamically mimic strain and create non-equilibrium magnetic properties by engineering the crystal structure with light. [1]. In particular, in the antiferromagnet CoF_2, we induce a ferrimagnetic phase transition through selective THz excitation of optical phonons. The effect takes advantage of the coupling of the local magnetic moment to the crystal field environment, which statically leads to a net magnetization under uniaxial strain (piezomagnetism). Rather than strain, we exploit nonlinear, three-phonon coupling to drive the desired crystal field distortions [2]. Optical measurements reveal that, as a result, a bi-directional ferrimagnetic moment is generated on a time scale of few to hundreds of picoseconds. The generated moment is nearly three orders of magnitude larger than previously achieved by strain, demonstrating phonon-driven control of magnetic order beyond the elastic limit.

5:00 AM *F.NM06.06.01
The Physical Origins of Extreme Cross-Polarization Extinction in Confocal Resonant Spectroscopy Khaled Karrai[1], Meryem Benelajla[1,2], Elena Kammann[1] and Bernhard Urbaszek[2,1]; [1]Attocube Systems AG, Germany; [2]Université de Toulouse, INSA-CNRS-UPS, LPCNO, France

In optical spectroscopy experiments, it is crucial to excite an emitter with a laser very close to its transition energy. Experiments under resonant excitation are essential for accessing the intrinsic optical and spin-polarization properties of large class of emitters [1–6].Using linear cross-polarization in a confocal setup has been successfully employed as a dark-field method to carry out resonant fluorescence experiments to suppress scattered laser light, with the added benefit of high spatial resolution. Resonant fluorescence experiments allow crucial insights into light-matter coupling, such as the interaction of a single photon emitter with its environment, with optical cavities and also studying single defects in atomically thin materials such asWSe2. Dark-field confocal techniques allow developing single photon sources with high degrees of photon indistinguishability and longer coherence. In practice dark-field laser suppression is not just a spectroscopy tool, it is also a

key part of more matured quantum technology systems. Despite many advances based on experiments in confocal microscopes with cross-polarization laser rejection, the physical mechanisms that make these experiments possible are not understood, hampering further progress in this field. The key figure of merit is the suppression of the excitation laser background by at least six orders of magnitude. Indeed a suppression by a factor of 10^8 up to 10^{11} (this work) have been measured. But this is very surprising as mirrors and beam-splitter in such a system reduce the theoretical extinction limit to the 10^3 to 10^4 range. In this work we explain the physics behind the giant enhancement of the extinction ratio by up to eight orders of magnitude that make microscopy based on dark-field laser suppression possible. The measurements of resonant fluorescence are typically performed in an epifluorescence geometry, for which laser excitation and fluorescence collection are obtained through the same focusing lens. This involves necessarily the use of a beam-splitter orienting the back-reflected light containing the fluorescence towards a detection channel. In our work we identify two key ingredients that explain the giant amplification of the cross-polarization extinction ratio : (i) a reflecting surface (i.e. the beam-splitter) placed between a polarizer and analyzer, and (ii) a confocal arrangement. We demonstrate giant extinction ratios in our experiments for different mirrors (silver, gold, dielectric, beam-splitter cubes) and polarizers (Glan-Taylor, nanoparticle thin films). We demonstrate that behind this general observation lies the intriguing physics of the Imbert-Fedorov effect, which deviates a reflected light beam depending on its polarization helicity. We discover that a confocal arrangement not only amplifies the visibility of the Imbert-Fedorov effect dramatically, taking it from the nanometer to the micrometer scale, but also exploits conveniently the symmetry of the newly observed Imbert-Fedorov modes to insure that the cross-polarized laser beam is not coupled, explaining the near complete suppression of the laser background signal. In other words, we cannot treat the spatial (i.e. modal) and polarization properties of light separately in our dark-field confocal microscope analysis. In addition to new developments in dark-field microscopy our experiments provide powerful tools to understand spin-orbit coupling of light, in the broader context of topological photonics. Photon Statistics as an Analytical Tool for Characterizing Solid-State Defects Rebecca Fishman, Raj N. Patel, David Hopper, Tzu-Yung Huang and Lee Bassett; University of Pennsylvania, United States

Photon correlation spectroscopy is a powerful technique for measurement and analysis of optical dynamics. Historically, analysis of photon detection times enabled early studies of fundamental quantum mechanical phenomena in trapped atoms and ions and was used to probe dynamics in single-molecule spectroscopy. More recently, it has been applied to solid-state emitters to enable their characterization for quantum technological applications. The predominant use of photon statistics in solid-state systems is as an indicator of single-photon emission, a desirable property for applications such as quantum key distribution and quantum repeaters. However, a more comprehensive analysis of photon statistics can reveal even more characteristics of a system such as the electronic structure, multi-level optical dynamics, and responses to external fields. We discuss photon correlation spectroscopy as a measurement tool for solid-state emitters and outline important methods and considerations for proper acquisition and analysis of photon statistics. In particular, we explore the differences between the two most common measurement techniques, start-stop histogram and time-tagged-time-resolved mode, and we highlight the technical considerations in accounting for background fluorescence and detector jitter for robust characterization of single-photon emission. We also discuss how both an emitter's internal dynamics and experimental nonidealities must be taken into account in order to guarantee reliable measurements. Finally, we illustrate how the photon statistics framework can be used to characterize quantum emitters by applying it to known emitters like the diamond nitrogen-vacancy center and unknown emitters in hexagonal boron nitride. Through comparison of the measurements to optical-dynamics simulations, we posit an optical level diagram for the unknown emitters, advancing understanding of their electronic structure and optical dynamics.

Exploiting Spin Interaction within Magnetic Nanoparticles Toward Remote Spatially Resolved Temperature Sensing Adam Biacchi, Thinh Q. Bui, Brianna B. dos Santos Correa, Cindi L. Dennis, Solomon I. Woods and Angela Hight Walker; National Institute of Standards and Technology, United States

Magnetic nanoparticles (MNPs) are an important class of low-dimensional materials displaying size-dependent magnetic

behavior. The controllable tunablility of magnetic anisotropy introduced at nanoscale size regimes allows for nanoparticles of ferro/ferrimagnetic materials to be dispersed in a medium, with the addition of colloidal stabilizers, and still produce a significant collective response to a dynamic applied magnetic field. This strong response to external applied fields, while still maintaining colloidal dispersity, is the basis for employing these magnetic materials in biomedical applications such as imaging, sensing, drug delivery, and hyperthermia.

Magnetic nanothermometry is an emerging application of MNPs. While conventional remote thermometry can measure the temperature of a microscale spot only on an object's surface or in a small local region of an optically transparent material, magnetic nanothermometry is being developed to accurately measure temperature throughout a three-dimensional volume. This metrology is based on the temperature-dependent nature of the spin interaction within each particle, and the ability of applied AC magnetic fields to penetrate through many materials to probe the magnetization therein as a function of position. However, commercially available MNPs display only modest magnetic thermosensitivity, especially near room temperature; this response must be strengthened as a prerequisite to practical remote volumetric nanothermometry. Carefully designed doped or multi-domain nanoparticles, with a strong AC magnetic response and selective control of thermosensitive temperature ranges arising from magnetic exchange interactions, represent a potential route to overcome these limitations.

Here, we engineer MNPs specifically for room-temperature thermometry applications. Their synthesis relies on reproducible, easily scalable, solution chemistry routes and is tunable to afford colloidal particles of controlled size, structure, and composition. We exploit compositional doping and exchange coupling between core-shell magnetic heterostructures as means of controlling their temperature-dependent spin interaction. We find that these structurally complex MNPs based on ferrites show improved temperature-dependent change in their magnetization. Analysis conducted using X-ray scattering and diffraction, Raman spectroscopy, and high-resolution electron microscopies provide correlations between the nanoscale structure of these particles with their magnetic thermosensitivity. Finally, we use an AC magnetic particle spectrometer to measure the magnetization-dependence of these nanothermometers as a function of temperature in their local environment. Our results demonstrate that complex ferrite MNPs are a promising material platform for remote thermometric sensing based on temperature-dependent spin ordering under an applied magnetic field.

Nanoscale Structure of the Orbital Magnetic Moment of a Single Dopant Spin in a Semiconductor Adonai R. Cruz[1] and Michael E. Flatté[2,1]; [1]Eindhoven University of Technology, Netherlands; [2]The University of Iowa, United States

The localized electron spin of a single impurity in a semiconductor is a promising system to realize quantum information schemes [1]. Coherent control of this spin depends on understanding the structure of the magnetic moment that couples the system with external fields. In this work we investigate the orbital contribution to the magnetic moment originated from the spin-orbit induced circulating current associated with the ground state of a single magnetic impurity in zincblende III-V semiconductor. This circulating current is dissipationless and represents an electron moving in a closed trajectory [2]. The orbital moment associated with the circulating current could be directly measured by the dc-magnetic field it produces through nanoscale magnetometry techniques provided by NV-centers in diamond [3].
In this project we developed a formalism employing Green's functions obtained by the Koster-Slater technique [4] with a $sp^3d^5s^*$ empirical tight-binding Hamiltonian [5,6] to describe the host material. We calculated the circulating current and orbital moments of a single Mn dopant in GaAs. The spin-correlated orbital moments originates from the hybridization between the Mn(d^5) spin-polarized electrons and the As dangling bonds leading to t_2-symmetric triplet acceptor states in the band-gap above the valence band edge.

Single Artificial Atoms in Silicon Emitting at Telecom Wavelengths Anais Dreau; Laboratoire Charles Coulomb, CNRS & University of Montpellier, France

Given its unrivaled potential of integration and scalability, silicon is likely to become a key platform for large-scale quantum technologies. Individual electron-encoded artificial atoms either formed by impurities [1] or quantum dots [2, 3] have emerged as a promising solution for silicon-based integrated quantum circuits. However, single qubits featuring an optical interface needed for large-distance exchange of information [4] have not yet been isolated in such a prevailing semiconductor.
We show the first isolation of single optically-active point defects in a commercial silicon-on-insulator wafer implanted with carbon atoms [5]. These artificial atoms exhibit a bright, linearly polarized single-photon emission at telecom wavelengths suitable for long-distance propagation in optical fibers. Our results demonstrate that despite its small bandgap (~1.1 eV) a priori unfavorable towards such observation [6], silicon can accommodate point defects optically isolable at single scale, like in wide-bandgap semiconductors [7]. This work opens numerous perspectives for silicon-based quantum technologies, from integrated quantum photonics to quantum communications [8] and metrology.

5:15 AM F.NM06.07.02
Hybrid System of Giant Magnetostrictive Material and Diamond NV Color Centers for Mass Imaging Ryota Kitagawa[1], Soki Urashita[1], Keigo Arai[1], Kosuke Mizuno[1], Hitoshi Ishiwata[1,2], Yota Takamura[1], Takayuki Iwasaki[1], Shigeki Nakagawa[1] and Mutsuko Hatano[1]; [1]Tokyo Institute of Technology, Japan; [2]Japan Science and Technology Agency, Japan

Mass imaging technique for multiple length-scales from single cells to tissues is necessary for a wide range of applications such as the development of anti-cancer agents with fewer side effects[1,2]. Theoretical calculation demonstrated a hybrid sensor using nitrogen-vacancy (NV) centers combined with giant magnetostrictive(GMS) material as a promising platform for such application [3,4]. For the realization of the hybrid sensor, deposition of GMS material and vector imaging of GMS material with NV center is necessary. In this study, we performed imaging of stray magnetic field vectors produced by deposited GMS material using NV centers. Perpendicular magnetic anisotropy (PMA) in SmFe2 was confirmed from both vibrating sample magnetometer (VSM) and vector imaging using NV center. SmFe2 also could make sensitivity higher than GMS material with in-plane magnetic anisotropy due to its smaller anisotropic magnetic field.
SmFe2 thin film with a thickness of 100 nm was deposited on a quartz substrate and Si/SiO2 substrate with the facing target sputtering. M-H hysteresis curve was measured on SmFe2 thin film using a VSM for testing PMA. Magnetostriction constant λ, directly related to the sensitivity of the hybrid sensor, was calculated from the change of the magnetic anisotropic energy density with bending stress of ± 10 MPa. Ensemble NV centers were fabricated on a IIa(100) diamond substrate by nitrogen ion implantation with implantation energy of 6 keV and 2×10^{13} cm^{-2} concentration. $SmFe_2$ thin film was placed on top of the ensemble NV center for vector magnetic field measurement. The stray magnetic field was imaged by pulsed-optically detected magnetic resonance (ODMR) with a uniform bias magnetic field of approximately 5 mT solving degeneracy of NV energies.
M-H hysteresis measurements using VSM indicated the PMA of the deposited SmFe2 thin-film and large magnetostriction constant of λ= -920 ppm which is the same order as general GMS materials. ODMR measurements using NV centers revealed a magnetic field vector profile produced by the SmFe2 thin-film with a spatial resolution of ~500 nm, a measurement field-of-view of 64 μm x 64 μm, and a magnetic field sensitivity of 50 $\mu T/Hz^{1/2}$. The stray field measured by NV centers was perpendicular to the surface, indicating that the $SmFe_2$ layer had PMA consistent with the VSM result. We

established essential techniques for constructing the hybrid system through deposition of $SmFe_2$ and magnetic field vector imaging using NV centers. We aim a mass sensitivity of ~1 ng/$Hz^{1/2}$ (1% change in cell mass (~1 ng) can be detected every 60 minutes) by optimizing the GMS thin film and the magnetic field sensitivity of NV center.

Predicted Strong Coupling of Solid-State Spins via a Single Magnon Mode Denis R. Candido[1,2,3], Gregory Fuchs[3], Ezekiel Johnston-Halperin[4] and Michael E. Flatté[1,2,5]; [1]University of Iowa, United States; [2]The University of Chicago, United States; [3]Cornell University, United States; [4]The Ohio State University, United States; [5]Eindhoven University of Technology,, Netherlands

We propose [1] an approach to realize a hybrid quantum system composed of a diamond nitrogen-vacancy (NV) center spin coupled to a magnon mode of the low-damping, low-moment organic ferrimagnet vanadium tetracyanoethylene [2,3]. We derive an analytical expression for the spin-magnon cooperativity as a function of NV position under a micron-scale perpendicularly magnetized disk, and show that, surprisingly, the cooperativity will be higher using this magnetic material than in more conventional materials with larger magnetic moments, due to in part to the reduced demagnetization field. For reasonable experimental parameters, we predict that the spin-magnon-mode coupling strength is g~10 kHz. For isotopically pure ^{12}C diamond we predict strong coupling of an NV spin to the unoccupied magnon mode, with cooperativity C~6 for a wide range of NV spin locations within the diamond, well within the spatial precision of NV center implantation. Thus our proposal describes a practical pathway for single-spin-state-to-single-magnon-occupancy transduction and for entangling NV centers over micron length scales.

The material is based on work supported by the U.S. Department of Energy, Office of Basic Energy Sciences, under Award Number DE-SC0019250.

Optically Detected Magnetic Resonance Study of Spin Properties in the Pristine and Mn-Doped CdSe/CdS Seeded Nanorods Joanna Dehnel, Yahel Barak, Itay Meir and Efrat Lifshitz; Technion Israel Institute of Technology, Israel

The discussed work deals with a control and characterization of spin degrees of freedom of photo-generated carriers in colloidal seeded nanorods (sNRs) - via magnetic doping. The material under consideration is CdSe/CdSe:Mn sNRs, including diluted concentration of Mn^{2+} ions at the rod region. Magnetic doping was implemented extensively in colloidal quantum dots, but with alimited way in anisotropic structures, wherein the latter posesses other significant properties (e.g., anisotropy and reduced Auger rates).
Our work reports a thorough investigation of spin degrees of freedom in the mentioned materials, monitored by an optically detected magnetic resonance (ODMR) spectroscopy tool, which provide a significant information on exact location of host carriers and dopants, as well as examine interactions between them.
More specifically, the comparison between the pristine structures (CdSe/CdS) and the magnetically doped derivative, CdSe/CdS:Mn, indicated that both include trapping of the photo-generated carriers at the interface between the seed and the rod. The trapped carriers are already unpaired spins that endow selective magneto-optical properties with extended radiative and spin-relaxation times. The dominant interaction with the magnetic dopant takes place along the seed/rod interface, leading to further enhancement of spin helicity and the radiative lifetime. Most importantly, the carrier-dopant interaction bestows an order of magnitude extension of spin-lattice relaxation time in doped sNRs with respect to that of the pristine material, with an extreme importance for practical applications. The extracted physical parameters from the ODMR experiments included: g-factors and their anisotropy, spin exchange interactions, angular momentum, carrier-dopant coupling constants, radiative and spin-lattice relaxation times.

The spin-properties in confined systems as mentioned here ,undoubtedly can play an important role in the development of new spin-based technologies.

Ultrafast Excitation of Coherent Spin Waves in 2D Antiferromagnets Xiao-Xiao Zhang; University of Florida, United States

The recently discovered atomically-thin magnetic crystals provide a unique playground to develop new approaches to manipulate magnetism. Rapid progresses have been made that demonstrate the potentials of utilizing 2D magnets to construct novel spintronics devices. However, their spin dynamics, which are crucial for microscopic understanding and determine the fundamental limit of spin manipulation, still remain elusive due to the difficulty of characterizing these micron-sized samples with conventional microwave techniques. In this talk, we will show how we can access and probe the collective spin-wave excitations in an antiferromagnetic bilayer CrI_3, which allows us to extract magnetic anisotropy and exchange energy. In particular, we will demonstrate the gate tunability of magnon frequencies, which is unique for the 2D magnet system.

Design of Giant Spin Hall Effect in Transition Metal Oxides Priyamvada Jadaun, Leonard Register and Sanjay Banerjee; UT Austin, United States

Spin Hall effect (SHE), a mechanism by which materials convert a charge current into a spin current, has attracted significant attention owing to its novel physics and potential applications to spintronics, magnetic memory and spin logic devices. However, there have remained fundamental gaps in our understanding of the essential factors that control SHE in materials. Here we answer this important question, presenting a comprehensive theory of five rational design principles for achieving giant intrinsic SHE in transition metal oxides. Stemming from the inherently geometric nature of SHE, two of these design principles are weak crystal fields and the presence of structural distortions. Additionally, we discover that novel materials such as anti-perovskites are a highly promising class of materials for achieving giant SHE, with predicted SHE values reaching an order of magnitude larger than that reported for any oxide. We further examine the SHE values found in a variety of anti-perovskite oxides. Moreover, we derive three other design principles for enhancing SHE. Our findings shed light on the physics driving SHE, uncover technologically important SHE materials, and could help enhance and externally control SHE values.

Van der Waals Epitaxy of Transition Metal Dichalcogenides by MBE Application to the Study of the Valley Nernst Effect in WSe_2 Minh-Tuan Dau[1], Celine Vergnaud[1], Alain Marty[1], Frederic Bonell[2], Cyrille Beigne[1], Serge Gambarelli[1], Vincent Maurel[1], Thomas Guillet[1], Timotee Journot[3], Berangere Hyot[3], Benjamin Grevin[2], Hanako Okuno[1] and Matthieu Jamet[1]; [1]CEA Grenoble, France; [2]CNRS, France; [3]CEA-LETI, France

Semiconducting transition metal dichalcogenides (TMDCs) have gained a great attention because of their fascinating electronic and optical properties when downing the thickness to one monolayer. In the monolayer form, due to the breaking of inversion symmetry and strong spin–orbit coupling, the carriers in TMDCs carry a valley index noted K+ or K−. This valley degree of freedom refers to local extrema in the band structure of TMDC monolayers at the K points of the two-dimensional Brillouin zone and it can be exploited to develop novel valleytronic devices. In MX_2 (M = Mo, W and X = S, Se) monolayers, the broken inversion symmetry and strong spin–orbit coupling originating from the d-orbitals of the transition metal atom align the electron spins near opposite valleys K+ and K− to opposite out-of-plane directions thus preserving time reversal symmetry. The broken spatial inversion symmetry also generates large Berry curvatures near the K valleys, the Berry curvatures being opposite at opposite valleys. This effect gives rise to unconventional electronic properties such as the valley Hall effect. An interesting growing field of investigation consists in coupling the valley physics with thermoelectrics. Several spin/valley-dependent thermoelectric effects have already been predicted theoretically in monolayer TMDCs such as the spin Nernst effect (thermoelectric counterpart of the spin Hall effect) and the valley Nernst effect (VNE). Hence, the experimental

demonstration of those effects could give rise to a new field called valley caloritronics (by analogy with spin caloritronics) with the advantage that the coupled valley-spin degree of freedom is more robust than the spin with respect to external magnetic fields due to the large intrinsic spin–orbit coupling.
In this presentation, I will first review our recent results on the MBE growth of transition metal dichalcogenides on various substrates over large areas and explain the mechanisms underlying the van der Waals epitaxy regime [1]. Using this growth technique, we could study the interplay between thermoelectricity and the valley degree of freedom in monolayers of WSe_2. For this purpose, high quality WSe_2 mono and multilayers were grown on epitaxial graphene on SiC. Using millimeter-sized samples, we were able to apply well-defined temperature gradients and demonstrate the very strong Seebeck response of this material. In a second step, we used the ferromagnetic resonance-spin pumping technique (FMR-SP) to (i) apply the temperature gradient by off centering the sample in the radio frequency (RF) cavity and (ii) address a single valley and break time reversal symmetry using the spin pumping through spin-valley coupling. For FMR-SP, we deposited in-situ the $Al/Ni_{81}Fe_{19}/Al$ magnetic stack on top of the WSe_2 layer. The combination of a temperature gradient and the valley polarization lead to the valley Nernst effect in WSe_2 that we could detect electrically in the RF cavity. The Nernst coefficient we measured is in very good quantitative agreement with the predicted value [2]. This effect could be exploited to generate large transverse valley currents for valleytronics applications.

Late News: Unusual Spin Physics and Charge Carrier Dynamics in Luminescent Dilute Organic Semiconductor for Spintronics Applications Tejasvini Sharma, Naveen K. Tailor and Soumitra Satapathi; Indian Institute of Technology Roorkee, India

The pyrene derivatives have been widely investigated in the field of organic electronics and spintronics. However, the fundamental understanding of their excited state dynamics and spin physics remains elusive. Here, we present the temperature-dependent photoluminescence (PL) and electron spin resonance (ESR) study of a model fluorescent organic dilute semiconductor where organic fluorophore pyrene is incorporated in the insulating Poly-methyl methacrylate (PMMA) polymeric backbone as pendant unit (py-PMMA). We observe that lowering the temperature from 300K to 140K, the monomer fluorescence emission from py-PMMA gets blue-shifted, and their intensity enhances, which is attributed to less charge carrier scattering by lattice sites at low temperature. Interestingly, we observe additional higher energy peaks at 368 nm (~3.36 eV) below 70K in fluorescence emission, which is explained by the self-confined exciton-phonon coupling. The strong spin-orbit coupling was observed in our system by temperature-dependent electron spin resonance (TDESR) spectroscopy, and spin relaxation time was calculated in order of picoseconds. The temperature-dependent intensity and bizarre linewidth behavior of the ESR signal are attributed to the phonon bottleneck effect. Our study provides the direction to examine and understand the electron-phonon interaction and spin-orbit coupling at low temperatures in organic polymers, which helps to design new organic devices in the field of spintronics.

Strain-Tunable Orbital Physics of Sr_2CrReO_6 Epitaxial Films Guillaume Marcaud[1], Alex Taekyung Lee[1], Sangjae Lee[1], Adam Hauser[2], Fengyuan Yang[3], Diego Casa[4], Mary Upton[4], Thomas Gog[4], Yilin Wang[5], Mark P. Dean[5], Frederick Walker[1], Sohrab Ismail-Beigi[1], Charles H. Ahn[1] and Ignace Jarrige[5]; [1]Yale University, United States; [2]The University of Alabama, United States; [3]The Ohio State University, United States; [4]Argonne National Laboratory, United States; [5]Brookhaven National Laboratory, United States

Rhenium-based double perovskites possess a rich array of properties including magnetic ordering at room temperature and an intricate interplay between structure, orbital ordering, and metal-insulator transitions (MIT). In particular, Sr_2CrReO_6 (SCRO) possesses a high Curie temperature of Tc=620K, a large strain-tunable magnetocrystalline anisotropy, and an insulating ground state with a bandgap of 0.21 eV. To determine the energy scale for the electronic interactions, we used resonant

inelastic X-ray scattering (RIXS) at the Re L_3 edge for two strain states of SCRO thin films, compressive -1% on a $(LaAlO_3)_{0.3}(Sr_2AlTaO_6)_{0.7}$ (LSAT) substrate and tensile +1% on a relaxed $SrCr_{0.5}Nb_{0.5}O_3$ buffer layer on LSAT. We observe three Raman-like excitations around 150, 600 and 1000 meV on both samples and a broad fluorescence above 8 eV. All the Raman-like peaks show a strong dependence on strain, and only the lowest energy peak shows a temperature dependence. Using the exact diagonalization RIXS toolkit (EDRIXS) [2], we are able to assign the Raman-like features to Re d orbitals excitations. Implications of the observed experimental strain and temperature dependences on the physics of SCRO are discussed. .

Optical and Microwave Spin Control of Donors in ZnO Kai-Mei Fu; University of Washington, United States

Electrons bound to donors in silicon are electrically-controlled qubits with exceptional spin coherence properties. Here we seek to find analogous donor systems in direct band gap semiconductors which will enable an efficient optical interface to the donor electron spin qubit. We show that ZnO donors, optically coupled to donor-bound excitons, are particularly promising candidates [1]. Due to low spin-orbit coupling, we find donors exhibit longitudinal spin relaxation times up to 0.5 s at 1.5 K with relaxation fundamentally-limited by phonon interactions. Both lambda and near-cycling optical transitions exist which are suitable for optical spin initialization and readout. Spin-echo coherence times, which we determine via both optical and microwave control, are in the tens of microseconds and likely limited by nuclear spins in natural isotopic ZnO. These characteristics are all extracted from measurements on an ensemble of Ga donors in a commercial substrate. We will present ongoing efforts and challenges toward single donor isolation in nanowires, dual optical-microwave control of donors and two-laser coherent spin-spectroscopy in this emerging qubit platform.

Direct Imaging of the AC Component of the Pumped Spin Polarization with Element Specificity Santa Pile[1], Martin Buchner[1], Verena Ney[1], Taddäus Schaffers[1], Kilian Lenz[2], Ryzard Narkowicz[2], Jürgen Lindner[2], Hendrik Ohldag[3,4] and Andreas Ney[1]; [1]Johannes Kepler Universität Linz, Austria; [2]Helmholtz-Zentrum Dresden-Rossendorf, Germany; [3]Stanford Linear Accelerator Center, United States; [4]Univ of California Santa Cruz, United States

In spintronics the generation and manipulation of pure spin currents is in the focus of research activities. Amongst the utilized fundamental effects is spin pumping where a precessing magnetization of a ferromagnet being at ferromagnetic resonance (FMR) transfers angular momentum to an adjacent nonferromagnetic layer [1]. The transfer of angular momentum into the nonferromagnetic layer can be described as a spin-current. The pumped spin current has a dc and an ac component corresponding to the reduction of the projection of the magnetization at FMR as well as the dynamic high-frequency magnetization, respectively. Spin pumping in a ferromagnet/nonferromagnet heterostructure is directly imaged with spatial resolution as well as element selectivity. The time-resolved detection in scanning transmission x-ray microscopy [2] allows to directly probe the spatial extent of the ac spin polarization in Co-doped ZnO which is generated by spin pumping from an adjacent permalloy microstrip complementing earlier results in Py/Co:ZnO heterostructures [3]. Comparing the relative phases of the dynamic magnetization component of the two constituents is possible and found to be antiphase. The correlation between the distribution of the magnetic excitation in the permalloy and the Co-doped ZnO reveals that laterally there is no one-to-one correlation. The observed distribution is rather complex, but integrating over larger areas clearly demonstrates that the spin polarization in the nonferromagnet extends laterally beyond the region of the ferromagnetic microstrip. Therefore the observations are better explained by a local spin pumping efficieny and a lateral propagation of the ac spin polarization in the nonferromagnet over the range of a few micrometers [4].

Transition Metal-Vacancy Centers in Zinc Sulfide Cuneyt Sahin and Michael E. Flatté; University of Iowa, United States

Wide bandgap semiconductors are essential to numerous commercial devices and have been extensively investigated due to their high optical transparency, controllable transport properties, carrier concentrations, and mobilities. Transition metal impurities and impurity-vacancy complexes in wide-gap semiconductors have also attracted both theoretical and experimental interest due to possible applications in single-photon emission with minimal decoherence [1], the possibility of robust exchange interactions of spin centers [2], and inducing also enhancing of the ferromagnetic order by doping [3]. Among various wide-gap semiconductors, zinc sulfide (ZnS) has been a platform for numerous applications such as display technologies, luminescent devices, nonlinear optical devices, solar cells, and other optoelectronic applications [4,5,6]. Furthermore, certain defects and defect-vacancy centers may provide a coherent, room-temperature interface between spins and photons in this host material.

Here we carry out the calculation of the electronic and structural properties of transition metal - vacancy complexes in ZnS within the density functional theory framework as implemented in the Vienna *ab initio* simulation package and projector-augmented wave approach. We simulate the host material ZnS as a 64 atom supercell and use a 2x2x2 Monkhorst-Pack k-point mesh for the sampling of the Brillouin zone. Perdew–Burke-Ernzerhof class of generalized gradient approximation is used for the treatment of the exchange-correlation potential. Both lattice constants and atomic positions are optimized with a convergence criterion of 1 meV. To fix the well-known band-gap problem of the density functional theory method, we use hybrid functionals resulting in a 3.65 eV gap, which agrees excellently with the experimental value.

Transition metal dopants are substitutionally replaced with a zinc atom, and the vacancy is formed at the neighboring sulfur atom. We then perform the ionic relaxations with a fixed lattice constant using the conjugate gradient algorithm. The defect formation energies are calculated following the formula of Ref. [7]. We have also calculated different charged states of the impurities in Zn-rich and S-rich conditions to establish the possibility of forming these impurities as a function of the Fermi level in the bandgap region. The charge transition levels are also computed from the relaxed final energies for different charged states. We have also included the charge corrections due to finite-size effects originating from the Columb interaction between impurities in the neighboring supercells using the Freysoldt-Neugebaure-Van de Walle scheme. [8]. Finally, we calculate the density of states, orbital projected densities, and electronic band structures of the system to identify states located in the bandgap and determine the characteristics of the impurities, such as deep vs. shallow. We conclude that ZnS is a strong candidate for a system in which impurity spin-light interfaces can be realized similarly to the nitrogen-vacancy color centers in diamond and divacancies in silicon carbide.

Ultrastrong Magnonic Coupling in Canted Antiferromagnets Takuma Makihara, Nicolas Marquez Peraca and Junichiro Kono; Rice University, United States

Light-matter coupling in the so-called ultrastrong coupling (USC) regime [1] has become an important general subject of modern science and technology. Many next-generation quantum technologies that exploit the extremely efficient light-matter interactions in the USC regime have been proposed. Further, a wealth of exotic phenomena has been predicted in the USC regime, such as quantum vacuum radiation or nonclassical ground states known as two-mode squeezed vacuums. The source of these phenomena is the so-called counter-rotating terms in the Hamiltonian, which are typically negligible compared to the so-called co-rotating terms for weaker coupling strengths. USC has now been achieved in diverse platforms, but the exotic nature of the ground state due to the counter-rotating terms has not been explored. We have recently observed unusual matter-matter USC phenomena in rare-earth orthoferrites. First, we observed cooperative, Dicke-type coupling between a paramagnetic Er^{3+} spin ensemble and a single mode of terahertz magnons of ordered Fe^{3+} spins in $ErFeO_3$ [2]. The data exhibited vacuum Rabi splitting values in the USC regime, indicating that rare-earth orthoferrites provide a rich playground in which to explore USC phenomena without light. Furthermore, we observed that magnons in $YFeO_3$ display USC with a dominant role played by the counter-rotating terms. Our system is described by an unusual Hamiltonian, where: (i) the coupling strengths are tunable, (ii) the counter-rotating interactions dominate the co-rotating interactions, and (iii) the ground state is a magnonic two-mode squeezed vacuum with quantum fluctuation suppression up to 5.9 dB. These observations demonstrate that $YFeO_3$ provides an extraordinary platform for both applied and fundamental studies of USC beyond the reaches of photonic platforms.

First Principles Calculation of the Electronic Structure of $V(TCNE)_2$ Yueguang Shi and Michael E. Flatté; The University of Iowa, United States

Over the past two decades there has been growing interest in organic magnetic materials, due to their potential applications in the field of magnonics and spintronics.[1,2,3,4] Vanadium tetracyanoethylene, $V(TCNE)_{x\approx2}$, is a room temperature ferrimagnetic semiconductor with a $T_c \sim 600$ K [5] which has very low loss ferromagnetic resonance and spin-wave propagation[1, 2]. Previous first principles calculations of the electronic structure have indicated a substantially larger band gap (0.8 eV) than experimentally inferred (0.5 eV) [6,7], and that the band gap itself is an indirect gap with the valence maximum located at the (0,0,0.5) point and the conduction minimum at the (0,0.5,0) point. Our crystal axes are defined so that an equatorial TCNE ligand lies in the plane (0 0 1) and an apical ligand lies in (1 1 0) in a unit cell. The study of Ref. 6 used a local-orbital calculation with B3LYP hybrid functional. Here we explore the electronic structure using a plane-wave code VASP[8,9,10]. We have tried the following functionals: Perdew-Burke-Ernzerhof (PBE), PBE0, Becke, 3-parameter, Lee-Yang-Parr (B3LYP), Heyd-Scuseria-Ernzerhof (HSE06). The ferrimagnetic structure is studied using both collinear magnetic structure calculations and non-collinear calculations. We confirm that the structure of VTCNE has a triclinic unit cell with each V atom surrounded by 6 organic ligands, as found in Ref. 6. However, in contrast to the previous study we find a direct band gap of 0.4 eV located at the (0,0.5,0.5) point. This band gap better agrees with the experimental inference from the conductivity activation energy [7]. Further studies will explore the optical properties of this material and its magnetic dynamics, including anisotropy and magnetoelastic properties.

We acknowledge funding from NSF Grant No. DMR-1808742.

High-Quality Magnetic Resonance in Cryogenic $V[TCNE]_x$ Thin Films Ezekiel Johnston-Halperin, Huma Yusuf,

Michael Chilcote, Seth Kurfman, Andrew Franson and Donley Cormode; The Ohio State University, United States

The ability to move beyond the study of isolated qubits to explore hybrid systems, i.e. where two or more component qubits coherently couple to yield new functionality, and to transduce and transmit quantum information is a key challenge for the emerging field of quantum information science and technology (QIST). Magnons (or spin-waves) provide an appealing avenue toward realizing this functionality as they can couple to a wide variety of spin-qubits using either exchange or dipole coupling, have coherence lengths from microns to millimeters, and can coherently transduce between spins, microwave photons, and phonons.

However, in order to fulfill this potential, materials with high quality-factor (high-*Q*), or low-loss, magnons are required. For almost half a century, we have been limited to yttrium iron garnet (YIG) despite substantial efforts to identify alternative materials. The molecule-based ferrimagnet vanadium tetracyanoethylene (V[TCNE]x; x ~ 2) has recently emerged as a compelling alternative to YIG. In contrast to other molecule-based materials, V[TCNE]x has a single-peaked, narrow magnetic resonance feature (less than 1 G at 10 GHz) and has a Curie temperature of over 600 K with sharp hysteresis switching to full saturation at room temperature. In addition to being magnetically robust, V[TCNE]x is a promising material for integration into solid-state quantum information systems due to its low damping ($\alpha = (3.98 \pm 0.22) \times 10^{-5}$), high quality factor (*Q* up to 8,000) microwave resonance, ease of patterning, and compatibility with a wide variety of substrates.

Here we will discuss how V[TCNE]x can be exploited for applications in quantum information science. We report anomalous temperature dependent anisotropy in $V[TCNE]_x$ thin films, where we observe switching of magnetic easy-axis from in-plane at 300 K to out of plane at 25 K with a clear absence of anisotropy at 100 K. Further, we observe a reversion to room temperature anisotropy and linewidth values at a temperature of 5 K, validating $V[TCNE]_x$ for low temperature quantum applications. We will discuss applications of patterned V[TCNE]x magnon-resonators in a hybrid quantum device.

Spin Wave Dynamics in 1D Patterend Magnonic Crystals of $V[TCNE]_{x\sim2}$ Kwangyul Hu[1] and Michael E. Flatté[1,2]; [1]University of Iowa, United States; [2]Eindhoven University of Technology, Netherlands

An organic semiconducting ferrimagnet, vanadium tetracyanoethylene ($V[TCNE]_{x\sim2}$) has a low magnetic damping and narrow ferromagnetic resonance linewidth[1-3], similar to a more commonly explored magnonic material, yttrium iron garnet (YIG)[4,5]. However, YIG requires high-temperature growth on a specific substrate, gadolinium gallium garnet, for high performance[6]. On the other hand, $V[TCNE]_{x\sim2}$ can be deposited on various rigid substrates at low temperature[1] without a substantial increase of damping. This allows integration of $V[TCNE]_{x\sim2}$ with other interesting materials.
Here we describe the spin wave dynamics in quasi one-dimensional patterened magnonic crystals of $V[TCNE]_{x\sim2}$ that can be formed by deposition of a uniform thickness film on a patterned substrate with ridges. The dispersion relations, linewidths and magnetization profiles are calculated by using the Landau-Lifshitz-Gilbert formalism[7,8]. For the structure, we considered alternatively aligned gratings on top and bottom of a thin film. Furthermore, we studied the symmetry of the magnon modes of this magnonic crystals under the influence of an arbitrarily oriented external magnetic field.

Optical Control of Spin Transfer in Hybrid Perovskites-TMDC Heterostructures Anna Stadlbauer[1], Lissa Eyre[1], Jonathan Zerhoch[1], Sean A. Bourelle[2] and Felix Deschler[1]; [1]Walter Schottky Institute - Technical University of Munich, Germany; [2]University of Cambridge, United Kingdom

It is a fundamental question how material properties of heterostructures can control spin transfer. This work investigates how spin can be transferred in a heterosystem of a hybrid metal-halide perovskite and a 2D material, with focus on transition metal dichalcogenide (TMDC) layers. Metal halide perovskites and TMDC have already been combined in type II heterostructure devices such as photodetectors [1,2]. However, spin transfer has not yet been reported to the best of our knowledge, which would open up opportunities for optical control in spintronics applications.

Following our study of spin-exciton interactions and spin depolarization times in hybrid perovskites, we aim to investigate how the properties of the heterostructures control spin transfer. The most suitable 2D materials for this approach are semiconducting TMDCs due to their reported controllable valley degree of freedom [3,4]. To benefit from the coupling between spins and valleys in TMD layers, the components in the investigated heterosystem require not only a suitable combination of bandgaps and appropriate band alignment but also positions in k-space that fulfill the optical selection rules [3].

We analyze the obtained heterostructures with ultrafast time resolved photoluminescence spectroscopy, circularly polarized transient absorption spectroscopy and Faraday rotation to resolve the excitation and spin dynamics.

From our fundamental insights into the spin transfer in TMDC-perovskite-heterosystems, we anticipate to discover avenues and design guidelines for application of our for emerging spintronic technologies.

Device Challenges for Neuromorphic Computing with Metal-Oxide Memristors Dmitri Strukov; University of California, Santa Barbara, United States

There have been many demonstrations of nonvolatile memory devices, whose memory states can be continuously tuned, and early experimental results of utilizing such functionality in analog and mixed-signal computing, most notably in neuromorphic circuits. In my talk, I will discuss the major challenges in the quest of building practically useful mixed-signal neuromorphic circuits based on analog-grade memory devices, focusing on the simplest, in terms of device requirements, yet most common neuromorphic inference operation. I will conclude my talk by reviewing experimental results for neuromorphic circuits based on intergrated metal-oxide memristors, one of the most promising types of devices for this applicaiton, in the context of these challenges.

5:15 AM *F.NM07.01.02
Resistance Switching Memories as Artificial Synapses for Spiking Neural Networks Sabina Spiga; CNR-IMM, Italy

Memristive devices have been receiving an increasing interest for a wide range of applications, such as storage class memory, in-memory computing and neuromorphic computing towards artificial intelligence at the edge. Indeed, neuro-inspired computing supported by memristive devices can pave the way to a revolution for an energy-efficient and area-efficient information processing that transcends von Neumann's computing. This goal can be achieved by developing computational substrates and engines able to mimicking the adaptation, interconnectivity, noise tolerance and energy efficiency of the human brain. Among the proposed memristive technologies, oxide-based resistance switching memory devices (RRAM) are based on redox reactions and electrochemical phenomena in oxides and are very promising because of low power consumption, fast switching times, scalability down to nm scale and CMOS compatibility. Therefore, they can be used as new hardware building blocks emulating electronic synapses in spiking neural networks (SNN) for real time and low power computation systems. In our work, we focus on the switching dynamics of HfO_2-based RRAMs and on their implementation as electronic synapses in spiking neural networks (SNN). The conductance of the RRAM devices can be tuned either in a digital or in an analog fashion by using proper programming algorithms and by engineering the material stack. The device dynamics is used to emulate the biological potentiation (conductance increase) and depression (conductance decrease) processes, over several cycles. Moreover, the conductance value update can be achieved by a spike timing and rate dependent plasticity mechanism, which is demonstrated at hardware level, and that is exploited as learning rule in a SNN. System level simulation of SNN are implemented by using experimental RRAM characteristics for the synaptic nodes and neural equations derived from hardware CMOS implementation. The effect of device switching dynamics (linear and non-linear) and synaptic resolution on the SNN performances is discussed.

5:00 AM F.NM07.02.02
A Statistical Analysis of Cu/SiO_2/W Devices Florian Maudet[1], Veeresh Deshpande[1] and Catherine Dubourdieu[1,2]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Freie Universität Berlin, Germany

Resistance switching memories are promising candidates for low power consumption non-volatile memory applications owing to their dimensional scalability and fast switching speed. Furthermore, the possibility to obtain multiple stable states in such systems is of importance for applications in neuromorphic computing. Among the proposed systems, Cu/SiO_2 based memory devices have demonstrated very promising performances, including quantized conductance with a switching voltage as low as 250 mV and allow easy integration with CMOS technology [1]–[5]. It is known that in such systems the different states originate from the formation of a Cu filament in the SiO_2 solid electrolyte [4]. This offers opportunity to use the different quantum states that occur during the filament growth as different memory states. However, because of its

filamentary nature, the devices are very sensitive to local inhomogeneities like defects in the SiO_2 dielectric or interface roughness. As a result, the set/reset voltage can have significant device-to-device variations and the poor repeatability of the different states limits the advantage of such devices for potential applications. Additionally, the retention and endurance of these memories are also a limiting factor and needs to be improved. In order to quantify and understand the origin of the distribution of these characteristics, we present a broad statistical analysis of the current-voltage behavior of $Cu/SiO_2/W$ devices, as such data are missing in the literature. Several batches of samples were prepared, with several dies on each samples and tens of devices on each die. The influence of different voltage sweep rates on the set and reset voltages is investigated. Furthermore, the distribution of the quantum states occurring at different current is also studied by means of voltage-current measurements. We evidence half- and quarter G_0 conductance states. We will discuss the identification of key parameters that can be optimized to reduce device-to-device and sample-to-sample variability.

Resistive Switching in V3O5—A Promising Candidate for Neuromorphic Computing Coline Adda, Min-Han Lee, Pavel Salev, Yoav Kalchheim and Ivan Schuller; University of California, San Diego, United States

Many neural networks are either implemented at the software level or in hardware using CMOS technology. While these have been shown to have unique functionalities, they are not easily scalable to large systems due to energetic considerations. Therefore, it is desirable to develop more energy-efficient solutions by implementing them directly in the hardware using the unique properties of quantum materials. In this fashion, neuronal and synaptic properties maybe implemented to emulate the behavior of biological systems. Recently, it has been shown that the volatile resistive switching in Mott Insulators could be used to implement Leaky, Integrate and Fire (LIF) neuron ("neuristor") models although scaling of these systems maybe an issue. Very recent studies have shown that combining two physical phenomena may provide the basis for a scalable LIF neuristor. These were based on VO2 and V2O3. In this work, we have synthesized and characterized another vanadium oxide, V3O5, which provides a higher transition temperature alternative. Its electrical properties were studied as a function of temperature, between 300 K and 450 K, across the metal-insulator transition. We show that V3O5 presents the required characteristics as a potential hardware based thermal neuron, and therefore is a promising candidate for neuromorphic computing. Acknowledgements: This work was supported as part of the Quantum Materials for Energy Efficient Neuromorphic Computing (Q-MEEN-C) Energy Frontier Research Center (EFRC), funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences under Award # DE-SC0019273.

5:20 AM F.NM07.02.05
Scaled VO2 Oscillators for Neural Network Applications Elisabetta Corti[1], Abhishek Khanna[1,2], Fabian Konemman[1], Kham Niang[3], John Robertson[3], Bernd Gotsmann[1] and Siegfried Karg[1]; [1]IBM Research, Switzerland; [2]University of Notre Dame, United States; [3]University of Cambridge, United Kingdom

Oscillatory Neural Networks are a novel, promising concept as hardware accelerator for neuromorphic computing. Systems of coupled oscillators present associative memory capabilities that can be used to implement tasks such as image recognition [1]. We fabricated compact electronic relaxation oscillators using the phase change properties of VO2, which undergoes a temperature driven metal-to-insulator Mott transition. We studied and developed fabrication techniques for the VO2 coupled oscillators on a Si platform, to retain compatibility with CMOS process. VO2 films were deposited with Atomic Layer Deposition on a SiO2/Si substrate. The as-deposited amorphous VO2 films crystallize during a post-annealing treatment under oxygen flow at a temperature of 450° for 20 minutes. Typically, polycrystalline films with an average grain size between 80 and 50 nm [2] form on the SiO2 surface. The annealed films show a phase transition at 340 K with a resistivity change of 2 to 3 orders of magnitude and a hysteresis width of about 10 K. The polycrystalline film was patterned with E-beam lithography and ICP etching to define scaled VO2 oscillator structures, with dimensions between 200 and 500 nm. The oscillators are tested in their switching characteristics, and the variability impact on their coupling dynamics is addressed. In

particular, we investigated the phase transition of the polycrystalline devices using electrical characterization and Scanning Thermal Probe Microscopy (SThM) [3] on a single grain level. The temperature maps obtained with the SThM provide nanometer resolution and allow to observe the thermal signature of single grain switching in the scaled oscillator devices. Hence, the current path can be visualized in the insulating and metallic phases of the VO2 device. The microscopic phase-change properties could be correlated with the characteristic waveforms of the oscillating pattern in a coupled oscillator system. In addition, a milli-second flash-anneal technique was tested and optimized to control the crystallization process. The average grain size could be reduced from 55 nm to 20 nm, resulting in more uniform electrical device characteristics and allowing further scaling of the VO2 oscillators. The devices were tested in vacuum and coupled through external electrical components. A network of coupled oscillators locks in frequency and establishes programmable phase relations depending on the strength of the coupling [4,5]. We demonstrate the capability of the oscillator network coupled with an array of tunable resistors to perform image recognition. Experimental results of a three-coupled oscillator system and simulations on larger networks are shown illustrating the associative memory capabilities of the oscillating neural network. This work is supported by the HORIZON2020 PHASE-CHANGE SWITCH Project (Grant No. 737109). [1] F. Hoppensteadt and E. Izhikevich, Phys. Rv. Lett, vol. 82, 2983-2986, 1999. [2] A. P. Peter et al, Adv. 5:30 AM F.NM07.02.06
Tuning Mixed Small Polaron-Ionic Conductors for Multiple Resistance State Neuromorphic Device Implementation Dmitri Kalaev, Alon Vardi and Harry Tuller; Massachusetts Institute of Technology, United States

Natural Intelligence (NI) and Artificial Intelligence (AI) differ in their corresponding analog and digital implementations. One of the consequences of that distinction is the ability of NI to perform logic and memory operations at the local level, without spatially and functionally separating NI computing resources. This functional plasticity of basic units of NI, e.g. nerve cells, is attributed to explain NI's superior energy and time efficacy in task solving, in particular image and speech recognition/interpretation. Previous attempts to mimic NI analog functionality in digital hardware fall short in terms of dimensional scaling and power requirements. The proposed solution is to develop basic computational units that are better suited for NI tasks, e.g. analog. The main requirements for such devices are scalability down to a few nanometers and their ability to process and store data using minimal power consumption. One of the leading candidates for the realization of these goals is the 'memristive device'. In these two-terminal devices, the resistivity is a temporal function of an applied electrical field. Due to their inherent plasticity and scalability, memristive devices are envisioned to provide long-term solutions for hardware implementation of neuromorphic algorithms and energy efficient Deep Neural Networks (DNNs).
We present simulation and experimental results for a possible implementation of devices with memristive characteristics. The device functionality is based on a non-stoichiometric oxide thin film, distinctively characterized by coupled ionic and electronic conductivity i.e. a mixed-ionic-electronic-conductor (MIEC). The modeling of the memristive device, in crossbar configuration, is based on the previous theoretical and experimental research on the thermodynamics and transport of oxygen vacancies in nonstoichiometric oxides[1-3] in conjunction with well-developed models of voltage pulse induced self-heating, similar to that used in phase change memories. The praseodymium doped cerium dioxide, $Pr_xCe_{1-x}O_{2-\delta}$, was chosen as a test memristive material that is electronically conductive via small polarons and ionically conductive via oxygen vacancies with thermal activation energies of 0.4 eV and 0.8 eV, respectively.[4] The conductivities, in the latter, can be tuned by changing the praseodymium doping, x, and the oxygen deficiency, δ, levels. The device modelling shows that in order to achieve nano-second 'write' times and sufficient non-volatility of the 'read' resistance states, both electronic conduction by small polarons and high thermal activation energy of ionic transport, are essential. Finally, a new method for characterization of the ionic transport in MIECs over wide temperature limits, relevant to the memristive device operation temperature (from room temperature up to several hundred centigrade) and structure (crossbar device), will be presented.[4]

Kinetics of Electric Field-Driven Proton Diffusion and Corresponding Metal-Insulator Phase Transition on $NdNiO_3$ Thin Film Umar Sidik, Azusa Hattori and Hidekazu Tanaka; Institute of Scientific and Industrial Research, Osaka University, Japan

Resistive state change exploiting abrupt Mott phase transition in strongly correlated RNiO$_3$ (R = rare earth elements) has the

potential to enable high speed and densely scaled non-volatile memories for emerging neuromorphic computing applications [1]. While the metal-insulator phase transition can be triggered by electrostatic or thermal excitation, ion doping via chemical reactions as an emerging field can completely reconstruct the electronic band structures by introducing extremely high carrier density resulting in giant resistivity modulation. In recent years, the vast resistivity modulation in the RNiO$_3$ family has been successfully demonstrated through this chemical route. For example, proton-doped SmNiO$_3$ (SNO) thin film, where protons are dissociated from hydrogen molecules by utilizing Pt catalytic effect and then doped into the thin film, can lead to an ~10^8 of colossal and reversible resistivity modulation at 300 K [2]. The colossal resistivity modulation is considered to be governed by proton motion in SNO, such as diffusion in the thin film. At the same time, the kinetics of such external control of proton diffusion, namely electric field, has not been clearly revealed. A comprehension of this matter is of relevance to the use of proton-doped correlated RNiO$_3$ materials in emerging memory and neuromorphic computing pulls.
In this work, we prepared NdNiO$_3$ (NNO) thin film resistor with different electrode materials (Pt and Au/Ti) and observed the effect of electric field-assisted hydrogenation. Because the hydrogen dissociates on the Pt but not on the Au/Ti electrode, by using this two-terminal resistor configuration, we were able to reveal that the resistivity modulation in NNO film during hydrogenation is associated with the proton diffusion controlled by the temperature (T) and polarity-dependent electric field ($V = \pm$V). To quantitatively investigate the correlation among them, simulations based on diffusion in semi-infinite solid were carried out for fitting of time-dependent diffusion coefficient (D_i). The estimated D_i were plotted against T^{-1} and are in satisfactory agreement with the Arrhenius function of temperature. From this plot, we acquired the activation energy of proton diffusion under positive bias +V ($E_{a(+)} = 0.55$ eV) and under negative bias -V ($E_{a(-)} = 0.83$ eV) application. Then, a kinetic model based on the estimated $E_{a(+)}$ and $E_{a(-)}$ was proposed to describe the correlation between resistivity modulation and proton-lateral diffusion along the NNO channel region. Our kinetic model suggests that the polarities of electric field can ease or blockade the proton-lateral diffusion by decreasing or increasing the diffusion energy activation, respectively. From this relation, we extracted the unadulterated activation energy of proton diffusion ($E_{a(0)}$) – which was about 0.69 eV and is slightly larger than that reported of 0.27-0.65 eV for SNO using a first-principles study [3]. The slight margin of that to our result is considered due to the discrepancy between the actual NNO film and the ideal SNO crystal structure. Generally, the value of $E_{a(0)}$ is important to understand and estimate the significance of external and dynamic control effect, such as electric field in the solid-state proton-gated transistor. In this regard, we finally estimated the efficiency of electric field ($\eta_{(E)}$) as a means to externally and dynamically control the proton-lateral diffusion in a-axis of NNO film following the established model. The estimated $\eta_{(E)}$ was 20.38%, which means that despite the generally accepted thermal hopping and concentration gradient effect, electric field can simultaneously be a driving force to diffuse the positively charged proton in NNO film - with a contribution rate of about ~20%. Our detail results and analysis will be discussed in the presentation.

Resistive Switching Based on Small Cations and Oxygen Vacancies for Neuromorphic Computing, Consistent Switching and Proton Synapse Bilge Yildiz; Massachusetts Institute of Technology, United States

Physical neural networks based on analog resistive switching processor arrays are promising for in-memory computing hardware which can implement machine learning algorithms at higher operating speed and lower energy cost. State-of-the-art analog resistive switches rely on the mechanism of either forming conductive filaments or inducing phase change. These processes suffer from poor repeatability or high energy consumption, respectively. The first part of this talk focuses on reducing the variability of the set/reset voltages using model systems of HfO2 grown on Nb:SrTiO3 and Si/TiN substrates. We control the oxide microstructure via growth paramters and thermal treatment, to compare amorphous HfO2 films with nanocrystalline columnar-grained films with both single (-111) texture and multiple orientations This work advances our understanding of the mechanisms behind device variability and achieving devices that meet the strict requirements of neuromorphic computing. The second part of the talk focuses on a deterministic charge controlled switching mechanism, that is small cation intercalation into active swithing materials. Herein we demonstrate a three-terminal resistive switching device that consists of a channel of active material probed by two terminals (source and drain), a proton reservoir layer as gate terminal, and a proton conducting solid electrolyte separating the two. The device is made of entirely inorganic and CMOS

compatible materials. The electrical conductivity of the active material can be modulated by the precise control of proton intercalation, providing a highly reproducible resistive switching behavior. More than 100 states with an on/off ratio exceeding 200 have been demonstrated by a 5 ms wide gate current pulse train of +/- 1?A. As the smallest cation, the shuffling of protons between the reservoir and the active material requires minimal energy. The energy consumption is only 3.5 fJ/?m2 per state, comparable with state-of-the-art demonstrations. The switching mechanism is probed by a combination of synchrotron X-ray spectroscopy methods. The advantages of this switching mechanism, namely, low energy dissipation and multi-state capability, are demonstrated.

5:15 AM *F.NM07.03.02
Redox Transistors for Neuromorphic Computing Elliot J. Fuller[1], Scott Keene[2], Armantas Melianas[2], Sapan Agarwal[1], Yiyang Li[1], Yaakov Tuchman[2], Christofer Bennet[1], Matthew Marinella[1], Alberto Salleo[2] and A. Talin[1]; [1]Sandia National Laboratories, United States; [2]Stanford University, United States

Efficiency bottlenecks inherent to conventional computing in executing neural algorithms have spurred the development of novel devices capable of “in-memory”computing. Commonly known as “memristors”, a variety of device concepts including conducting bridge, vacancy filament, phase change and other types have been proposed as promising elements in artificial neural networks for executing inference and learning algorithms. I will review the recent advances in memristor technology for neuromorphic computing and discuss strategies for addressing the most significant performance challenges, including 'write' asymmetry, high read/write currents, and endurance. As an alternative to two-terminal memristors, I will introduce the three-terminal electrochemical memory based on the redox transistor (RT) which uses a gate to tune the redox state of the channel. Charge-compensated redox reactions in the bulk of the transistor enable high-density synaptic weight storage. Decoupling the 'read' and 'write' operations with a third terminal enable low-energy operation without compromising analog performance. I will discuss the RT operating mechanisms using organic and inorganic materials, approaches for array integration, and prospects for achieving the device density and switching speeds necessary to make electrochemical memory competitive with established digital technology.

5:30 AM *F.NM07.03.03
The Voltage-Triggered Transition in Mott Insulators—Mechanisms, Dynamics and Applications Ivan Schuller; University of California, San Diego, United States

Volatile resistive switching, as observed in Mott materials, is a promising phenomenon which may allow for the implementation of artificial spiking neurons. Despite the technological potential and intense research efforts, many fundamental questions about the nature of this transition remain unsolved. The mechanism driving the insulator-metal (IMT) transition, the nature of the percolation process and the time dynamics still need to be addressed. In this talk, new insights about the resistive switching process in Mott insulators [1,2] will be shown:
Underlying mechanism. Two mechanisms may trigger the IMT: Joule heating and E-field destabilization of the Mott insulator. Which of these mechanisms in dominant depends on the material and defect concentration.
Filamentary percolation. Direct nanoscale imaging of the domain distribution during resistive switching, reveals the inhomogeneous nature of the percolation process.
Dynamics. We observe, for the first time, the switching process with temporal and spatial resolution. The presence of strain leads to slow dynamics both during filament formation and relaxation, with important consequences for the dynamic properties of Mott-based devices.
Mimicking neuron functionalities. We demonstrate that both charge build-up and heat transfer can be used to implement basic biological neuronal functions.
These results provide a deeper understanding of the voltage triggered IMT and the technical challenges to solve in order to implement it in a neuromorphic computing scheme.
This work was supported as part of the Quantum Materials for Energy Efficient Neuromorphic Computing (Q-MEEN-C) Energy Frontier Research Center (EFRC), funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences under Award # DE-SC0019273.

The Microstructure Observation of Brownmillerite Thin Film as the Memristive Device with *In Situ* TEM Research Hyoung Gyun Kim[1], Ventaka R. Nallagatla[2], Chang Uk Jung[2] and Miyoung Kim[1]; [1]Seoul National University, Korea (the Republic of); [2]Hankuk University of Foreign Studies, Korea (the Republic of)

Redox-based memristive devices are one of the most attractive candidates for future non-volatile memory applications and neuromorphic circuits. Many recent studies reported that resistive switching phenomena in transition metal oxides (TMO) by an external bias are associated with the migration of oxygen ions. Here, we study Sr2Fe2O5 brownmillerite structure on the SrRuO3/SrTiO3 substrate and Nb: SrTiO3 substrate as a bottom electrode in order to understand the role of oxygen migration in resistive switching. Topotactic phase changes between the brownmillerite structure and perovskite structure appear by the oxygen ion migration. Using the fast ion path on the brownmillerite structure, it is possible to impede the random movements of oxygen vacancies. In-situ electric biasing holder was used to investigate the changes in atomic configurations as well as electronic structure caused by the transition of the oxygen vacancies. Electric biases were applied to the TEM samples directly in real time which makes it possible to compare the structure changes in the same TMO regions through SET and RESET cycles. To understand the mechanism of whether the oxygen ions are coming from the top or the bottom electrode in the topotactic phase change, the experiment was carried out with different kinds of bottom electrode. This provides a deeper understanding to control the oxygen ions of the redox-based memristive devices to improve and optimize performances.

5:55 AM F.NM07.03.06
***In Situ* Soft and Hard X-Ray Photoelectron Spectroscopy of Analogue Resistive Switching in HfO_x-Based Memristive Devices** Finn Zahari[1], Matthias Kalläne[1,1], Gitanjali Kolhatkar[1], Christoph Schlueter[2], Yury Matveyev[2], Florian Diekmann[1,1], Kai Rossnagel[1,2] and Hermann Kohlstedt[1]; [1]Christian-Albrechts-Universität zu Kiel, Germany; [2]Deutsches Elektronen-Synchrotron DESY, Germany

Analogue neuromorphic systems are attracting considerable attention for their potential in novel bio-inspired computing architectures. For this purpose, circuits presenting advantageous features such as low power dissipation and cognitive capabilities need to be developed. Double-barrier memristive devices (DBMDs) with the layer sequence Nb/AlO_y/$HfO_{\square\square}$/Au are promising candidates for such applications. These devices can, e.g., be exploited to emulate the plastic behaviour of biological synapses in analogue electronic circuits. Their resistance can be varied by applying suitable voltage bias to the device electrodes, an effect known as resistive switching. While kinetic Monte Carlo simulations indicate that the drift of charged defects leads to a modulation of the Schottky barrier height and, hence, to resistive switching, experimental verification has been missing so far. Clearly, a deeper understanding of the resistive switching mechanism could pave the way towards tailoring of application specific devices. Here, we show that resistive switching in DBMDs is due to changes in the chemical composition of the HfO_x layer. This is demonstrated using soft and hard x-ray photoelectron spectroscopy at photon energies of 1550 eV and 7000 eV, respectively. Corresponding experiments were performed at beamlines P04 and P22 of PETRA III (DESY, Hamburg, Germany). Using soft x-rays, Hf *4f* core-level emissions from the buried HfO_x layer were measured *in situ* for two different resistance states. Hard x-rays, on the other hand, were used to probe resistance state-dependent changes in the emissions from the buried metal oxides (Hf $3d_{5/2}$, Al *1s*) under varying emission angle (15°, 41.4°, and 60°). Spectral shifts between bulk emissions and emissions from Au/HfO_x and HfO_x/AlO_y interfaces were observed for the different resistance states and were analysed in terms of varying chemical composition and defect concentration in the device. The results suggest that the applied electric field induces oxygen vacancy motion in the HfO_x layer, resulting in local oxygen concentration changes and a modification of the Schottky barrier height at the Au/HfO_x interface. In addition, the AlO_y composition is revealed to vary in the bulk, whereas the AlO_y composition at the HfO_x/AlO_y interface appears not to be affected by the resistive switching. The experimental results therefore provide evidence that oxygen vacancy motion within the HfO_x layer is directly related to the resistive switching in DBMDs. Engineering of the oxygen content in the HfO_x layer is foreseen to enable a tailored device response.

Electrochemical Redox Transistors as Analogue Memory in the Electronic and Optical Domains Yiyang Li[1], Jorik Van de Groep[2], Elliot J. Fuller[1], Shiva Asapu[3], Tomochika Kurita[1], Sapan Agarwal[1], J. Joshua Yang[4], Mark L. Brongersma[2] and A. Talin[1]; [1]Sandia National Laboratories, United States; [2]Stanford University, United States; [3]University of Massachusetts Amherst, United States; [4]University of Southern California, United States

Neuromorphic in-memory computing can significantly decrease the energy consumption of important algorithms such as inference and backpropagation by eliminating the need to shuttle information from memory to processor. The key challenge is finding materials and devices that not only contain a large number of analogue non-volatile states but also have the ability to reliably switch between these states. We show how redox transistors, operating on the basis of electrochemical ion

insertion, can be used to dynamically tune the concentration of dopants in transition metal oxides. Such dynamic dopants are able to tune the electronic and optical properties of materials in a linear and analogue fashion and can be used to emulate synaptic weights in neural networks. We study the effect of lithium insertion into TiO2 and WO3. In both cases, lithium acts as an n-type donor that adds an electron which localizes on the transition metal. This extra dopant changes the electronic and optical properties of the transition metal host. In the case of TiO2, we harness changes in electronic properties to create a low-voltage synaptic transistor based on electrochemical redox. This synaptic transistor has over 200 distinguishable analogue non-volatile states based on the lithium concentration; these were used to emulate the synaptic weights in a neural network. More importantly, it is possible to switch between neighboring states in a linear and symmetric fashion with low current and voltages. When implemented into a crossbar, simulations show that this allows for high training and classification accuracy, and significantly lower energy consumption than a digital processor. We also explore the case of lithium insertion into WO3. Here, we utilize changes in the optical refractive index nthat arise during lithium insertion, which alters the bandgap of WO3. These changes in bandgap combined with a resonant plasmonic structure enable a device with tunable, analogue optical response. Such system can be utilized for computing in the optical or the hybrid electronic-optical domains. References: Y. Li et al. Impedance Spectroscopy on Hafnium Oxide Based Memristive Devices Richard Marquardt[1], Jürgen Carstensen[1], George Popkirov[2,1], Finn Zahari[1], Hermann Kohlstedt[1] and Martin Ziegler[3]; [1]Kiel University, Germany; [2]Bulgarian Academy of Science, Bulgaria; [3]Ilmenau University of Technology, Germany

Memristive devices for neuromorphic computing schemes for non-volatile memories are getting a rapidly increased amount of attention in the last couple of years. However, the requirements for the devices are sometimes very different for the different fields of applications. In neuromorphic electronics, memristive devices characterized by gradual resistance switch or multi-level resistance states are required, where bi-layer oxide systems have emerged as promising candidates for that field. An example for such a device structure is the double barrier Nb/Al/Al2O3/HfOx/Au memristive device, which possess a filamentary-free, homogenous interfacial resistive switching mechanism. The double layer device has a Al2O3 tunnel barrier of 1.2 nm and an ultra-thin active HfOx layer of 3.5 nm. The key mechanism is due to mobile oxygen ions confined within the 3.5 nm thin HfOx layer which alter the Schottky barrier of the top HfOx/Au interface. To gain a deeper insight into the switching mechanism, impedance spectroscopy was applied to correlate the inner electronic and ionic processes with the observed *I-V* characteristics. In detail, potentiodynamic impedance spectroscopy (PDIS) and time resolved impedance spectroscopy (TRIS) were used in the course of this investigation. Evidence of ion motions at 1.8 V directly related to changes in Schottky barrier resistance has been found as the active mechanism. The results of the impedance analysis were translated into a more general model for memristive devices based on homogeneous ionic motion to map the physical processes during the switching of the memristive device.

SESSION F.NM07.04: Neuromorphic Device—Ferroelectric

Ferroelectric Materials for Neuromorphic Device Applications Jang-Sik Lee; Pohang University of Science and Technology, Korea (the Republic of)

Ferroelectric materials have spontaneous polarization states that can be maintained even without an external electric field. Delicate control of polarization is possible because domains in ferroelectric materials can be controlled by an applied electric field. Each polarization state of the ferroelectric layer can be confirmed by changes in channel conductance; to exploit this characteristic, ferroelectric materials have been evaluated as the dielectric layer in transistors. The conductance of channel material in ferroelectric transistor can be gradually controlled by the polarization of ferroelectric materials. These characteristics can be the solution to solve some problems in current synapse devices, such as a small on/off ratio, non-linear weight updates, and variations in electrical properties. Neuromorphic computing has attracted much attention due to its power-efficient data processing. To realize efficient neuromorphic hardware systems, the development of reliable and robust synaptic devices is essential. However, the limited performance of the synaptic devices remains as a challenge for realization

of neuromorphic hardware systems. Analog memory characteristics has been demonstrated in the ferroelectric thin-film transistor (FeTFT) based on oxide semiconductor and ferroelectric hafnium oxide layer. The conductance of the oxide semiconductor channel is modulated by controlling the polarization of the ferroelectric hafnium oxide layer. Conductance modulation characteristics of FeTFT were used to demonstrate potentiation and depression characteristics. The desired synaptic device characteristics, such as high linear weight update, small variation, and multiple states were achieved in FeTFTs. In addition, the possibility of FeTFT as a synaptic device in neural network was evaluated by artificial neural network simulation. This work can offer a possibility for FeTFT as a synaptic device to be used in neuromorphic hardware systems.

Emerging Low-Dimensional Materials for Mid-Infrared Sensing and Detection Han Wang; University of Southern California, United States

Emerging low dimensional materials, including both two-dimensional and quasi-one-dimensional materials, provide new optical and electronic properties attractive for developing novel detection and sensing functionalities in the mid-infrared wavelength, including dynamic bandgap tuning covering a broad spectral range in mid-IR, light polarization sensitivity and the ease for electronics integration. Many of these new features are available in the existing mid-IR devices based on traditional semiconductor materials. In this talk, the recent progress in our study of low-dimensional material based mid-IR detector and sensors will be discussed, focusing on layered materials black phosphorus, tellurene and quasi-one-dimensional material $BaTiS_3$. The common and distinct characteristics of these emerging materials will be examined relating to their crystal structures, optical properties, and the device functionalities. Key performance metrics including the gain and detectivity will be benchmarked, and the new detection features including the polarization sensitivity are studied. I will also provide perspectives about how these new materials may change the future mid-infrared photonics technology.

5:30 AM *F.NM07.04.03
Memristors and Neuristors in Epitaxy Land—A Deeper Look in the Materials Properties Beatriz Noheda[1], Mart Salverda[1], Yingfen Wei[1], Pavan Nukala[1] and Sylvia Matzen[2]; [1]University of Groningen, Netherlands; [2]Université Paris-Saclay, France

The search for devices that can emulate the behavior or neurons and synapses, to be used in brain-inspired, in-memory or on-edge computing, is extending among different research fields with an increasing number of materials scientists involved in the quest. However, the number of materials that have been considered as the key elements in devices that are able to produce action potentials and provide tunable conductivity and/or resistive memory, is so far still restricted to the few materials that are compatible with CMOS integration. However, the need to limit the processing to low temperatures, often produces polycrystalline or amorphous materials that diminishes the control of the material's properties, reduce the device endurance and device-to-device reproducibility and obscure the understanding of the physical mechanisms at play. Thus, in order to acquire a better control of the final device, we propose that a detour into the world of epitaxial, single-crystalline materials should not be seen as a waste of resources but rather as a way to find a direct access to the key materials issues and their solution. In addition, the emergent efforts towards epitaxial growth of complex oxides by ALD[1] allows us to dream of a future of epitaxial oxide microelectronics for which we want to be prepared. In this talk, we will show two examples of epitaxial materials that show interesting neuromorphic features that, to our knowledge, have not been reported in other materials: the particular self-oscillating behavior of epitaxial $TbMnO_3$ [2] as a compact neuristor [3] and the synaptic plasticity of ferroelectric memristors and ferroelectric field-effect transistors (FeFETs) fabricated with epitaxial, rhombohedral, $Hf_{0.5}Zr_{0.5}O_2$[4], a phase that is different from the ferroelectric phase of hafnia originally discovered[5], whose outstanding properties have put these materials in the spotlight.

From Synaptic to Neuronal Functionality Using Ferroelectric Tunnel Junctions Sayani Majumdar[1,2]; [1]Aalto University, Finland; [2]VTT Technical Research Centre of Finland, Finland

Parallel information processing, energy efficiency and unsupervised learning make the human brain a model computing system for unstructured data handling. Oxide memristors, from filamentary to metal-insulator transition devices have been shown to emulate synaptic and neuronal functionalities in artificial neuromorphic circuits. However, challenges like non-linear conductance update, cycle-to-cycle and device-to-device variability and leakage current related issues in a dense crossbar structure are still not resolved. For neurons, often a circuit with multiple active or passive components are required which can complicate circuit designs in a large-scale neural network. In our earlier work, we reported solution-processable ferroelectric tunnel junctions (FTJs) with P(VDF-TrFE) copolymer barriers on semiconducting bottom electrode can show analog memristive behavior with a broad range of accessible conductance states and low energy dissipation of 100 fJ for the onset of depression and 1 pJ for the onset of potentiation by resetting small tunneling currents on nanosecond timescales. Key synaptic functions like programmable synaptic weight, long and short-term potentiation and depression, paired-pulse facilitation and depression, and Hebbian and anti-Hebbian learning through spike shape and timing-dependent plasticity are demonstrated. 1 In the current work, we demonstrate that by manipulating the carrier concentration of the semiconducting bottom electrode in FTJs, it is possible to control the dynamics of ferroelectric domain rotations in a way so that from synaptic devices they can act similar to neuronal devices. 2 These results offer a promising outlook for the FTJ memristors on semiconducting bottom electrodes as both synapse and neuron devices in artificial neural networks by controlling carrier doping concentrations only. One-Shot Regression and Classification with Crosspoint Memory Arrays Daniele Ielmini[1], Giacomo Pedretti[1], Piergiulio Mannocci[1] and Zhong Sun[2]; [1]Politecnico di Milano, Italy; [2]Peking University, China

As artificial intelligence (AI) becomes a popular feature in industry, social networks, smart homes and transportation, there is an increasing need for AI accelerators in edge computing, to solve for excessive traffic to the cloud and ensure privacy and security of the processed data. In this frame, in-memory computing (IMC) has risen as low-power processing approach for data intensive problems. Matrix-vector multiplication (MVM) can be accelerated in crosspoint arrays by leveraging the Kirchhoff's law for current summation and the Ohm's law for voltage-conductance multiplication, as well as taking advantage of the parallelism in the memory array. Connecting the crosspoint array in a feedback loop also allows to accelerate inverse operations, i.e., one-step solutions of linear systems such as Ax = b where the NxN matrix A is stored as conductance values in the array, vector b represents applied currents and solution vector x is the output voltage. O(1) complexity of eigenvector extraction and O(N) complexity of matrix inversion have been demonstrated, which outperforms

classical digital computing and even quantum computing.
In this work, we show that the same circuit concept can serve to accelerate regression and classification problems, which are two key problems of AI. Linear regression is solved within two coupled crosspoint arrays by computing the pseudo-inverse matrix in one step. M-dimensional linear regression allows to make predictions based on an existing data set or temporal sequence, thus enabling fast, energy efficient machine learning on the edge. The same circuit enables logistic regression, hence one-step classification within the crosspoint array, which allows for one-shot training of multiple layer perceptrons (MLP). The implications of these novel concepts for AI acceleration and the best technological implementation for data-intensive computing will be discussed.

5:15 AM *F.NM07.05/F.SM05.03
Progress in Analog DNN Hardware Accelerators Using Phase Change Materials Charles Mackin, Hsinyu Tsai, Pritish Narayanan, Stefano Ambrogio, Katie Spoon, Andrea Fasoli, Alexander Friz, An Chen and Geoffrey W. Burr; IBM, United States

Neuromorphic computing with analog memory can accelerate deep neural networks (DNNs) by enabling multiply-accumulate (MAC) operations to occur within memory. Analog memory, however, presents a number of device-level challenges having macro-implications on the achievable accuracy and reliability of these artificial neural networks. This talk focuses on the adverse effects of conductance drift in phase-change memory (PCM) on network reliability. It is shown that conductance drift can be effectively compensated in a variety of networks by applying a 'slope correction' technique to the squashing functions to maintain accuracy/reliability for a period of ~1 year. In addition to conductance drift, PCM poses considerable variability challenges, which impact the accuracy of the initial weights. This talk summarizes recent advances in optimizing initial weight programming, and provides evidence suggesting that the combination of 'slope correction' and programming optimization techniques may allow DNN acceleration using analog memory while maintaining software-equivalent accuracy with reasonable reliability.

Atomic Memory and Computing Applications Deji Akinwande[1] and Mario Lanza[2]; [1]The University of Texas at Austin, United States; [2]Soochow University, China

This talk will present our latest research adventures on 2D atomic nanomaterials towards greater scientific understanding and computing applications. In particular, the talk will highlight our work on non-volatile memory (atomristors) that can be employed in various applications including information storage, brain-inspired computing, and zero-power RF switches. Non-volatile memory device based on atomically-thin materials is an application of defects, and is a rapidly advancing field with rich physics that can be attributed to metal ion binding to native defects. The promising 2D materials for neuromorphic computing include MoS2 and hBN. In particular, hBN memory devices feature very low switching energy, a relatively wide range of stable programmable resistance states, and good endurance and retention. Recent progress has also demonstrated wafer-scale integration of 2D memory devices with a prospect to leverage silicon electronics for fully integrated systems.

5:45 AM F.NM07.05/F.SM05.05
High-Throughput Computational Screening to Identify Novel Proton Conducting Electrolytes for All-Solid-State Neuromorphic Devices Konstantin Klyukin, Pjotrs Zguns, Ju Li and Bilge Yildiz; Massachusetts Institute of Technology, United States

Artificial electrochemical synapses based on the charge-driven proton intercalation demonstrate much promise toward brain-inspired neural computing [1]. Proton transport plays a critical role in these devices determining switching speed and reliability. Despite great attention and intensive experimental investigations, even the cutting-edge proton conductors still suffer from sluggish ion transport kinetics at low temperatures or are not compatible with current CMOS fabrication processes. Therefore, there is an urgent need for fast solid-state proton conductors operating below 100 °C, much required for rapidly growing proton-based neuromorphic computing applications.

In this work, we consider a large class of solid-state materials having hydrogen as a part of their nominal structure such as solid acids and inorganic hydrates. By considering different combinations of common acids and metal ions, it is possible to synthesize thousands of materials with widely varying structures and physicochemical properties, and yet many of them remain relatively unexplored for the ability to conduct protons. We performed a high-throughput computational screening of the available materials datasets to identify chemical compositions and structure types that are likely to have high proton mobility. To estimate proton conductivity, we used ab initio molecular dynamics simulations. We further correlated this data with simple structural features and built a classification model to preselect a small set of materials for more detailed

investigations. Based on our simulations, we identified promising materials and suggested effective strategies for improving proton conductivity.

Metal-Insulator Transition Property for the Nano-Confined Electric Domain in the Strongly Correlated $NdNiO_3$ Azusa Hattori, Takashi Yamanaka, Akira Nanba and Hidekazu Tanaka; Osaka University, Japan

Strongly correlated metal oxide (SCMO), such as manganite, nickelate, and so on show first-order metal-insulator phase transition (MIT) with a change in conductivity by several orders magnitude. Since a discovery of the phase separation during MIT process, many researchers have been trying to capture a nanoscale electric domain and investigate its exotic properties. Typical SCMO material, rare earth Ni oxides ($ReNiO_3$, Re = Nd, Sm, and Eu) having a perovskite structure, show giant resistance change due to MIT at a wide temperature range of 150 K to 500 K. In this family, bulk neodymium nickelate: $NdNiO_3$ (NNO) shows 1-2 orders resistance change through MIT at around 200 K [1]. Very recently, the coexistence of insulator and metal domains with a few hundred nm size was observed during the MIT process for NNO system [2]. This phase-separated phenomenon is also observed in typical SCMOs, such as VO_2 and manganite. The overall observed MIT property, i.e., the resistance change for a sample, is considered to be dominated by competing nanoscale electronic phases. A step resistance change due to the electronic phase confinement effect: increase in resistance change rate has been reported in nanoscale samples comparable to domain size [3]. Therefore, it is expected that the nanoscale NNO sample shows a step resistance change due to MIT property of single nanoscale electronic phases. In this study, we fabricated NNO nanowire structures with 50-200 nm widths and measured their transport properties.

The NNO thin films were fabricated on $NdGaO_3$(110)(a_{pc} = 0.3858 nm), LSAT(100)(a = 0.3868 nm), and $SrTiO_3$(100)(a = 0.3858 nm) substrates by pulsed laser deposition method. NNO nanowires with different wire widths from 50 nm to 500 nm were fabricated by electron beam (EB) lithography and Ar ion milling process. All films and nanowire samples showed the resistance changes corresponding to MIT, but the RT curves shape were quite different. While the thin film sample showed gradual resistance change, the nanowire sample showed some step resistance changes both in cooling and heating processes. This step changes indicate that the nano electronic phases are confined in the NNO nanowire and a single electric domain shows first-order MIT with a single-step change in electrical transport property. For example, we found that the 50 nm width nanowire on $SrTiO_3$ substrate showed the intermittent step-resistance change, implying the further confine electronic phases to a nanometer space. Interestingly, the nanowires on $NdGaO_3$(110) and LSAT(100) substrates showed more prominent step resistance changes than that on $SrTiO_3$(100) substrate, which imply the nano-confinement condition were affected by the strain. The dR/dT vs. T plot showed that the transition temperature distribution of each electronic phase in the nanowires were different. This is probably because the strains depending on the three different substrate effect where on the Ni-O-Ni angular distribution, which affected the MIT properties of $NdNiO_3$ nano-electronic phase. In the presentation, we will present the quantitative correlation between nano-spatial size and nano-confinement MIT properties. We will also discuss the revealed the MIT property for a single domain in a NNO nanowire and the strain effect for the nano-confined domains behaviors.

Ionic Liquid Regulated Silver Filament Formation in a Solid Polymer Electrolyte for Neuromorphic Applications Zhongmou Chao, Ke Xu and Susan Fullerton; University of Pittsburgh, United States

Much progress has been made over the past decade using conductive bridge random access memory (CBRAM) to emulate both artificial synapses and artificial neurons for neuromorphic applications. However, the intrinsically stochastic switching process of metal filament formation and dissolution results in unreliable analog synaptic weight updating, while the non-volatile characteristic of CBRAM prevents the leaky integrate-and-fire function—a hallmark characteristic of an artificial neuron. We have previously reported that silver nanofilament growth dynamics in a polymer electrolyte can be regulated by the addition of ionic liquid (IL) by: (1) reducing stochasticity of the filament switching (shifting its formation time distribution from power-law to Gaussian) and (2) creating a competition between the formation of IL electrical double layers (EDL) and silver electrodeposition. The competition enables the tuning of filament growth dynamics from abrupt to gradual, with gradual growth introducing multiple well-defined resistance states—a feature necessary for emulating the

communications between neurons in an artificial neural network. We also observed a linear correspondence ($R^2 = 0.95$) between nanofilament resistance states and program pulses, which is essential to improve learning accuracy in Deep Neural Networks (DNNs). Here, we report on silver filament formation and dissolution in response to presynaptic programming biases and focus on benchmarking the performance against the requirements for artificial synapses. The temporal stability of "abrupt growth" silver filaments is also studied. Lastly, we demonstrate a system integrating both gradual and abrupt silver filaments to implement some key artificial neuron functionalities.

6:15 AM *F.NM07.05/F.SM05.08
Computing with Memristive and Memcapacitive Devices J. Joshua Yang; University of Southern California, United States

Memristive devices have become a promising candidate for unconventional computing(1) due to their attractive properties(2, 3). Computing can be implemented on a Resistive Neural Network (ResNN) with memristor synapses and neurons or a Capacitive Neural Network (CapNN) with memcapacitor synapses and neurons. For ResNNs as computing accelerators, we have built a dot-product engine based on a 128 x 64 1T1R crossbar array using traditional non-volatile memristors with 64 stable analog resistance levels(4). Accurate image compression and filtering have been demonstrated with such analog computing accelerator(4). In addition, we have demonstrated efficient and self-adaptive in-situ learning in a two-layer neural networks using such memristive arrays(5), which is expected to significantly improve the speed and energy efficiency of machine learning. A variety of neural networks based on such accelerators have been demonstrated, including reinforcement learning(6), LSTM(7), recurrent CNN(8) memristive networks. For ResNNs beyond accelerator applications, we developed diffusive memristors(9) with diffusion dynamics that is critical for neuromorphic functions. Based on the diffusive memristors, we have further developed artificial synapses(10) and neurons(11) to more faithfully emulate their bio-counterparts. We then integrated these artificial synapses and neurons into a small neural network, with which pattern classification and unsupervised learning have been demonstrated(11). For CapNNs, we have developed pseudo-memcapacitive devices based on the diffusive memristors. Capacitive synapses and neurons enabled by these memcapacitive devices have been developed and used to form a fully integrated CapNN(12), which has shown spiking signal classification and Hebbian-like learning functions. Moreover, the diffusive memristors can be used for cybersecurity(13, 14) and robotics applications(15). The requirements on device properties, and thus the corresponding challenges and solutions, are different for ResNNs and CapNNs, which will be discussed in detail in this talk. J. J. Yang, D. B. Digital Memcomputing—From Logic to Dynamics to Topology Massimiliano Di Ventra; University of California, San Diego, United States

Memcomputing [1, 2] is a novel physics-based approach to computation that employs memory to both process and store information on the same physical location. Its digital version [3, 4] is designed to solve combinatorial optimization problems.

A practical realization of digital memcomputing machines (DMMs) can be accomplished via circuits of non-linear, point-dissipative dynamical systems engineered so that periodic orbits and chaos can be avoided. A given logic problem is first mapped into this type of dynamical system whose point attractors represent the solutions of the original problem. A DMM then finds the solution via a succession of elementary instantons whose role is to eliminate solitonic configurations of logical inconsistency (''logical defects'') from the circuit [5, 6]. I will discuss the Physics behind memcomputing and show many examples of its applicability to various combinatorial optimization problems demonstrating its advantages over traditional approaches [7, 8]. Work supported in part by DARPA, DOE, MemComputing, Inc. (http://memcpu.com/), and CMRR.

MoS2-Based LIF Neurons for Spiking Neural Networks Durjoy Dev, Adithi Pandrahally Krishnaprasad Sharada, Mashiyat Sumaiya Shawkat, Yeonwoong Jung and Tania Roy; University of Central Florida, United States

Compared to all other neural networks, Spiking Neural Networks (SNN) mimic the brain most faithfully. Memristors are considered as promising candidates for realizing these SNNs because of their reduced complexity and nanoscale foot-print when compared to conventional complementary metal oxide semiconductor (CMOS) technology [1]. Volatile switching in memristors is used to emulate neurons in SNNs. In this work, we present neurons realized by memristors using chemical vapor deposited (CVD) MoS2. The neurons realized by volatile MoS2 threshold switching memristors (TSM), facilitated by using Ag electrodes, exhibit the characteristics of a leaky integrate and fire (LIF) neuron. The LIF neurons exhibit temporal response modulated by circuit elements and input voltage pulses. The volatile switching is obtained due to the diffusion of Ag+ ions into Au/MoS2/Ag stack. The device shows exceptional characteristics like high ON/OFF ratio of 106, low threshold voltage (~0.2 V), high compliance current (100 μA), and a pulsed endurance of 107 switching cycles making it an exceptional candidate for artificial neuron application. The volatile switching characteristics are utilized to implement a LIF neuron. The TSM is integrated with a series resistor and parallel capacitor. The device shows continuous spiking when subjected to input pulses of amplitude of 0.5 V and duration of 5 μs. The output spiking frequency of the neuron increases with increasing amplitude and pulse width. The variation in the spiking frequency follows the sigmoid activation function of ANN. The spiking frequency increases with an increase in the input pulse width. The spiking frequency decreases with increasing pulse interval. MoS2-Based Electronic Synapses for Unsupervised Learning Adithi Pandrahally Krishnaprasad Sharada, Durjoy Dev, Mashiyat Sumaiya Shawkat, Yeonwoong Jung and Tania Roy; University of Central Florida, United States

Memristors are considered as promising candidates for realizing synapses for neuromorphic computing because of their reduced complexity and nanoscale foot-print when compared to conventional complementary metal oxide semiconductor (CMOS) technology. Non-volatile switching with multiple conductance states in memristors is employed to emulate synapses. In this work, we present synapses realized by memristors using chemical vapor deposited (CVD) MoS2. Graphene is used as electrode for this device. These synapses exhibit linear and symmetric weight update with identical pulses, considered to be the “holy grail”for unsupervised learning. The graphene/MoS2 (G/M) synaptic device exhibits 4 distinct states in both DC potentiation and depression regimes. Additionally, it exhibits data retention for >104 s. For efficient unsupervised learning, the synapses should exhibit linear and symmetric weight update with identical input pulses and a high maximum/minimum conductance ratio (Gmax/Gmin). Resistive random-access memory (RRAM), phase change memory

(PCM) and ferroelectric field effect transistors (FeFET) have been used to emulate a synapse. But these devices exhibit non-linear weight update with identical pulses paired with reduced Gmax/Gmin ratio. Identical input voltage pulses with tON= 500 µs and amplitude of 6 V (-4 V) are applied to observe potentiation (depression) in the G/M synapse. With 25 input pulses applied for each regime, we obtain linear and symmetric weight update with an ideal symmetry of 0. The non-linearity factor (NLF) is 0 for both potentiation and depression regimes, and Gmax/Gmin is 16.5. These device characteristics are then incorporated in a pseudo-crossbar array of a 2-layer multi perceptron network with the help of the circuit macro model Neurosim1 to obtain online learning accuracy of 84.33 %. We benchmark our G/M synapse with other emerging synapse devices with respect to NLF, asymmetry, Gmax/Gmin and learning accuracy with Neurosim and show that our device is superior to all other emerging synaptic devices in all these categories. 1 P.-Y. Chen, X. Peng, and S. Yu, IEEE Transactions on Computer-Aided Design of Integrated Circuits and Systems 37 (12), 3067 (2018).

5:35 AM F.NM07.06.05
A Stochastic Tantalum Disulfide Charge-Density-Wave Neuronal Oscillator Hefei Liu[1], Tong Wu[2], Xiaodong Yan[1], Jiangbin Wu[1], Jing Guo[2] and Han Wang[1,1]; [1]University of Southern California, United States; [2]University of Florida, United States

Due to the unique physical properties, charge-density-wave (CDW) materials have been vastly investigated in the past half century, including the direct observation of atomic structure, phase transition, transport mechanism, and applications ranging from superconductor to electronic oscillator. As a layered CDW material, the CDW phase transition of 1T-TaS2 can be incurred by external electric field at room temperature, accompanied by the significant decrease of resistance. The electric-field-driven phase transition makes a room temperature oscillator possible. Furthermore, the quench-and-melt dynamics leads to the random reconfiguration of CDW domains during phase transition, which implies the intrinsic stochasticity of the oscillator. Therefore, here we report a CDW stochastic neuronal oscillator based on 1T-TaS2 thin film. Two working regimes, the regular and stochastic regimes, were found in this device. In stochastic regime, the CDW neuronal oscillator can generate spike trains with random interspike intervals following exponential, Gaussian and Gamma distribution with tunable parameters, closely matching the spike trains of biological neurons. Owing to the stochasticity, many key features of the Hodgkin-Huxley description of neurons can be realized in this compact two-terminal neuronal oscillator. Statistical analysis was conducted on the spike train generated by the CDW neuronal oscillator. By establishing a generalized linear model to describe the statistical distribution of interspike intervals and to quantify the correlation, we demonstrated that the artificial neuron resembles the neurons in the superior olivary complex of mammalian nervous system, in terms of its interspike interval distribution, the time-correlation of spiking behavior and its response to acoustic stimuli. The CDW oscillator can hence provide a new pathway, utilizing statistical features and pattern change in the interspike interval to transmit information, to the design of neuronal component for more sophisticated spiking neural networks and brain emulation.

Improvement of Analog Resistive Switching Characteristics in TaOx-Based Synaptic Devices Through Complementary Resistive Switching Toshiki Miyatani, Yusuke Nishi and Tsunenobu Kimoto; Kyoto University, Japan

Neuromorphic chips which mimic the human brain working with extremely low power consumption of 20 W are intensively studied, because current artificial intelligence systems require enormous power consumption. Resistive switching (RS) cells as synaptic devices play an important role in neuromorphic chips by controlling the cell resistance continuously. However, conventional transition metal oxide-based RS cells often show an abrupt decrease in the cell resistance (set process) [1], which inhibits the continuous control of the cell resistance. In this paper, we report improvement of RS continuity in Ta2O5-based RS cells by suppressing the abrupt set process. We fabricated Pt/TaOx/Ta2O5/Pt stack cells on SiO2/Si substrates. A Pt layer was deposited by DC sputtering as a bottom electrode (BE). A Ta2O5 layer and an O-deficient TaOx layer were deposited by reactive radio frequency sputtering. Pt top electrodes (TEs) with a diameter of 100 ?m were subsequently formed. The introduction of the TaOx layer caused diffusion of oxygen vacancies (VOs) from the TaOx layer to the Ta2O5 layer. Consequently, the Ta2O5 layer can be considered to consist of a VO-rich layer and a VO-poor layer for simplicity [2]. We measured electrical characteristics of the cells at room temperature with the TE grounded. We reported that two modes of bipolar RS (BRS), which show hysteresis curves of current-voltage (I-V) characteristics in opposite directions each other, were selectively obtained in a single Pt/TaOx/Ta2O5/Pt cell by appropriately adjusting a range of the applied voltage after a unique forming process [3]. One mode of BRS exhibits set and reset processes at positive and negative voltage, respectively, that is, RS characteristics in the direction of drawing the figure-eight. The other mode of BRS conversely presents RS characteristics in the counter direction. In this study, the maximum applied voltage after the forming was adjusted between the voltage of 1.0 V for the figure-eight BRS and that of 2.5 V for the counter figure-eight BRS. As a result, we demonstrated complementary RS (CRS) from ?1.5 V to 1.5 V, in which a set process and a subsequent reset process occur symmetrically in both bias directions as the magnitude of the applied voltage increases. The CRS characteristics have been expected as one of

the ways to solve a sneak path problem. The typical CRS cell consist of anti-serially connected two BRS cells, and its characteristics can be generally interpreted by superposition of the two modes of BRS. However, we found that the stack structure of the VO-rich and VO-poor layers could exhibit stable CRS characteristics. This suggests that each of the two modes of BRS is dominated by RS phenomena which occur in the VO-rich and VO-poor layers. Moreover, we could separate two types of BRS operations with different polar for set and reset processes each other by changing the range of the applied voltage from ?0.5 V to 1.0 V or from ?1.0 V to 0.5 V after several CRS operations. Note that these RS characteristics were sufficiently gradual. Therefore, the cell resistance could be continuously controlled approximately between 0.2 k? and 1 k? by applying the appropriate voltage, indicating that analog RS characteristics were improved through CRS operations. The improvement of analog RS characteristics can be understood by the competition of a set process in the VO-rich layer and a reset process in the VO-poor layer, or vice versa, through the CRS operations. In other words, the CRS operations can be useful to not only suppress sneak pass current but to improve the continuity of RS. [1] D. Ielmini, Microelectronic Engineering, 190, 44 (2018). [2] T. Miyatani et al., Jpn. J. Appl. Phys., 58, 090914 (2019). [3] T. Miyatani et al., Mater. Res. Soc. Spring Meeting, EP09.07.02 (2019).

Metal Oxide Based Three-Terminal Electrochemical Memory Devices Towards Energy Efficient Neuromorphic Computing Device Dagil Ryu, Yangho Jeong, Hyunjoon Lee, Young Ho Chu and Yun Seog Lee; Seoul National University, Korea (the Republic of)

Deep neural network (DNN) based on the backpropagation(BP) has demonstrated outstanding performance in speech recognition, image detection, and natural language processing. Despite the great success, training of large DNNs is computationally intensive task that requires high energy consumption. To achieve massively parallel and energy-efficient DNN algorithms, in-memory computing with resistive memory devices such as RRAM, PCM, CBRAM, FRAM, etc., have been widely studied. These analog synaptic devices, however, have non-ideal characteristics including nonlinearity of conductance response, asymmetry, and variation originated from their operating mechanism or material properties, resulting in time consuming feedback programming scheme. In this contribution, we propose metal oxide based three-terminal electrochemical memory devices as artificial synapses for neuromorphic computing. Various metal oxides are employed as resistive channel material and a solid electrolyte deposited on the channel decouples the update and read operations. By injecting proton or oxygen ions into the channel, the conductance states of the channel can be tuned precisely. We investigate device structure designs and operation conditions for symmetrical programming with a wide range of states and long term stability through the reversible electrochemical intercalation or redox reaction with a charge control through the gate. More importantly, we discuss issues of the metal oxide based three-terminal electrochemical memory devices for CMOS process-compatibility and a large scale array fabrication.

Tunable Volatile and Non-Volatile Resistive Switching of Non-Stoichiometric CuOx Nanowire for Selector and Memory Application Chi-Hsin Huang[1], Kosuke Matsuzaki[2] and Kenji Nomura[1]; [1]University of California, San Diego, United States; [2]Tokyo Institute of Technology, Japan

Resistive random-access memory (ReRAM)/memristive devices based on electrical resistance switching are highly expected to overcome persistent technological limitations in current memory technology and to develop next-generation nonvolatile memory because of its superior characteristics. These characteristics include high speed, high scalability, low power consumption, fast fabrication process, multistate storage, and compatibility with complementary metal-oxide semiconductor (CMOS). Particularly, nanowire-based resistive switching devices offer an ideal platform for a deeper understanding of resistive switching properties due to the confined nanostructure and the opportunity to develop nanoscale-memristive device for next-generation memory and neuromorphic computing. In addition, copper oxide is one of the attractive candidates for ReRAM/memristor due to the existing multiple oxidation states from “+2” to metal state (CuO, Cu4O3, Cu2O, Cu) for inducing resistive switching, which is believed to involve the phase transition with multiple oxidation state induced by redox reaction. In this work, we report the volatile and non-volatile resistive switching effect in p-type non-stoichiometric CuOx nanowires, which are fabricated using insulator CuO nanowires via a thermal-annealing technique with hydrogen atmosphere. These resistive switching modes were effectively controlled by the stability of conductive filament via the compliance current in the SET process. The non-volatile resistive switching exhibited low electric-field-induced switching, high ON/OFF ratio of 107, and long retention time of 104 seconds for ReRAM application. On the other hand, the volatile threshold switching was operated with low compliance current for selector application, and the device showed bidirectional operation, selectivity (104), low OFF-current (<100 pA), and stable reliability with endurance over 105 cycles under pulse operation. The presented work will discuss a nanoscale resistive switching mechanism based on hole-based conducting filament formation originated from the local redox reaction.

5:20 AM F.NM07.07.03
Photo Induced Synaptic Behaviors Emulated in Monolayer MoS2 Devices for Realizing Artificial Cogni-Retina Molla Manjurul Islam, Sonali Das, Durjoy Dev, Adithi Pandrahally Krishnaprasad Sharada, Madison Manley and Tania Roy; University of Central Florida, United States

Neuromorphic computing, inspired by the human brain, provides efficient energy utilization, massive parallelism, flexible adaptive capability, and information processing and transmission. It has the potential to realize computational techniques requiring recognition, learning and decision making; fundamentally overcoming the bottleneck in von Neumann architectures.[1] Artificial synapses form the backbone of neuromorphic computing; emulating controlled functions related to learning and memory. Furthermore, to functionalize devices beyond their synaptic functions, it is essential to merge them with biometric sensing elements such as vision, auditory, touch and olfactory sensors. Optical stimuli in a synaptic device renders ultrafast computational speed due to high bandwidth, low crosstalk, and ultralow power consumption.[2] A photonic synaptic transistor based on 2D materials provides ultra-low power consumption along with flexibility and thickness scalability. Graphene, the first 2D material leads to a short photocarrier lifetime and high dark current due to its zero bandgap and is therefore unfavorable for use as an efficient synapse material. Unlike graphene, monolayer MoS2 having a direct bandgap would allow a high absorption coefficient and efficient electron–hole pair generation under photoexcitation, becomes suitable in various neuromorphic applications. We demonstrate the concept of artificial cogni-retina; an optic-neural synaptic device that features synaptic and optical-sensing functions. It has the potential to replace bulky systems comprising of video camera and processing units. A MoS2 based photonic synaptic transistor for emulating the superior and complex features of artificial cogni-retina is reported. The device finds application in prosthetic human eyes and robotic eyes in artificial intelligence based platforms of autonomous vehicles. The device shows synaptic behavior with high conductance ratio of 103 facilitated by gate tunability and a long-term memory of 104 s with an extremely low energy consumption (15 pJ/event). High quality large area (2cm×2cm) monolayer MoS2 (grain size of 50 ?m) is grown on SiO2/Si substrate via CVD technique by maintaining the precursor at 950°C. As grown MoS2 coated with PMMA is immersed in BOE to release the MoS2 film by removing the underlying SiO2. The PMMA supported MoS2 film is transferred to DI water bath and finally to

SiO2/ p+ silicon substrate with nickel source/drain contacts. The final sample is heated for increasing the adhesion of the transferred film, and the PMMA layer is etched by acetone followed by a forming gas annealing. MoS2 is patterned to form the channels of the transistor by reactive ion etching in CF4. We explore the spectral response of our device, expressed through its photoresponsivity, over a wavelength of 400-700 nm for varying intensity. The negligible photoresponsivity obtained for wavelengths above 680 nm clearly depicts the bandgap of monolayer MoS2 corresponding to 1.8 eV. The synaptic transistor exhibits excellent responsivity of 2×103 AW-1 (EQE of 6×105 %) under illumination (450 nm, 10 ?W/cm2) for VG = 0 V and VD = 5 V. Both the responsivity and EQE of the device increase with gate voltage due to lowering of the barriers at the contacts. The device shows n-type behavior (ON/OFF current ratio of 105) and under illumination, an enhancement in current is observed for both ON (VG>VTH) and OFF (VGTH) states for all gate voltages. This indicates that the photocurrent dominates over thermionic and tunneling currents. Gate dependent potentiation and data retention of the device is observed by varying the gate bias. The device also demonstrates other essential synaptic behaviors, such as short-term potentiation (paired-pulse facilitation of 150%), spike-frequency dependent plasticity, spike-duration dependent plasticity. Memristive Devices—From Atomistic Simulations to Circuit Modeling Thomas Mussenbrock; Brandenburg University of Technology, Germany

Almost 40 years after Chua introduced his theory of memristive devices (nowerdays aka resistive switching devices), they have been identified as promising candidates for non-volatile memory applications due to their distinct key features which are i) low power consumption, ii) passivity, and iii) scalability into the nanometer scale. Beyond these applications as non-volatile memories, memristive devices have turned out to be applicable as artificial synapses in neuromorphic circuits. Many of the available metal-oxide resistive switching devices rely on the stochastic phenomenon of creation and rupture of conductive metal filaments within a solid state electrolyte matrix. Inherent are initial electroforming procedures and distinct “on” and “off ” states. The latter are in fact beneficial for memory applications. However, in the context of neuromorphic applications a more "analog" behavior is needed, rather than a purely “digital” behavior. To overcome these limitations, various kinds of interface-based resistive switching devices have been developed, tested, and applied. Although these devices are quite simple with respect to their structural compositions, the analog switching behavior itself - as a result of multiscale multiphysical phenomena - is in fact rather complex and not fully understood yet. This contribution is intended to provide an overview over our modeling and simulation approach in order to describe memristive devices on the human timescale, yet allowing for physical phenomena on the atomistic scale.

5:15 AM *F.NM07.08.02
DNN Training Algorithm for Nonsymmetric Devices Tayfun Gokmen; IBM T. J. Watson Research Center, United States

Resistive cross-point devices arrays that can simultaneously store and process data locally and all in parallel, are promising candidates for intensive deep neural network (DNN) training workloads. However, when the training is performed using the conventional state of the art learning algorithm, stochasticity gradient descent (SGD) using backpropagation (BP) algorithm, these array architectures must meet a set of stringent device requirements for the cross-point element. A key requirement is that the resistive devices must change conductance in a symmetrical fashion when subjected to positive and negative pulse stimuli. Here, we present an alternative training algorithm, so-called the Tiki-Taka algorithm, so that this stringent symmetry requirement of the cross-point element can be relaxed to a very large extend. We tested the validity of the Tiki-Taka algorithm on a range of network architectures such as fully connected, convolutional and LSTM networks. For all these networks, the Tiki-Taka algorithm with nonsymmetric devices characteristics results in training accuracies that are in par with the ones achieved with the conventional SGD algorithm with symmetric devices. Thanks to the relaxed device specification, this algorithmic improvement would enable earlier adaptation of crossbar-based hardware accelerators for DNN training workloads.

Towards Multilevel Phase Change Memory (PCM) Based on Engineered Multilayer Group III-Sb Alloys Rubab Ume,

Haibo Gong, Vadim Tokranov, Michael Yakimov, Sandra Schujman, Devendra K. Sadana and Serge Oktyabrsky; SUNY Polytechnic Institute, United States

Phase change memory is currently considered as one of the promising candidates for the next-generation non-volatile memory devices and Resistive Processing Units for neuromorphic computing. Multilevel functionality of the PCM is a crucial next step in enhancing the bit density per unit cell. We investigated the potential of Tellurium-free group III-Sb alloys, specifically Al-Sb and Ga-Sb thin multilayer films deposited under UHV conditions by molecular beam epitaxy for obtaining multiple resistance states. Bulk films of group III-Sb binary alloys of different compositions showed intermediate resistance plateaus upon heating which is a promising first step to achieve multilevel functionality in PCMs. The resistance versus temperature curves of the multilayer films exhibited up to four distinct intermediate states that have the capability of stabilizing multiple PCM resistance levels and potentially reduce drift in PCM arrays. The calculated activation energy for crystallization ranged from 2.5-5.3 eV. Naturally transitions with the highest activation energies show projected data retention as high as 10 years at 160°C. Transmission Electron Microscopy (TEM) analysis of the samples revealed crystalline grain size of 30-100 nm upon annealing. TEM and X-Ray Diffraction (XRD) analysis of Ga-Sb samples annealed at different temperatures showed growth of crystallites mostly in A7 Antimony phase with further tendency to phase separation of Sb and GaSb phases. Initial pulse measurements were done on binary alloy mushroom PCM cells with TiN heater size of down to 100 nm. Test cells demonstrated reversible switching with a set/reset resistance ratio of ~100 for set voltage <1.5 V and pulse widths down to 200 ns. The multilayer film has the potential to be used similarly to the binary cell showing reversible switching. We believe the results obtained in this study demonstrate a path to enable multiple logic states in PCM materials.

5:35 AM F.NM07.08.04
Ionic Analog Synapses for Deep Learning Accelerators Kevin Limanta, Ahmad Zubair and Tomas Palacios; Massachusetts Institute of Technology, United States

The need to reduce the power consumption of machine learning applications while improving performance has driven the development of specialized hardware accelerators. While digital CMOS-based accelerators have sped-up training and inference in neural networks, they have several limitations. Most notably, a spatially-separated memory and computation, volatile memory, and the lack of connectivity between nodes, all hinder the realization of ubiquitous, low-power deep learning accelerators. Alternatively, crossbar arrays of non-volatile memory (NVM) devices able to perform arithmetic (e.g. bit multiplication), are projected to be six orders of magnitude more energy-efficient than current state-of-the-art GPU accelerators. Borrowing bio-related terminology, these analog “synapses” perform in-memory computation, reducing the distance data travels and overall energy consumption. Unfortunately, current state-of-the-art analog “synaptic” devices based on resistive memories suffer from stochastic, asymmetric, and non-linear weight updates, detrimental to training accuracy. Meanwhile, electrochemical ion-based synaptic devices have been shown to be fast, energy-efficient, and exhibit symmetric, linear weight updates. However, the electrolytes for the electrochemical reaction are often CMOS incompatible and suffers from scalability.

Scalable, CMOS-compatible devices are needed for future large-scale production. In this project, we develop a MOS field-effect transistor(FET)-based analog synapse. Doping the SiO_2 gate oxide with protons by exposing the oxide to hydrogen plasma, allows non-volatile electrostatic control of the semiconductor channel conductance. Applying a short voltage pulse on the gate shifts the distribution of the protons, tuning the artificial neural network node weights. Ion trapping in the oxide maintains non-volatility. Electrostatics of a uniform sheet of ions predicts a linear relationship between the number of voltage pulses and the threshold voltage shift. Linear weight updates are expected, necessary for efficient training with crossbar array accelerators. Initially, we study the electrostatics and proton diffusion via Silvaco Atlas. Simulations predict a threshold voltage shift due to the presence of ions at different locations in the gate oxide. We then fabricate n-Si/ALD SiO_2/Al MOS capacitors with proton doping, and characterized their ionic transport. We observe that the MOS gate stack exhibits hysteretic behavior below 2V, indicating non-volatility and low-voltage operation. C-V measurements estimate the ionic concentration to be $10^{12}cm^{-2}$. To demonstrate switching characteristics, we fabricate and measure proton-doped GaN FETs as a quick testbed due to its simple fabrication and high carrier concentration. GaN has been intensively investigated as a BEOL material for future 3D integrated Si CMOS systems. Our results indicate that it could also be used for MOSFET synapses with proton-doped gate-oxides. These results are generalizable beyond GaN and they shed light on the feasibility of scalable, CMOS-compatible ionic devices for the next generation of neural network hardware accelerators.

2D Memtransistors and Gaussian Heterojunction Transistors as Artificial Synapses and Spiking Neurons Vinod K.

Sangwan, Hong-Sub Lee, Megan Beck and Mark Hersam; Northwestern University, United States

Hardware implementation for neuromorphic computing aims to overcome the von Neumann bottleneck by co-locating memory and logic. In this context, resistive switches, phase-change devices, electrochemical systems, and complementary metal-oxide semiconductor (CMOS) transistors have been explored extensively for artificial synapses and spiking neurons in artificial neural networks. While each of these strategies has its attributes, none of them has clearly emerged as a universal approach for neuromorphic hardware, which suggests that alternatives should continue to be evaluated. For example, neuromorphic devices based on nanomaterials such as quantum dots, nanotubes, and two-dimensional (2D) monolayers have begun to show promise due to their controlled chemical composition, unique architectures, and compatibility with ultimate scaling and speed limits [1]. Furthermore, low-dimensional materials possess low dielectric screening that provides enhanced electrostatic control, thus allowing functions that better mimic a biological neuron [2]. In this presentation, recent advances in the development of artificial synapses and neurons based on 2D semiconductors and mixed-dimensional van der Waals heterojunctions will be discussed [3]. In particular, dual-gated memtransistors based on polycrystalline MoS_2 show novel synaptic responses in crossbar arrays [4]. The non-volatile memory states of these devices are tuned by both biasing history and the field-effect from the two gate terminals [5]. In this manner, the dual gates allow independent addressing of nodes in the crossbar by minimizing sneak currents in addition to facilitating tunability of synaptic weight update rules that resulted in a 94% recognition rate of hand-written digits using a multi-level perceptron model [4]. Since neuromorphic architectures require both artificial synapses and neurons, this talk will also introduce a Gaussian heterojunction transistor design that realizes the functionality of an integrate-and-fire neuron [6]. Specifically, dual-gated, self-aligned, mixed-dimensional *p-n* heterojunctions based on carbon nanotubes and MoS_2 operate as anti-ambipolar transistors where all parameters of the Gaussian transfer curves can be controlled by the applied gate potentials. These Gaussian heterojunction transistors enable a wide range of spiking behavior including constant spiking, latency, and bursting [6]. Since atomically thin dual-gated memtransistors and Gaussian heterojunction transistors are prepared using standard materials processing and fabrication schemes, they are well-poised to be integrated together and/or with traditional electronic devices for next-generation neuromorphic computing architectures.

Scalable Method to Find the Shortest Path in a Graph with Circuits of Memristors Alice Mizrahi[1,2], Thomas Marsh[1], Brian Hoskins[1] and Mark Stiles[1]; [1]National Institute of Standards and Technology, United States; [2]University of Maryland, United States

Biological systems have evolved to perform computing tasks while consuming little energy. Taking inspiration from the methods used by biological systems is therefore a promising path for building low energy computers, as demonstrated by the large body of work on neuromorphic computing. Here we propose to take inspiration from ant colonies, and in particular the way they are able to solve the shortest path in a graph problem without supervision, in a massively parallel way. Algorithms inspired from ant colonies have been proven useful for tackling the wide range of optimization problems that map to finding the shortest path between two given nodes in a graph. However, on conventional computers, they are mostly sequential and therefore the time and energy required to find the path scales with the size of the graph. Here propose a different approach: to implement this bio-inspired system directly in hardware, using circuits of memristors. The graph to study is constructed by interconnecting memristors so that the length of each edge of the graph is embodied by its number of memristors. When a voltage is applied across two nodes, the least resistive branch – i.e. the shortest path – between them receives more current than the other branches. This causes the memristors on the shortest path to turn on, attracting even more current. Our method leverages this reinforcement mechanisms intrinsic to memristors physics, in order to obtain a steady state where the memristors on the shortest path have a much higher conductance than the memristors on the rest of the graph. In consequence, the user can find the shortest path by a simple conductance measurement. Using numerical simulations, we

show that using a voltage ramp makes this method reliable. We validate it on graphs of different sizes and topologies. It is both valid for an experimentally derived memristor model and robust to device variability. We found that, contrary to conventional methods, the time and energy of the computation scale with the length of the shortest path rather than with the size of the graph. In consequence, this method is particularly attractive for solving large graphs with small path lengths (such as neural networks, social networks and power grids). Applying our method to these graphs opens the door to fast and low energy analysis of complex networks with wide ranges of applications.

A Bio-Inspired Perceptual Decision-Making Circuit Based on the Hassenstein-Reichardt Direction Detector Tom Birkoben[1], Mirko Hansen[1], Marina Ignatov[1], Martin Ziegler[2] and Hermann Kohlstedt[1]; [1]Faculty of Engineering, Kiel University, Germany; [2]Technische Universität Ilmenau, Germany

Decision-making belongs to one of the most prominent principles in the nerve system of living species. The crucial trade-off between time to decide (speed) and accuracy is essential for a creature to react to environmental stimuli and most importantly, relevant for survival. In-depth studies of coherent motion tasks in primates, based on two-choice decision experiments, led to a profound understanding of neuronal information processing and even bridged the gap to behavioural psychology. Three fundamental processing stages are needed to successfully perform a two-choice decision experiment based on a saccadic eye movement task: the neuronal representation of the sensory signal, the integration of the incoming stimuli and the comparison of the accumulated information to a threshold for a final decision. In accordance to the results of decision-making experiments with primates, an analogue electronic decision-making circuit was developed. Our concept study includes a LED-matrix showing moving light dots (i.e. the tasks screen in primate experiments), an array of photo diodes (i.e. retina of the primate, sensory evidence), a Hassenstein-Reichardt Detector (HRD) based motion detection (i.e. a correlation-type motion detector with a high biological relevance, based on an inhibitory circuit and delay lines) and finally a signal integration circuit. The latter stage represents the decision-making unit and is realised through an inhibitory mutual coupling of the accumulated signals. The entirely analogue circuit is based on integrate and fire relaxation oscillators to mimic firing neurons. We would like to emphasise that the presented real time decision-making system is closely related to biological information pathways in nerve systems. Neither a digital computer nor programming is necessary for decision-making, which might be an interesting approach for real time data processing in autonomous robots.

6:15 AM F.NM07.08.09
A-TiO2 Nanoparticle Suspension Ink for Fully-Printed Electronic Synapses Varvara Salonikidou[1], Yasunori Takeda[2], Jonathan England[1], Shizuo Tokito[2] and Radu A. Sporea[1]; [1]University of Surrey, United Kingdom; [2]Yamagata University, Japan

Biomimetic electronic devices such as electronic synapses that emulate both short-term and long-term plasticity constitute an auspicious building block for neuromorphic computing systems and bioinspired electronic applications. The electronic synapse constitutes an energy efficient and versatile solution for new computing paradigms, however, to date such devices with well-controlled plasticity and synaptic behaviour are scarce. Most of the current fabrication processes are limited to conventional techniques, which are typically time-consuming and use ecologically harmful chemicals with considerable material waste. The present work aims on fully inkjet-printed MAM (metal-active-metal) electronic synapses. The fabrication technique introduces an alternative time- and cost-efficient method of low environmental impact. All of the layers are deposited in an additive manner without any material subtraction or chemical treatment. Active inks consisting of TiO2 nanoparticle suspension developed in-house are presented and characterised in this work. The ink synthesis is based on low temperature and low complexity process that includes a mixture of solvents and acids. The active inks are analysed in terms of nanoparticle and morphological characteristics. Additionally, the resulted Z number [(inertial force x surface tension)1/2 / viscous force], which defines the jettability of an ink, are defined experimentally. The formulations used seem to strongly affect the dispersity and sedimentation along with the nanoparticle size of the solution-ink, indicating a route to optimization for improved jettability, shelf life and in general ink robustness. The developed nanolayers of the fully-printed devices are in the range of 100-200 nm thickness, uniform and crack-free. Electrical characterisation of initial devices indicates low power (?m to 1 mA window of output current) and biomimetic properties of synaptic plasticity when trigger voltage pulses of 1 V are applied. The tuning of the active ink's rheological characteristics along with the investigation of the electrical framework under which the electronic devices respond synaptically present a favourable approach to alternative fabrication methods for versatile and flexible electronics.

Analog Ionic Switches Based on LiCoO2/SiO2/TiO2 Two-Terminal Devices for the Realization of Bio-Inspired Neural Functionalities Driven by the Reversible Li-Ion Migration Panagiotis S. Ioannou[1], Evripides Kyriakides[1], Ioannis Giapintzakis[1] and Olivier Shcneegans[2]; [1]University of Cyprus, Cyprus; [2]CNRS, Centrale Supélec, France

Although in its embryonic state, bio-inspired computing has never been closer to its realization, due to the recent advances in neuromorphic hardware implementation with non-volatile, binary and analog, devices based on established and novel switching oxides. While binary or multibit information storing as synaptic weights, through the stimulated resistance modulation of such devices, enables in-memory computing and non-Von Neumann architectures, synaptic plasticity will enable direct emulation of biological neural activity. Bio-realistic synaptic plasticity can be facilitated through the pulse stimulation of devices with transient switching behaviour, with an internal timing mechanism through their inherent diffusive dynamics. Consequently temporal association of stimulating pulses, governs the triggered response of such devices, in a manner reminiscent of biological neural behaviour. Searching beyond filamentary resistive switching devices, diffusion based ionic switches, both in three-terminal and two-terminal configurations, receive noticeable attention. Robustness of non-filamentary switching mechanisms, along with unique switching characteristics and plasticity attributes, can expedite the integration of these devices in functional neural networks with bio-inspired capabilities. Cation-based ionic switches, and specifically Li ion diffusion driven switching oxides, attract reasonable attention in the neuromorphic community. Electrochemical relevancy of Li cation with cations such as Na, K and Ca, involved in the polarization/depolarization of neuron cells, apart from being philosophically sensational, disclose great potential for the realization of artificial neurons with synaptic plasticity. This work investigates the memristive/synaptic behaviour and underlying mechanism of two terminal, thin film battery-like, ionic switches based on LiCoO2-cathode, SiO2 electrolyte and TiO2 anode on a Si substrate. Acting as a self-doped p-type semiconductor, highly stoichiometric LiCoO2 presents a reversible insulator to metal transition (IMT) upon electrochemical lithium removal. Each Li ion vacancy induces the oxidation of Co3+ to Co4+, injecting an electron hole and consequently increasing the conductivity of Li-deficient LiCoO2. Controlling the Li concentration in the switching oxide, via voltage stimulated electrochemical migration of Li cations, through a solid electrolyte SiO2 layer and storing them in a TiO2 anode layer, the conductance of the battery-like stack can be tuned. The devices have been characterized by means of dc-cycling and non-abrupt, analog, switching with I-V hysteresis was recorded. Furthermore, non-symmetric, diode-like, characteristics with high rectification effect in reverse bias was evident, along with the rise and decay of an electromotive force after each potentiation. Pulse characterization of the devices lead to the observation of gradual conductance enhancement through a paired pulse facilitation mechanism. Diffusive dynamics of this system, were observed in the form of a decaying excitatory post synaptic current. Regardless, non-volatile multistate conductance enhancement was also monitored. Spike timing dependent plasticity functions where generated, through non-overlapping postsynaptic and presynaptic pulse-pair stimulation. Analog switching observed by these devices, in combination with the diffusive dynamics and the paired pulse facilitation mechanism, effectively facilitate the direct emulation of bio-inspired synaptic functionalities like STDP. Spontaneous state decay, in the form of an excitatory post synaptic current can be advantageous for the emulation of habituation processes observed in biological neurons. Finally non-filamentary switching with rectification characteristics can be beneficial upon device integration in dense cross-bar arrays, effectively enhancing durability and suppressing leakage currents respectively.

Proton Intercalation in Solid-State Electrochemical Synapse for Energy-Efficient Neuromorphic Computing Nicolas Emond, Xiahui Yao, Murat Onen, Seungchan Ryu, Jesus A. del Alamo, Ju Li and Bilge Yildiz; Massachusetts Institute of Technology, United States

Deep learning based on neural networks is a promising approach to accelerate machine learning applications. However, state-of-the-art processing units, based on Complementary Metal–Oxide–Semiconductor (CMOS) circuits, and computer systems based on von Neumann architecture, requires large memory space and high power consumption when simulating neural networks. Improvements in computing performance therefore requires designing novel scalable, fast and energy-efficient hardware structures with both processing and storage capabilities.

It has been demonstrated that crossbar-type arrays containing two-terminal resistive switches, whose electrical conductivity is electrically modulated, enable energy-efficient and fast-processing physical neural networks. Two main types of mechanisms

have been demonstrated in artificial intelligence applications to change the conductance of the switches, conductive-filament and phase-change mechanisms. A more recent concept, electrochemical cation intercalation-based resistive switches with three-terminal structures have the potential to circumvent issues faced by other mechanisms. Indeed, multistate capability and low energy consumption was recently demonstrated for inorganic Li-based[1] and organic proton-based[2] electrochemical devices. However, these devices also suffer from a scaling challenge as they are not compatible with current CMOS processes due to presence of Li and organic switching materials, respectively.

Our group is therefore working on the development of an all solid-state inorganic proton (H^+) electrochemical intercalation resistive switch, which relies on a deterministic charge-controlled mechanism. Our initial design consists of a channel of active material, whose electronic conductivity is modulated through protonation/deprotonation, enabling for a continuum of resistance states[3]. A solid proton reservoir layer serves as the gate terminal while a proton conducting solid electrolyte separates the channel and the reservoir. Employing protons, the smallest cation, as the doping ion presents several advantages including high operation speed, good compatibility with Si technology and long lifetime.

Herein, I will first present our demonstration of this concept[3] for a device that includes tungsten trioxide (WO_3) as an inorganic active channel material, and Pd-hydride as a solid hydrogen reservoir that is also used for gating the device. Hydrated Nafion is used as the polymer-based proton conducting electrolyte. The device has a very low energy consumption, nearly symmetrical protonation/deprotonation behavior and long cycling lifetime. While the channel and gate materials are CMOS-compatible, a challenge is to come up with CMOS-compatible inorganic proton conducting solid electrolytes. Another challenge is to find more insulating channel materials that can switch faster. I will therefore also present our work on the improvement of the device properties and integrability by exploring alternative materials for the active channel and the proton electrolyte. Vanadium pentaoxide (V_2O_5), which is reported to efficiently intercalate small cations in its crystal structure along the (001) orientation (channel-like structure), and tantalum (Ta_2O_5) pentaoxide, a potential two-phase system that could allow to fix the device open-circuit potential, are the two active materials studied within this context. On the other hand, nanocrystalline yttrium-doped barium zirconate (BZY), a state-of-the-art solid-state proton conducting ceramic, is considered as a possible alternative to replace Nafion polymer.

Proton-Controlled Bimodal Operation of Tyrosine-Rich Peptide Memristor Min-Kyu Song[1], Seok Daniel Namgung[2], Daehwan Choi[1], Hyeohn Kim[2], Hongmin Seo[2], Misong Ju[2], Yoon Ho Lee[2], Taehoon Sung[1], Yoon-Sik Lee[2], Ki Tae Nam[2] and Jang-Yeon Kwon[1]; [1]Yonsei University, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

With the advent of artificial intelligence(AI), neuromorphic computing inspired by efficient data processing in human brain has widely attracted immense research interest in various fields. Recent development of AI processor optimized for parallel computing including GPU, FPGA and ASIC has advanced AI-based industries including big data, autonomous vehicles, and internet of things. Nevertheless, CMOS based AI processor has theoretical limits of data bandwidth and energy efficient due to data shuttling between memory and computing units in terms of von Neumann bottleneck. Therefore, new concepts of electronic device have been proposed to mimic biological synapse responsible for both information storage and processing in human brain, termed in-memory computing. Memristors, a portmanteau of memory and resistor, is considered as one of the promising candidates for in-memory computing device because of its desirable properties as tunable resistance, non-volatility, low energy consumption, and fast operation. However, the key difference in working mechanism of biological synapses from artificial electron-based synthetic devices is the cooperative and multimodal activation process which includes the transfer of ions or molecules. In this study, we demonstrate bi-modal operation of peptide memristors, which is analogous to synaptic operation, by electronic and environmental inputs. Based on our understanding on coupling of electron and proton conduction, we designed sequence of amino acids in peptide to obtain controllability on resistive switching characteristics through proton injection by humidity control. As a result, the memristor based on Tyr-Tyr-Ala-Cys-Ala-Tyr-Tyr(Y7C) peptide operates not only by applying voltage inputs but also by applying humidity sweep without voltage sweep corresponding to signaling process by extracellular proton concentration in synapse.
Similar to previous reported electrochemical metallization memory, our peptide-based memory showed resistive switching characteristics owing to redox reactions of metal. However, we examined involvement of phenolic hydroxyl group of

tyrosine in resistive switching by introducing dehydroxylated tyrosine, phenylalanine, instead of tyrosine, resulting in 6-fold increment of set voltage. We assumed that electron transfer from tyrosine to Ag metal and vice versa through deprotonation and protonation promotes formation of Ag conductive filament. Thus, increasing relative humidity(RH) would promote resistive switching due to increased proton conduction in Y7C peptide. As a result, set voltage of peptide memristor showed linear dependency on RH values and, further, only humidity injection without voltage sweep induced reversible and non-volatile resistive switching, namely humidity mode of memristor was realized. Once transition from high resistive state to low resistive state is occurred by a forward RH sweep, the device maintained its state in wide range of RH condition for over 10^4 s, meaning data storage. To erase the data, a reverse RH sweep was applied and transition back to high resistive state was occurred in extremely low RH condition. On off resistance ratio reached up to 10^4. Complementary bimodal operation of the peptide memristor was successfully carried out by writing data using humidity input and erasing data using voltage input in one device. Peptide film was characterized using circular dichroism(CD) analysis, nuclear magnetic resonance(NMR) spectroscopy and transmission electron microscopy(TEM). Proton conductivity of the peptide film was calculated by electrochemical impedance analysis(EIS). Proton involvement in the device was studied by kinetic isotope effect(KIE) of deuterium oxide vapor. This result suggests that proton can act as another control knob for neuromorphic computing devices and multimodal and biomimetic memory operation can be facilitated by material design, especially in tyrosine-rich peptide.

Photo Induced Synaptic Behaviors Emulated in Monolayer MoS2 Devices for Realizing Artificial Cogni-Retina Molla Manjurul Islam, Sonali Das, Durjoy Dev, Adithi Pandrahally Krishnaprasad Sharada, Madison Manley and Tania Roy; University of Central Florida, United States

Neuromorphic computing, inspired by the human brain, provides efficient energy utilization, massive parallelism, flexible adaptive capability, and information processing and transmission. It has the potential to realize computational techniques requiring recognition, learning and decision making; fundamentally overcoming the bottleneck in von Neumann architectures.[1] Artificial synapses form the backbone of neuromorphic computing; emulating controlled functions related to learning and memory. Furthermore, to functionalize devices beyond their synaptic functions, it is essential to merge them with biometric sensing elements such as vision, auditory, touch and olfactory sensors. Optical stimuli in a synaptic device renders ultrafast computational speed due to high bandwidth, low crosstalk, and ultralow power consumption.[2] A photonic synaptic transistor based on 2D materials provides ultra-low power consumption along with flexibility and thickness scalability. Graphene, the first 2D material leads to a short photocarrier lifetime and high dark current due to its zero bandgap and is therefore unfavorable for use as an efficient synapse material. Unlike graphene, monolayer MoS2 having a direct bandgap would allow a high absorption coefficient and efficient electron–hole pair generation under photoexcitation, becomes suitable in various neuromorphic applications. We demonstrate the concept of artificial cogni-retina; an optic-neural synaptic device that features synaptic and optical-sensing functions. It has the potential to replace bulky systems comprising of video camera and processing units. A MoS2 based photonic synaptic transistor for emulating the superior and complex features of artificial cogni-retina is reported. The device finds application in prosthetic human eyes and robotic eyes in artificial intelligence based platforms of autonomous vehicles. The device shows synaptic behavior with high conductance ratio of 103 facilitated by gate tunability and a long-term memory of 104 s with an extremely low energy consumption (15 pJ/event). High quality large area (2cm×2cm) monolayer MoS2 (grain size of 50 ?m) is grown on SiO2/Si substrate via CVD technique by maintaining the precursor at 950°C. As grown MoS2 coated with PMMA is immersed in BOE to release the MoS2 film by removing the underlying SiO2. The PMMA supported MoS2 film is transferred to DI water bath and finally to SiO2/ p+ silicon substrate with nickel source/drain contacts. The final sample is heated for increasing the adhesion of the transferred film, and the PMMA layer is etched by acetone followed by a forming gas annealing. MoS2 is patterned to form the channels of the transistor by reactive ion etching in CF4. We explore the spectral response of our device, expressed through its photoresponsivity, over a wavelength of 400-700 nm for varying intensity. The negligible photoresponsivity obtained for wavelengths above 680 nm clearly depicts the bandgap of monolayer MoS2 corresponding to 1.8 eV. The synaptic transistor exhibits excellent responsivity of 2×103 AW-1 (EQE of 6×105 %) under illumination (450 nm, 10 ?W/cm2) for VG = 0 V and VD = 5 V. Both the responsivity and EQE of the device increase with gate voltage due to lowering of the barriers at the contacts. The device shows n-type behavior (ON/OFF current ratio of 105) and under illumination, an enhancement in current is observed for both ON (VG>VTH) and OFF (VGTH) states for all gate voltages. This indicates that the photocurrent dominates over thermionic and tunneling currents. Gate dependent potentiation and data retention of the device is observed by varying the gate bias. The device also demonstrates other essential synaptic behaviors, such as short-term potentiation (paired-pulse facilitation of 150%), spike-frequency dependent plasticity, spike-duration dependent plasticity. Ionic Nanoarchitectonics for Creating Artificial Intelligence Devices Kazuya Terabe, Takashi Tsuchiya and Tohru Tsuruoka; NIMS, Japan

At present days, an enormous number of semiconductor devices are used in information communications equipment. The memory and computational functions resulting from integration of semiconductor devices have progressed as a result of the development of ultrafine processing technologies, but it is said that this progress will slow down in the near future. Therefore, continued improvement of information communication equipment performance requires not only the further development of semiconductor devices, but also the creation of innovative devices that operate on new principles. Furthermore, development of Artificial Intelligence (AI) hardware such as a brain-type computer that operates with low power consumption and small size is expected in recent years. In order to realize such AI hardware, it will be necessary to create devices that achieve various unique functions such as brain ones. These devices will no longer be based on conventional semiconductors, which exhibit characteristics suitable for digital arithmetic processing. They will be based on new operating principles.
One group such promising novel devices is the nanoionic device's group, these nanoionic devices operate by controlling local ion migration and electrochemical reactions instead of by electron and hole migration. The control of local ion migration allows for any reconstruction of internal and surface nanostructures of device materials, as well as heterointerface one. Namely, it is a nanoarchitecture of materials achieved by the control of ion migration (referred to as ionic nanoarchitectonics). The unique physical and chemical phenomena and functions are caused by the ionic nanoarchitectonics, and we can create interesting nanoionic devices with a variety of novel functions.
So far, we have already made some nanoionic devices with diverse functions by using the ionic nanoarchitectonics. These devices include an atomic switch, decision-making devices, artificial synapse device, solid-state electric-double-layer transistor, multi-functional on-demand-type device, magnetization and magnetoresistance tuning device, and so on [1,2]. We believe that the ionic nanoarchitectonics is promising as a new method for creating AI devices.

Memristive Stochastic Learning for Neuromorphic Computing Martin Ziegler; TU Ilmenau, Germany

Memristive devices because of their non-volatile memory behavior and their relatively simple structure as an electronic counterpart to synapses for hardware-based artificial neural networks (neuromorphic circuits). An important behavior of devices is their inherent stochastic nature, which applies especially to devices. Here, the change in resistance is due to the formation and dissolution of electrically conductive paths in a solid state electrolyte, which result in changes in the resistance switching process and nondeterministic device behavior.
In this talk, a learning scheme is presented that uses the randomness of the switching process for neuronal-inspired computing. It is shown that the switching probability of ReRAM cells follows a Poisson distribution at a certain voltage and pulse width, the switching probability being controllable by the number, amplitude and width of the programming pulses. To demonstrate the power of stochastic learning for neuromorphic systems, a neural circuit for pattern recognition is presented, and one that mimics perceptual behavior.

Resistive Switching Dynamics in Core-Shell Nanowire Networks for Neuromorphic Hardware Applications Shangradhanva Eswara Vasisth and Juan Claudio Nino; University of Florida, United States

There is a recognized need to develop analog neuromorphic hardware to tackle the ever-increasing digital computation time and resources demanded by current artificial neural networks (ANNs). Here, we demonstrate novel neuromorphic architectures based on Ti/HfO2/Pt and Pt/HfO2/Pt memristive systems and discuss their electrical performance and their potential applications as ANNs. Current state-of-the-art systems are built on a crossbar array of memristors for neuromorphic computing. With a limit on the number of neurons and regular connectivity, the networks lack sparsity and randomness which results in high wiring cost and poor functional connectivity. To address these limitations, we have fabricated a random array of core-shell memristive wires to form the connectivity matrix for neuromorphic hardware. In the systems listed above,

the conductive core (Ti or Pt) serves as a conductive path or intermediate electrode with a memristive shell (HfO2) that can be electroformed with a set of top electrodes (Pt) deposited on the surface. These random nanowire networks are fabricated via electron-beam lithography on a 200 ?m × 200 ?m write field. Network quantifying simulations revealed a small-world coefficient of 2.89, the shortest path length of 3.61 and a clustering coefficient of 0.057. Remarkably, depending on the forming process, the individual core-shell wires can exhibit eight-wise (8W), counter eight-wise (C8W) bipolar resistive switching (BRS), and complementary resistive switching (CRS). At a low potential ranges (±1.5 V), the wires switch in a bipolar fashion between LRS (~11.2 k?) and HRS (~0.3 M?). Symmetric arrangement of layers in the wires along with 8W and C8W switching implies two memristors connected anti-serially. This configuration results in the wires exhibit CRS at higher potentials (±2 V). This ability to switch the devices via BRS or CRS enables us to dynamically control the read-write process. Moreover, due to the transient ON in CRS mode, both the currents and power consumption during the operation of the devices is comparatively lower. Given the low switching voltages, low processing temperatures and materials utilized, these neuromorphic devices can be considered CMOS compatible. In this presentation, the fabrication process, the memristive characteristics (endurance, resistance retention, pulse measurements, etc.), switching mechanism and synaptic characteristics (LTP, STP, and LTD) of the above-listed systems will be discussed in detail.

Polymer Linked Gold Nanoparticle Networks for Information Storage and Processing—A Molecular Dynamics Study Xingfei Wei and Rigoberto Hernandez; Johns Hopkins University, United States

At the era of information technology, the growth of data is quickly moving beyond the processing capability of traditional silicon devices. New paradigms for data storage and processing are therefore needed. The answer may be hidden within the structure of your brain. We aim to construct nanoparticle networks inspired by the architecture of actual neural networks to perform brain-like computing. In this work, we show that polymer linked gold nanoparticle (AuNP) networks can function like neuronal networks in information storage and processing. Molecular dynamics (MD) simulations are used to realize their performance. A simple coarse-grained model (AuNP-PAH) is built, which contains one polyallylamine (PAH) chain of 200 repeating units wrapping on a 4 nm diameter citrate capped AuNP. A 2D network model with 100 AuNPs (10*10*1) and a 3D network model with 125 AuNPs (5*5*5) are constructed by replicating the simple AuNP-PAH structure. The network connection is formed by thermally heating and is also manipulated by an external electric field. The effect of the AuNP volume fraction on network formation will also be reported. We find that these AuNP-PAH networks can process through information differently from existing computing architectures.

Non-Ohmic Behavior and Resistive Switching of Au Cluster-Assembled Films Beyond the Percolation Threshold Paolo Milani[1], Matteo Mirigliano[1], Francesca Borghi[1], Alessandro Podestà[1], Aleandro Antidormi[2] and Luciano Colombo[2]; [1]Università degli Studi di Milano, Italy; [2]Università degli Studi di Cagliari, Italy

Networks based on nanoscale resistive switching junctions are considered promising for the fabrication of neuromorphic computing architectures [1]. To date random networks of nanowires, nanoparticles, and metal clusters embedded in a polymeric matrix or passivated by shell of ligands or oxide layers have been used to produce resistive switching systems. The strategies applied to tailor resistive switching behavior are currently based on the careful control of the volume fraction of the nanoscale conducting phase that must be fixed close to the electrical percolation threshold.
Here, by blending laboratory and computer experiments, we demonstrate that metallic nanostructured Au films fabricated by bare gold nanoparticles produced in the gas phase and with thickness well beyond the electrical percolation threshold, show a non-ohmic electrical behavior and complex and reproducible resistive switching. We observe that the nanogranular structure of the Au films does not evolve with thickness: this introduces a huge number of defects and junctions affecting the electrical transport and causing a dynamic evolution of the nanoscale electrical contacts under the current flow. To uncover the origin of the resistive switching behavior in Au cluster-assembled films, we developed a simple computational model for determining the evolution of a model granular film under bias conditions. The model exploits the information provided by experimental investigation about the nanoscale granular morphology of real films.
Our results show that metallic nanogranular materials have functional properties radically different from their bulk counterparts, in particular nanostructured Au films can be fabricated by assembling bare gold clusters which retain their individuality to produce an all-metal resistive switching system [2].

Tunable Volatile and Non-Volatile Resistive Switching of Non-Stoichiometric CuOx Nanowire for Selector and Memory Application Chi-Hsin Huang[1], Kosuke Matsuzaki[2] and Kenji Nomura[1]; [1]University of California, San Diego, United States; [2]Tokyo Institute of Technology, Japan

Resistive random-access memory (ReRAM)/memristive devices based on electrical resistance switching are highly expected to overcome persistent technological limitations in current memory technology and to develop next-generation nonvolatile memory because of its superior characteristics. These characteristics include high speed, high scalability, low power consumption, fast fabrication process, multistate storage, and compatibility with complementary metal-oxide semiconductor (CMOS). Particularly, nanowire-based resistive switching devices offer an ideal platform for a deeper understanding of resistive switching properties due to the confined nanostructure and the opportunity to develop nanoscale-memristive device for next-generation memory and neuromorphic computing. In addition, copper oxide is one of the attractive candidates for ReRAM/memristor due to the existing multiple oxidation states from "+2" to metal state (CuO, Cu4O3, Cu2O, Cu) for inducing resistive switching, which is believed to involve the phase transition with multiple oxidation state induced by redox reaction. In this work, we report the volatile and non-volatile resistive switching effect in p-type non-stoichiometric CuOx nanowires, which are fabricated using insulator CuO nanowires via a thermal-annealing technique with hydrogen atmosphere. These resistive switching modes were effectively controlled by the stability of conductive filament via the compliance current in the SET process. The non-volatile resistive switching exhibited low electric-field-induced switching, high ON/OFF ratio of 107, and long retention time of 104 seconds for ReRAM application. On the other hand, the volatile threshold switching was operated with low compliance current for selector application, and the device showed bidirectional operation, selectivity (104), low OFF-current (<100 pA), and stable reliability with endurance over 105 cycles under pulse operation. The presented work will discuss a nanoscale resistive switching mechanism based on hole-based conducting filament formation originated from the local redox reaction.

6:10 AM F.NM07.10.07
Dissolution of Conductive Filaments by Heat in NiO-Based Resistive Switching Cells Yusuke Nishi and Tsunenobu Kimoto; Kyoto University, Japan

Resistive switching (RS) operations offer various useful applications for nonvolatile memories and neuromorphic computing. However, driving forces of the RS operations have remained unclear and controversial yet. We reported that conductance quantization in nickel-oxide (NiO)-based RS cells was observed upon a voltage sweep [1,2]. Moreover, not only conductance quantization but conductance fluctuations appeared in the cells by controlling amount of oxygen vacancies in NiO thin films [3]. In this study, disappearance conditions of conductance filaments are investigated through experiments and simulations.

A platinum (Pt) bottom electrode was deposited by sputtering on a silicon-dioxide/p-silicon substrate inserted by a titanium adhesion layer. An 80-nm-thick NiO layer as a resistance change material was subsequently deposited by radio-frequency reactive sputtering. The substrate temperature during sputtering was kept at 350°C. Pt top electrodes with a diameter of 100 μm were deposited on the NiO layer. As a result, a host of Pt/NiO/Pt RS cells were fabricated on the substrate. The first abrupt current jump by an initial voltage sweep to the cell made the cell conductance equivalent to the quantized conductance ($2e^2/h$), indicating the formation of a conductive filament with a quantum point contact (QPC). Moreover, conductance fluctuations before and after the abrupt current jump were observed in several cells.

We investigated temperature dependences of cell conductance upon heating the sample. While the conductance in several cells did not change between before and after heating to 400 K, the conductance in other cells decreased by the quantized conductance at 370 K, which means that the conductive filament with a QPC is possibly ruptured by heat at a temperature of merely 370 K [1]. In the same manner, we found that the conductance fluctuations, which originate from the modification of oxygen-vacancy densities at grain boundaries in the NiO layer, possibly disappeared upon heating to, at least, 470 K [3]. In contrast, a fat filament with higher conductance than the quantized conductance created by the conventional forming remained unchanged upon heating to 600 K during a few days. These results indicate a relatively small heat is sufficient for the disappearance of the conductance quantization and fluctuations.

We estimated the temperature rise owing to Joule heat to destroy the conventional fat filament by rough simulation using solvers of heat transfer, electric current, and (particle) diffusion in commercial software COMSOL Multiphysics. The diameter of a cylindrical conductive filament and the diffusion coefficient of oxygen vacancies are assumed to be 10 nm and 10^{10} m^2/s, respectively. The simulation revealed that an applied voltage required for reaching the maximum temperature of 600 K in the filament was 0.34 V, independent of the voltage sweep rate in the range from 0.01 to 1000 V/s. The estimated voltages for reset increased from 0.68 to 1.16 V as the sweep rate increased, which agrees with our experiments to reset upon voltage sweeps. Moreover, the estimated temperature at reset was turned out to be over 680 K. These results indicate that the

temperature required for the diffusion of oxygen vacancies is higher than 600 K. Comparing the simulation to the above heat experiments, temperature required for dissolution of the conductive filament with a QPC is estimated to be lower than 600 K, irrespective of external heat or Joule heat.

The conductance quantization seemed to be a special form of the conductance fluctuations. Although the fluctuations may have poor thermostability at the present, the fluctuations imply the existence of multilevel resistances, which offers the possibility of multiple discrete weighting of synaptic devices.

Energy-Effective Image Restoration Algorithms for Bioimages Enabled by Neuromorhpic Computing at Edge Charlotte Reed[1], Chanyeol Choi[2] and Jeehwan Kim[2]; [1]Independent Scholar, United States; [2]Massachusetts Institute of Technology, United States

The deep learning in medical image processing had a significant impact on computer-aided diagnosis for the last decade. Although the advanced medical image processing on deep learning allows improvements in image detection, recognition, segmentation, and registration, some of these applications still suffer from the low quality of input images directly from analogue sensors like photodetectors. Here we suggest that an energy-efficient neuromorphic computing platform where low-quality bioimages can be directly processed at edge without energy-hungry image signal processor (ISP). Even with a small convolutional kernel operation for image processing, a peak signal to noise ratio (PSNR) of images from GaAs detectors has been subsequently improved from 16.25 to 19.26 in ten random bio cell images with > 30 % energy savings compared to silicon-based ISP technology. In a segmentation task after image processing, a cell detection accuracy increases from 75 % to 95 % and an detection error rate decreases from 10 % to 2 %. We believe that our edge neuromorphic computing solution can offer fast image processing time and low energy consumption, and thus provide quick and reliable data while maintaining intuitive and safe image reading.

F.NM07.11.06
Modelling Electronic-Thermal-Driven Electrical Conduction in Analog-Based Memristor for Neuromorphic Computing Applications Qishen Wang[1], Karthekeyan Periasamy[1], Yi Fu[2], Ya-Ting Chan[2], Cher-Ming Tan[2], Natasa Bajalovic[1], Jer-Chyi Wang[2] and Desmond Loke[1]; [1]Singapore University of Technology and Design, Singapore; [2]Chang Gung University, Taiwan

Device transport processes in the switching of analog-based memristors rely on device conduction mechanism, whose complexity still cannot be captured by traditional modelling approaches. Here we apply the concept of the unique combination of electronic and thermal considerations to modelling device conduction in such systems. The approach can fully account for the rich conduction behavior, as well as analog-type resistive switching, and is therefore, ideal for device films, composites and other geometries. Modelling of the analog-based memristor agrees well with experimental data and reveals conduction behavior not yet captured by conventional models. Fitting of device measurements even allows conduction properties to be extracted, which are subsequently harnessed to guide the prediction of analog-based memristors with improved device performance. Our hybrid approach, together with a simple calculation tool, now allows researchers with limited computation experience to perform realistic simulations.

F.NM07.11.07
Dielectric Breakdown by Electric-Field Induced Phase Separation Dimitrios Fraggedakis and Martin Bazant; Massachusetts Institute of Technology, United States

The control of the dielectric and conductive properties of device-level systems is important for increasing the efficiency of energy- and information-related technologies. In some cases, such as neuromorphic computing, it is desirable to increase the conductivity of an initially insulating medium by several orders of magnitude, resulting in effective dielectric breakdown. Here, we show that by tuning the value of the applied electric field in systems with variable electric permittivity and conductivity, e.g. ion intercalation materials, we can vary the device-level electrical conductivity by orders of magnitude. We attribute this behavior to the formation of filament-like conductive domains that percolate throughout the system.

F.NM07.11.08
Correlation Between Depth Distribution of Chemical Compositions and Resistive Switching Characteristics in Metal/Ta_2O_5/Pt Cells Toshiki Miyatani, Yusuke Nishi and Tsunenobu Kimoto; Kyoto University, Japan

Resistive switching cells are one of the strong candidates for synaptic devices thanks to analog controllability of the cell resistance. Many previous studies have reported continuous increase in the cell resistance when a voltage is applied to the cell, so-called gradual reset [1]. Nevertheless, the origin of the gradual reset is not clear because it is extremely difficult to determine an ultrafine region where resistive switching occurs. In this study, we investigated depth distribution of chemical compositions in the entire fabricated sample by high-resolution Rutherford backscattering spectrometry (HRRBS) without sample sputtering. Moreover, we discuss correlation between the depth distribution and electrical characteristics in TaO_x-based resistive switching cells.

We fabricated two types of Metal/tantalum-oxide (Ta_2O_5)/platinum (Pt) stack structures on SiO_2/Si substrates. As common fabrication processes, a Pt bottom electrode was deposited by DC sputtering. Then, a Ta_2O_5 film was deposited by radio-frequency (RF) reactive sputtering. Finally, a metal layer was deposited by RF sputtering. We used nickel (Ni), titanium (Ti), and Ta as materials of the metal layer. As for one type of the Metal/Ta_2O_5/Pt structure, the metal layer covered a 5-nm-thick Ta_2O_5 film. The thickness of the metal layer was 10 nm. For these samples, we investigated depth distribution of chemical compositions by the HRRBS. The depth distribution can be obtained without sample destruction, which means intrinsic data are not hidden by a knock-on effect. Moreover, the HRRBS has a higher depth resolution on the order of nanometers than the normal RBS. Then, the actual depth distributions were obtained by fitting energy spectra simulated from assumed depth distributions to experimental energy spectra. Note that RBS measurements at two scattering angles of 77 and 122 degrees improved accuracy in the depth distributions by a comparison of the obtained data each other in the same sample. As for the other type of the Metal/Ta_2O_5/Pt structure, the metal layer was deposited with a thickness of 20 nm and a diameter of 150 μm by using a mask as a top electrode on a 10-nm-thick Ta_2O_5 film. We examined resistive switching characteristics for these Metal/Ta_2O_5/Pt cells at room temperature with the Pt bottom electrode grounded.

Comparing the depth distributions of the as-deposited Metal/Ta_2O_5/Pt samples, thickness of the oxygen diffusion area in the Metal/Ta_2O_5 interface, which is less than 10 nm, increased in the order of Ni/Ta_2O_5/Pt, Ta/Ta_2O_5/Pt, and Ti/Ta_2O_5/Pt samples. The diffusion of oxygen from the Ta_2O_5 film to the metal layer corresponds to supply of oxygen vacancies from the metal layer to the Ta_2O_5 film. Here, the standard Gibbs energy of oxide formation of the metal layer is −4.39 eV (Ni), −7.92 eV (Ta), and −9.21 eV (Ti) [3], indicating that more oxygen vacancies tend to be supplied to the Ta_2O_5 film as the magnitude of the standard Gibbs energy is higher.

The Ni/Ta_2O_5/Pt cells show relatively high initial resistance at 0.1 V of roughly 10^{12} Ω before a forming process. On the other hand, the Ti/Ta_2O_5/Pt cells show lower initial resistance of about 10^6-10^9 Ω because more oxygen vacancies are supplied to the Ta_2O_5 film. Furthermore, when a negative voltage is applied to the Ni/Ta_2O_5/Pt cells, the cell resistance abruptly increases, approximately at −1 V from 100 Ω to 10 MΩ. In contrast, in the case of the Ti/Ta_2O_5/Pt cells, the cell resistance gradually increases from 1 kΩ to 100 kΩ when a voltage is applied from −1 V to −3 V.

These results suggest that the analog controllability of the cell resistance in the reset processes can be improved by supplying a larger number of oxygen vacancies to the Ta_2O_5 film.

Post Metallization Annealing Effect Utilizing Pt Gate Electrode for MFSFET with Ferroelectric Nondoped HfO_2 Formed by Ar/O_2-Plasma Sputtering Shun-ichiro Ohmi, Masakazu Kataoka and Masaki Hayashi; Tokyo Inst of

Technology, Japan

Introduction
Ferroelectric nondoped HfO_2 has advantages compared to the doped HfO_2 in the reduction of crystallization temperature and threshold voltage (V_{TH}) control to realize the Metal-Ferroelectrics-Si FET (MFSFET) [1,2]. We have reported that the ferroelectric nondoped HfO_2 formation on the Si(100) substrates by controlling the Ar/O_2 flow ratio during the reactive sputtering [3-5]. In this paper, we have investigated the effect of post metallization annealing (PMA) utilizing Pt gate electrode for the MFSFET with ferroelectric nondoped HfO_2 gate insulator.

Experimental Procedure
After the active region patterning, n^+ source/drain (S/D) ion implantation was carried out followed by the activation annealing at 900°C/20 min in N_2 ambient. Then, the 1 nm thick Hf interlayer was deposited to improve the film quality followed by the 20 nm thick HfO_2 in-situ deposition at room temperature (RT) by the RF magnetron sputtering with the Ar/O_2-plasma utilizing Hf target. The flow rate of Ar for Hf interlayer and Ar/O_2 for HfO_2 was 3.6 and 2.3/0.5 sccm, respectively, with the sputtering power of 60 W. Then, the 20 nm thick Pt gate electrode (G) was in-situ deposited at RT with the Ar flow rate of 4.4 sccm and the sputtering power of 80 W. Next, the S/D contact region was patterned followed by the Pt layer deposition for S/D. Then, PMA was carried out at 600°C/30 s in N_2 ambient followed by the G and S/D patterning. The gate length (L) and width (W) was 10/90 μm. The MFS diodes were fabricated in a same process, and the post deposition annealing (PDA) was also examined utilizing evaporated Al gate electrode for the comparison.

Results and Discussion
The remnant polarization ($2P_r$) of 2.5 $\mu C/cm^2$ was obtained from the P-V characteristics for the MFS diodes formed by the PMA process under the ±8 V sweep which is larger than the $2P_r$ of 2.3 $\mu C/cm^2$ for the MFS diodes formed by the PDA process. From the C-V characteristics, the memory window (MW) was markedly increased from 0.22 V for the MFS diodes formed by the PDA process to 0.44 V for the MFS diodes formed by the PMA process. This is due to the enhancement of the orthorhombic phase HfO_2 formation by the PMA process which was confirmed by the grazing incident x-ray diffraction (GI-XRD) observation. The physical thicknesses were confirmed as 3.6 nm for SiO_2 interfacial layer (IL) and 20.8 nm for HfO_2 from the cross-sectional transmission electron microscopy (TEM) image. By considering the coercive voltage (V_c) of 1.08 V extracted from the P-V characteristics, the coercive field (E_c) was estimated as 0.52 MV/cm. The ferroelectric HfO_2 formation without doping realized the lower E_c compared to the reported data for the doped HfO_2.
Next, the MFSFET fabricated utilizing PMA process was evaluated. From the I_D-V_G characteristic, MW of 0.41 V was obtained under the V_G sweep from -1 V to 3 V. The program and erase (P/E) characteristics were also examined. The MW obtained from the threshold voltage (V_{TH}) difference of 0.41 V were also confirmed utilizing the P/E pulses of -5.5 V/100 ms and 6.5 V/100 ms, respectively. The MW of 0.15 V was obtained even at the P/E pulse width of 100 ns.

Conclusions
In this paper, we investigated the effect of PMA for the device characteristics of MFSFET with ferroelectric nondoped HfO_2 formed by the Ar/O_2-plasma sputtering. It was found that the small E_c was obtained for the 20 nm thick ferroelectric nondoped HfO_2. Furthermore, the MW of 0.15 V was realized under the P/E pulse width of 100 ns with P/E voltages of -5.5 V and 6.5 V, respectively.

"Metal-Organic Frameworks × Ionic Liquids" as an Electrolyte for Conductive Bridge Random Access Memory Sang-Gyu Koh and Kentaro Kinoshita; Tokyo University of Science, Japan

Conductive bridge random access memory (CBRAM) is one of the most promising nanodevices for future information technology with applications not only for memory, but also for logic and neuromorphic computing because of its low power consumption and response times in the nanosecond range, as well as scalability down to the atomic level [1]. Recently, we

have reported that several drastic improvements for controllability of memory performance can be achieved by using ionic liquids (ILs) as a tunable solvent supplied into the grain boundaries of metal oxide film [2, 3]. We focused, as a next step, on the electrolyte engineering, in which the electrolyte should not be regarded as a diffusive medium for the migration of metal ions as ever but should be regarded as a porous body retaining ILs which mediates the ion migration in it. Metal-organic frameworks (MOFs), which is three-dimensional nanoporous materials composed of metal ions and organic ligands coordinated together, are the best candidate for the porous body retaining ILs without compromising their features owing to structural and functional flexibility in the design for uniformly sized nanopores, as well as relatively high thermal stability [4]. Although there are some reports so far that investigate the electrical characteristics of MOFs, most of their experiments has been done using pellet or polycrystalline film samples from which it is difficult to extract intrinsic bulk properties due to a lot of grain boundaries [5]. Moreover, ILs-loaded MOFs for the application of CBRAM has not yet been discussed so far. In this work, basic investigations in terms of electrical properties for HKUST-1 (Cu_3(1,3,5-benzenetricarboxylic acid)$_2$), which is to be easily synthesized and stable in air, were carried out using single crystalline sample. We clarified the dominant conduction mechanism of the HKUST-1 single crystals which include much less grain boundaries, by measuring the electrical conductivity as functions of a bias voltage, temperature and humidity. Ion conductivities of the IL ([emin][TFSI] (1-ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)-imide)) loaded into the nanopores of HKUST-1 single crystal were compared with that of bulk IL as a function of temperature using electrochemical impedance spectroscopy. The both activation energies extracted from the temperature dependence of ion conductivities were comparable, suggesting that the HKUST-1 enables to retain the IL without compromising its original property. We, furthermore, demonstrated by means of electromotive force measurement that the ionization of the electrochemically active electrode in a Ag/HKUST-1/Au structure under bias voltage, which is the first important step in CBRAM operation, was drastically promoted by loading the IL into the nanopores of HKUST-1. The ILs-loaded MOFs system provides a novel electrolyte which endow CBRAM with further improved memory performance.

Complex Electrical Spiking Activity in Resistive Switching Nanostructured Au Two-Terminal Devices Paolo Milani[1], Matteo Mirigliano[1], Davide Decastri[1], Alberto Pullia[1], Alberto Casu[2] and Andrea Falqui[2]; [1]Università degli Studi di Milano, Italy; [2]King Abdullah University of Science and Technology, Saudi Arabia

Networks of nanoscale objects are subject of increasing interest as resistive switching systems for the fabrication of neuromorphic computing architectures. Nanostructured films of bare gold clusters produced in gas phase with thickness well beyond the electrical percolation threshold, show a non-ohmic electrical behavior and resistive switching resulting in groups of current spikes with irregular temporal organization [1]. Here we report the systematic characterization of the temporal correlations between single spikes and spiking rate power spectrum of nanostructured Au two-terminal devices consisting of a cluster-assembled film deposited between two planar electrodes. By varying the nanostructured film thickness we fabricated two different classes of devices with high and low initial resistance respectively. We show that the switching dynamics can be described by a power law distribution in low resistance devices whereas a bi-exponential behavior is observed in the high resistance ones [2]. The measured resistance of cluster-assembled films shows a 1/f^α scaling behavior in the range of analyzed frequencies. Our results suggest the possibility of using cluster-assembled Au films as components for neuromorphic systems where a certain degree of stochasticity is required.

Investigation and Characterization of the Annealing Effects on the Ferroelectric Behavior of $BaTiO_3$ Deposited by Pulsed Laser Deposition Joshua Mayersky[1], Albert Hilton[2], Shanee Pacley[3], Rashmi Jha[1] and Amber N. Reed[3]; [1]University of Cincinnati, United States; [2]KBR, United States; [3]Air Force Research Laboratory, United States

In pursuit of the goal of mimicking how the human brain learns and functions, emulation of synaptic plasticity, i.e. the ability of synapses to strengthen or weaken over time, is a critical requirement for the implementation of learning in neuromorphic systems. Finding the proper materials to synthesize nanoscale synapses and neurons that are reliable, durable, replicable and scalable remains a challenge. Recent developments on ferroelectric field effect transistor based non-volatile memory are

encouraging in this respect; in particular, their multiple threshold voltage states based on the polarization state of a ferroelectric oxide may offer a suitable structure for synaptic applications. This work investigates the ferroelectric behavior of $BaTiO_3$ (BTO) with and without annealing of the deposited film. 100 nm of BTO was deposited via Pulsed Laser Deposition (PLD) on a Niobium doped Strontium Titanate (Nb:STO) substrate. The process parameters included a temperature of 750 °C, an operating pressure of 10 mTorr under 35 sccm of O_2, and a laser energy of 300 mJ. After deposition, the film was characterized via a coupled 2-theta-omega X-Ray Diffraction (XRD) scan; looking for the peak associated with the tetragonal phase of BTO. This was followed by characterizing the poling/switching characteristics using Piezoresponse Force Microscopy (PFM). Following these initial characterizations, the film was subjected to a 30 minute anneal at 850 °C in 100 Torr of O_2. After this annealing step, the film was once again re-characterized using XRD and PFM. The BTO 2-Theta peak shifted from the annealed vs. non-annealed sample, to around 44.2 °, closer to the expected value for the tetragonal phase. A small region was then poled at +5 V, and the phase of the film monitored for the next 24 minutes. The poling did not result in any damage nor oxidation to the surface, which differed from the non-annealed BTO film. No degradation in the poled region was visible for the duration of measuring, whereas for the non-annealed film, the poled region started relaxing after 8 minutes. Finally, 100 nm of W was sputtered and patterned into 100 µm by 100 µm contact pads, and the film was subjected to electrical testing. This consisted of a forming sweep (PUND – Positive, Up, Negative, Down) of varying pulse lengths and amplitudes, followed by a hysteresis sweep of varying pulse lengths and amplitudes. For each test, an average was taken from 3 different devices. For a given forming sweep amplitude, pulse length, and a hysteresis sweep amplitude, an increasing pulse length of the hysteresis sweep resulted in an increase in the measured remnant polarization from 1.3 $\mu C/cm^2$ to 6 $\mu C/cm^2$. Similarly, for all other variables constant, an increase in the pulse length of the forming sweep resulted in an increase in the remnant polarization from 3.53 $\mu C/cm^2$ to 5.73 $\mu C/cm^2$. And again, all other variables constant, an increase in the forming amplitude resulted in an increased remnant polarization from 2.9E-3 $\mu C/cm^2$ to 5.9 $\mu C/cm^2$. Here we demonstrate multiple, distinct polarization states of BTO as a function of the forming and hysteresis sweep pulse lengths and amplitudes.

Late News: Modeling Resistive Switching in Nanogranular Metal Films Walter Tarantino and Luciano Colombo; Università degli Studi di Cagliari, Italy

Nanogranular golden films present an interesting resistive switching behavior that can be exploited in the designing of components for neuromorphic computing. Its investigation has started only recently [Mirigliano *et al.* 2019, Mirigliano *et al.* 2020] and the underlying microscopical physical mechanisms are far from being clear. We address the challenge of its theoretical charaterization from the limited information on the microscopic structure of the films with the tools of Effective Mean Theory, and present a model for thermally regulated local structural rearrangements that may explain the observed data.

SESSION F.SM01.10: Live Keynote I: Lessons from Nature—From Biology to Bioinspired Materials
Session Chairs: Boaz Pokroy and Nicolas Vogel

8:00 AM *F.SM01.04.01
Skeletons with Eyes Joanna Aizenberg; Harvard University, United States

The most finely tuned, rapidly responsive, and precisely directed optical systems currently known can be found on the surfaces of living organisms. Studies of brittlestars' tunable microlenses, sea sponges' optical fibers, butterflies' and beetles' intense colors, and squids' nearly perfect camouflage have revealed 3D architectures so intricately patterned down to the nanoscale that the topography itself controls the wavelengths and direction of reflected light. We are developing bioinspired, bottom-up self-assembly techniques that allow us to create comparably elaborate yet tunable hierarchical photonic structures, and integrate these into the design of a new class of dynamic, responsive optical materials.

Organisms Manipulate Light with Nano-Scale Crystal Mirrors Benjamin A. Palmer, Gan Zhang, Ofir Friedman, Anna Hirsch, Venkata J. Yallapragada, Dan Oron, Leeor Kronik, Leslie Leiserowitz, Steve Weiner and Lia Addadi; Weizmann Institute of Science, Israel

Organisms construct 'devices' based on assemblies of organic nano-crystals with optical functions. The structure, polymorph, size, morphology and superstructural arrangement of the crystals determine the optical properties of the 'device'. All the crystals have unusually high refractive indexes in the directions along which the light penetrates the crystal. The controlled assembly of nano-crystals forms multilayer reflectors that create structural colors, or mirrors and light scattering layers that function to increase vision sensitivity in the eyes of the organisms. Scallops have tens of eyes, each containing a concave multi-layered mirror perfectly tiled with a mosaic of square guanine crystals, made up of composite twins, reflecting light to form images onto the overlying retinas [1]. Crustacean decapods such as shrimps, crayfish and lobsters possess compound eyes that contain two sets of mirrors, composed of isoxanthopterin crystals. The two mirrors have very different ultrastructures and functions that we can rationalize in terms of the optical performance of the eye [2,3]. The unusual zander fish eyes contain two layers of organic crystals: thin guanine crystals, form a reflective layer in the back of the eye, whereas block-shaped crystals of 7, 8-dihydroxanthopterin in the inner tapetum layer back-scatter light onto the retina, increasing the light sensitivity of the eye [4]. Finally, insects commonly known as jumping bristletails, form large amounts of xanthine crystals in their median and lateral ocelli [5]. The structure-function relations in this last example are still under investigation. In all these examples, the constituent molecules are mostly purines and pteridines, which raises the question of what molecular and structural characteristics of these crystals, favor their use for optical functions in organisms. Furthermore, the organization of the crystalline functional components is controlled from the crystal structure at the nanoscale to the complex 3D structure at the millimeter level, extending the interest in the relation between structure and optical properties to higher hierarchical levels.

Bone—Deciphering the Tissue Organization and Materials Properties in 3D Using FIB SEM Steve Weiner[1], Emeline Raguin[1], Neta Varsano[1], Heden Haimov[1], Lia Addadi[1] and Ron Shahar[2]; [1]Weizmann Institute of Science, Israel; [2]Hebrew University, Israel

Bone is both a tissue, comprising cells, vasculature and extracellular matrix, and a material comprising mainly mineral, collagen and water. It is thus a challenge to characterize bone's 3D structural organization in order to gain insights into how bone forms and functions. Focused ion beam-scanning electron microscopy (FIB SEM) can provide information at nanometer resolution to enable, for instance the identification of the collagen D-banding. At this resolution the spatial arrangement of fibrils can be assessed in volumes of thousands of microns cubed which can include tissue components. For example, examination of mineralized osteonal pig bone shows unidirectional collagen arrays oriented alternatively in different directions or changing direction progressively. These unidirectional arrays are separated by layers of collagen organized in a bidirectional patchwork motif. Earlier studies of demineralized lamellar bone showed that the layers with the patchwork motif stain heavily with osmium and Alcian Blue and have a disordered appearance.
Another example is the cryo- FIB SEM examination after cryo-fixation and under cryo-conditions, of the mineralized murine growth plate. It reveals the presence of a complex zone that includes blood vessels with mineral containing vesicles, blood vessel extremities surrounded by bone mineralizing matrix, and cartilage hypertrophic cells surrounded by ordered and disordered cartilage mineralizing matrix.
By exploiting the options for examining mineralized bone, demineralized bone matrix and the soft tissue components as well as the bone, FIB SEM can provide invaluable insights into bone organization. By combining FIB SEM in a correlative manner with 3D confocal light microscopy and microCT, it will be possible to address many fundamental questions in bone biology and mechanics.

9:30 AM *F.SM01.01.03
Osmotic Force Generation in Biological Materials Peter Fratzl; Max Planck Institute of Colloids and Interfaces, Germany

Biological extracellular tissues are based on proteins, polysaccharides and, in certain cases, minerals. Their complex multiscale structure confers them a wide range of properties in accordance with the tissues' functions. While active functionality are usually attributed to cells, there are also examples of materials synthesized by living organisms, such as plant seeds, which fulfil an active function without living cells and work as mechanosensors and actuators. Water is an important component of all such extracellular tissues. While it is well known that the level of hydration determines the mechanical properties of many biological materials, it is less appreciated that water also plays an active role in generating forces within the materials. In particular water absorption and desorption provides actuation in a variety of plant seeds, including wild wheat, stone plant and banksia seed capsules. The shape change upon water uptake that provides the actuation is controlled by specific cellulose fibre architectures. In this way, well-controlled movements, such as bending, twisting or curling are programmed in these materials by structure of the underlying cellulose microarchitecture. The required deformation energy is provided by the absorption of water from the environment. Finally, the absorption of water to specific molecules and the resulting osmotic pressure is also providing internal stresses which control, for example, the mechanical behaviour of collagen in tendon, bone and dentin. The lecture will review general concepts for the roles of water in biological materials, both in the context of biology and of bioinspired engineering.

3D Materials Systems as Bioelectronic Neural Interfaces and Bioinspired Passive Microfliers John A. Rogers;

Northwestern University, United States

3D mesostructures represent essential, ubiquitous design features in biology, from the spherical constructs of living organoids to the aerodynamic shapes of swirling maple seeds. This talk presents our work in two corresponding areas of 3D materials engineering. The first focuses on mechanically compliant, 3D multifunctional neural interfaces to cortical spheroids and assembloids. Detailed studies of the spreading of coordinated bursting events and the cascades associated neuroregeneration represent two of the many opportunities in neuroscience research uniquely enabled by these platforms. The second area is in exploratory 3D materials architectures that mimic the aerodynamic features of gliding, spinning and twirling seeds that facilitate their dispersal. The talk will emphasis both basic and applied aspects of these two distinct classes of materials systems.

5:39 PM *F.SM01.07.04
Bio-Inspired Photosynthetic, Robotic and Bioactive Materials Samuel I. Stupp; Northwestern University, United States

The soft and hard materials that make up biological systems are a great source of inspiration in materials science for design of functional systems, particularly those that are critical in supporting the most intelligent processes in the plantea and animalia kingdoms. Great ideas from these systems include, the notion of self-assembly and reversible formation of structures, creating adaptive behaviors for specific environments, materials with capacity for self-repair, the engineering of autonomous motion, and the integration of multiple functions in a single structure, among many others. In this lecture bio-inspired synthetic systems are described based on supramolecular polymers as well as “hybrid bonding polymers (HBPs), which we define as materials that rationally integrate covalent and supramolecular polymers. HBPs are biomimetic structures critical in systems such as biological membranes, muscles, tendons, and the cytoskeleton. One of the systems to be described is based on supramolecular polymers that are highly dynamic and therefore strongly effective at signaling cells for regeneration. The lecture will also describe photosynthetic materials, inspired by leaves, in which HBPs are used to couple light harvesting assemblies and catalysts to make fuels. Finally robotic materials that emulate living creatures will be discussed in which HBPs or organic-metal hybrid hydrogels are configured to respond to light and magnetic fields in order to generate locomotion of macroscopic objects on surfaces.

6:03 PM *F.SM01.07.02
A Portable, Biologically-Inspired Platform for Color and Pattern Sensing and Display Leila Deravi; Northeastern University, United States

A small number of animals have the ability to actively change their visual appearance to perform important biological tasks. Cephalopods rank high on this list due to their ability to rapidly change color and texture - in some cases - for defense and signaling and have been a source of inspiration for the design of next generation adaptive systems. Recently, the electrochemical properties of the primary pigment found in cephalopod skin, xanthommatin, have been harnessed and applied in color-switching electrochromic displays with low power requirements. We describe the translation of this technology into a compact form factor that can sense and measure color from the environment then activate spatially patterned coloration with rapid (ca. seconds) response times. Our device uses reflectance-based sensors to measure color then triggers the formation of hue matched patterns by arrayed display components that can match and/or “hide” on surfaces of varying geometry, color, and luminous intensity. In future iterations of our approach, these principles may be applied to expand the palette of measured and displayed colors or to construct soft, deformable systems that can alter their optical signatures in response to environmental cues.

6:27 PM *F.SM01.02.01
Bio-Enabled Nanocomposites with Unique Physical Properties Vladimir Tsukruk; Georgia Institute of Technology, United States

Bio-enabled nanocomposites represent a novel class of functional bioderived materials, which uses principles of bioinspiration and biomimetic to design hierarchically organized hybrid materials with co-assembled biological and synthetic components to bring best of synthetic and biological worlds: versatile functions with responses to mechanical, optical, chemical, and light stimuli and mechanical strength, flexibility, biocompatibility, and environmental robustness [1, 2]. In first set of examples, we discuss uniformly aligned chiral bio-photonic films from a liquid crystal phase formed by a cellulose nanocrystal solution placed in a thin capillary [3]. This spatial and fluidic flow confinement facilitates homogeneous growth of chiral pseudo-layers parallel to the interface in contrast to the highly heterogeneous assembly of random tactoids. The resulting iridescence films show a narrower optical reflectance band and uniform birefringence over larger macroscopic regions than heterogeneous conventional drop-cast films. In another example, enhanced chiral properties of organized helical

patterned films with high asymmetry of circular polarization have been template-assembled via preferential orientation of high-aspect cellulose nanocrystals onto optical microgrids [4]. Bright chiral emission has been co-assembled in organized biopolymer photonic films from core-shell nanorods of cellulose nanocrystals and co-assembled carbon quantum dots mediated by polymer linkers [5]. Finally, co-assembly of cellulose nanocrystals with amorphous polysaccharides resulted in the formation of robust and flexible films with the preservation of the original structural photonic and fine control of the pitch length due to intimate intercalation of macromolecular backbones into the interstitial nanoscale pores of neighboring nematic monolayers [6].

Exploiting Supramolecular Associations in Interpenetrating Networks and Elastomers LaShanda Korley and Chase Thompson; University of Delaware, United States

Supramolecular interactions may hold the key to the development of network systems with tunable mechanics and modulated architecture, such as observed in the muscle protein titin. It is the dynamic nature of these physical associations that we have exploited in the design of tough supramolecular materials that super-impose covalent and non-covalent interactions to tailor tensile response. We have developed supramolecular elastomers and interpenetrating network (IPN) systems that probe the interplay of non-covalent and covalent interactions in structural organization and mechanical response. By tailoring physical associations via control of self-assembly and composition, we have demonstrated enhanced supramolecular dynamics driven by architecture and toughness enhancements due to phase behavior. Recently, non-covalent interaction strength, network regularity, and chemoresponsiveness have been utilized as handles to derive gradient materials and to induce actuation behavior. New insights into supramolecular nanoscomposites are also highlighted.

Chemically Controlled Shape-Morphing of Elastic Sheets Anna C. Balazs[1], Raj K. Manna[1], Oleg E. Shklyaev[1] and Howard A. Stone[2]; [1]University of Pittsburgh, United States; [2]Princeton University, United States

The shape-morphing of two-dimensional elastic materials into three-dimensional structures is a vital and ubiquitous transformation in biological systems, as evidenced, for example, by the morphogenesis in cells and tissues, the formation of well-defined curvatures in growing flowers and leaves, and reconfiguration of seedpods in the release of seeds. The functionality of such biological reconfigurations has inspired the development of synthetic shape-changing materials that are useful for soft robotics and soft actuators. Here, we use theory and simulation to devise a distinctive approach for driving shape changes of 2D elastic sheets in fluid-filled microchambers. The sheets are coated with catalyst to generate controllable fluid flows, which transform the sheets into complex 3D shapes. A given shape can be achieved by patterning the arrangement of the catalytic domains on the sheet and introducing the appropriate reactant to initiate a specific catalytic reaction. Moreover, a single sheet that encompasses multiple catalytic domains can be transformed into a variety of 3D

shapes through the addition of one or more reactants. Materials systems that morph on-demand into a variety of distinct structures can simplify manufacturing processes and broaden the utility of soft materials.

Diffusiophoresis—From Physicochemical Effects to Biofilm Mitigation Howard A. Stone; Princeton Univ, United States

Diffusiophoresis refers to the motion of colloid materials in concentration gradients. I describe some of our studies of these problems, using experiments and mathematical modeling, such as the influence of ion valence and the effect of multiple electrolytes. Also, we demonstrate that these effect can influence of the movement of bacteria. For example, I summarize our observations of the migration of wild-type V. cholerae and a mutant lacking flagella (ΔflaA), as well as S. aureus and P. aeruginosa, near a dissolving CO2 source, which shows that diffusiophoresis of bacteria is independent of shape and Gram stain. With long-time experiments, we show that CO2-driven diffusiophoresis can reduce surface contamination, which suggests that the mechanism can be applied to cleaning systems and anti-biofouling surfaces. This work involves contributions from Suin Shim, who investigated the diffusiophoretic response of bacteria, as well as Ankur Gupta, Jessica Wilson and others in my research group.

7:30 PM *F.SM01.05.02
Bioinspired Assembly and Collective Motion of Nanocomposite Hydrogel Sheets at Air/Water Interfaces Ryan C. Hayward; University of Colorado Boulder, United States

We describe a platform of temperature-responsive hydrogel nanocomposites adsorbed at air/water interfaces that exhibit a variety of bioinspired non-equilibrium behaviors due to temperature gradients generated by illumination with visible light. In one example, we exploit spatial variations in thermally-induced deswelling of the gel particles to drive buckling of thin sheets into 3D shapes with non-zero Gaussian curvature. Similar to the mechanism exploited by numerous insects to climb menisci or drive clustering, pinning of the three-phase contact line at the sheet edges gives rise to capillary ‘multipole’ interactions between different objects, leading to assembly, repulsion, and even sustained rotational motion, depending on the geometry. In a second example, we exploit Marangoni forces resulting from temperature gradients to drive motion and interaction of planar particles, once again inspired by well-known strategies employed by aquatic insects. A simple method for Marangoni optical trapping is realized by shining appropriate patterns of light on the interface, enabling the definition of easily customized geometries in which to study coupled motion of multiple oscillators and spinners.

8:00 PM *F.SM01.01.04
Mapping the Phase Space of Protein Encapsulation via Complex Coacervation Whitney C. Blocher McTigue, Xianci Zeng and Sarah L. Perry; University of Massachusetts Amherst, United States

The encapsulation of biomacromolecules is an important area of research, particularly in the context of medicine where increasing numbers of therapeutics are protein based. One particular encapsulation strategy takes advantage of the associative liquid-liquid phase separation phenomena known as complex coacervation. The self-assembly of complex coacervates is spontaneous, driven by electrostatic attractions and the entropic gains associated with the release of small ions upon complexation. Furthermore, coacervation enables the sequestration of therapeutic proteins and other cargo at high concentrations, and without the need for organic solvents.

A number of recent studies have highlighted strong parallels between the dense, polymer-rich droplets resulting from coacervation and membraneless organelles that have been observed in cells. Of particular interest is the ability of these liquid-liquid phase separated granules to recruit specific proteins, RNAs, and other biomolecules, either for storage in times of stress, or as a hub of catalytic activity. Inspired by these biological structures, we look to understand the design rules whereby complex coacervation can be used to encapsulate and potentially stabilize cargo proteins. Our work focuses on complex coacervation involving two oppositely-charged polypeptides and a cargo protein. The use of two-polymer coacervates allows for the encapsulation of even weakly charged proteins at a variety of different conditions, even near their isoelectric point. We look to map out range of conditions where both phase separation is observed, and the degree to which proteins are incorporated into the coacervate phase as a function of the composition of the two polymers and the encapsulated protein. Preliminary results suggest the potential for using the protein itself as a majority component of the coacervate to achieve incorporation at levels that could be used for therapeutic injection. We intend to use proof-of-concept studies with model proteins as a foundation upon which further research into therapeutic proteins can be built.

A Study on the Mechanical Properties of a Natural and Chemically Functionalized Chitin Structure Devis Montroni, Simona Fermani and Giuseppe Falini; Alma Mater Studiorum, University of Bologna, Italy

In this presentation two case of studies involving the use of the protein wrapped β-chitin matrix from the squid pen *Loligo vulgaris* are presented.
In the first one we addressed how the mechanical properties of the squid pen are related to intra- and inter- interactions among chitin and proteins. Chemical treatments were applied to modify the interactions involving proteins, through unfolding and/or degradation processes. The data analysis showed that chemical treatments did not modify the multi-scale hierarchical structure of the β-chitin matrix. This allowed to derive from the mechanical test analysis the following conclusions: (i) the maximum stress (σ_{max}) relies on the presence of the disulfide bonds; (ii) the Young's modulus (E) relies on the overall correct folding of the proteins; (iii) the whole removal of proteins induces a decrease of E (> 90%) and σ_{max} (> 80%), and an increase in the maximum elongation. These observations indicate that in the chitin matrix the proteins act as a strengthener, which efficacy is controlled by the presence of disulfide bridges. This reinforcement links the chitin fibrils avoiding them to slide one on the other and maximizing their resistance and stiffness.[1]
In the second case of study the multi-scale hierarchical structure of the β-chitin matrix used as substrate to prepare new materials bio-inspired. Finding inspiration from the byssus, and with the aim to mimic its peculiar mechanical properties, we chemically functionalize the chitin matrix with catechols, the main functional group of the byssus. The obtained functionalized matrix preserves its multi-scale structural organization and is able to chelate reversibly Fe(III). Thus, it behaves as the byssus, acting as a metal cross-linkable matrix that upon metalation increases the Young‘s modulus, E (> 10 times). This new material can be further cross-linked by oxidation of the catechols. This process generates an increase of the E (> 10 times) and first failure stress (> 5 times). The combination of oxidation and metalation of the functionalized matrix only slightly increases the mechanical properties. The produced stimulus responsive materials show that levels of complexity can be added to a multi-scale organized natural hierarchical matrix providing new properties.[2]
In conclusion we showed that the mechanical properties of the squid pen are controlled by the di-sulfide bonds and that its multi-scale organized β-chitin matrix can be chemically functionalized providing additional properties.

Colour Engineering—Form Nature to Applications Silvia Vignolini; University of Cambridge, United Kingdom

The most brilliant colours in nature are obtained by structuring transparent materials on the scale of the wavelength of visible light. By controlling/designing the dimensions of such nanostructures, it is possible to achieve extremely intense colourations over the entire visible spectrum without using pigments or colourants. Colour obtained through a structure, namely structural colour, is widespread in the animal and plant kingdom [1]. Such natural photonic nanostructures are generally synthesised in ambient conditions using a limited range of biopolymers.
In this seminar, I will review our recent advances to fabricate bio-mimetic photonic structures with cellulose and chitin and I will give examples of how to fabricate novel photonic materials based on chiral nematic architectures using low-cost polymers in ambient conditions [2-7].

Bio-Inspired Hierarchical Porous Materials Made by 3D Printing André R. Studart; ETH Zurich, Switzerland

Hierarchical porous materials are attractive structures for a variety of applications due to their enhanced mechanical efficiency and their high surface area with minimum permeability loss. Nature showcases remarkable examples of hierarchical porous materials that benefit from such unusual set of properties, including bamboo, bone, marine sponges and wood. However, synthetic porous materials have yet to reach the elaborate architectural design found in their biological counterparts. To fill this gap, processing routes that enable deliberate control over the material's porous structure at multiple length scales are highly demanded. In this talk, I will show how 3D printing technologies can be exploited to fabricate hierarchical porous materials with unprecedented mechanical efficiency and architectural control. The key feature of our approach is to design inks with an internal structure that serves as a template for the formation of tailored pores within the printed object. Using oil droplets, air bubbles or phase-separating mixtures as templating structures, this methodology enables independent tuning of porosity and pore sizes at multiple length scales. To demonstrate the potential of the process, we 3D printed complex-shaped parts with bioinspired multiscale porosity and enhanced mechanical efficiency that cannot be achieved through conventional fabrication technologies.

A Study on the Mechanical Properties of a Natural and Chemically Functionalized Chitin Structure Devis Montroni, Simona Fermani and Giuseppe Falini; Alma Mater Studiorum, University of Bologna, Italy

In this presentation two case of studies involving the use of the protein wrapped β-chitin matrix from the squid pen *Loligo vulgaris* are presented.
In the first one we addressed how the mechanical properties of the squid pen are related to intra- and inter- interactions among chitin and proteins. Chemical treatments were applied to modify the interactions involving proteins, through unfolding and/or degradation processes. The data analysis showed that chemical treatments did not modify the multi-scale hierarchical structure of the β-chitin matrix. This allowed to derive from the mechanical test analysis the following conclusions: (i) the maximum stress (σ_{max}) relies on the presence of the disulfide bonds; (ii) the Young's modulus (E) relies on the overall correct folding of the proteins; (iii) the whole removal of proteins induces a decrease of E (> 90%) and σ_{max} (> 80%), and an increase in the maximum elongation. These observations indicate that in the chitin matrix the proteins act as a strengthener, which efficacy is controlled by the presence of disulfide bridges. This reinforcement links the chitin fibrils avoiding them to slide one on the other and maximizing their resistance and stiffness.[1]
In the second case of study the multi-scale hierarchical structure of the β-chitin matrix used as substrate to prepare new materials bio-inspired. Finding inspiration from the byssus, and with the aim to mimic its peculiar mechanical properties, we chemically functionalize the chitin matrix with catechols, the main functional group of the byssus. The obtained functionalized matrix preserves its multi-scale structural organization and is able to chelate reversibly Fe(III). Thus, it behaves as the byssus, acting as a metal cross-linkable matrix that upon metalation increases the Young‘s modulus, E (> 10 times). This new material can be further cross-linked by oxidation of the catechols. This process generates an increase of the E (> 10 times) and first failure stress (> 5 times). The combination of oxidation and metalation of the functionalized matrix only slightly increases the mechanical properties. The produced stimulus responsive materials show that levels of complexity can be added to a multi-scale organized natural hierarchical matrix providing new properties.[2]
In conclusion we showed that the mechanical properties of the squid pen are controlled by the di-sulfide bonds and that its multi-scale organized β-chitin matrix can be chemically functionalized providing additional properties.

Osmotic Force Generation in Biological Materials Peter Fratzl; Max Planck Institute of Colloids and Interfaces, Germany

Biological extracellular tissues are based on proteins, polysaccharides and, in certain cases, minerals. Their complex multiscale structure confers them a wide range of properties in accordance with the tissues' functions. While active functionality are usually attributed to cells, there are also examples of materials synthesized by living organisms, such as plant seeds, which fulfil an active function without living cells and work as mechanosensors and actuators. Water is an important component of all such extracellular tissues. While it is well known that the level of hydration determines the mechanical properties of many biological materials, it is less appreciated that water also plays an active role in generating forces within the materials. In particular water absorption and desorption provides actuation in a variety of plant seeds, including wild wheat, stone plant and banksia seed capsules. The shape change upon water uptake that provides the actuation is controlled by specific cellulose fibre architectures. In this way, well-controlled movements, such as bending, twisting or curling are programmed in these materials by structure of the underlying cellulose microarchitecture. The required deformation energy is provided by the absorption of water from the environment. Finally, the absorption of water to specific molecules and the resulting osmotic pressure is also providing internal stresses which control, for example, the mechanical behaviour of collagen in tendon, bone and dentin. The lecture will review general concepts for the roles of water in biological materials, both in the context of biology and of bioinspired engineering.

Mapping the Phase Space of Protein Encapsulation via Complex Coacervation Whitney C. Blocher McTigue, Xianci Zeng and Sarah L. Perry; University of Massachusetts Amherst, United States

The encapsulation of biomacromolecules is an important area of research, particularly in the context of medicine where increasing numbers of therapeutics are protein based. One particular encapsulation strategy takes advantage of the associative liquid-liquid phase separation phenomena known as complex coacervation. The self-assembly of complex coacervates is spontaneous, driven by electrostatic attractions and the entropic gains associated with the release of small ions upon complexation. Furthermore, coacervation enables the sequestration of therapeutic proteins and other cargo at high concentrations, and without the need for organic solvents.

A number of recent studies have highlighted strong parallels between the dense, polymer-rich droplets resulting from coacervation and membraneless organelles that have been observed in cells. Of particular interest is the ability of these liquid-liquid phase separated granules to recruit specific proteins, RNAs, and other biomolecules, either for storage in times of stress, or as a hub of catalytic activity. Inspired by these biological structures, we look to understand the design rules whereby complex coacervation can be used to encapsulate and potentially stabilize cargo proteins. Our work focuses on complex coacervation involving two oppositely-charged polypeptides and a cargo protein. The use of two-polymer coacervates allows for the encapsulation of even weakly charged proteins at a variety of different conditions, even near their isoelectric point. We look to map out range of conditions where both phase separation is observed, and the degree to which proteins are incorporated into the coacervate phase as a function of the composition of the two polymers and the encapsulated protein. Preliminary results suggest the potential for using the protein itself as a majority component of the coacervate to achieve incorporation at levels that could be used for therapeutic injection. We intend to use proof-of-concept studies with model proteins as a foundation upon which further research into therapeutic proteins can be built.

Analytical and Spectroscopic Studies of Ancient Silicified Plants—What Can We Learn? Victor V. Volkov, Graham J. Hickman, Anna Sola Rabada and Carole C. Perry; Nottingham Trent University, United Kingdom

Inspiration from ancient plant species that abound wherever the ground is disrupted and can grow through concrete and bitumen. What can we learn in terms of mineral usage and reproduction?
Equisetum species are primitive vascular plants that benefit from the biogenesis of silica bio-organic inclusions in their tissues and participate in the annual biosilica turnover in local eco-systems. As means of Equisetum reproduction and propagation, spores are expected to reflect the evolutionary adaptation of the plants to the climatic conditions at different times of the year. Combining methods of Raman and scanning electron microscopy and assisted with density functional theory, we conducted material spatial-spectral correlations to characterize the distribution of biopolymers and silica based structural elements that contribute to the bio-mineral content of the elater. We propose the expansion of elater tips upon germination and the form of silica including encapsulated biopolymers are designed for ready dispersion, release of the polysaccharide-arginine rich content and to facilitate silica uptake to the developing plant. This behavior would help to condition local soil chemistry to facilitate competitive rooting potential and stem propagation. Further, X-ray and analytical electron microscopy studies of plant materials show an amazing array of minerals that can be isolated for use in applications as diverse as sensing, optics and catalysis.

6:10 AM F.SM01.01.06
Black Drum Fish's Teeth—Stiff and Wear-Resistant for Crushing Mollusk Shells Zhifei Deng[1], Hyunchae C. Loh[2], Zian Jia[1], Admir Masic[2], Ron Shahar[3] and Ling Li[1]; [1]Virginia Polytechnic Institute and State University, United States; [2]Massachusetts Institute of Technology, United States; [3]The Hebrew University of Jerusalem, Israel

The black drum fish (*Pogonias Cromis*), being the largest durophagous sciaenid, has stiff, hard, and wear-resistant teeth on the powerful pharyngeal jaws to adapt to its almost exclusive diet on hard-shelled mollusks. With estimated biting force reaching 11,000 N at the largest body size (60 kg), the black drum fish's teeth have one of the highest bite force quotient (BFQ) among all living species. In this work, we aim to uncover the structural origins of such remarkable performance of these teeth via systematic structural, chemical and mechanical analysis across multiple length scales. The black drum fish's teeth consist of a stiff enameloid layer (90-110 GPa in reduced modulus E_r, and 3~7 GPa in hardness H) and a softer inner dentin layer (20-50 GPa in E_r, and ~1 GPa in H) separated by the dentin-enameloid-junction (DEJ). The gradient in microstructures from the enameloid (rods with increasing diameters and gradually twisted orientations) to the DEJ then to the dentin (parallel tubules with increasing curvy oscillation towards the interior), and the compositional gradient, *i.e.*, doping of Zn and F in the hydroxyapatite (HA) crystals in the enameloid layer *vs*. the Mg substitution in HA crystals in the dentin, contribute to the intricate gradient design of the teeth. The outer enameloid resists strong loadings; the DEJ deflects cracks to avoid catastrophic failure; and the inner dentin provides enhanced toughness. At the macroscale, the 90°-locking between the inner dentin and the bony plates provides additional bonding between the individual tooth and the pharyngeal jaw. Beyond critical loading, the tooth units first detach from the bony plates, which facilitates the erupting process of the new teeth from underneath.

From Nano to Macro—Artificial Muscles for Real-World Applications Seyed M. Mirvakili and Robert Langer; Massachusetts Institute of Technology, United States

Actuators, also known as artificial muscles, are an integral part of daily life. From transportation means to biomedical devices, they all utilize actuators for one or more vital tasks. Cycle life, cost, output force, strain, energy density, power density, and efficiency are the key performance metrics that are used to evaluate the suitability of actuators for a specific application. The emerging field of soft actuators has been introducing new classes of stimuli-responsive materials that can mimic muscle's properties (*i.e.*, generating strain, changing stiffness). While these materials outperform the performance of the human muscle in one or more of the mentioned attributes, there is still no stimuli-responsive material that can beat the human muscle in all of them. In this talk, an overview of the field will be given and the current challenges and possible directions will be discussed.

6:30 AM F.SM01.01.08
Hierarchically Organized Liquid Crystal Structure of Ultra-Rigid Polymers Made with Coiled Coil Peptide Bundles Kyunghee Kim[1], Christopher Kloxin[1], Jeffery G. Saven[2] and Darrin Pochan[1]; [1]University of Delaware, United States; [2]University of Pennsylvania, United States

Biomimetic assemblies using synthetic peptides facilitate a fabrication of nanoscale materials with desired structures, exhibiting several attractive features for biotechnological applications due to an ability to mimic structures and properties of nature. Sequence specificity in peptide building blocks allows designed nanostructures to have almost atomistic precision as in biological systems. Furthermore, higher-ordered materials with well-defined structures can be also produced through several processing methods such as sequential, hierarchical assembly or fiber spinning. The ability to precisely design and control the structure at the molecular level is crucial to construct new materials with well-designed structures at multiple length scales. This ability allows one to target desired properties such as the mechanical properties of the materials. Herein, peptide building blocks are employed to construct a hierarchically organized fiber material at macroscopic scale. The basic peptide building blocks are computationally designed to assemble into a cylindrical shape comprised of homotetrameric coiled coil bundles with an anti-parallel arrangement giving rise to a pair of reactive sites at each end of the bundles for further chemical reactivity. The bundles with complementary chemical functionality serve as supermonomer units and are directly connected to each other, resulting in hybrid physical/chemical peptide-based polymers. The polymeric chains exhibit highly rigid rod structure owing to a rigidity of constituent bundles and direct linkages between them through covalent interactions. Moreover, due to the unique physical characteristics, the rod chains in concentration solution exhibit liquid crystalline behavior. The resultant rigid rod-like polymers can further be assembled into a hierarchical organization on macroscopic scales via electrospinning processing, while preserving their unique rod-like structural characteristics. The organization of rods in concentrated liquid crystal solutions was characterized via polarized optical microscopy, x-ray and neutron scattering, and rheology in order to understand the control of liquid crystal behavior for the processing of concentrated solutions into fiber materials.

6:40 AM F.SM01.01.09
Nano-Mechanics Reveal Resilience in Nacre of Mollusk Shells and Pearls Jiseok Gim[1], Noah Schnitzer[1], Laura Otter[2], Yuchi Cui[1], Alden Koch[3], Sébastien Motreuil[4], Frédéric Marin[4], Stephan Wolf[5], Dorrit Jacob[2], Amit Misra[1] and Robert Hovden[1,1]; [1]University of Michigan, United States; [2]Macquarie University, Australia; [3]Univerisity of Michigan, United States; [4]Université de Bourgogne Franche-Comté (UBFC), France; [5]Friedrich-Alexander-University Erlangen-Nürnberg (FAU), Germany

The inherent tradeoff between strength and toughness inspires new design approaches to structural materials with high damage tolerance. Optimizing mechanical properties for predictable and non-catastrophic failure motivates novel design of modern high-performance structural materials. Among the diverse set of structural biominerals that straddle the gap between strength and toughness, nacre is the prototypical supermaterial. Nacre forms in many mollusk shells and is the primary structure of lustrous pearls. In nacre of both pearls and shells, we show a nanostructure that optimizes structural resilience. The biomineralization precisely controls secretion of organic and inorganic ingredients and hierarchically designs the combination of soft nanoscale organic components with inorganic nanograins that govern the formation of pearls and shells. After crack initiation, bulk nacre shows a 40-fold higher fracture toughness than the monolithic/single crystal calcium carbonate from which it is constructed. Thus, a central focus has been placed on understanding the principle mechanisms of nacre's excellent mechanical properties to inspire new designs of next-generation high-performance structural materials. However, nacre's ability to undergo limited deformation and dissipate critical stresses before fracture has not yet been quantified nor correlated with nanomechanical processes. Understanding nanomechanical responses across the 3D hierarchical architectures is critical to understanding how the individual nacre components work together to create properties greater than the sum of their parts (i.e. far exceeding the rule of mixtures).
Our investigation of toughening strategies in nacre reveals nanomechanical deformation of organic interfaces, nanocrystallites, and organic inclusions as key to the increased damage-tolerance of nacre. High-resolution scanning /

transmission electron microscopy (S/TEM) combined with in-situ nano-indentation has been adapted to biomineral systems to allow sub-nanometer resolution imaging of the nanomechanical deformation processes and provide precise assessment of when and where fracture occurs. We show that during compressive indentation nacre undergoes non-destructive locking where inorganic tablets come into contact across organic interfaces. Remarkably, the completely locked interface recovers its original morphology without any deformation after releasing compression and retains its full mechanical strength. During compression, the aragonite grains and organic inclusions reversibly rotate and deform indicating nanoscale resilience of the nacre tablets. Prior to tablet locking, strain attenuates up to 80% between the decoupled tablets. However, by 3% engineering strain of the first tablet, the tablets have locked to redistribute stress continuously across the organic interface and the strain attenuation decreases. When fracture occurs, we show the organic components restrict crack propagation both within and between tablets, sustaining the overall macroscale architecture through multiple fractures to allow further structural loading. This allows nacre to absorb significantly greater mechanical energy than monolithic aragonite. This extends the damage tolerance of the superstructure beyond a single fracture. The present in situ S/TEM nanoindentation study illuminates nacre's distinct non-linear elastic deformation processes that provide high resilience.

The Benefits of Disorder in Biological Cellular Materials Derek Aranguren van Egmond[1,2], Glenn Hibbard[1] and Benjamin Hatton[1]; [1]University of Toronto, Canada; [2]National Research Council, Canada

Biological cellular materials, such as trabecular bone, sponge, and wood, typically exhibit disordered arrangements of pores that are neither fully random, nor perfectly ordered (hexagonal honeycomb). In fact, this degree of order/disorder has not been systematically quantified before. We have used equivalent Voronoi patterning to quantify the disorder (variation in cell size) for a wide range of biological and engineered cellular materials, through thresholds in cell nuclei spacing. We have identified a common range of disorder (pseudo-hexagonal in 2D) for biological materials (δ of 0.5 to 0.8). Using 3D printed honeycomb models with systematically increasing disorder, we demonstrate that this range of 'pseudo-order' in 2D stochastic cellular solids exhibits a >30% increase in fracture toughness and equivalent strength compared to ordered (hexagonal) solids of the same density. This work demonstrates that there are significant improvements in defect tolerance for architected cellular solids having a certain degree of disorder. Highly ordered (hexaongal) arrays result in straight, catastrophic crack propagation, while too much disorder has highly branched cracks, but low strength. FEA models confirm a delocalization of damage during fracture. We suggest that the disorder in these biological materials may be optimal for the 'survivability' of fracture. We hypothesize that the delocalization of damage (cracks) limits their absolute size to that which is repairable through primary repair mechanisms, and provides an advantage for natural selection. We suggest that 'tailored disorder' in cellular solids represents a new design principle for the digital design of architected materials in general, to improve damage tolerance.

7:00 AM F.SM01.01.11
Transparent Nacre-Like Composites Toughened Through Mineral Bridges Tommaso Magrini[1], Simon Moser[1], Madeleine Fellner[2], Alessandro Lauria[2], Florian Bouville[3] and André R. Studart[1]; [1]Complex Materials, Department of Materials, ETH Zürich, Switzerland; [2]ETH Zürich, Switzerland; [3]Imperial College London, United Kingdom

Bulk materials with remarkable mechanical properties have been developed by incorporating design principles of biological nacre into synthetic composites. However, this potential has not yet been fully leveraged for the fabrication of tough and strong materials that are also optically transparent. [1] In this work, a manufacturing route that enables the formation of nacre-like mineral bridges in a bioinspired composite consisting of glass platelets infiltrated with an index-matching polymer matrix is developed. By varying the pressure applied during compaction of the glass platelets, composites with tunable levels of mineral bridges and platelet interconnectivity can be easily fabricated. [2] The effect of platelet interconnectivity on the mechanical strength and fracture behavior of the bioinspired composites is investigated by performing state-of-the-art fracture experiments combined with in situ electron microscopy. The results show that the formation of interconnections between platelets leads to bulk transparent materials with an unprecedented combination of strength and fracture toughness. This unusual set of properties can potentially fulfil currently unmet demands in electronic displays and related technologies.

Understanding Synergy in the Nonlinear Mechanics of Composite (Bio)polymer Networks Justin Tauber[1], Simone Dussi[1], Federica Burla[2], Gijsje Koenderink[3] and Jasper van der Gucht[1]; [1]Wageningen University & Research, Netherlands; [2]AMOLF, Netherlands; [3]Delft University of Technology, Netherlands

Composite materials offer a unique opportunity to achieve novel (improved) material properties without the need for the development of new components. Sometimes, synergistic mechanics can be achieved, i.e. the mechanical properties of the composite are even better than the sum of the individual components. This synergy has been demonstrated within many material classes and on many length scales, from reinforced concrete to molecular polymeric composites [1,2,3] to the extracellular matrix supporting our tissues [4]. Here I will present our effort to rationalize the synergy observed in the non-linear mechanics of biopolymer composites [4] and in the fracture behaviour of generic elastic double networks [1], both containing a stiff polymer network embedded in a soft polymer matrix. We will show that the entanglement of these networks at the microscopic level is the key to the synergistic mechanics.

We look for mechanical synergy in composite biopolymer networks, inspired by the tuneable nonlinear mechanics of the extracellular matrix (ECM). In the ECM collagen is the main-component responsible for the nonlinear strain-stiffening response [5,6]. However, we show that hyaluronic acid (HA), the second most abundant biopolymer in the extracellular matrix, can significantly delay the strain-stiffening if the stiff collagen network is embedded in a much softer HA matrix [4]. Similarly, we show that the HA network enhances the linear elastic response of the collagen-HA composite. In both regimes the synergistic response is governed by mechanisms occurring at the microscopic level, but have a drastic effect on the macroscopic stress-strain response.

Experiments on synthetic double networks [2,3] show that a soft elastic matrix can not only have a significant effect on the elastic response of a stiff network, but also on the failure behaviour, shifting the failure response from brittle to ductile. By implementing bond breaking in a coarse-grained network simulation [1] we can demonstrate that the brittle-to-ductile transition can be captured by a simple force-balance between the two networks. Furthermore, our model predicts four mechanical regimes that are also observed in experiment. In particular, the simulations reveal that the four regimes are associated to differences in the microscopic failure response as well. Understanding these phenomena allows a better control over the synergistic failure response of double network materials.

Our findings not only elucidate how biology combines polymers with complementary properties to finely-tune the mechanics of living tissues, but also provide a new avenue for the design of synthetic elastic materials tuning their stress-strain response from the linear-regime until global failure.

Dissipative Structures in Polysaccharide Solution by Water Evaporation Kosuke Okeyoshi, Kulisara Budpud, Gargi Joshi and Tatsuo Kaneko; Japan Advanced Institute of Science and Technology, Japan

The air-water interface is expected to play an important role in establishing a universal model of dissipative structures in nature. Viscous fingering, as an example of fluidic flow, is an unstable situation that is widely known as *tears of wine*. This has been explained through the Marangoni effect, coffee ring effect, Saffman-Taylor instability, etc. However, due to the transitional nature of these phenomena, there are few strategies for immobilizing such fluidically regulated interfaces. Recently, such phenomena have been applied successfully to an immobilized structure by controlling the evaporation of a mixture of polymer and water.[1]
In this study, we present a brief discussion of "meniscus splitting phenomenon". More precisely, an air-liquid interface is divided into multiple interfaces to partition a space. In particular, by using a mixture of polysaccharides and water, a macroscopic pattern following a specific rule could be confirmed. When the mixture is dried from a top open cell, the polymer forms deposits at specific positions to split the meniscus by bridging a millimeter-scale gap. Because water irreversibly evaporates from the liquid phase to the air phase through a gap, the air-liquid interface is in a nonequilibrium

state between polymer deposition and water evaporation. The interfacial instability is comparable to the mechanical instability of gels at the phase transition or to the skin layer of gel surfaces during shrinking. Furthermore, the deposited polymer film acts as vapor-sensitive materials. Here, the phenomenon and the material's behavior would be discussed from physicochemical viewpoints: polymer science, interface science, and colloidal science.

Exploring the Growth and Form of Strontium Sulfate Biominerals Using X-Ray Nanotomography Dawn Raja Somu[1], Timothy Cracchiolo[1], Imke Greving[2] and Vivian Merk[1]; [1]Florida Atlantic University, United States; [2]Helmholtz-Zentrum Geesthacht, Germany

Acantharia (*Acantharea*) are wide-spread marine protozoa, presenting one of the rare examples of strontium sulfate ($SrSO_4$, celestite) mineralization in the biosphere. The unicellular organisms produce complex star-shaped skeletons with 20 spicules that radiate from the center according to a unique geometric pattern. Specifically, two quartets of polar spicules alternate with two quartets of tropical spicules and one quartet of equatorial spicules. It has been speculated that the crystallographic arrangement of the spicules stems from an interplay between crystallochemical and biological control, reconciling an optimum use of space at the spicular joint with the crystallographic requirements of an orthorhombic crystal lattice. The Acantharia class encompasses approximately 150 species with highly diverse, taxon-specific skeletal morphology, suggesting exquisite genetic regulation of the mineral deposition. Their sizes range from roughly 50µm to 1mm, depending on their developmental stage and origin. Exploring the three-dimensional skeletal architecture of the Acantharia is essential for understanding the underlying principles of biomineralization.
Synchrotron-based X-ray micro-computed tomography is a powerful method for visualizing nano-scale features without major sample preparation artefacts. Here, we used synchrotron-based nanotomography at the P05 imaging beamline (PETRA III, DESY, Hamburg, Germany) to resolve the complex internal morphology of Acantharian endoskeletons. Our analysis revealed pronounced morphological differences between taxa, suggesting species-specific crystal growth mechanisms. The study focused on how the spicules emanate from the central junction, as it might be the key to understanding inorganic morphogenesis. We used a correlative imaging approach, combining nanotomography with electron-optical investigations and Atomic Force Microscopy. Based on the experimental results, we hope to gain a deeper understanding of the skeletal development from rod-shaped, diametral crystals in juvenile Acantharia to well-developed skeletons in the adult organism. Interesting parallels might be drawn to smoothly curved, fenestrated spicules in subtropical sea urchins and marine sponges, whose skeletons are based on far more common biomineral systems. We will further discuss how bio-inspired model systems mimic the $SrSO_4$ crystallization in uncultured protists.

7:40 AM F.SM01.01.15
Late News: The Different Destinies of DOPA—Spatiotemporal Regulation of Catechol Crosslinking During Mussel Byssus Formation Tobias Priemel[1], Ranveer Palia[1], Margaryta Babych[2], Christopher Thibodeaux[1], Steve Bourgault[2] and Matthew J. Harrington[1]; [1]McGill University, Canada; [2]UQAM, Canada

Natural materials such as mussel byssal threads serve as inspiration for the design of new sustainable polymers. Byssal threads consist of proteins forming a complex hierarchical structure closely linked to the impressive mechanical properties including underwater adhesion, high toughness and self-healing. Each fiber forms within 5 min as a secretion of several proteins which self-assemble and crosslink into a rigid, yet extensible fiber. Interestingly, all proteins contain between 1 and 30 mol% of the post-translationally modified amino acid 3,4-dihydroxylphenylalanine (DOPA). The complex chemistry of DOPA enables a range of different interactions including metal coordination, oxidative crosslinking and hydrogen bonding. Evidence indicates that DOPA plays a key role in the post-secretion curing of the fibers though the details are still unclear. Here, we investigated the spatiotemporal regulation of DOPA cross-linking during thread assembly, using histological staining in combination with confocal Raman microspectroscopy. These methods were combined with induced thread formation to follow cross-linking at different stages of the formation process and in different parts of the thread. Results show that different parts of the thread utilize different DOPA interactions for crosslinking. Furthermore, these DOPA interactions are likely regulated by controlling their redox environment facilitating covalent crosslinking over DOPA-metal coordination or vice versa. These insights provide relevant physicochemical pathways for the design of mussel-inspired catechol-based polymers and could lead to the development of new sustainable materials with industrial and biomedical applications.

5:00 AM *F.SM01.02.01
Bio-Enabled Nanocomposites with Unique Physical Properties Vladimir Tsukruk; Georgia Institute of Technology, United States

Bio-enabled nanocomposites represent a novel class of functional bioderived materials, which uses principles of bioinspiration and biomimetic to design hierarchically organized hybrid materials with co-assembled biological and synthetic components to bring best of synthetic and biological worlds: versatile functions with responses to mechanical, optical, chemical, and light stimuli and mechanical strength, flexibility, biocompatibility, and environmental robustness [1, 2]. In first set of examples, we discuss uniformly aligned chiral bio-photonic films from a liquid crystal phase formed by a cellulose nanocrystal solution placed in a thin capillary [3]. This spatial and fluidic flow confinement facilitates homogeneous growth of chiral pseudo-layers parallel to the interface in contrast to the highly heterogeneous assembly of random tactoids. The resulting iridescence films show a narrower optical reflectance band and uniform birefringence over larger macroscopic regions than heterogeneous conventional drop-cast films. In another example, enhanced chiral properties of organized helical patterned films with high asymmetry of circular polarization have been template-assembled via preferential orientation of high-aspect cellulose nanocrystals onto optical microgrids [4]. Bright chiral emission has been co-assembled in organized biopolymer photonic films from core-shell nanorods of cellulose nanocrystals and co-assembled carbon quantum dots mediated by polymer linkers [5]. Finally, co-assembly of cellulose nanocrystals with amorphous polysaccharides resulted in the formation of robust and flexible films with the preservation of the original structural photonic and fine control of the pitch length due to intimate intercalation of macromolecular backbones into the interstitial nanoscale pores of neighboring nematic monolayers [6].

Bio-Inspired Hierarchical Porous Materials Made by 3D Printing André R. Studart; ETH Zurich, Switzerland

Hierarchical porous materials are attractive structures for a variety of applications due to their enhanced mechanical efficiency and their high surface area with minimum permeability loss. Nature showcases remarkable examples of hierarchical porous materials that benefit from such unusual set of properties, including bamboo, bone, marine sponges and wood. However, synthetic porous materials have yet to reach the elaborate architectural design found in their biological counterparts. To fill this gap, processing routes that enable deliberate control over the material's porous structure at multiple length scales are highly demanded. In this talk, I will show how 3D printing technologies can be exploited to fabricate hierarchical porous materials with unprecedented mechanical efficiency and architectural control. The key feature of our approach is to design inks with an internal structure that serves as a template for the formation of tailored pores within the printed object. Using oil droplets, air bubbles or phase-separating mixtures as templating structures, this methodology enables independent tuning of porosity and pore sizes at multiple length scales. To demonstrate the potential of the process, we 3D printed complex-shaped parts with bioinspired multiscale porosity and enhanced mechanical efficiency that cannot be achieved through conventional fabrication technologies.

5:30 AM *F.SM01.02.03
Exploiting Supramolecular Associations in Interpenetrating Networks and Elastomers LaShanda Korley and Chase Thompson; University of Delaware, United States

Supramolecular interactions may hold the key to the development of network systems with tunable mechanics and modulated architecture, such as observed in the muscle protein titin. It is the dynamic nature of these physical associations that we have exploited in the design of tough supramolecular materials that super-impose covalent and non-covalent interactions to tailor tensile response. We have developed supramolecular elastomers and interpenetrating network (IPN) systems that probe the interplay of non-covalent and covalent interactions in structural organization and mechanical response. By tailoring physical associations via control of self-assembly and composition, we have demonstrated enhanced supramolecular dynamics driven by architecture and toughness enhancements due to phase behavior. Recently, non-covalent interaction strength, network regularity, and chemoresponsiveness have been utilized as handles to derive gradient materials and to induce actuation behavior. New insights into supramolecular nanoscomposites are also highlighted.

5:45 AM F.SM01.02.04
Direct Observation of Water Droplet by Scanning Electron Microscope Noriyuki Inoue[1], Shunsuke Asahina[2] and Natasha Erdman[1]; [1]JEOL USA, Inc., United States; [2]JEOL Ltd., Japan

A variety of materials developed in recent years have featured artificial water repellent surface structure inspired from organisms. However, an optical microscope cannot observe interfacial structural relationship with water droplet accurately due to problems of resolution and depth of focus. Therefore, we have applied the Scanning Electron Microscope (SEM) that can be used to observe the surface of specimen accurately. Traditionally, water droplets cannot be observed by SEM due to strict vacuum requirements for electron beam based imaging. Therefore, we have been developed a unique method called Aqua Cover method that allows observation of water directly in SEM [1].
SEM has a Low Vacuum (LV) mode that can facilitate imaging of water containing specimen. The chamber pressure of LV mode is able to reach several hundred Pa, but this pressure is insufficient to keep liquid water. There is also a method called Environmental SEM (ESEM). This method can maintain water droplets on a specimen by dew condensation. This is achieved by introducing the water vapor into the specimen chamber and cooling a specimen stage in LV mode. Although this method can make many tiny water droplets on the specimen surface, it cannot drop a water droplet directly at a specific site on the specimen surface. Unfortunately, tiny water droplets are also formed in crevices of uneven structures, so the Wenzel state is created even under the conditions that should be Cassie-Baxter state [2, 3]. From this reason, it is difficult to observe a behavior of sub mm to mm order water droplet, like a raindrop, on the specimen surface accurately, but it is important for development of fine structures and quality control in artificial water repellent materials.
As a method to solve this problem, Aqua Cover method that can keep the size of a water droplet from atmospheric pressure to pressure of LV mode and be observed by SEM is developed. Using this method, the interface relationship between water droplet dropped at atmospheric pressure and the specimen surface is observed by SEM and determined whether the water repellent state was Cassie-Baxter or Wenzel.
The experimental method is as follows: approximately 10 mm x 10 mm of lotus leaf was fixed on a 45 ° tilt specimen stub and installed on a cooling stage set at 0°C. 1 mL water droplet was then dropped onto the specimen surface. The Aqua Cover method was used for SEM observation at a specimen chamber pressure of 650 Pa and an accelerating voltage of 25 kV.
As a result of SEM Aqua Cover observation, air pockets were observed at the interface between surface unevenness structure and water droplet, so the state of this condition was determined to be Cassie-Baxter.

Engineering the Seed Microenvironment Benedetto Marelli, Hui Sun and Augustine Zvinavashe; Massachusetts Institute of Technology, United States

Bioinspired by the tardigrade and bombyx mori we engineer the seed microenvironment to encapsulate, preserve and deliver Rhizobium tropici. Scientific discoveries in agriculture and sustainability are at the crossroads of material science,

biochemistry, agriculture and biology. They underpin the innovative technological solutions that will impact water, energy and food security (WEFS). These new technologies can then be implemented to address major societal problems that are linked to climate change, soil degradation and soil salinization. In particular, our objective is to augment agricultural outputs (*i.e.* crop yield and production) while decreasing inputs (*e.g.* water, energy, fertilizers, land, pesticides) by deploying plant-growth-promoting-bacteria (PGPBs) in the soil to alleviate plant stressors to be specific soil salinity. Using PGPBs as a substitute to synthetic fertilizer our design approach engineers the seed microenvironment by coating the seeds with PGPB laden biopolymers. PGPBs are well known to enhance crop production and protect plants from biotic and abiotic stresses, while decreasing the need for water and fertilizers. However, the bacteria's delicate nature has hindered their use in current agricultural practices. We use a silk and trehalose mixture that is able to encapsulate, protect, preserve and deliver Rhizobium tropici to Phaseolus Vulgaris. The coated Phaseolus Vulgaris seed are shown to be able to significantly alleviate soil salinity stress in Moroccan soil when compared with uncoated (control) Phaseolus Vulgaris seeds.

Enzymes—Efficient Biological Catalysts and Useful Tool for the Sustainable Degradation of Plastics? Eva Krakor, Isabel Gessner and Sanjay Mathur; University of Cologne, Germany

Worldwide 350 to 400 million metric tons of synthetic polymers are produced every year and it is estimated that 5 to 13 million metric tons of plastic will enter the ocean every year. This leads to negative consequences for various ecosystems and the human and animal health. For the removal of plastic, enzymes have come into focus of recent research due to their high selectivity and catalytic efficiency under mild conditions and their sustainable alternative to toxic catalysts. Esterases and hydrolases such as lipase and cutinase, respectively, catalyze the hydrolysis of lipids and cutin, a complex hydrophobic polyester the main component of the plant cuticle.
Nevertheless, enzymes constitute an expensive catalyst making a reusable system where the enzymes are attached on the surface of magnetic particles a cost-efficient platform. Therefore, magnetic ellipsoidal-shaped SiO_2@Fe_3O_4 particles were synthesized by coating ellipsoidal shaped α-Fe_2O_3 particles in a two-step sol-gel process with SiO_2. Afterwards the α-Fe_2O_3 core is reduced to magnetic Fe_3O_4 in a H_2/argon atmosphere. Covalent immobilization of the enzyme was achieved by first modifying the particles with 3-(aminopropyl)triethoxysilane to obtain terminal amino groups which upon addition of glutaraldehyde formed a stable bond to the enzyme. The successful attachment of the enzyme was proven via Zeta potential, IR and CHNS measurements. Moreover, the activity of the enzyme was demonstrated using the optical conversion of 4-nitrophenyl acetate to 4-nitrophenol. This approach was extended to polymeric materials using polycaprolactone fiber mats which were analyzed regarding morphology changes upon enzymatic degradation.

Natural Layered Structures in Biogenic Magnesium Calcite Single Crystals Alex Katsman and Boaz Pokroy; Technion - Israel Institute of Technology, Israel

Some calcitic biominerals have been shown to be formed through the crystallization of a Mg-rich amorphous calcium carbonate (Mg-ACC) precursor. Formation mechanisms of multiscale biogenic single crystal structures at ambient temperatures, in conditions of limited solid phase diffusion, remain largely incomprehensible. Based on experimental results, we develop a model describing the formation of the brittle star Mg-calcite nanostructure from an amorphous Mg-ACC precursor to a Mg-calcite nanostructure containing periodic layers with varying concentrations of coherent Mg-rich nano-inclusions. The formation route is rationalized in a two-step model: the first step involves spinodal decomposition of a liquid or gel-like Mg-ACC precursor into Mg-rich nanoparticles and a Mg-depleted amorphous matrix. The second step is the crystallization of the decomposed Mg-ACC precursor. The crystallization of Mg-depleted ACC matrix is accompanied by the exclusion of Mg ions into a diffusion zone adjacent to the crystallization front; after crystallization of a certain layer, the Mg concentration ahead of the layer exceeds the critical value above which the Mg-ACC matrix becomes unstable against spinodal decomposition. A secondary spinodal decomposition will then start and result in the formation of additional Mg-rich nano-domains. As a result, the density of Mg-rich nano-domains changes periodically and forms periodic layered structure inside magnesium calcite single crystals. The model was supported by our experimental results in synthetic Mg-calcite, which suggest a spinodal decomposition in the amorphous precursor. These new insights have significant implications for fundamental understanding of the biogenic layered structures formation.

Templated Crystallization of Structural Biopolymers for Tailored Hierarchical Materials Hui Sun and Benedetto Marelli; Massachusetts Institute of Technology, United States

Living systems regulate the disorder to order transition of biomacromolecules to achieve complex materials with a variety of functionality and structural hierarchy, which has long been an inspiration for similar endeavors in synthetic materials. In particular, materials generation in nature often involves the use of templates to direct the assembly pathway and subsequent hierarchical organization of nanoscale building blocks, with the most prominent example being biomineralization that is ubiquitous in the natural world. The same principle underpins amyloid fibrils formation through pathogen (such as prions and misfolded Aβ oligomers) templating, which follows a nucleation-elongation model. In this presentation, we introduce templated crystallization of structural biopolymers as a process to nanofabricate hierarchically structured materials up to centimeter scale, using silk fibroin as an example. The process involves the use of ordered peptide supramolecular assemblies as templates to drive a phase transformation of silk fibroin from unordered to ordered conformations, thereby enabling further assembly of the silk fibroin chains into nanostructured materials (i.e. β-sheeted nanofibrils). Multiple parameters including the relative concentration between silk fibroin and peptide seeds, silk fibroin molecular weight, pH and peptide conformation are investigated to fine tune the assembly kinetics and silk polymorphs. Combining the templated crystallization with various top-down fabrication such as soft lithography and printing enables (i) formation of different silk polymorphs at selected areas, generating free-standing patterned silk films, where the different molecular structures can be used to store or encrypt information; (ii) surface functionalization with topographical control over silk nanofibrils growth on pre-deposited peptide seeds; and (iii) three-dimensional manipulation of silk nanofibrils into macroscopic structures with customized shapes and controlled anisotropy. Together, these results pave the way for nanofabrication of a new generation of smart and adaptive materials built from the bottom up.

Late News: Accelerated Solar-Thermal Energy Harvesting Within Phase Change Materials Through Learning from Nature Peng Tao, Chao Chang, Qinxian Ye, Xiaoxiang Li and Tao Deng; Shanghai Jiao Tong University, China

Converting abundant sunlight as storable heat within phase change materials (PCMs) is an attractive way to harness solar energy for a broad range of heating-related applications. Current PCMs, however, generally suffer from a low thermal conductivity, which seriously limits the solar-thermal energy harvesting (STEH) process. In nature, STEH is also vital for normal functioning of biological species, but they have developed different strategies. For example, butterflies rely on spreading their wings towards sunlight to absorb solar photons to quickly warm the body and dynamically folding their wings to mediate the body temperature. Inspired by such unique mechanism, we demonstrate dynamic movement of the solar-thermal converters along the melting solid/liquid interface as an effective strategy to accelerate transportation of solar photons within PCMs thereby achieving fast STEH. By magnetically tuning the distribution of Fe_3O_4@graphene nanoparticles within the paraffin composite the STEH rate was increased by ~3 times. The low loading concentration requirement also enables the composites to fully retain and even slightly increase the fusion enthalpy of the PCMs. We further demonstrate rapid roll-to-roll STEH through illuminating the thin flexible form-stable composite PCM sheets while being continuously rolled. Due to shortened heat-diffusion distance and rollability of the composites, it achieves fast and uniform STEH within the bulk PCMs. The flexibility of charged composites also enables broad tuning of the discharging behavior, and provides the possibility to explore wearable thermotherapy and other flexible solar-thermal applications.

6:45 AM F.SM01.02.12
Late News: Hydroxycitrate-Controlled Brushite Crystallization in Aqueous Solution Ma. Charlene C. Tapia[1], Naoyuki Miyashita[2,2], Wei Weilin[2], Kazuki Miyata[2,2], Takeshi Fukuma[2,2], Jem Valerie Perez[1] and Bryan G. Alamani[1]; [1]University of the Philippines, Philippines; [2]Kanazawa University, Japan

Brushite is one of the most important polymorphs of calcium phosphate in the context of bio-inspired mineralization. It has been used as reconstruction materials, dental cements and in formulation chemistry. It is also a precursor of hydroxyapatite which is a common component of bones and teeth. Due to its wide application as a functional material and a precursor of other bioceramics, the control of its crystal morphology is important. The performance of a functional material significantly depends on its shape and surface properties. Fundamentally, carboxylates are known modifiers of crystal growth. One example is hydroxycitrate (HCA) which have effectively curbed and controlled calcium oxalate mineralization. Here we reported the effect of HCA in the crystal shape, aspect ratio and number density. The bulk crystallization was coupled with interfacial studies using atomic force microscopy to further evaluate its impact on the surface of brushite. Analysis shows a 50% reduction in the number of crystals formed and a change in brushite's morphology event at a very small inhibitor concentration (Ca/inhibitor=25000). Amplitude and Frequency Modulated AFM studies show that surface roughness increased through time in the presence of the HCA. Changes in the periodic features at near atomic resolution was also observed in the presence of HCA implying possible modifier-hydration layer interactions. Results obtained in this study may serve as a step in understanding the HCA's effect on brushite and in designing bio-inspired calcium phosphate materials and

precursors.

Late News: Emergent Behavior of Bioinspired Multicompartment Capsules Triggered by Temperature or Oxidants Sai Nikhil Subraveti, Kerry DeMella and Srinivasa Raghavan; University of Maryland, United States

Life is an "emergent" property – i.e., one exhibited by living systems as a whole, but not by any of their individual parts. In a single eukaryotic cell, there exist internal compartments called organelles, such as the nucleus and mitochondria. While the organelles each have distinct functions, it is the overall cell that has the property of life – i.e., the whole is greater than the sum of the parts. Here, we describe our attempts to create millimeter-scale polymer capsules that exhibit emergent properties. In particular, we have created multicompartment capsules (MCCs) that have many internal compartments, each with distinct contents. We have also found ways to perfectly encapsulate (hermetically seal) aqueous solutes in a capsule core until an external stimulus is applied. The key to this property is to utilize hydrophobic shells that are impermeable to aqueous solutes. However, the shells can be degraded or made permeable by external triggers – either by heat or by oxidants that generate reactive oxygen species (ROS).

Using these concepts, we have activated multi-step or cascade reactions within MCCs. In one example, we use the MCC as a factory to synthesize fluorescent gold nanoclusters (AuNCs). Individual non-fluorescent reagents are encapsulated in internal compartments. When a stimulus is applied, the reagents leave the compartments and come into contact with each other, thus producing AuNCs. The overall MCC thereby displays an emergent property (fluorescence) that is not exhibited by any of its individual components. In a second example, we encapsulate a chemical fuel and catalytic particles in separate compartments. When the compartments are triggered to open up, the catalyst comes into contact with the fuel, which results in the production of oxygen gas. The gas causes the entire MCC to inflate, and this inflation is again a property that emerges from the interactions between the components of the MCC.

7:05 AM F.SM01.02.14
Late News: Dynamic Color-Change in Multi-Responsive Photonic Microspheres Formed by Hierarchical Assembly of Colloidal Nanogels Golnaz Isapour; Massachusetts Institute of Technology, United States

Soft photonic materials formed from colloidal crystals are highly-desirable platforms for sensing and signaling in biomedical, chemical, and mechanical application scenarios [1–3]. A particularly accessible attribute of such materials is structural coloration; by using stimuli-responsive and reconfigurable colloidal crystals, dynamic coloration can be achieved, akin to the inspiring ability of chameleons to change their color appearance[4]. To date many concepts for the lab-scale creation of such photonic materials are known[5], however a lack of efficient and scalable production methods with sufficient control of properties persists. In addition, in hybrid materials with multiple stimuli-responsive components, interactions among components tend to be overlooked. Here, we propose a simple and scalable method to prepare stimuli-responsive photonic hydrogel balls of several tens of microns in diameter, in which pH- responsive colloidal nanogels are embedded in a scaffolding hydrogel. We show a dynamic color-change spanning the entire visible spectral range through a variation of pH or temperature, which triggers the nanogels or the scaffolding hydrogel, respectively. We discuss the mutual swelling interactions between the colloidal nanogels and the scaffolding hydrogel. The response characteristics, such as timescale and spectral range of the photonic balls can be tuned by altering the composition, and responsive properties of the colloidal nanogel and the scaffolding hydrogel. These photonic hydrogel balls could be applied as optically interrogated sentinels in label-free multiplexed chemical, thermal, and mechanical sensing scenarios with sub-mm resolution. In addition, by employing modular assembly strategies, they can be used to form dynamic color-changing materials at scale.

Late News: Structure, Assembly and Material Properties of Model Cephalopod Proteins Preeta Pratakshya, Atrouli

Chatterjee, Rylan J. Kautz and Alon Gorodetsky; University of California, Irvine, United States

Cephalopods are known for their remarkable ability to camouflage by rapidly changing the color and reflectance of their skin, a property that is enabled by the presence of subcellular structures composed of unique structural proteins called reflectins. Given the critical role played by reflectins in regulating the optical behavior of these organisms, and their technological potential for the development of biophotonic and bioelectronic devices, these proteins have recently emerged as a desirable target for the design of novel functional biomaterials. However, the development of such materials has been impeded by a lack of complete understanding of the structure and assembly of this class of proteins. Here we will highlight the proteins' multi-faceted material properties within the context of bioelectronic and biophotonic platforms. Specifically, we will discuss how the structure and stimuli-responsive assembly of these proteins enables their electrical and optical functionality. Our findings not only underscore the potential of reflectins as functional materials but also hold relevance for the development of cephalopod-inspired bioelectronic technologies.

7:25 AM F.SM01.02.16
Late News: 3D Nanostructure of Collagen Smectic Liquid Crystal Phase Used to Form Mussel Byssus Threads Franziska Jehle[1,2], Tobias Priemel[1], Peter Fratzl[2], Luca Bertinetti[2,3] and Matthew J. Harrington[1,2]; [1]McGill University, Canada; [2]Max Planck Institute of Colloids and Interfaces, Germany; [3]B CUBE Center for Molecular Bioengineering TU Dresden, Germany

Marine mussels (*Mytilus* spp.) fabricate tough and self-healing collagenous biofibers known as byssal threads via self-assembly. The hierarchical organization of the protein building blocks comprising the fibers was previously demonstrated to be crucial for their outstanding mechanical properties. Evidence suggests that self-assembly of this hierarchical structure is aided by the storage of the collagenous precursor proteins as a colloidal liquid crystal (LC) phase within micron-scale secretory vesicles. Currently, however, very little is understood about the molecular level forces controlling LC phase formation. Here, we harnessed advanced electron microscopy methods to reconstruct the 3-dimensional LC nanostructure of the collagen precursors within the secretory vesicles with unprecedented detail, including visualization of specific LC defects. Specifically, we identified the presence of a lyotropic smectic LC phase that we posit arises from the block co-polymer-like primary structure of the specialized byssus collagen precursor, consisting of clear demarcations in hydropathy and charge distribution. We further propose that terminal pH-responsive protein domains enriched in histidine provide the impetus for the fluid to fiber transition during thread formation. These findings may inspire new strategies for fabricating nanostructured soft materials with complex material properties through supramolecular self-assembly, which is relevant to ongoing efforts in sustainable polymers and tissue engineering.

SESSION F.SM01.03: Bio-Inspired Surfaces and Coatings

F-SM01

5:00 AM F.SM01.03.01
Frost-Free Surface Design Inspired by Macrotextured Leaves Christian Machado and Kyoo-Chul (Ken) Park; Northwestern University, United States

Numerous studies have focused on a low surface energy coating and a micro/nanoscale surface texture to design functional surfaces that delay frost formation and reduce ice adhesion. However, the scientific challenges for long-term icephobic surfaces have not been fully addressed because of degradation such as mechanical wearing. Inspired by the suppressed frost formation on concave regions of natural leaves, here we report findings on the frosting process on surfaces with various serrated structures. Dropwise condensation, the first stage of frosting, is enhanced on the peaks and suppressed in the valleys when the wavy surface is exposed to humid air, causing frosting to initiate from the peak. The condensed droplets in the valley are then evaporated, resulting in a non-frost band. The effects of surface topography on the frost pattern are systematically studied by varying the serrated geometry defined as the vertex angle, and numerically modeling the spatial distribution of diffusion flux of water vapor on the wavy surface. Under different ambient humidity levels, the magnitudes of diffusion flux at the non-frost boundaries of the surfaces are nearly identical, implying that the critical value of diffusion flux is the key to understanding the non-frost pattern.

5:10 AM F.SM01.03.02

'Antifouling' Porous Lignocellulosic Biomass with Internal Microchannels as Solar Absorbers and Water Pumpers for Thermal Desalination Chao Liu, Qiang Li, Pengcheng Luan and Hongli Zhu; Northeastern University, United States

Water pollution and freshwater shortages present two of most emerging societal challenging issues. Although many advances have been explored in obtaining clean water, such as reverse osmosis technologies, membrane treatments, ion exchange, and some multi-effect distillation systems, these technologies are still costly. Water desalination and purification from seawater and wastewater have been developed for addressing the globally growing need of clean water, among which solar-driven evaporation has drawn tremendous attention because it uses abundant solar energy and has a small environmental footprint. Conventional sunlight absorbers include carbon-based materials with strong light absorption abilities, heat localizing plasmonic nanoparticles, and hydrophilic sponges with carbonized surfaces. However, their relatively low energy conversion efficiencies, high cost, limited capacity for continuous steam generation, and salt accumulation induced efficiency decay have hindered the development. As a new solar technology, interface steam generation has great prospects for the application of desalination and fractionation. In this work, we report a sustainable, efficient and accessible solar evaporator with bilayer structure from lignocellulosic biomass. Loofah is a pervasive vegetable in our daily life. The mature loofah is comprised of natural fibers with high hydrophilicity, hierarchical macropores, and microchannels, which are essential features and structures for steam generators. We prepared a bilayer loofah-derived solar evaporator, which had a top carbonized layer that functioned as efficient solar absorbers with broad light absorption and high light trapping and a bottom loofah fiber layer for sufficient water pumping to the localized heating surface from different directions. During desalination, the salt concentration gradient of the macropores and microchannels allowed for efficient salt drainage in loofah and prevented the accumulation of salt on the surface of the evaporator, thus enabling the antifouling properties that provided the loofah solar evaporator a long-term stability. This economical light absorber and water-pumping natural fibers exhibited a steam generation rate of 1.42 kg m^{-2} h^{-1} and an efficiency of 89.9% under 1 Sun. This low-cost, abundant, and stable material from lignocellulose biomass thus have great potential for future large-scale solar steam applications.

5:20 AM F.SM01.03.03
Antiviral and Antimicrobial Biomaterials Inspired by Mussel Adhesive Chemistry Bruce Lee; Michigan Technological Univ, United States

Marine mussels secrete adhesive proteins that enable these organism to anchor themselves to various substrate (i.e., ship hull, rock) in a rough, intertidal zone. These mussel foot proteins contain a unique amino acid, L-3, 4 dihydroxyphenylalanine (DOPA), that is responsible for strong interfacial binding. Specifically, the catechol side chain of DOPA is capable of participating in reversible interactions and covalent crosslinking. Many investigators utilize the catechol adhesive moiety in designing biomimetic adhesives and coatings. In contrast to these applications, our lab has been developing antiviral and antimicrobial biomaterials utilizing the redox chemistry of catechol. Catechol generates reactive oxygen species (ROS), such as superoxide and hydrogen peroxide, when it becomes oxidized. The generated ROS was antimicrobial against both gram-negative (*Escherichia coli*) and gram-positive (*Staphylococcus epidermidis*) bacteria and reduced the infectivity of a non-enveloped porcine parvovirus and an enveloped bovine viral diarrhea virus. Most importantly, the generation of ROS can be easily activated by simple hydration of catechol-containing microgel or coating. Most recently, we chemically modified catechol with various halogens. These halogenated catechol demonstrated broad spectrum antimicrobial property against multiple strains of multidrug resistance bacteria. The combination of moisture-resistant adhesive property and inherent antimicrobial property greatly enhanced the potential for using catechol for designing multifunctional bioadhesives, wound dressings and coatings with antipathogenic properties.

5:30 AM F.SM01.03.04
Bio-Inspired Active Skins for Surface Texture Morphing Yujin Park and Kenneth J. Loh; University of California San Diego, United States

There has been tremendous interest in optimizing artificial surfaces that can continuously morph their surface texture for various purposes, such as camouflage, signaling, and hunting. In recent years, smart materials like stimuli-responsive polymers and hydrogels were leveraged to achieve surface texture morphing. However, their real-world applications are limited given their slow actuation and weak mechanical properties. Thus, the aim of this research is to broaden the current knowledge of surface texture morphing by designing instability-induced morphable structures using patterned, auxetic geometries. Our previous study introduced 3D-printed and thin-film-like Active Skins based on a star-reentrant geometry, and it was shown that unique patterns of out-of-plane deformations could be induced when uniaxial strains were applied. Moreover, geometrical imperfections or notches were introduced to program the surface morphing behavior of Active Skin in a desired manner. In this study, the geometrical dependence of surface morphing response (i.e., the nonlinear response of 3D-printed Active Skins) was characterized using both experiments and finite element model (FEM) simulations. First,

experimentally calibrated FEM simulations were employed to design the width and angles of the rib of unit cell geometries. Second, the locations of geometrical imperfections were selected by identifying regions where stress concentrations were greatest in the unit cell. Last, unit cells with these designed imperfections were replicated by 3D-printing. Both the experimental and FEM results confirmed that the Active Skins could deploy pre-programmed 3D features on-demand, reversibly, and effectively through a controlled buckling-induced deformation mechanism.

5:40 AM F.SM01.03.06
Bio-Inspired Vascularized Polymers Control Bacteria at Interfaces Kayla Marquis, Benjamin Chasse and Caitlin Howell; University of Maine, United States

Nearly all methods of introducing bioactive compounds to the surface of a substrate rely on application from above or fail over time due to depletion. In this work, we use a bio-inspired approach to deliver target molecules to an interface from below, making use of both theoretical modeling and experimental validation to rationally design customizable patterns and gradients. Mimicking the vascular systems of living organisms, networks of empty 3D-printed channels are filled with liquid containing the compound of interest, which flows through the vascular network and diffuses through the polymer, eventually reaching the substrate surface. In proof-of-principle experiments using *Escherichia coli* and *Bacillus subtilis* as model organisms, we demonstrate both theoretically and experimentally that the concentration of antibiotic and duration over which it is delivered to the surface can be controlled by varying the location of the vascular channels and concentration of the antibiotic solution inside. The result is a well-defined and predictable patterned response from the bacteria growing on the surface, a first step toward developing new types of adaptive antifouling surfaces and cell culture tools.

5:50 AM F.SM01.03.07
Compact Bio-Inspired Nanoscale Textures Reduce Contact Time of Bouncing Droplets Lin Wang, Ruoxi Wang, Jing Wang and Tak-Sing Wong; The Pennsylvania State University, University Park, United States

Many natural surfaces are capable of shedding water droplets rapidly, which has been attributed to the presence of low solid fraction ($\Phi_s \sim 0.01$) (*1*) according to the classical wetting theories (*2-4*). However, recent high-resolution microscopic observations revealed the presence of unusual high solid fraction nanoscale textures on water-repellent insect surfaces. For example, superhydrophobic mosquito eyes, springtails, and cicada wings possess solid fractions (Φ_s) as high as 0.25 – 0.64 (*5-7*). In addition, the texture size on these insect surfaces is typically on the order of 100 – 300 nm. To understand why both high solid fraction and nanoscale textures are important for these superhydrophobic insect surfaces, we systematically designed and fabricated a series of textured surfaces with texture size varying from 100 nm to 30 μm at solid fractions of 0.25 and 0.44, and investigated their static and dynamic wetting behaviors. Here we show that the contact time of bouncing droplets on high solid fraction surfaces can be reduced by reducing the texture size to nanometer scale. Specifically, we discovered that high solid fraction surfaces ($\Phi_s \sim 0.44$) with texture size ~100 nm could reduce the contact time by ~2.6 ms compared to that with texture size >300 nm. This texture-size dependent contact time reduction on solid surfaces has not been observed previously, and cannot be explained by existing surface wetting theories. We showed theoretically that the reduction in droplet contact time can be attributed to the dominance of three-phase contact line tension (*8*) on compact nanoscale textures. Through pressure stability analysis and experiments, we have further shown that high solid fraction ($\Phi_s > 0.25$) is an important requirement for insects to withstand high-speed impacting raindrops. Our results suggest that the compact and nanoscale textures on water repellent insect surfaces may work synergistically to repel and shed impacting raindrops rapidly, which could be an important survival strategy for flying insects. Technologically, the ability of compact nanoscale textured materials to repel high-speed impact of liquid droplets with reduced contact time may find use in a range of applications including fouling-resistant personal protective equipment (PPE), insect-sized flying robots, and miniaturized drones (*9*).

Fabrication of Durable and Transparent Superhydrophobic Coatings Based on Novel Architecture Obtained by Pickering Emulsion Templating Karthik Ananth Mani and Guy Mechrez; Agricultural Research Organization, Volcani Center, Israel

Despite the enormous research activity in the field of Pickering emulsions and the study of diverse emulsion systems such as O/W[1], O/O[2], W/O[3], O/W/O, W/O/W[4]. There are only very few studies which presents the implementation of Pickering emulsions toward the development of superhydrophobic coatings and surfaces[5-9]. It is possible to obtain a hierarchical porous structure by application of Pickering emulsions on a given surface and evaporation of the solvents, this procedure is termed *emulsion templating*. Although that enormous amount of studies have previously reported the successful development of superhydrophobic coatings and surfaces, only very few of them exhibit significant durability and transparency that would be suitable for real life applications. The current study presents the development of highly durable and transparent superhydrophobic coating based on oil-in-oil (O/O) Pickering emulsions. The combination of superhydrophobicity with significant abrasion resistance and transparency is obtained due to the formation of unique structures of shrinked colloidosomes on the surface of the coating. The coating is formed by emulsion templating of the O/O Pickering emulsion. The studied Pickering emulsions were applied on different types of polymeric substrates such as polypropylene and polycarbonate by using standard coating application methods including spin coating and roll coating.

Rational Design of Bio-Inspired Nanowire Architectures for Preventing Marine Biofouling Jing Wang, Sudarat Lee, Ashley R. Bielinski, Kevin A. Meyer, Abhishek Dhyani, Alondra M. Ortiz-Ortiz, Anish Tuteja and Neil P. Dasgupta; University of Michigan, United States

Biofouling has a negative impact on human health and economic development. In particular, biofilms in the marine environment grow easily, adhere strongly on most surfaces, and continuously generate adhesive proteins from the living organisms in the film. They cause increased fuel penalty, attenuation of sensor signals, and more [1]. To overcome these challenges, several natural surfaces, including shark skin [2], crab eyes [3], and dragonfly wings [4], have shown reduced biofilm settlement, nucleation, and adhesion because of their micro- and nano- surface textures.
Inspired by natural surfaces, herein, we present the rational design and fabrication of ZnO/Al_2O_3 core-shell nanowire (NW) architectures to significantly reduce marine biofouling (algae: cyanobacteria and diatoms) and further suppress the biofilm formation by tuning the NW geometry (length, spacing, branching) and surface chemistry [5]. Specifically, for hydrophilic NWs, we demonstrated algal fouling on NWs was only 40% of the fouling coverage on planar control surfaces when they were fully covered. These NWs outperform the surfaces with micrometer length-scale textures in marine fouling reduction under a multi-species fouling environment. Two mechanisms of the fouling reduction were summarized with geometric and mechanical effect of the NWs: (*1*) reduced effective settlement area, and (*2*) mechanical cell penetration. For superhydrophobic NWs, we demonstrated anti-biofouling performance for up to 22 days, which is one order of magnitude longer duration than what have been reported in the literature [6] under biofouling environment. A mass diffusion and thermodynamic model was developed to explain and predict the anti-fouling duration on NWs in the Cassie state. Furthermore, the nanowire surfaces are transparent across the visible spectrum, making them applicable to windows and oceanographic sensors. Through the rational control of surface nano-architectures, the coupled relationships between

wettability, transparency, and anti-biofouling performance are identified. We envision that the insights gained from the work can be used to systematically design surfaces that reduce marine biofouling in various industrial settings.

Late News: Substrate-Mediated Colloidal Assembly for Templating Tunable Structural Color Bianca C. Datta, Sunanda Sharma, Christine Ortiz and Neri Oxman; Massachusetts Institute of Technology, United States

To harness the spectacular functionality found in nature, scientists and engineers have developed a multitude of biomimetic and bio-inspired techniques, each with its own strengths and constraints. One classic example is structural color exhibited by organisms such as birds, insects, and cephalopods that produce compelling and vibrant visual displays, which provides a fascinating case study for exploring the role of material design on macroscale properties. Recent research has identified self-assembly of colloidal structures as a cheap, simple way to mimic aspects of this coloration, often using materials like polystyrene or silica as scattering elements.

Self-assembly of spherical and non-spherical particles is an appealing approach as it can be scalable, low cost, conducted under ambient and aqueous conditions, and versatile. There are many factors involved in the drying behavior of colloids which relate to self assembly and color visibility. Structure formation can be tuned by modulating particle composition, surface functionality, particle size and concentration, coating, solvent, substrate wettability and roughness, drying and deposition conditions, particle shape, and the temperature, humidity, and pH of the environment. By manipulating these conditions, the final colloidal assembly structure can be indirectly controlled, yielding a host of fascinating visual effects relevant to bio-inspired design. In this work, we examine the role of melanin for light absorption and polystyrene for light scattering in order to mimic the combination of pigment and structure found in nature, and ultimately demonstrate means to control patterns.

Here we explore the role of the substrate on evaporative dynamics and the interplay between pigment and structure in pattern formation. We influence the rate of the kinetics by tuning surface properties such as hydrophilicity, thereby controlling the color vibrancy. We observe the droplet behavior on different printed surfaces through optical microscopy and macroscopic imaging and demonstrate a visible difference in resulting patterns based on substrate wettability. We record the drying process to observe differences in the dynamics and relate kinetic processes to these final structures.

We utilize polystyrene microparticles with diameters from 173 – 500nm (Sigma Aldrich and Ted Pella), and eumelanin from cuttlefish ink (Sigma Aldrich and MP Biomedicals). By mixing polystyrene and melanin, we generate disordered structures in contrast to ordered structures formed by polystyrene alone, but take advantage of the absorptive properties of melanin to yield more saturated colors than typical amorphous colloidal systems. Polystyrene particle suspensions are mixed with melanin solutions at various ratios and evaporatively assembled on a variety of substrates with the ultimate goal of connecting initial droplet shape, contact angle and speed of evaporation, indirectly tuned using the substrate, to the resulting structure.

We thus present a comparison of drying behavior across several different surfaces, macro-patterning between pigment-based and structural responses to demonstrate color patterns, spectroscopic characterization of the performance of these assemblies on different surfaces, and novel insights about the dynamics of the drying process and the placement of absorbing melanin and scattering polystyrene on the dried surfaces. Properties such as reflectance, absorption, packing and organization, and global architectures are studied using a variety of methods, including timelapse imaging, scanning and transmission electron

microscopy, light microscopy, and angular spectroscopy. This work provides a path towards expanding the palette of achievable colors and patterns through bio-inspired design techniques. Such colloidal assemblies are of interest for optical devices, cosmetics, displays and inks, functional coatings, biocompatible products, sensors, and art elements.

6:30 AM F.SM01.03.13
Late News: Optical Manufacture and Application of Large-Area, Mechano-Responsive Photonic Sheets Benjamin Miller, Helen Liu and Mathias Kolle; Massachusetts Institute of Technology, United States

Dynamic optical appearance plays a critical role for many animals that rely on adaptive camouflage or bright and varying color displays for their survival. The photonic materials used by these organisms are not just of interest to biologists, but have also captured the imagination of physicists, chemists, materials scientists, and engineers, who are trying to emulate their dynamic optical behavior in synthetic bio-inspired material systems. Mechanically-responsive soft photonic materials, for instance, represent a versatile material platform for colorimetric force sensing in a variety of different research and technology fields, including healthcare, robotics, and human-computer interaction. Existing fabrication approaches are varied, including self-assembly of colloids or liquid crystals, magnetically induced self-assembly, block copolymer self-assembly, sequential spin coating, and laser writing and interference lithography. However, the application of these materials has been limited by drawbacks relating to their optical quality, mechanical properties, limited scalability, or cost and complexity of manufacture. We have recently developed a new optical fabrication approach that is capable of tackling these challenges, harnessing the century-old technique of Lippmann photography combined with recent advances in holographic recording materials. This process can be performed using just a desktop projector, aluminum foil, and many off-the-shelf holographic recording materials, at low cost and over large areas. Our manufacturing approach also permits spatially patterning different photonic structures and mechanical properties, with micron-scale resolution. In principle, this technique can be extended to realize an almost unlimited range of pattern morphologies that we know from biological photonic materials. We anticipate that our mechano-responsive photonic sheets will facilitate a range of new applications, and we will demonstrate initial prototypes in the fields of human-computer interaction and robotics.

6:40 AM F.SM01.03.14
Late News: Mussels Fabricate Hard and Flexible Composite Coatings from Immiscible Multiprotein Coacervates Franziska Jehle[1,2], Elena Macias-Sanchez[1], Sanja Sviben[1], Peter Fratzl[1], Luca Bertinetti[1] and Matthew J. Harrington[1,2]; [1]Max Planck Institute of Colloids and Interfaces, Germany; [2]McGill University, Canada

Mussel byssal threads are proteinaceous biofibers self-assembled by mussels in order to attach to surfaces at the rocky seashore. Byssal threads are protected by a thin cuticle that combines high hardness and extensibility, making it a useful role model for advanced flexible coatings. Cuticle mechanics have been shown to arise from DOPA-metal coordination cross-links, as well as from its composite micro- and nanostructure, which consists of biphasic granules within an amorphous matrix phase. Although the byssus cuticle has become an important source of bio-inspiration for producing tough, self-healing metallopolymers, the biochemical nature of the different cuticle structures and the assembly process by which the cuticle is formed are far from clear.

Here, we performed a compositional and ultrastructural investigation of the protein secretory vesicles used to fabricate cuticle and followed their self-assembly during cuticle formation utilizing advanced electron microscopy methods including FIB-SEM and STEM-EDX[1]. Findings suggest that the different proteins destined to form granules vs. matrix are pre-organized in a co-existing condensed fluid phase within secretory vesicles via phase separation of immiscible DOPA- and cysteine-rich precursors. During thread formation, the condensed fluid protein phases from multiple vesicles coalesce and solidify during secretion with the immiscible phases forming the matrix and granules, respectively. FIB-SEM 3D reconstruction of granule ultrastructure revealed a bicontinuous internal structure resembling a phase-separated block-copolymer, while elemental analysis with STEM-EDX exhibited an unusual partitioning of vanadium and iron between the DOPA-rich granules and cysteine-rich matrix, respectively, which may play a role in determining cuticle mechanics. These findings have direct relevance for production of nanostructured soft materials with complex and dynamic material properties.

6:50 AM F.SM01.03.15
Bio-Inspired Swellable Hydrogel-Forming Double-Layered Adhesive Microneedle Protein Patch for Regenerative Internal/External Surgical Closure Eun Young Jeon[1,2], JungHo Lee[1], Guenbae Lim[1], Justin J. Chung[2] and Hyung Joon

Cha[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Korea Institute of Science and Technology (KIST), Korea (the Republic of)

Significant tissue damage, scarring, and an intense inflammatory response remain the greatest concerns for conventional wound closure options, including sutures and staples. In particular, wound closure in internal organs poses major clinical challenges due to air/fluid leakage, local ischemia, and subsequent impairment of healing. Herein, to overcome these limitations, inspired by endoparasites that swell their proboscis to anchor to host's intestines, we developed a hydrogel-forming double-layered adhesive microneedle (MN) patch consisting of a swellable mussel adhesive protein (MAP)-based shell and a non-swellable silk fibroin (SF)-based core. By possessing tissue insertion capability (7-times greater than the force for porcine skin penetration), MAP-derived surface adhesion, and selective swelling-mediated physical entanglement, our hydrogel-forming adhesive MN patch achieved ex vivo superior wound sealing capacity against luminal leaks (139.7 ± 14.1 mmHg), which was comparable to suture (151.0 ± 23.3 mmHg), as well as in vivo excellent performance for wet and/or dynamic external and internal tissues. Collectively, our bioinspired adhesive MN patch can be successfully used in diverse practical applications ranging from vascular and gastrointestinal wound healing to transdermal delivery for proregenerative or anti-inflammatory agents to target tissues.

F-SM01

5:00 AM *F.SM01.04.01
Skeletons with Eyes Joanna Aizenberg; Harvard University, United States

The most finely tuned, rapidly responsive, and precisely directed optical systems currently known can be found on the surfaces of living organisms. Studies of brittlestars' tunable microlenses, sea sponges' optical fibers, butterflies' and beetles' intense colors, and squids' nearly perfect camouflage have revealed 3D architectures so intricately patterned down to the nanoscale that the topography itself controls the wavelengths and direction of reflected light. We are developing bioinspired, bottom-up self-assembly techniques that allow us to create comparably elaborate yet tunable hierarchical photonic structures, and integrate these into the design of a new class of dynamic, responsive optical materials.

5:15 AM F.SM01.04.02
Chitin Nanocrystals Confined to a Polymer Microgel Sujin Rebecca Lee, Elsa Reichmanis, Jung O Park and Mohan Srinivasarao; Georgia Institute of Technology, United States

Chitin is the second most abundant polysaccharide after cellulose, which can be extracted from exoskeletons of crustaceans and also from cell walls of fungi and insects. Similar to cellulose nanocrystals, chitin nanocrystals can be isolated through acid hydrolysis and form cholesteric phase. We investigate chitin nanocrystals confined to pnipam microgels using microfluidics device. The twisted structure of chitin nanocrystals are preserved within the polymer spheres, as characterized by optical microscopy. The droplet radius, R of the microgels can be adjusted by changing the volumetric flow rate of oil phase in a microfluidics device. Interestingly, the fabricated microgels shows bipolar structure with the shape of prolate spheroids. They exhibit swelling-deswelling behavior upon temperature change along the axis of helix.

5:25 AM F.SM01.04.03
A Soft Lithography Method to Generate Arrays of Microstructures on Hydrogel Surfaces Yolanda Vasquez[1], Hasani G. Jayasinghe[1], Mughees Khan[2] and Sundar V. Madihally[1]; [1]Oklahoma State University, United States; [2]Harvard University, United States

Research on synthetic mimics of microstructures found on natural organisms, such as the structured skin of the shark or the surface of the lotus leaf, have resulted in surfaces that dynamically change rigidity, adhesion, or wettability. Structured surfaces also have potential biomedical applications in tissue engineering and as drug delivery systems, sensors, and actuators. For the aforementioned biological applications, hydrogels are the materials of choice due to their biocompatibility,

biodegradability, and tunable mechanical properties. Generating patterns of intricate microstructures onto the hydrogel surfaces, however, is challenging because of the low mechanical strength, adhesion, or chemical incompatibility of hydrogels with various molds. Here, we report the use of a soft lithography technique to successfully pattern arrays of micropillars onto a poly(2 –hydroxyethyl methacrylate) based hydrogel. The swelling of the hydrogel in solvents such as phosphate buffered saline, deionized water, 60% ethanol, and absolute ethanol, facilitates the reproducible replication of the pattern. Furthermore, the micropillar pattern promotes the attachment of HeLa cells onto this hydrogel which is not inherently adhesive when unpatterned.

5:35 AM F.SM01.04.04
Bioinspired Multiscale Pores and Channels Xu Hou; Xiamen University, China

Nature provides a huge range of biological materials with various smart functions over millions of years of evolution and serves as a big source of bioinspiration for biomimetic materials that can bring impetus to the development of multifunctional materials and structures. From small biological ion channels to large oil pipelines, the structures with "Pore" and "Channel" are everywhere. Ion channels existing in living organisms play a significant role in maintaining balanced physiological conditions and serve as “smart” gates to ensure selective ionic transport. Pipelines, which are commonly used in chemical industry, food industry, agriculture, and energy-petroleum transportation, can be treated as macroscale channels. Multiscale pore and channel systems have been intensively explored and contributed to new developments in materials science, membrane science and technology, or micro/nanotechnology for analytical, biomedical, and energy applications. Stimulated by the achievements and the even larger potential of multiscale pore and channel systems, increasing research activities are devoted to important aspects such as energy saving, anti-fouling, anti-corrosion, and anti-blocking functionalities, switch ability and controllability integration of various functionalities, and good stability in such confined space. The most recent examples of mechanisms and strategies the learning from Nature are described, including bioinspired and smart multiscale pore/channel systems, especially building bioinspired liquid-based gating systems for bringing a new generation of design ideas of membrane separation technology; and bioinspired stimuli responsive micro/nanochannel systems for biomedical applications.

5:45 AM F.SM01.04.05
Bioinspired Cross-Linking of Preceramic Polymers via Metal Ion Coordination Bonding Kara L. Martin[1,2], Maria Parvulescu[1,2], Pavel Mogilevsky[1,2] and Matthew Dickerson[2]; [1]UES, Inc., United States; [2]Air Force Research Laboratory, United States

The polychaete worms of the Nereididae family are distinguished by lightweight, conical teeth that exhibit a hardness level analogous to human dentin. While comparable in material properties to the mineral comprising dentin, the polychaete worm’s teeth are proteinaceous material built from histidine rich proteins cross-linked with Zn^{+2} ions through coordination chemistry. The exemplified material properties achieved through coordination cross-linking of such biomaterials has inspired us to extend this method of cross-linking to preceramic polymers. Preceramic polymers require rigorous cross-linking as a means to reduce volume shrinkage and mass loss during pyrolysis, and often require extensive thermal curing steps to prepare a green body viable for ceramitization. Coordination cross-linking offers a faster, dynamic platform to preparing preceramic green bodies. Herein, we report the functionalization of commercially available polysiloxane and polycarbosilane backbones with pyridyl-moieties and the subsequent coordination cross-linking of these polymers with Zn^{+2} and Ti^{+4} ions. The rapidly cross-linked materials were characterized with ATR-FTIR, oscillatory rheology, and thermal gravimetric analysis. The cross-linked green bodies were then pyrolyzed at 1400°C to ceramic materials, and characterized with XPS, XRD, and TEM. Ceramics generated from coordination cross-linked preceramic polymers represent the metal ion cross-linker, with Ti^{+4} cross-linked polymers generating TiC/SiC, and Zn^{+2} cross-linked materials generating SiC, as Zn^{+2} evaporates between 1000–1200°C. Coordination cross-linking is a single dial that can adjust material characteristics before and after pyrolysis. Particularly, the viscoelastic properties, thermal stability, and ceramic yields at 800°C can be systematically changed with the loading equivalents of metal cross-linker and the ceramic composition can be changed by metal ion choice. To the best of our knowledge, this is the first example of silicon-based preceramic polymers cross-linked through pyridine-based metal ion coordination.

5:55 AM F.SM01.04.06
Design of Bio-Inspired Functional Nanomaterials and Their Applications Nurxat Nuraje[1,2]; [1]Nazarbayev University, Kazakhstan; [2]Texas Tech University, United States

With learning and getting inspiration from Nature, many trivial scientific questions and industrial problems can be resolved via proper designing the materials and creating unique structures, which lead to emerging materials in the field of renewable energy, sensors, and nanomedicine. Mimicking nanotechnology existed in Nature, we are able to create unique assembled structures to improve certain properties of materials and device, and design tool box to generate functional emerging nanomaterials. The main goals of this research are to synthesize novel bio-inspired and biomimetic functional nanomaterials, characterize and investigate their properties, and apply them to understand fundamental science via creating their hierarchical nanostructured materials. Basic understanding from those above investigations are then applied to address problems in solar energy conversion, and coatings. This research will focus on the following topics: (a) synthesis of bio-inspired functional nanomaterials; (b) fabrication of unique nanoarchitectures to better understand fundamental science; and (c) Applying these unique nanomaterials and nanostructures to resolve the scientific and technical problems in energy harvesting and conversion, and functional coatings.

6:05 AM F.SM01.04.08
Late News: PEDOT:PSS Based Bilayer Actuators for Soft Robotics Najathulla Bhagavathi Chalil, Mudrika Khandelwal and Atul S. Deshpande; Indian Institute of Technology Hyderabad, India

Poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) is a well known conducting polymer preferred owing to high conductivity and processability. PEDOT:PSS on application of a potential bias attracts oppositely charged ions causing volume expansion. This reversible expansion is exploited to prepare bilayer actuator with bacterial cellulose as the substrate. A stable fish tail like deflection of over 5 mm was observed at 1 V. Effect of amount and properties of PEDOT:PSS on deflection is studied along with energy conversion efficiency. This electro-chemical actuator can have potential applications in biomimetic soft robotics.

5:00 AM *F.SM01.05.01
Organisms Manipulate Light with Nano-Scale Crystal Mirrors Benjamin A. Palmer, Gan Zhang, Ofir Friedman, Anna Hirsch, Venkata J. Yallapragada, Dan Oron, Leeor Kronik, Leslie Leiserowitz, Steve Weiner and Lia Addadi; Weizmann Institute of Science, Israel

Organisms construct 'devices' based on assemblies of organic nano-crystals with optical functions. The structure, polymorph, size, morphology and superstructural arrangement of the crystals determine the optical properties of the 'device'. All the crystals have unusually high refractive indexes in the directions along which the light penetrates the crystal. The controlled assembly of nano-crystals forms multilayer reflectors that create structural colors, or mirrors and light scattering layers that function to increase vision sensitivity in the eyes of the organisms. Scallops have tens of eyes, each containing a concave multi-layered mirror perfectly tiled with a mosaic of square guanine crystals, made up of composite twins, reflecting light to form images onto the overlying retinas [1]. Crustacean decapods such as shrimps, crayfish and lobsters possess compound eyes that contain two sets of mirrors, composed of isoxanthopterin crystals. The two mirrors have very different ultrastructures and functions that we can rationalize in terms of the optical performance of the eye [2,3]. The unusual zander fish eyes contain two layers of organic crystals: thin guanine crystals, form a reflective layer in the back of the eye, whereas block-shaped crystals of 7, 8-dihydroxanthopterin in the inner tapetum layer back-scatter light onto the retina, increasing the light sensitivity of the eye [4]. Finally, insects commonly known as jumping bristletails, form large amounts of xanthine crystals in their median and lateral ocelli [5]. The structure-function relations in this last example are still under investigation. In all these examples, the constituent molecules are mostly purines and pteridines, which raises the question of what molecular and structural characteristics of these crystals, favor their use for optical functions in organisms. Furthermore, the organization of the crystalline functional components is controlled from the crystal structure at the nanoscale to the complex 3D structure at the millimeter level, extending the interest in the relation between structure and optical properties to higher

hierarchical levels.

Bioinspired Assembly and Collective Motion of Nanocomposite Hydrogel Sheets at Air/Water Interfaces Ryan C. Hayward; University of Colorado Boulder, United States

We describe a platform of temperature-responsive hydrogel nanocomposites adsorbed at air/water interfaces that exhibit a variety of bioinspired non-equilibrium behaviors due to temperature gradients generated by illumination with visible light. In one example, we exploit spatial variations in thermally-induced deswelling of the gel particles to drive buckling of thin sheets into 3D shapes with non-zero Gaussian curvature. Similar to the mechanism exploited by numerous insects to climb menisci or drive clustering, pinning of the three-phase contact line at the sheet edges gives rise to capillary ‘multipole’ interactions between different objects, leading to assembly, repulsion, and even sustained rotational motion, depending on the geometry. In a second example, we exploit Marangoni forces resulting from temperature gradients to drive motion and interaction of planar particles, once again inspired by well-known strategies employed by aquatic insects. A simple method for Marangoni optical trapping is realized by shining appropriate patterns of light on the interface, enabling the definition of easily customized geometries in which to study coupled motion of multiple oscillators and spinners.

5:30 AM F.SM01.05.03
Bioinspired Smart Materials—Sensing, Solar Harvesting and Soft Robotics Ximin He; University of California, Los Angeles, United States

From the cellular level up to the body system level, living organisms are able to sense and adapt to local environment for various functions, from detecting and transporting molecules in the complex bio-fluids to harvesting energy from the environment and generate motions to keep alive. These graceful capabilities arise from the coordination of the chemo-mechanical actions, such as the molecular configuration changes and micro/macroscopic mechanical motions. Stimuli-responsive hydrogels are a class of synthetic materials that can change their volume and physical properties in response to environmental cues including temperature, light, and specific molecules. Inspired by these unique abilities, we have developed a series of dynamic material systems based on hydrogels. This presentation will introduce several novel functionalities that this broad-based platform has demonstrated, ranging from beetle-inspired ultrafast colorimetric sensing of chemical and biological species (*Adv. Mater.* 2018; *Adv. Opt. Mater.* 2019), autonomous sorting of target molecules in complex biofluids or wastewater (*Nat. Chem.* 2015), and plant-mimetic adaptive light tracking and harvesting (*Nat. Nanotech.* 2019), as well as self-sensing actuators for soft robotics (*Sci. Robotics* 2019). Overall, the environment-adaptive, dynamic material systems would have broad impacts in areas ranging from wearable sensors to smart devices that regulate energy usage and fully autonomous soft robots.

5:40 AM F.SM01.05.04
Biorobotic Hybrid Heart—A Biomimetic Approach to Recreating the Heart’s Pumping Motion Clara Park and Ellen Roche; Massachusetts Institute of Technology, United States

The heart is a uniquely challenging organ to recreate due to its dynamic three-dimensional (3D) motion and its detailed internal structures. Motivated by the lack of a synthetic or biological method to recapitulate both the complex motion and anatomical features of the heart, we recently developed a biorobotic hybrid heart that combines passive organic structures (intracardiac tissue) whose motion is driven by an active synthetic cardiac muscle. In this talk, we will describe a biomimetic design approach to programming the active synthetic cardiac muscles by replicating the intricate arrangements of cardiac fibers, which synchronously contract along to achieve efficient pumping motion of the heart. Instead of replicating the complex fiber structures directly in 3D, we took inspiration from the helical ventricular myocardial band theory – which proposes that the ventricle of the heart can be unraveled into a singular muscular band that is spirally arranged in the 3D space – to simplify the design and fabrication process of the synthetic cardiac muscles. We constructed a two-dimensional (2D) biomimetic matrix that has multiple linearly contracting pneumatic artificial muscles, which were oriented to match that of the muscle fibers in the unraveled heart tissue, in a soft elastomeric sheet. Then, the soft robotic matrix was rewrapped in a 3D helical fashion to recreate the hierarchical, functional architecture, and the global 3D motion of the ventricular cardiac muscle. Once assembled with the organic component, the biorobotic hybrid heart replicated the volumetric displacement of the heart at a physiological level upon cyclic actuation.

Dynamic and Programmable Self-Assembly of Micro-Rafts at the Air-Water Interface Wendong Wang, Gaurav Gardi, Vimal Kishore and Metin Sitti; Max-Planck-Institute, Germany

From the thermodynamic point of view, most materials are either in their equilibrium states, such as inorganic and organic crystals, or in kinetically trapped non-equilibrium states, such as porous materials. Life, on the other hand, is in dissipative non-equilibrium (or dynamic) state, with hierarchically ordered complex structures and highly coordinated functions. Developing dynamic materials systems where structural orders are sustained by continuous energy input and dissipation will not only introduce a new paradigm in materials science but also impact robotics. In the context of robotics, a micro-robot collective is a dynamic and programmable materials system, where fundamental physical and chemical principles guide the designs of local interactions and global behaviors. Here we show the collective patterns and behaviors of up to 250 micro-rafts spinning at the air-water interface and demonstrate the link between order and information in the collective motion. These micro-rafts display a rich variety of collective behaviors that resemble thermodynamic equilibrium phases such as gases, hexatics, and crystals. Moreover, they show emergent properties and functions when coupled with reconfigurable magnetic potentials. We devise information theoretical measures to quantify the information content of the spatiotemporal patterns and demonstrate their close relations with the order. Our findings are relevant for analyzing collective systems in nature and for designing collective robotic systems.

6:00 AM F.SM01.05.07
In Pursuit of a Deeper Understanding of the Effects of Surface Flexibility on Ion Mobility Veselina Marinova, Colin Freeman and John Harding; The University of Sheffield, United Kingdom

Crystallisation is an important process in a wide selection of problems – from the manufacture of pharmaceutical ingredients and inorganic materials to the prevention of scale formation and the production of minerals in living organisms. An understanding of the mechanisms which promote crystallisation can allow control over the formation of specific polymorphs, preventing the formation of crystals where it is undesirable, and tailoring crystalline materials for applications. In an uncontrolled environment, crystallisation typically occurs on foreign surfaces. Understanding the surface characteristics which promote and direct nucleation is key to the design and control of surface-aided crystallisation.

Compelling examples from literature show that flexible surfaces can strongly affect crystallisation rates. Self-assembled monolayers (SAMs) of alkenethiols, supported on gold or silver, can promote the nucleation of $CaCO_3$ with a high degree of orientational specificity[1,2,3]. We use molecular dynamics simulations to understand the mechanisms through which defect-induced disorder in the flexible SAM of 16-mercaptohexadecanoic acid (16-MHDA) on an Au (111) surface can affect the ability of Ca^{2+} and CO_3^{2-} to form clusters.

To achieve this, we use molecular simulations to study possible defects in the monolayers through the removal of one or several surface atoms from the underlying Au (111) surface. This procedure forms step edges and vacancy islands which promote interactions between head groups of neighbouring chains through the offset created. As a reference case, we use an ordered SAM with a characteristic spacing of 0.498 nm between chains and a 30° angle of the carbon backbone with the underlying gold surface[4]. An all-atom AMBER[5] forcefield is used to reproduce the interactions between the alkenethiol chains, while a forcefield developed by Raiteri et al.[6] was used for an accurate representation of $CaCO_3$ and its interactions

with water. The Schröder method was used to obtain the interactions between the SAM and the Ca^{2+} and CO_3^{2-} ions.

Our findings suggest that the presence of defects not only disrupts the local structure of the solvent, but in some cases can induce longer-ranged disorder effects, reducing the longevity of the solvent adsorbed state. The introduction of ions into the system reveals how the disrupted surface layer of the solvent affects ion mobility on and near the surfaces, shedding light on the role of defects in flexible surfaces on the formation of crystalline clusters. This is an important step towards the defining and understanding of effective nucleating agents.

Learning from Viruses—Efficient Cellular Translocation and Accumulation of Nanoparticle-Based Carriers Using an Optimized Class of Cell-Penetrating Peptides Isabel Gessner, Annika Klimpel, Eva Krakor, Merlin Klußmann, Ines Neundorf and Sanjay Mathur; University of Cologne, Germany

The discovery that viruses such as the Human Immunodeficiency Virus (HIV) contain proteins that allow the virus to overcome cellular barriers and achieve efficient cell penetration without need for a receptor represents a milestone in medicinal research. Since then, the Trans-Activator of Transcription (Tat) protein has been identified as first cell-penetrating peptide (CPP) and was linked to various cargos including large multimeric protein complexes to allow for their transport across cell membranes. The high translocation efficiency is thereby highly dependent on the sequence, secondary structure, and charge of the protein.
Given the increasing demand for intracellular delivery of nanoparticle-based therapeutics, we studied how the cell uptake of silica nanoparticles can be modulated after decoration with differently active CPPs. Employed CPPs were derived from antimicrobial peptide CAP18 and were systematically modified regarding the position of specific amino acids in their sequence. Interestingly, we found out that significant differences in uptake efficiency and intracellular accumulation of nanoparticle-CPP conjugates were observed depending on amphipathicity, alpha-helical structure formation and charge of the peptide, as well as the carrier size. These results demonstrate how we can learn from viruses to overcome current medicinal challenges, revealing the huge potential of sequential fine-tuning of CPPs and providing insights into their interaction with inorganic nanocarrier surfaces.

Mechanistic Understanding of Metal-Coordination Bond Dissociation in Biological and Synthetic Materials for Tunable Mechanical Properties Eesha Khare, Niels Holten-Andersen and Markus Buehler; Massachusetts Institute of Technology, United States

Metal-coordination complexes are emerging as a broad class of supramolecular crosslinks for use in advanced structural materials with tunable mechanical properties. Unlike conventional covalent bonds, these bonds have the capacity to reform after rupture, thereby enabling dynamic, tunable, and reversible (self-healing) mechanical properties. An increasing number of biological organisms, such as marine mussels (*Mytilus)* and marine worm jaws (*Nereis virens)*, have been found to take advantage of these unique properties of metal-coordinate complexes in the secretion of loadbearing materials for complex extraorganismal functions. Inspired by the role of these bonds in biological materials, several studies have incorporated metal-coordination bonds as crosslinks in model hydrogel systems to tune dynamic mechanical properties over a broad spectrum of timescales. However, a deeper understanding of how microscopic behavior of metal-coordination bonds affect bulk mechanical properties is still missing, rendering predictive implementation in designing mechanical properties of materials a continued challenge.

This study presents a multiscale computational model of various metal-coordination complexes to elucidate how these complexes affect bulk mechanical properties of protein and synthetic metal-coordinated materials. First, we study how coordinating ligands specific to biological and synthetic contexts affect mechanical properties of the bulk material. Comparisons are drawn between imidazole, naturally found in marine mussels and worm jaws, and histidine, used in synthetic hydrogel studies, to demonstrate clear differences between biological and synthetic materials. Density functional

theory (DFT) and steered molecular dynamics (SMD) studies on individual coordination complexes reveal how the dissociation path of histidine-Ni2+ or imidazole-Ni2+ underpin bond lifetime and bulk material relaxation time. Second, we study how clusters of metal-coordination complexes affect bulk mechanical properties. To understand this effect, model systems with various coordination complexes are designed and tested. MD studies reveal that these different model systems significantly affect bulk relaxation time and strength. Results from studies on these model systems are qualitatively compared to metal-coordinate crosslinks in the *Nereis virens* marine worm jaw protein structure. This comparison may lend insight into how the structure of *Nereis* worm jaw optimizes the positioning of metal-coordination interactions for precise mechanical control. Altogether, this work proposes key design criteria for how metal-coordination chemistry can be advanced for biological applications with dynamic mechanical materials properties.

6:30 AM F.SM01.05.10
Mechanical Modulation of Lipid Membranes by Phospholipid Peroxidation Changjin Huang[1], Choon-Peng Chng[1], Yoel Sadovsky[2] and K. Jimmy Hsia[1]; [1]Nanyang Technological University, Singapore; [2]Magee-Womens Research Institute, United States

The imbalance between the production of reactive oxygen species (ROS) by various mechanisms, including both internal metabolic processes and external environmental stimuli, and the endogenous antioxidant defences in mammalian cells often leads to oxidative stress and contributes to various pathological conditions, such as aging, neurodegenerations in Parkinson and Alzheimer diseases, and cancer. Under oxidative stress, the ROS initiates a series of oxidation reactions of cell membranes through the formation of hydroperoxides at the sites involving double-bonded carbon atoms along unsaturated fatty acid chains of phospholipids. Being hydrophilic in nature, the hydroperoxide group tends to migrate towards the water-membrane interface and changes to the internal structure of the lipid membrane. Despite the improved knowledge in the biological and chemical events during lipid peroxidation, how lipid peroxidation modulate the mechanics of lipid membranes remains largely elusive. In this study, we have investigated the peroxidation of polyunsaturated (more than one double-bond per fatty acid chain) phospholipids, a process involved in a recently identified form of programmed cell death, namely ferroptosis. By performing systematic coarse-grained molecular dynamics simulations, we have identified that lipid peroxidation affects the physical and mechanical properties of lipid membranes in an oxidation site-dependent manner. Our results show that the lipid peroxidation softens the membrane when the oxidation site is deep inside the hydrophobic core, while it tends to strengthen the membrane when the location of the oxidation is close to the water-membrane interface. Our study provides an insightful understanding on the modulation of membrane mechanics by lipid peroxidation.

Muscle-Inspired Highly Elastic Liquid Crystal Elastomer-Carbon Nanotube Composite Filaments as Programmed Actuators Jiaqi Liu, Yuchong Gao, Haihuan Wang, Ryan Poling-Skutvik, Chinedum Osuji and Shu Yang; University of Pennsylvania, United States

Many animals in nature possess musculoskeletal systems with astonishing actuation speed, strength, and adaptivity. To mimic their agile and forceful locomotion, liquid crystal elastomers (LCEs) are a promising candidate among all synthetic actuator materials, as they exhibit reversible and anisotropic deformation by multiple external stimuli. So far, most studies on LCEs have focused on accomplishing complex deformation in 2D thin films over centimeter scale areas with relatively small specific energy densities, which is different from the 1D fiber-based contraction mechanism of muscles. Herein, using an extrusion process, meter-long LCE composite filaments that are responsive to both infrared light and electrical fields are fabricated. In the composite filaments, a small quantity of cellulose nanocrystals (CNCs) is incorporated to facilitate the alignment of liquid crystal molecules along the long axis of the filament. Up to 2wt% carbon nanotubes (CNTs) is introduced into the LCE matrix without aggregation, which in turn greatly improves the mechanical property of filaments and their actuation speed, where the Young's modulus along the long axis reaches 40MPa, the electrothermal response time is within 10s. The maximum work capacity is 38J/kg with 2wt% CNT loading. Finally, shape transformation and locomotion in several soft robotics systems achieved by the dual responsive LCE/CNT composite filament actuators are demonstrated.

6:50 AM F.SM01.05.12
Peptidoglycan Isolated from *Bacillus subtilis* Spores Shows Extreme Stimuli-Responsive Actuation Zhi-Lun Liu[1,2], Haozhen Wang[2,2] and Xi Chen[1,2]; [1]The City College of New York, United States; [2]The City University of New York, United States

Actuators and artificial muscles require high-efficiency stimuli-responsive materials that transduce an energy form, such as electric voltage, thermal gradient, pneumatic pressure, or chemical potential, to their structural deformations. However, energy conversion efficiency of most man-made stimuli-responsive materials fail to compete with natural muscles, such as

human and insect muscles whose efficiencies reach 40 and 16%, respectively. Here, we report that peptidoglycan (PG) isolated from *Bacillus (B.) subtilis* spores exhibits powerfully humidity-responsiveness, and it efficiently transduces water's chemical potential energy into mechanical motions with an energy conversion efficiency of ~35%. We isolated PG from other protein-based components in spores by using several denaturing agents, and subsequently identified its structure by using a SEM and a liquid chromatography-electrospray ionization-mass spectrometry (LC-ESI-MS). Due to the lack of database of *B. subtilis* spore PG's chemical structure, we developed our own algorithm to deconvolute the LC-ESI-MS detected mass to charge ratio (*m/z)* and identified 6 hydrolysates with an error less than 4 ppm. Our results suggest that our isolated PG are composed of long glycan chains that are loosely cross-linked by short peptide stems, forming a 3-dimensional amphiphilic hierarchical structure. When isolated PG is exposed to humidity changes or water gradients, we found that PG can forcefully swell and shrink. For example, when local relative humidity is increased from 5% to 90%, PG expands up to 50.1% of its original height with a swelling pressure of 302.17 MPa. Using a thermodynamic cycle, we characterized PG's energy density and power density which reach 59.9 MJ m^{-3} and 5.9 MW m^{-3}, respectively, exceeding that of all natural muscles. By using PG, we also created a large-scale bilayer structure that reversibly bends in response to RH changes, demonstrating the possibility of using PG to develop high-efficiency actuators.

7:00 AM F.SM01.05.13
Physical Implementation of Ant Colony Intelligence in Colloidal Particle System Bokusui Nakayama and Toshiharu Saiki; Keio University, Japan

In the conventional computing paradigm based on the von Neumann architecture, a tremendous amount of data is transferred between memory and processor and the program operates on the data in a step-by-step fashion, which imposes a bottleneck in the speed and scalability of the architecture. A new paradigm beyond the von Neumann architecture is needed to address the problem fundamentally. The most promising approaches include implementation of swarm intelligence algorithm, like ant colony, to solve optimization problems. In order to implement natural computing algorithm into some physical systems, phase change materials (PCMs) are advantageous as a key platform due to its plasticity and threshold behavior (nonlinearity), which provide memory and processing functionalities, respectively. Based on the idea, we proposed an idea to implement an algorithm for Ising spin glass problem to the system of coupled plasmon particles interacting with PCM.
In this study, we attempt to implement ant pheromone algorithm. Ant colony optimization is a problem to find the shortest path between their nest and food using pheromone trails. Ants emit pheromone on the ground which works as a signal to attract other ants. If an ant follows the pheromone trail, it itself also emits more pheromone, thus emphasizing the trail. The more ants follow the trail, the pheromone deposition also increases (positive spiral). Pheromone strength decays over time due to the evaporation resulting in much less pheromone on less popular paths (negative spiral). These positive and negative spirals enable ants to find the shortest path autonomously.
In the experimental setup, polystyrene beads (PBs) with a diameter of 500 nm suspended in water were used to mimic the behavior of agent ants. The suspension was confined in a two-dimensional slit formed with two glass plates. A GeSbTe film, as a PCM, was deposited on the bottom glass plate. The PBs move around in Brownian motion on the GeSbTe film, which was initially in the amorphous phase. Under uniform light irradiation (sub-nanosecond-pulsed laser) over a wide area, the GeSbTe just beneath the PBs is crystallized due to the near-field lens effect of PB. The crystalline trail, which is expected to work as the pheromone trail, absorbs more light and becomes more heated than the amorphous background and thus a convection flow is formed such as to attract other PBs towards the crystalline trail. In addition to the convection flow, the electrostatic interaction between the PB and GeSbTe in the crystalline phase, the PBs trace the crystalline trail. By providing larger fluence pulses, the crystalline trail is amorphized, which is equivalent to the evaporation of pheromone. On this experimental platform, we demonstrated mimicking smart behavior of ants, which includes formation of trail by following a PB ahead and finding shortcut path through thermal communication of PBs.

7:10 AM F.SM01.05.14
Reconfigurable Microbots Folded from Simple Colloidal Chains Tao Yang[1], Brennan Sprinkle[2], Yang Guo[1], Jun QIan[3], Daoben Hua[3], Aleksandar Donev[2], David Marr[1] and Ning Wu[1]; [1]Colorado School of Mines, United States; [2]New York University, United States; [3]Soochow University, China

Overcoming the reversible nature of low-Reynolds number flow, a variety of biomimetic micro-robotic propulsion schemes and devices capable of rapid transport have been developed. However, these approaches have been typically optimized for a specific function or environment and do not have the flexibility that many real organisms exhibit to thrive in complex microenvironments. Here, inspired by adaptable microbes and using a combination of experiment and simulation, we demonstrate that one-dimensional colloidal chains can fold into geometrically complex morphologies including helices, plectonemes, lassos, and coils and translate via multiple mechanisms that can be varied with applied magnetic field. With chains of multi-block asymmetry, the propulsion mode can be switched from surface-enabled to bulk, mimicking the motion

of organisms such as flagella-rotating bacteria, tail-whipping sperm, arching and stretching inchworms, and sidewinding snakes. We also demonstrate that reconfigurability enables navigation through three dimensional and narrow channels mimicking capillary blood vessels. Our results show that flexible microdevices based on simple chains can transform both shape and motility under varying magnetic fields, a capability we expect will be particularly beneficial in complex *in vivo* microenvironments.

7:20 AM F.SM01.05.16
Soft Robotic Rapid Actuation Using Vibrating Mesh Atomization Han-Joo Lee and Kenneth J. Loh; University of California San Diego, United States

Conventional soft robotic structures are actuated by inflating the elastomer with a pneumatic pump. However, this method involves heavy, bulky pumps that should be tethered to the system with multiple tubes. More recently, soft actuation by liquid vaporization is receiving much attention, since it only requires a small heater and liquid embedded in the elastomer. The volume of the liquid expands during vaporization, which inflates and deforms the structure. Despite their benefits, they still face several limitations that have prevented their practical use. For instance, vaporization requires heating the embedded fluid in the structure to its boiling point, while actuation ceases when the system is tilted, and the heater is no longer in contact with the liquid. In addition, cooling the system to return the structure to its original shape takes a long time, thus limiting actuation frequency. In this study, these limitations were addressed by designing a soft robotic structure that actuates based on the principles of atomization and vaporization. First, a soaked wick was embedded in the soft elastomer structure in lieu of directly encasing liquid in cavities. A miniature piezoelectric ring transducer with a metal mesh in its center was positioned on the surface of the wick, thus making contact with the embedded fluid at all times and even when the system is tilted. Second, the piezoelectric ring was excited using a high-frequency electrical signal to vibrate the metal mesh while dispersing the embedded liquid into small droplets. These droplets were ejected into a small, embedded heater to enable rapid evaporation of the ejected droplets, which required significantly less temperature, power, and time than directly boiling the embedded fluid. A uniaxial motion bellows structure was fabricated with the soaked wick, piezoelectric ring with a metal mesh, and miniature heater. Their force and displacement performance were tested, characterized, and compared with conventional liquid vaporization. Overall, the developed method was shown to be faster, consumed less power, and enabled rapid cyclic motions as compared to actuation by boiling. The results also showed promising performance attributes comparable to pneumatic pumps but with the added benefits of being easier to miniaturize for portable or untethered soft robotic systems.

7:30 AM F.SM01.05.17
Regenerated *Bombyx Mori* Silk that Mimics Spider Silk's Superior Water Responsive Actuation Yaewon Park[1], Yeojin Jung[1,2] and Xi Chen[1,2]; [1]The City University of New York, United States; [2]The City College of New York, United States

Water-responsive (WR) materials that swell and shrink in response to changes in relative humidity or water gradient provide new engineering opportunities for adaptive structures, soft robotics, and sustainable energy. Spider dragline silk is a WR materal that have demonstrated a significant acutation energy density of 0.5 MJ m^{-3}, which is higher than most stimuli-responsive materials used for actuators and artificial muscles. However, spider silk's low availability and the poor understanding of its structure-WR property relationship impede pratical applications or *de novo* design of its mimetic structures. Here, using *Bombyx (B.) mori* silk that shares a similar supramolecular structure to that of spider silk proteins, we demonstrate tunable water-responsinveness of *B. mori* silk and found that a higher β-sheet crystallinity strongly correlates to a higher WR energy density. To mimic spider dragline silk's secondary structures and investigate its structure-WR relationship, we used a series of solvent treatments that allow us to control the crystallinity of regenerated *B. mori* silk. Suprisingly, when *B. mori* silk is processed to have a similar β-sheet content (48.6 %) as that of spider dragline silk, the *B. mori* silk possess a similar WR energy density (0.48 MJ m^{-3}) to spider silk. When *B. mori* silk's crystallinity was further increased to 57.6 %, its WR energy density reaches 1.6 MJ m^{-3}, surpassing that of all known natural muscles. Response time of WR *B. mori* silk could be reduced by rendering surface hydrophilicity and pore structures. As a proof-of-concept, we have demonstrated a regenrated *B. mori* silk muscle that can reversibly lift a load about 1200 times heavier than the silk's own weight.

7:40 AM F.SM01.05.18
Mimicking Nacre Through Magnetically Driven Self-Assembly of Colloids Joelle Medinger and Marco Lattuada; University of Fribourg, Switzerland

Nature's intelligent design of composite materials leads to enhanced mechanical properties compared to the individual constituents, which can for example lead to a combination of high stiffness and toughness [1]. Nature design principles have

inspired scientists to fabricate reinforced synthetic materials by mimicking the architecture of biological systems. Nacre is one of the most studied systems [1-3]. It is a composite material formed of alternating layers of inorganic aragonite platelets intercalated by a biopolymer [4]. Nacre displays remarkably high mechanical properties going far beyond the rule of mixture of its constituents.
We tried to mimic this layered composite structure using silica as inorganic material. In order to obtain a layered porous and anisotropic silica network, we modified the conventional sol-gel process, which leads to porous silica monoliths, by adding superparamagnetic iron oxide nanoparticles (SPIONS) and applying an external rotating magnetic field during the sol-gel transition [5-6]. The magnetic nanoparticles will self-assemble into layered structures in the presence of a high frequency rotating field, aligned in the plane of rotation of the field. Silica having an affinity for the iron oxide nanoparticles will nucleate on them adopting the same structure as the SPIONS, which act as smart templates to dictate the final structure of the monolith, which is permanently fixed after gelation. The final inorganic-organic nacre inspired composite is created by filling the porous structure with a polymer. Compressions tests of the platelet-structured composite show the desired increase of the mechanical properties of the silica monolith.

Self-Regeneratable Living Material Produced from Microbial Cells Avinash Manjula Basavanna[1,2], Anna Duraj-Thatte[1,2] and Neel Joshi[1,2]; [1]Harvard University, United States; [2]Northeastern University, United States

Human-made materials are generally considered to be the resultant of heat-beat-treat strategies due to their energy-intensive, high temperature/pressure and harsh chemical treatments, whereas the biomaterials made by living cells are fabricated at ambient conditions from abundantly available benign components. Thus, drawing inspirations from nature and harnessing the unparalleled manufacturing capabilities restored in living cells could lead to the development of an ultimate materials technology. Just like a seed that can grow into a living wood, we envision that living cells can be engineered to fabricate living materials that have life-like properties. In this regard, we present a simple and versatile strategy to fabricate living materials from engineered microbial cells at ambient conditions. Remarkably, our living materials comprises of living cells and a fraction of the material can self-regenerate itself. This work opens up unprecedented avenues to integrate synthetic biology, materials engineering, microbiology, nanotechnology and biomimicry - to develop futuristic materials and systems for a sustainable world by employing microbial factories.

8:00 AM F.SM01.05.20
Bioinspired Materials with Self-Adaptable Mechanical Behaviors Santiago Orrego[1,2], Zhezhi Chen[2], Urszula Krekora[2], Decheng Hou[2], Seung-Yeol Jeon[2], Matthew Pittman[2], Carolina Montoya[1], Yun Chen[2] and Sung H. Kang[2]; [1]Temple University, United States; [2]Johns Hopkins University, United States

Nature produces outstanding materials for structural applications such as bones and woods that can adapt to their surrounding environment. For instance, bone regulates mineral quantity proportional to the amount of stress. It becomes stronger in locations subjected to higher mechanical loads. This leads to the formation of mechanically efficient structures for optimal biomechanical and energy-efficient performance. However, it has been a challenge for synthetic materials to change and adapt their structures and properties to address the changes in loading conditions. To address the challenge, we are inspired by the findings that bones are formed by the mineralization of ions from blood onto scaffolds. We report a material system that triggers mineral deposition from ionic solutions on organic scaffolds upon mechanical loadings so that it can self-adapt to mechanical loadings. For example, the mineralization rate within the material system could be modulated by controlling the loading condition, and a 30-180% increase in the modulus of the material was observed upon cyclic loadings whose range and rate of the property change could be modulated by varying the loading condition. We envision that our findings can open new strategies for making synthetic materials with self-adaptable mechanical properties.

Diffusiophoresis—From Physicochemical Effects to Biofilm Mitigation Howard A. Stone; Princeton Univ, United States

Diffusiophoresis refers to the motion of colloid materials in concentration gradients. I describe some of our studies of these problems, using experiments and mathematical modeling, such as the influence of ion valence and the effect of multiple electrolytes. Also, we demonstrate that these effect can influence of the movement of bacteria. For example, I summarize our observations of the migration of wild-type V. cholerae and a mutant lacking flagella (ΔflaA), as well as S. aureus and P. aeruginosa, near a dissolving CO2 source, which shows that diffusiophoresis of bacteria is independent of shape and Gram stain. With long-time experiments, we show that CO2-driven diffusiophoresis can reduce surface contamination, which suggests that the mechanism can be applied to cleaning systems and anti-biofouling surfaces. This work involves contributions from Suin Shim, who investigated the diffusiophoretic response of bacteria, as well as Ankur Gupta, Jessica Wilson and others in my research group.

5:15 AM *F.SM01.06.02
Chemically Controlled Shape-Morphing of Elastic Sheets Anna C. Balazs[1], Raj K. Manna[1], Oleg E. Shklyaev[1] and Howard A. Stone[2]; [1]University of Pittsburgh, United States; [2]Princeton University, United States

The shape-morphing of two-dimensional elastic materials into three-dimensional structures is a vital and ubiquitous transformation in biological systems, as evidenced, for example, by the morphogenesis in cells and tissues, the formation of well-defined curvatures in growing flowers and leaves, and reconfiguration of seedpods in the release of seeds. The functionality of such biological reconfigurations has inspired the development of synthetic shape-changing materials that are useful for soft robotics and soft actuators. Here, we use theory and simulation to devise a distinctive approach for driving shape changes of 2D elastic sheets in fluid-filled microchambers. The sheets are coated with catalyst to generate controllable fluid flows, which transform the sheets into complex 3D shapes. A given shape can be achieved by patterning the arrangement of the catalytic domains on the sheet and introducing the appropriate reactant to initiate a specific catalytic reaction. Moreover, a single sheet that encompasses multiple catalytic domains can be transformed into a variety of 3D shapes through the addition of one or more reactants. Materials systems that morph on-demand into a variety of distinct structures can simplify manufacturing processes and broaden the utility of soft materials.

5:30 AM F.SM01.06.03
Differential Growth and Shape Formation in Plant Organs Changjin Huang[1], Zilu Wang[2], David Quinn[2], Subra Suresh[1] and K. Jimmy Hsia[1]; [1]Nanyang Technological University, Singapore; [2]Carnegie Mellon University, United States

Morphogenesis is a phenomenon by which a wide variety of functional organs are formed in biological systems. In plants, morphogenesis is primarily driven by differential growth of tissues. Much effort has been devoted to identifying the role of genetic and biomolecular pathways in regulating cell division and cell expansion and in influencing shape formation in plant organs. However, general principles dictating how differential growth controls the formation of complex 3D shapes in plant leaves and flower petals remain largely unknown. Through quantitative measurements on live plant organs and detailed finite-element simulations, we show how the morphology of a growing leaf is determined by both the maximum value and the spatial distribution of growth strain. With this understanding, we develop a broad scientific framework for a morphological phase diagram that is capable of rationalizing four configurations commonly found in plant organs: twisting, helical twisting, saddle bending, and edge waving. We demonstrate the robustness of these findings and analyses by recourse to synthetic reproduction of all four configurations using controlled polymerization of a hydrogel. Our study points to potential approaches to innovative geometrical design and actuation in such applications as building architecture, soft robotics and flexible electronics.

5:40 AM F.SM01.06.05
Effect of Ultraviolet Radiation on the Broadband Optical Properties of Synthetic Melanin Coatings Anvay Patil[1], Weiyao Li[1], Xuhao Zhou[2], Zhao Wang[2], Ming Xiao[1], Matthew Shawkey[3], Nathan Gianneschi[2,2] and Ali Dhinojwala[1]; [1]The University of Akron, United States; [2]Northwestern University, United States; [3]Ghent University, Belgium

Melanin, a ubiquitous material present in all forms of the living kingdom, and its synthetic mimics have been extensively

studied owing to its intriguing properties like broadband absorption, ultraviolet (UV)-protection, and other multi-functional properties. In the recent decade, synthetic melanin (especially polydopamine) has been extensively employed to study structural color, optical filters and other optical applications. However, there is a lack of understanding on how the optical properties of these materials would be affected after intensive exposure to UV radiation (320-450 nm). In this work, we characterize the complex refractive index of synthetic melanin thin films using spectroscopic ellipsometer through the UV-NIR range, before- and after-UV treatment. Atomic force microscopy (AFM) is used as an independent technique, recording thickness changes to improve the fitting process of the ellipsometric parameters (delta and psi) for derivation of the complex refractive index. This information has a crucial meaning in elucidating the optical properties of melanin and provides new prospective to melanin's UV protection behavior.

Enhancing the Toughness and Structural Safety of Eggshells—Effects of Defects and Soft Membrane Zian Jia[1], Zhifei Deng[1], Leigh Kadlec[1], Mary C. Stoddard[2] and Ling Li[1]; [1]Virginia Tech, United States; [2]Princeton University, United States

The eggs of birds and many reptiles are protected by hard eggshells composed mainly of calcium carbonate (~94 wt%). While the evolutionary success of birds and reptiles clearly suggests an effective biological design of eggshell, how eggshells achieve structural safety and robustness from such a thin shell with weak constituents is not fully understood. Even more puzzling is the observation that the inner side of eggshells is abundant with crack-like defects resulted from mammillary cones, which appear to weaken the eggshells. In this study, we developed a micromechanics model that takes microstructural defects, post-fracture deformation, and the underlying soft membrane of eggshell into account. With this model, we discover that membrane and crack-like defects play a critical role in amplifying the energy absorption and structural safety of eggshells. Impressively, the membrane can remain intact at displacements an order of magnitude greater than instances in which fracture is initiated in the hard shell. This improves the energy absorption by over 200%. On the other hand, the crack-like defects between mammillary cones accommodate the membrane deformation over a large area, enhancing the integrity of the membrane during post-fracture deformation. These findings are verified by three-point bending tests on both emu and hen eggshells, suggesting a general design strategy for eggshells. Such smart engineering of defects and a soft membrane in eggshell may further be adapted to the design of pressurized vessels and space capsules, where hard outer shells and structural safety are required simultaneously.

6:00 AM F.SM01.06.07
Investigating the Viscoelastic Behavior of Collagen Fibrils *via* Atomics Scale Modeling Mario Milazzo[1,2], Alessio David[3], GangSeob Jung[1], Serena Danti[4,1,2] and Markus Buehler[1]; [1]Massachusetts Institute of Technology, United States; [2]Scuola Superiore Sant'Anna, Italy; [3]Politecnico di Milano, Italy; [4]University of Pisa, Italy

Bone is mineralized tissue that constitutes the frame of the musculoskeletal system to support and protect body structures. In addition to other functions, bone plays a remarkable role in sound conduction. From a mechanic standpoint, bone is an anisotropic viscoelastic material, capable of transmitting and dissipating energy, preventing structural failures and their propagation.
We propose a computational study that aims at fully exploring the viscoelasticity of collagenous fibrils with different mineralization contents. We investigate the mechanical response of the tissue upon cyclic and impulsive loads to observe the viscoelastic phenomena from either shear or extensional strains *via* atomics scale modeling. We perform a sensitivity analysis that takes into account a number of benchmarks: intrafibrillar mineralization percentage, hydration state, and amplitude of the external load.
We prepare the building block of collagen (COL) fibrils, the so-called *D*-period of about 67 nm, composed of the overlap and gap region. The gap volume is the part where hydroxyapatite (HA), the mineral component of bone, is mostly accumulated. Based on the amount of HA, we define three structures for our study: COL/HA 100/0 (w/w%), for resembling pure collagenous tissues; COL/HA 80/20 and 60/40, to describe mineralized tissues.
We pre-process our structures based on the boundary conditions: full periodicity is used for the cyclic-loading study (CLS) while, concerning the investigation with impulsive loads (ILS), we apply the periodicity only to the axes that are transversal to the wave direction. We apply to the CLS a sinusoidal shear strain (γ) with two amplitudes (viz., 0.017 rad and 0.17 rad) ranging in 1-10 GHz frequency. As for the ILS, we cut the bonds along the loading axis in order to apply the impulsive load at one edge (viz., a uniform displacement delivered in 2 ps with input velocities ranging between 100 m/s and 1000 m/s) and a fixed constraint to the opposite one. All the topologies are equilibrated *via* LAMMPS aiming at relaxing the structures and reaching the convergence of the potential energy and RMSD (Root-mean-square deviation).
Our results from the CLS show a growth of the elastic modulus (G') with the increase of the mineral percentage, which is more pronounced at low angular strains (up to 3000 MPa). The viscous part (G'') increases with %HA at high values of γ (up to 40 MPa) while it is almost constant at low γs, below 10 MPa. When considering the intrafibrillar water, the material

softens the elastic component with a wet/dry ratio that is almost 0.5, but increase considerably its viscosity, especially at high frequencies (G'' up to 600 MPa). This behavior is also confirmed by the response of the material in ILS, in which water drastically reduces the relaxation times by one order of magnitude with respect to the dehydrated topologies, independently of the input velocity.
Our results may be used to improve the knowledge of the physiology of pure collagenous tissues or intrafibrillar mineralized tissues upon different conditions (e.g., traumas, diseases like osteoporosis or *osteogenesis imperfecta*). Moreover, although the main focus of this study is about the effect of the mineralization and hydration on the mechanical behavior of bone, our results are not limited to tissue engineering applications. From a materials science standpoint, our research may represent a contribution to the development of a larger class of bioinspired/biomimetic bone-like materials for impact loading, fatigue, prosthetics, and acoustic applications.
This work has received funding from the European Union's Horizon 2020 research and innovation program under the Marie Sklodowska-Curie grant agreement COLLHEAR No 794614.

6:10 AM F.SM01.06.08
Modeling Shape-Programmable and Reconfigurable Dielectric Elastomer Actuator Sheets Bekir Aksoy and Herbert R. Shea; Ecole Polytechnicque Federale Lausanne, Switzerland

Nature abounds with examples of living beings that can change their morphologies in complex ways to rapidly adapt to changing environmental conditions. Soft actuators able to generate programmable and reconfigurable shapes will enable the development of dynamic and adaptive systems. Simultaneously having both reconfigurability and high holding forces is a central challenge.
We report here a model and its experimental validation for a programmable soft material sheet that allows both dynamic control of shape and zero-power shape locking. The multimorph soft actuator combines the deformation mechanism of dielectric elastomers actuators (DEAs) with the multistability of heat-activated shape memory polymers (SMPs). Stretchable heaters are integrated to spatially tune the stiffness of SMP fibers. Spatial and temporal stiffness modulation allows us to actively define temporary soft axes. By controlling the location and the orientation of these axes, we use a single DEA covering the entire sheet to reach many distinct deformations. The shape can be fixed by cooling down the heated fibers when the target deformation is reached. This approach has potential to bridge the gap between soft and conventional robotics by offering both soft actuation state and load-bearing latched state.
The actuator sheets have an active area of 28 mm x 28 mm with a total thickness of less than 750 µm. Two SMP layers in a grid pattern are bonded to the stack of the DEA and the heaters. Two sets of three heater arrays are aligned in different directions, allowing spatially varying temperature distribution. The six heaters reduce the Young's modulus of SMP segments by 250 times. By dynamically addressing a combination or a time sequence of these heaters, complex and different shape deformations are achieved upon DEA actuation. We previously demonstrated that this technique can be implemented in DEA grippers to augment their grasping ability to pick and place objects with different shapes that are not possible with a single shape transformation.[1]
The actuator sheets consist of several layers (up to 11 layers include including one or two DEA layers, SMP grids, heaters, and electrical and thermal insulator layers). This requires a carefully optimization of the design parameters to reach both large actuation deformation and high load-bearing capacity: thick SMP layers enable high blocking forces thanks to high stiffness in the glassy state, however they limit the deformation due to the non-zero stiffness in the rubbery state. We report here an analytical model that provides insights into the role of SMP thickness and as well as other design parameters on the device performance, e.g. the location of the DEA and the order of passive layers. The model couples the Maxwell pressure from a dielectric elastomer, beam deflection, and thermo-mechanical modeling of different materials. It accurately predicts the quasi-static behavior of the devices at different states of the actuator and the predictions agree well with the experimental results. The actuator sheet designed based on the model output can achieve a bending deflection of over 300° and can hold a force greater than 25 mN. It can be easily adapted to different scenarios where specific displacement and blocking force are needed.
This approach to shape-programmable sheets does not require joints or additional latching mechanisms, it can be easily integrated into a range of biomimetic soft robotics or wearable robotic applications.

Modeling Zinc Ion Coordination in Structural Proteins, Including the *Nereis virens* Jaw Protein (Nvjp-1) and Amyloid-β Peptides Alby J. Joseph, Eesha Khare, Niels Holten-Andersen and Markus Buehler; Massachusetts Institute of Technology, United States

Nature has engineered biological materials with remarkable mechanical properties, including stiffness, toughness, and self-

healing properties. Transition metal coordination chemistry is an important component of proteinaceous materials that can impart such properties. Unlike conventional covalent bonds, metal coordination bonds are kinetically labile and tunable, enabling access to a wide range of dynamic mechanical properties. As such, coordination complexes have generated interest as a biomimetic strategy for engineering the mechanics of bioinspired artificial materials. For instance, Zn(II) metal-coordinated cross-linking is responsible for the high stiffness of the *Nereis* marine worm jaw (10-20 GPa), which is comparable to that of biomineralized materials. Interestingly, Zn(II) metal ion coordination can also play a structural and mechanical role in the assembly and aggregation of amyloid proteins. Natural amyloid peptides have the intrinsic capacity to self-assemble and form extraordinary fibrillar nanostructures rich in β-sheets with elastic moduli as high as 10-30 GPa. This aggregation has received much attention due to its pathological role in neurodegenerative disease, such as Alzheimer's Disease (AD). Given the remarkably high concentrations of Zn(II) (up to millimolar range) in the plaques of AD brains, experimental studies have sought to understand the effect of Zn(II) on amyloid-β peptide aggregation; however, this still remains poorly understood.

This study aims to contribute to a mechanistic, molecular-level understanding of the role Zn(II) plays in the mechanics and assembly of structural proteins, such as *Nereis* virens jaw protein (Nvjp-1) and amyloid-β (Aβ). Computational tools present a useful strategy to achieve this molecular-level understanding. Molecular dynamics simulation techniques, including replica exchange molecular dynamics (REMD) and steered molecular dynamics (SMD), are employed to study the concentration-dependent effect of Zn(II) metal ion coordination on the conformational free energy landscape and mechanical stability of these structural proteins. Through the comparison of structure-property relationships in Nvjp-1 and Aβ, this work has the potential to inform the design and engineering of transition metal coordination complexes in bioinspired nanomaterials.

6:30 AM F.SM01.06.10
Late News: Coarse Grained Atomistic Simulations of Mechanical Behavior in Nacre-Inspired Composites Raghavan Ranganathan and Param Punj Singh; Indian Institute of Technology Gandhinagar, India

The quest for improving mechanical properties of synthetic materials has been, unexpectedly, bolstered by the structure and organization of natural materials such as animal shells, bone, silk, etc. Among this class of biomaterials, the mollusk shell, also called as nacre has proved to be a fascinating material with superior toughness. Though the bulk (95%) of nacre is made up of the hard but brittle crystalline aragonite phase, the hierarchical "brick-and-mortar" nature of the microstructure of nacre held together by organic fillers is thought to be responsible for these superior properties.

Atomistic simulations on nacre-inspired materials have predominantly focused on expressing the inorganic and organic components via high-fidelity force fields that are computationally expensive and have limited scope for detailed structure-property elucidation. Here, we employ large-scale atomistic *coarse-grained* simulations of nacre-inspired microstructures, made up of crystalline grains that are held together by polymer chains. We show that coarse graining allows us to study the effect of several properties such as microstructure (grain morphology and size), polymer-crystal interactions and the effect of grafting. We explore tensile, compressive and viscoelastic behavior of these composites along with elucidation of nanoscale mechanisms. While being able to capture mechanisms for mechanical behavior reported in the literature qualitatively (such as the saw-tooth behavior in stress-strain curve under tensile loading), we show that our coarse grained models offer a promising alternative for efficient structure-property studies for design of novel biomimetic architectures.

SESSION F.SM01.07: Application and Design of Bio-Inspired Materials (e.g. Optics, Sensing, Actuation, Medicine)

5:00 AM *F.SM01.07.01
3D Materials Systems as Bioelectronic Neural Interfaces and Bioinspired Passive Microfliers John A. Rogers; Northwestern University, United States

3D mesostructures represent essential, ubiquitous design features in biology, from the spherical constructs of living organoids to the aerodynamic shapes of swirling maple seeds. This talk presents our work in two corresponding areas of 3D materials engineering. The first focuses on mechanically compliant, 3D multifunctional neural interfaces to cortical spheroids and assembloids. Detailed studies of the spreading of coordinated bursting events and the cascades associated neuroregeneration represent two of the many opportunities in neuroscience research uniquely enabled by these platforms. The second area is in

exploratory 3D materials architectures that mimic the aerodynamic features of gliding, spinning and twirling seeds that facilitate their dispersal. The talk will emphasis both basic and applied aspects of these two distinct classes of materials systems.

5:15 AM *F.SM01.07.02
A Portable, Biologically-Inspired Platform for Color and Pattern Sensing and Display Leila Deravi; Northeastern University, United States

A small number of animals have the ability to actively change their visual appearance to perform important biological tasks. Cephalopods rank high on this list due to their ability to rapidly change color and texture - in some cases - for defense and signaling and have been a source of inspiration for the design of next generation adaptive systems. Recently, the electrochemical properties of the primary pigment found in cephalopod skin, xanthommatin, have been harnessed and applied in color-switching electrochromic displays with low power requirements. We describe the translation of this technology into a compact form factor that can sense and measure color from the environment then activate spatially patterned coloration with rapid (ca. seconds) response times. Our device uses reflectance-based sensors to measure color then triggers the formation of hue matched patterns by arrayed display components that can match and/or “hide” on surfaces of varying geometry, color, and luminous intensity. In future iterations of our approach, these principles may be applied to expand the palette of measured and displayed colors or to construct soft, deformable systems that can alter their optical signatures in response to environmental cues.

5:30 AM *F.SM01.07.03
Colour Engineering—Form Nature to Applications Silvia Vignolini; University of Cambridge, United Kingdom

The most brilliant colours in nature are obtained by structuring transparent materials on the scale of the wavelength of visible light. By controlling/designing the dimensions of such nanostructures, it is possible to achieve extremely intense colourations over the entire visible spectrum without using pigments or colourants. Colour obtained through a structure, namely structural colour, is widespread in the animal and plant kingdom [1]. Such natural photonic nanostructures are generally synthesised in ambient conditions using a limited range of biopolymers.
In this seminar, I will review our recent advances to fabricate bio-mimetic photonic structures with cellulose and chitin and I will give examples of how to fabricate novel photonic materials based on chiral nematic architectures using low-cost polymers in ambient conditions [2-7].

5:45 AM *F.SM01.07.04
Bio-Inspired Photosynthetic, Robotic and Bioactive Materials Samuel I. Stupp; Northwestern University, United States

The soft and hard materials that make up biological systems are a great source of inspiration in materials science for design of functional systems, particularly those that are critical in supporting the most intelligent processes in the plantea and animalia kingdoms. Great ideas from these systems include, the notion of self-assembly and reversible formation of structures, creating adaptive behaviors for specific environments, materials with capacity for self-repair, the engineering of autonomous motion, and the integration of multiple functions in a single structure, among many others. In this lecture bio-inspired synthetic systems are described based on supramolecular polymers as well as “hybrid bonding polymers (HBPs), which we define as materials that rationally integrate covalent and supramolecular polymers. HBPs are biomimetic structures critical in systems such as biological membranes, muscles, tendons, and the cytoskeleton. One of the systems to be described is based on supramolecular polymers that are highly dynamic and therefore strongly effective at signaling cells for regeneration. The lecture will also describe photosynthetic materials, inspired by leaves, in which HBPs are used to couple light harvesting

assemblies and catalysts to make fuels. Finally robotic materials that emulate living creatures will be discussed in which HBPs or organic-metal hybrid hydrogels are configured to respond to light and magnetic fields in order to generate locomotion of macroscopic objects on surfaces.

6:00 AM F.SM01.07.06
Antibacterial Activity of Melanin Biopolymers Isolated from Horsehair Fibers Tahmineh Rahmani Eliato, Joshua Smith, Young J. Kim and Cheryl Andam; University of New Hampshire, United States

Recent advances of biomaterials research have shown that biopolymers can be served as versatile materials in a variety of applications including structural, and electronics. Melanins are the broad class of biopolymers that can be found from many types of living organisms, including bacteria, fungi, plants, and animals. When melanin is extracted from different natural sources, or even synthesized *in vitro*, variability in the resulting macromolecular structures leads to different properties. There have been many studies that focus on the melanin isolated from the cuttlefish *Sepia officinalis* ink (*Sepia*Mel) or synthetic melanin (SynMel). However, the properties of melanins sourced from dark-color fibers of mammalian fur are less studied, comparatively. Herein, we isolate melanins from dark-color horse fibers (*Equus*Mel) using the acid hydrolysis method to investigate its structural and functional properties. Electron microscopy and X-ray scattering studies showed that *Equus*Mel has a homogeneous elliptical shape in a sub-micron scale while *Sepia*Mel exhibits a spherical nanostructure. *Equus*Mel consists of chemical functionalities of pendant catechols and secondary amines that are similar to *Sepia*Mel and SynMel. We hypothesized that well-ordered microstructure with chemical functionality of *Equus*Mel can facilitate the generation of reactive oxygen species (ROS) within the hydrated condition. The antibacterial activity of melanins was tested against *Escherichia coli*. Our results reveal that *Equus*Mel has considerable antibacterial activity due to its generation of ROS. After a four-hour incubation with *E. coli*, the bactericidal activity rate of *Equus*Mel was 6.87%, 69.06%, 98.12%, and 100% at melanin concentrations of 2.5 mg/ml, 5 mg/ml, 20 mg/ml, and 150 mg/ml, respectively. Measurable levels of H_2O_2 were detected in all samples, indicating the potential of *Equus*Mel to generate ROS, which can damage bacterial cells. Facile extraction of melanins and their unique antibacterial property would make this biomaterial an ideal candidate for use as an antibacterial agent to mitigate bacteria colonization and biofilm formation. Potential applications in food packaging, filtration membranes, and medical device surfaces should be further explored.

6:10 AM F.SM01.07.07
Aqueous Synthesis of Bio-Templated Halide Perovskite Nanostructures with Complex Morphologies Masoud Aminzare, Sara Mahshid and Noemie-Manuelle Dorval Courchesne; McGill University, Canada

Halide perovskites (HPs) have recently experienced unprecedented development as outstanding materials for optoelectronic applications. Because HPs are water soluble, they have been synthesized using organic solvents and ligands (mainly toxic solvents and materials), and thus, the aqueous synthesis routes and biological applications have been hardly considered. Nonetheless, preliminary studies demonstrate stabilization of HP nanocrystals in aqueous buffers by balancing solubility equilibrium. Here, we report the implementation of a sustainable and environmentally friendly aqueous synthesis, using biomaterials (proteins, natural biomolecules, etc.) as nucleation templates to produce novel HPs morphologies. Via this biomineralization approach, electrostatic forces together with hydrogen bindings contribute to interactions between inorganic crystals and bio-templates over multiple length scales, and the bio-templates act as biological scaffolds to assemble hierarchical structures. In thisstrategy, first, we form metal carbonates (MCO3, M = Ca, Ba) using different bio-templates with desirable nano- and microstructures. Second, we apply ion exchange reactions to introduce appropriate cations and halide groups to from the HPs while the original morphology is preserved. Consequently, we can engineer the structure of the HPs at the nano- and microscale to acquire a variety of complex structures that would be hardly attainable via other methods. In addition, working in aqueous media has the potential to improve the biocompatibility of HPs synthesis process, paving the way towards greener synthesis approach.

6:20 AM F.SM01.07.09
Bio-Inspired Luminescent Surfaces with Tailored Angular Emission for Compact Dark-Field Imaging Devices Cecile Chazot[1], Sara Nagelberg[1], Christopher Rowlands[2], Maik Scherer[3], Igor Coropceanu[1], Kurt Broderick[1], Yunjo Kim[1], Moungi Bawendi[1], Peter So[1] and Mathias Kolle[1]; [1]Massachusetts Institute of Technology, United States; [2]Imperial College London, United Kingdom; [3]Papierfabrik Louisenthal, Germany

A comprehensive understanding of nature's strategies to manipulate light spectrally and spatially, gained through the ongoing efforts in the field of biological optics and photonics has repeatedly provided opportunities for the design of bio-inspired dynamic optical materials with utility in specific applications. Here, we demonstrate how insights into the optical mechanisms and structural designs underlying the wing coloration of the *Papilio blumei* butterfly have informed the

conception of a novel light management strategy that enables dark field imaging of low-contrast biological specimen. We simplify and downsize dark-field microscopy equipment by generating the high-angle illumination cone required for dark-field microscopy directly with a luminescent photonic substrate that relies on a structural design informed by the photonic structures found on *P. blumei*'s wing scales. The surfaces' light-emitting micro- and nanoscale components provide a controlled angular emission profile. We demonstrate the ability of these hierarchically structured luminescent surfaces to generate high-contrast dark-field images of micrometer-sized living organisms using standard optical microscopy equipment. This new type of substrate forms the basis for miniaturized lab-on-chip dark-field imaging devices that are compatible with simple and compact light microscopes.

6:30 AM F.SM01.07.10

Bio-Inspired Molecular Bridging in a Hybrid Perovskite Leads to Enhanced Stability and Tunable Properties Arad Lang[1,1], Iryna Polishchuk[1,1], Eva Seknazi[1,1], Jochen Feldmann[2], Alexander Katsman[1,1] and Boaz Pokroy[1,2]; [1]Technion–Israel Institute of Technology, Israel; [2]Ludwig-Maximilians-Universität München, Israel

Biominerals possess superior mechanical properties relatively to their synthetic counterparts. This, among else, is due to internal stresses induced by incorporation of organic molecules. Similarly, inorganic hosts, such as $CaCO_3$, ZnO and Cu_2O can synthetically incorporate single amino acids. This incorporation induces lattice strains and morphology changes, along with changes in the mechanical and optical properties of the host.
In this work, we wanted to expand our knowledge regarding this phenomenon to a more complicated non-oxide system: the hybrid organic-inorganic perovskite methylammonium lead bromide ($MAPbBr_3$). Hybrid lead halide perovskites have demonstrated exceptionally high performance as the active materials in opto-electronic applications (*i.e.* photovoltaics, photodetectors and light emitting diodes). Their major set-back is their poor stability under ambient conditions, especially due to decomposition under humidity, which hinders their commercialization.
We grew $MAPbBr_3$ in the presence of all 20 common amino acids, in two growth routes: fast growth (low temperature), and slow growth (high temperature). We noticed that Lysine (Lys), possessing two NH_3^+ groups (similar to the MA^+ cations), is incorporated in a significant higher extant than all the others amino acids. We used high-resolution powder X-ray diffraction, together with *in-situ* cooling, to measure the lattice parameter of $MAPbBr_3$ grown with different amounts of Lys. Both lattice parameter and thermal expansion coefficient demonstrated a significant decrease with the increase of the amount of incorporated Lys. This decrease, along with the observed changes in the cubic-to-tetragonal phase transition temperature of the perovskite, suggest that Lys acts as a "molecular bridge", holding the crystal together. While all the Lys-containing samples showed an increase in the optical band gap, a drastic difference between slow and fast grown samples was observed. This difference can be attributed to the difference in incorporation mechanisms between the two growth routes. Moreover, electrochemical measurements of the perovskite dissolution kinetics revealed noticeable changes in the dissolution rate constants of $MAPbBr_3$ with and without incorporated Lys molecules. Specifically, when grown in high temperature (*i.e.* slow growth), $MAPbBr_3$ dissolution rate decreased in ~40% due to Lys incorporation.

6:40 AM F.SM01.07.11

Developing Extraordinary Mechanical Properties Through Machine Learning Enhanced Design of Bio-Inspired Composites Ashish Ghimire[1], Yu-Chuan Hsu[2], Ya-Yun Tsai[2], Chuin-Shan Chen[2], Shu-Wei Chang[2] and Po-Yu Chen[1]; [1]National Tsing Hua University, Taiwan; [2]National Taiwan University, Taiwan

Natural organisms hold mastery over designing intricate structures in various length scales that exhibits remarkable mechanical properties, one such ingenious biomineral structure is nacre's brick and mortar like structure. In light of the demand for mechanically robust synthetic material, researchers have amply studied nacre. Here, we present an extensive exploit on nacre's structural features employing a machine learning model to predict composite design with high strength and toughness often mutually exclusive in artificial materials, over a large design space of $3.6*10^{10}$ including 320 topologies. The predicted models show multi-stage gracious failure with two major peaks in the tensile stress-strain curve, which are distinct from conventional brittle, ductile, or tough type deformation curves. The design guideline extracted from the predicted models is adapted to fabricate nacre inspired composites using a multi-material 3D printer. In addition to the composite with a rectangular tablet, an interlocking tablet design inspired by geometrically interlocking suture of the diatom is also synthesized. We report previously unseen and tunable work hardening phenomena and subsequent failure mechanisms in nacre inspired composites leading to the magnification of mechanical properties. Toughening mechanisms like crack reorientation during multi-stages failure under normal and shear stress, plastic deformation of soft phase, sliding and the interlocking of tablets and elastic deformation of the hard phase are elucidated by comparing experimental and simulation results. Interlocked tablet composites outperform the rectangular tablet composite in all regards, simulation results reveal that the geometry of interlocked tablets promotes higher normal stress concentrations on the tablets before the stress flow to the

soft interfaces leading to higher load-bearing capacity, delay of crack initiation, and gracious propagation which amplifies the overall mechanical properties reasonably. These novel observations provide significant new insights into developing synthetic composites with superior mechanical properties.

6:50 AM F.SM01.07.12
Fish Gill-Inspired Electrochemical Reactors for High Efficiency Redox Flow Systems Andrew A. Wong[1], Michael Aziz[2] and Eric B. Duoss[1]; [1]Lawrence Livermore National Laboratory, United States; [2]Harvard University, United States

Despite the wide variety of aquatic species on our planet, the microscopic architecture of gills in fish remains largely self-consistent, suggesting an evolutionary optimization [1]. These organs, used predominantly as gas exchange interfaces against an external, parallel-flowing aqueous solution, are used as inspiration for the design of a hierarchical electrochemical reactor. Leveraging insights from a new method for comparing porous electrodes used in redox flow batteries [2], this work explores the physical and electrochemical properties pertinent to enhancing the performance of these bio-inspired structures. Inspired by the high fidelity of the single-pass oxygen uptake inherent to ram ventilation in continuously moving fish, we explore the opportunities and limitations for high, single-pass electrochemical conversion. A computational model will be presented, applying these design principles to a liquid-fed CO_2 utilization system. The ohmic, kinetic, viscous, and mass transport loss limitations across a range of gill-like architectures and operating conditions will be discussed. This work provides a framework for applying bioinspired gas-exchange architectures to enhance the performance of electrochemical systems including flow batteries and CO_2 reactors for efficient energy conversion.

7:00 AM F.SM01.07.13
Hybrid Materials for Optoelectronics from Diatoms Microalgae Gianluca M. Farinola[1], Stefania R. Cicco[2], Roberta Ragni[1], Danilo Vona[1], Gabriella Leone[1] and Gabriella Buscemi[1]; [1]University degli Studi-Bari Aldo Moro, Italy; [2]CNR-ICCOM, Italy

Diatoms are a large class of single cell microalgae combining photosynthetic activity with production of mesoporous biomineralized silica shells, called frustules [1]. Frustules exhibit features such as high surface area, transparency, mechanical resistance and periodic porosity, that make them appealing biomaterials for applications in photonics, sensing, optoelectronics and biomedicine [2]. Furthermore, *in vivo* and *in vitro* protocols enable frustules silica modification with functional molecules or nanoparticles. We have recently demonstrated that *in vivo* incorporation of organic [3] and organometallic emitters, such as iridium complexes [4], into *Coscinodiscus spp.* frustules represents a promising biotechnological route to biohybrid luminescent silica-based materials, whose properties result from the combination of the frustule nanostructures with the photoluminescence of incorporated molecules. We have also recently demonstrated that *Phaeodactylum tricornutum* diatom cells self-populate and propagate on transparent conductive ITO electrodes, either in the presence or in the absence of biochemical activators of adhesion. Our results demonstrate the suitability of diatoms as self-adherent microalgae capable of photocurrent production under eco-friendly conditions, paving the way to the development of a new generation of living photosynthetic organisms-based devices for optoelectronic applications.

Influence of Structural Disorder on the Optical Properties of Natural Bragg Mirrors Sébastien R. Mouchet[1,2] and Pete

Vukusic[1]; [1]University of Exeter, United Kingdom; [2]University of Namur, Belgium

In the fabrication processes of photonic crystals, structural disorder arises in the synthesised structures from the limitations in the resolution of the synthesis processes. Such undesired disorder affects the optical properties of the fabricated photonic crystals. It must often be taken into account. Elucidating the influence of structural disorder helps reducing its optical effects and allows using it in technological applications.
Photonic structures found in the integuments of insects are interesting examples to investigate since they are known to be very tolerant of and resilient to structural or material defects and imperfections. The benefit and cost of these defects have not been so far comprehensively assessed.
In this contribution, we investigated the extent of structural disorder in Bragg mirrors occurring on the wings of beetles [1]. Some beetles exhibit indeed shiny iridescent colours ranging from violet to red thanks to such photonic structures. Due to structural disorder, variations in the optical response can be observed by optical microscopy. Using electron micrographs, we analysed the disorder in these photonic structures. We related this disorder to the optical properties, thanks to microspectrophotometric measurements of reflected light. We performed optical simulations for typical Bragg mirrors occurring in beetle wings. It allowed to assess the optical benefit and cost of structural disorder. This analysis showed that the optical response of natural Bragg mirrors in beetle wings is very resilient to disorder.

7:20 AM F.SM01.07.15
Interacting Macromolecules Create a Distinct Chemical Environment Favorable for Calcite Nucleation Leilah Krounbi[1], Konrad Hedderick[2], Zohar Eyal[1], Lara Estroff[2] and Assaf Gal[1]; [1]Plant and Environmental Sciences, Weizmann Institute of Science, Israel; [2]Cornell University, United States

Organic macromolecules are a key ingredient in the formation of biogenic crystals. One example of biominerals formed in the presence of organic macromolecules is calcite scales, or coccoliths, created intracellularly by marine microalgae. Organic components associated with coccoliths can be divided into two groups, soluble coccolith-associated acidic polysaccharides (CAPs), and an insoluble organic plate-like structure called a base plate. Previous in vitro work has shown that these components cooperate to bind and localize calcium ions as a dense phase around the base plate, where calcite eventually crystallizes. However, the function and composition of this dense interphase in calcite nucleation in coccoliths is unknown. To further our understanding of the role of this dense Ca-rich interphase in calcite nucleation, we sought out a synthetic compound able to mimic the function of the biogenic macromolecules in vitro. Using scanning electron microscopy and dynamic light scattering, we have identified a polymer, poly(acrylic co-maleic acid), able to reproduce the particulate morphology of the CAP-calcium precipitates on the base plate. We also discovered that the precipitation of calcium with this polymer on the base plate commences at concentrations below the saturation point of calcium and polymer in solution. Thus, the base plate functions as a nucleator, engendering a chemical environment distinct from the bulk solution.
Current experiments focus on nucleating calcite within the dense polymer-calcium phase on the base plate. Preliminary observations show precipitation of elongated calcium carbonate crystals growing from the base plate rim. We aim to identify the mechanism by which the organic components determine how living cells control calcite crystallization.

Interplay Between Order and Disorder in the Optical Response of Crosslinked Hydroxypropyl Cellulose-Based Photonic Films Chun Lam Clement Chan[1], Mélanie M. Bay[1], Gianni Iacucci[1], Roberto Vadrucci[1], Cyan A. Williams[1], Gea T. van de Kerkhof[1], Richard M. Parker[1], Kevin Vynck[2], Bruno Frka-Petesic[1] and Silvia Vignolini[1]; [1]University of Cambridge, United Kingdom; [2]CNRS, Institut d'Optique Graduate School, University of Bordeaux, France

Hydroxypropyl cellulose (HPC) is a cellulose derivative that combines the biocompatibility and edibility of cellulose and the processability of a water-soluble polymer. Therefore, it has found large industrial applications from coatings in pharmaceutical products to binder or thickening agent in food applications. Recently, HPC has also become a very attractive material for photonic applications due to its capability of forming a lyotropic chiral nematic liquid crystal phase in aqueous solution, which is responsible for a metallic and iridescent colour response. As a direct result of the chiral nematic phase, HPC, in fact, is capable of reflecting right–handed circular polarized light with specific colours and such colouration is usually strongly dependent of the direction of observation.

Here, we present a crosslinking method which allows us to drastically alter the visual appearance and photonic properties of

HPC, in terms of both angular and polarisation response. Specifically, we demonstrate that it is possible to achieve an angular independent colour reflection as well as a strong reflection of light with both handedness.

Our method not only allows us to preserve the photonic response of HPC in the absence of solvent, but highlights an approach to, using the same system, completely redesign the visual appearance of the material from iridescent and metallic to matte. With such control of appearance, we therefore demonstrate the potential of HPC as a biocompatible, biosourced photonic material that can replace traditional pigment and dyes.

7:40 AM F.SM01.07.17
Macropores in Bird Eggshells Give Rise to Mie Backscattering in the Ultraviolet Range Mathieu Ladouce[1], Tarek Barakat[1], Bao-Lian Su[1,2,3], Olivier Deparis[1] and Sébastien R. Mouchet[1,4]; [1]University of Namur, Belgium; [2]Wuhan University of Technology, China; [3]University of Cambridge, United Kingdom; [4]University of Exeter, United Kingdom

Eggshell is crucial for the reproduction and development of birds. The optical properties of the shells have an impact on biological functions such as heat and UV protection, recognition by the parents and camouflage. Whereas ultraviolet reflection by bird eggshells has been superficially described in the scientific literature [1,2], the physical origin of this phenomenon has remained poorly understood so far. In this contribution, macropores have been morphologically characterised by electron microscopy and mercury intrusion porosimetry in the eggshells of several breeds of domestic hens (*Gallus gallus domesticus*), one breed of duck and one breed of quail. They are located in the so-called "calcified shell" part of the eggshells (namely, at depths ranging from ca. 20 µm and ca. 240 µm from the shell outer surface). Two reflectance peaks (ca. 20-50%) were observed in the near UV range by spectrophotometric measurements from these eggshells. Progressively thinning down the cuticle of eggshells with ethylenediaminetetraacetic acid (EDTA) solutions allowed us to show that the so-called calcified shell is an efficient UV scattering structure whereas the cuticle partly absorbs UV radiation. Thanks to modelling relying on Mie scattering theory and an effective approach accounting for multiple scattering, we found the observed macropores were most likely giving rise to these peaks through Mie backscattering [3]. This optical response was discussed in terms of the visual sensation of chickens and human beings. Eggs displaying an achromatic visual appearance for humans appear chromatic for chickens. Fluorescence emission from the eggshells was measured and attributed to molecules of biliverdin IXα and protoporphyrin IX embedded within the shell. This emission is rather low in terms of quantum efficiencies and probably does not play any role in the visual appearance of the eggshells. In addition, electron microscopy imaging revealed the presence of pores within the so-called "calcified shell" part (i.e., between ca. 20 µm and ca. 240 µm deep from the outer surface). The average radii of these pores range from 120 to 160 nm, depending on the egg varieties. Mercury intrusion porosimetry allowed to highlight a distribution of pore radii around 175 nm. Spectral measurements of excitation and emission by fluorescence revealed the presence of fluorophores embedded in the shells. In addition, numerical and analytical predictions using scattering theory indicate that these pores are responsible for the optical response observed in the UV range. Due to the similarities between the pore size distributions observed among the eggshells of the investigated poultry eggshells, we expect Mie backscattering to be at the origin of the UV response from the eggshells of many other bird species.

Methods for Iterative Design and Fabrication of Bio-Inspired Structural Color Bianca C. Datta and Christine Ortiz; Massachusetts Institute of Technology, United States

Biological structures perform a variety of complex functions with a limited material set. One particularly exciting area of bio-inspired research is structural color, though present synthetic analogs are still limited, either by fabrication challenges or an incomplete understanding of structure-property relationships. Structural color not only provides a fascinating case study for exploring the role of material design on macroscale properties, but can provide insights on animal evolution, photonic devices, human and animal communication, signalling, and art. While this is a lively and active area of research, we are still finding the balance between what is physically possible and easy to fabricate and understanding the full extent of the color gamut that we can access. As replicating natural structurally-colored designs can be challenging and costly, we instead

explore methods for generating structures inspired by nature to create desired effects, while proposing surface designs that are physically producible with rapid prototyping. Interaction of light with Morpho butterfly structures is used as a starting point to determine key parameters and these principles are applied towards our simulations and designs. Methodologies for combined design, simulation, and material fabrication to generate colors through new structural surfaces are implemented. A computational inverse design methodology has been developed for the formulation of nanostructures exhibiting structural coloration, and opportunities for scalability are identified. A simple model based on scalar diffraction theory is used for the relationship between structural elements and optical response, where altering the surface changes the visible functionality. Through the use of larger scale optimization based on tiled repeat units and motifs, large scale arrays, displays, sensors, and art can be achieved. Simulated surfaces are then fabricated using two-photon polymerization, and optically characterized. We compare our simulations to fabricated structures using optical microscopy, scanning electron microscopy, and angular spectrometry to quantify reflected color and angular response. Through these methods, we contribute to an understanding of a) the limitations of this approach, b) the extent of the parameter or design space, c) the feasibility of this inverse design approach, and c) the limitations imposed by fabrication restrictions. By exploring different levers for production of structural color, the boundaries of our ability to mimic and expand upon natural color production are illuminated. This work provides an additional perspective on bio-inspired materials design with applications ranging from light harvesting and steering, to chemical sensing, high performance displays, responsive products and architecture. The limitations and trade-offs of our approach as it relates to scale-up and industrial use are discussed.

8:00 AM F.SM01.07.19
Natural and Bioinspired Electronic Conductors from Supramolecular Protein Assemblies Allon Hochbaum; University of California Irvine, United States

Electronic material properties are conventionally considered the domain of man-made materials and devices, but electronically conductive materials are also synthesized by some organisms as part of their native metabolic pathways. These biological conductors lack many of the structural characteristics typical of inorganic and organic conductors or semiconductors, and therefore represent an exciting new opportunity to study electron transport at the nexus of physics, chemistry, and biology. Well-studied microbes in oxygen-free environments, such as aquatic sediment, respire anaerobically by accessing alternative extracellular oxidants. This class of microbes displays a variety of mechanisms to shuttle spent electrons from inside the cell to remote electron acceptors. Some anaerobic bacteria, such as *Geobacter sulfurreducens*, synthesize protein supramolecular assemblies that exhibit inherent electronic conductivity and are key to their respiratory metabolism. Based on fundamental differences between the protein building blocks of these assemblies and the canonical building blocks of inorganic and organic conductors and semiconductors, it is clear that Nature has developed unique design principles for long-range electronic conductivity in amino acid materials. The biomolecular identity and supramolecular order underpinning biological conductive materials are poorly understood, as are the mechanisms by which these structures support electron transport. This talk will cover our ongoing work in the characterization of structure-function relationships in conductive protein and peptide materials. These efforts establish distinctive biomolecular design principles for long-range electron transport in self-assembling *de novo* peptide nanofibers, engineered biological materials, and native bacterial appendages. Such materials serve as an experimental platform to understand long-range charge transport in biological materials in general, and as promising technological platforms for bioelectronic interfaces.

8:10 AM F.SM01.07.21
Platelet Heterogeneity Leads to Emergent Collective Behavior Enhancing Blood Clot Contraction Yueyi Sun[1], David Myers[1,2], wilbur lam[1,2] and Alexander Alexeev[1]; [1]Georgia Institute of Technology, United States; [2]Emory University, United States

Blood clots are an active biomaterial in which anucleate cells, called platelets, can extend micrometer-long filopodia to impose contractile forces on the fibrin scaffold that lead to drastic macroscopic changes in clot volume and elastic modulus. Blood clots are involved in physiologic and pathologic processes, such as wound healing, fibrosis, and musculoskeletal contractures. We use experiments and mesoscale modeling to examine the biophysics of clot contraction by directly linking the microscale platelet movements to macroscale biomaterial properties and behavior. We find that the clot contraction is optimized through the intrinsic heterogeneity of platelets. When platelets within the clot are exposed to thrombin, they do not contract simultaneously as one can be expected, but rather contract over time at a sequential manner. We show that this temporal heterogeneity of platelets leads to emergent behaviors that significantly enhance the biomaterial volumetric contraction. We rationalize this surprising effect by the ability of heterogeneous platelets interact with fibers that are initially located out of their influence range. We show that only by accounting for platelet the cellular heterogeneity we are able to replicate the experimentally measured clot forces. This points to the importance of examining biomaterials as a 4D (space + time) system in which natural cellular heterogeneity can be harnessed to enhance the mechanical efficiency. Furthermore, our

results suggest a new direction of developing synthetic and hybrid stimuli-responsive composites in which engineered heterogeneity can serve to enrich the mechanical responses and shape transformations.

8:20 AM F.SM01.07.22
Rayleigh Blue—Elaboration and History Anne Pillonnet[1], Anne Goyer[1], Amina Bensalah-Ledoux[1], Cécile Le Luyer[1], Davy Carole[1] and Romain Thomas[2]; [1]Univ of Lyon1-CNRS, France; [2]Université Paris Nanterre, France

The blue coloration in nature is mainly of non-pigmentary origin [1] and is known as Rayleigh or Tundall blue. This non-pigmentary or structural blue coloration is, for example, the blue color of the sky and mountains in the distance, the blue color of human or animal eyes, the blue color of feathers of some birds like *cotinga mayn*ama, a turquoise bird of Peru and Ecuador, for instance. The origin of this non-iridescence blue color is attributed to the constructive interference of scattered light from quasi-amorphous structures of self-assembly of mono-dispersed particles, typically closely packed air cavities in b-keratin for eyes or plum. Reproducing the phenomenon in thin film materials requires nanoparticles randomly dispersed in a transparent layer deposited on a highly absorbent dark film. The refractive index between the particles and the matrix must be different, thus pores containing air or contrary particles of high refractive index could be used. In our research work, the original idea to produce this coloration has originated from an encounter with a contemporary artist who intuitively realized for the first time this blue color from crushed white chalk, colorless oil and viscous black mineral peas collected in a natural resurgence. The using tools are only brushes, a mortar and a marble table to manually grind the materials. A collaboration with our scientific research laboratories made it possible to identify the optical phenomenon involved and to find a robust protocol to create this blue color in a reproducible and intense way, keeping the materials and the artist's tools and by optimizing the gestures [2]. The intensity of the produced blue color highlights the potentialities of using this coloring with simple materials and technologies for ecological and environmentally friendly coloring applications. Beyond this important issue, the intensity of this blue color has led to a discussion among the history of art, and the possibility that the ancient masters used this non-pigmentary blue coloring in their famous paintings at a time when the blue color was a major economic issue, before the advent of chemistry and the discovery of synthetic pigments and coloring [2]. Some ancient manuscripts mention it but, on the works it is not yet proven, knowing that this blue color is very fragile as it is very much linked to the architecture of the material and therefore very sensitive to ageing.

8:30 AM F.SM01.07.23
Reconstructing *Bombyx mori* Silk Fibroin into a 3D Porous Microneedle Array for Detection of Food Bacteria Doyoon Kim, Yunteng Cao, Dhanushkodi Mariappan, Michael S. Bono, A. John Hart and Benedetto Marelli; Massachusetts Institute of Technology, United States

Natural structures made of silk fibroins, such as cocoons and spider webs, have inspired researchers to utilize their mechanical properties and biocompatibility for various engineering applications. Recently, silk fibroins extracted from *Bombyx mori* silkworm cocoons have emerged as promising technical materials for food contact applications due to their non-toxic and edible nature, in addition to their tunable mechanical and chemical properties. Here, by leveraging water-based processing of *Bombyx mori* silk fibroin, we build a porous silk microneedle platform for the detection of bacteria in food. The microneedles can transport internal food fluid by capillary action to a colorimetric sensor on the backside of the array. We demonstrate detection of food contamination within 16h after injection of *E. coli* in fish fillets, by color-change of a polydiacetylene-based sensor printed onto the backside of the microneedle array. This response by *E. coli* contamination can be distinct from common food spoilage measured via an increase in sample pH. We also show that the microneedle sensor can pierce commercial food packaging, indicating the feasibility of successful adaptation of the technology downstream in current food supply chains. The platform developed in this study can contribute to food quality monitoring, which is critical to global food safety and to minimizing food loss and waste.

8:40 AM F.SM01.07.24
Structural Color as a Tool to Monitor Colloidal Cluster Formation Junwei Wang, Chrameh Fru Mbah, Praveen Bommineni, Silvan Englisch, Thomas Przybilla, Erdmann Spiecker, Michael Engel and Nicolas Vogel; Friedrich-Alexander University Erlangen-Nürnberg, Germany

It is well-acknowledged that nature uses ordered nanostructures to generate vivid iridescent color such as opals. To mimic such structures, colloidal particles are widely used, due to their uniform and tunable sizes, to form colloidal crystals of densest closed-packed structure in bulk. Recent discoveries in butterfly scales reveal the role of isolated finite-size crystallites

as building blocks for their hierarchical structure. In this contribution, we present discrete colloidal clusters fabricated from self-assembly of colloidal particles encapsulated in emulsion droplets. Unusual equilibrium crystal structures with icosahedral, decahedral or fcc symmetry arise from the spherical droplet confinement. Combining simulations and electron tomography, we show that these colloidal clusters are in energy minima when the number of particles satisfies certain rules, leading to a “magic number” effect previously known only at subatomic and atomic length scale. We analyse their unique structural color resulting from the complex cluster structures, which can be used to monitor cluster rotation and colloid crystallization in spherical confinement in real-time. At last, we give examples of hierarchical structural design using colloidal clusters.

8:50 AM F.SM01.07.26
Membrane-Based Ionotronics Inspired by Neurons Thomas B. Schroeder[1], Varinder S. Takhar[2] and Joanna Aizenberg[1]; [1]Harvard University, United States; [2]University of Waterloo, Canada

Neurons generate electrical signals in response to chemical stimuli by altering the selective permeability of their membranes in the presence of an electrolyte gradient. After some integration, these signals move quickly along the length of the neuron before triggering a downstream chemical signal. Nervous systems, which are complex assemblies of these chemo-electro-chemical signaling units, are capable of guiding the autonomous function of animals.

Inspired by the architecture and biophysics of neurons, we present a hydrogel/organogel/hydrogel trilayer scheme capable of generating electrical potentials from chemical and optical signals. Energy is stored in an electrolyte gradient between the two aqueous compartments. Triggering the selective permeabilization of the initially insulating organogel membrane using stimuli-responsive chemistry causes a change in the electrical potential between the two aqueous domains on the order of 100 mV. We compare the spatial decrement of the signal along these membranes to the passive spread of an electrical potential in neurons. We further describe an electrochemical end effector intended to produce a chemical response spatially decoupled from the initial permeabilizing signal. We aim to interface this scheme with electrical detectors or network them to enable computation, feedback loops, or autonomous behavior.

5:00 AM F.SM01.08.01
Late News: Helical Microstructures of the Mineralized Coralline Red Algae Determine their Mechanical Properties Nuphar Bianco-Stein[1], Iryna Polishchuk[1], Gabriel Seiden[2], Julie Villanova[3], Alexander Rack[3], Paul Zaslansky[4] and Boaz Pokroy[1]; [1]Technion−Israel Institute of Technology, Israel; [2]Moriah Scientific Consulting, Israel; [3]The European Synchrotron, France; [4]Charité–Universitätsmedizin Berlin, Germany

Biominerals produced by living organisms have superior properties compared to their synthetic counterparts. Even though biominerals are formed at ambient conditions and from a limited variety of available building blocks, they possess remarkable structures and often combine desired qualities such as low weight and improved mechanical properties.
The coralline red algae secrete high-Mg calcite as a part of their skeleton, with Mg levels exceeding the thermodynamically stable one. They are highly prevalent around the world's oceans and contribute to reef ecology. The structure of these algae has not been widely studied previously and information on their nanostructure is largely missing.
In our attempt to gain a better understanding of nature's extraordinary designs, we study an articulated coralline red alga that resides in the shallow waters of the Mediterranean Sea. Because of its erect structure growing upright, this alga has to endure the great stresses applied to it by the sea waves. We explored its structure from the nano to the macroscale utilizing various state-of-the-art techniques such as synchrotron radiation nanotomography and high-resolution aberration-corrected TEM. We discovered that its structure is highly porous, with porosity levels reaching as high as 64 vol%. We showed that its structure is intricate and is hierarchical with several orders from the nano to the macroscale, formed by plate-like crystals with nanometric diameters. Surprisingly, we revealed its macrostructure is helical rather than cylindrical and proved that this configuration confers the alga great compliance, allowing it to be ~20% more compliant under compressive stress, as compared to a cylindrical structure with the same porosity.
The result is a sophisticated lightweight and compliant structure allowing the alga to sustain external stresses from its natural environment. This study can lead toward a better understanding of the structure-function relation of biomineralized

structures, and the synthesis of lightweight structures with improved mechanical properties.

Removal of Rare Earth Metal Ions from Contaminated Water by Sustainable Carboxycellulose Nanofibers Derived from Agave Through Nitro Oxidation Process Isha Brahmbhatt[1,2], Sunil Sharma[1], Priyanka Sharma[1], Marc Nolan[1] and Benjamin Hsiao[1]; [1]Stony Brook University, The State University of New York, United States; [2]Ardsley High School, United States

There is a growing need for rare earth metal ions such as lanthanides for use in electronics, fuel cells, and various other applications. These precious ions are currently derived by mining, causing major pollution and contamination in nearby water sources. As cellulose is the most abundant organic material, we derived carboxycellulose nanofibers from raw agave biomass using the simple nitro oxidation process for the removal of lanthanide ions. The nitro oxidation method converts untreated biomass to carboxycellulose nanofibers in a one step process using nitric acid and sodium nitrite. Zeta potential indicates that the fibers are highly electronegative (zeta potential -117.3 mV), and the conductometric titration method reveals that the fibers have a high carboxylate content (0.75 mmol/g). SEM measurements show that the fibers contain clearly visible fibrous structures. The TEM measurements of the fibers record fiber lengths of 55-690 nm and average fiber widths of 5-6 nm, and AFM data displayed an average thickness of 1.6 nm. The oxidation of the agave nanofibers was confirmed with ^{13}C CPMAS NMR data. The lower crystallinity of the agave nitro oxidized carboxycellulose nanofibers compared to raw agave was determined by WAXD. The nitro oxidation approach also offers beneficial reductions in the consumption of water and electric energy as well as the need for multi-chemicals when compared with conventional multiple-step processes at bench scale (e.g. TEMPO oxidation). Remediation studies on lanthanide ions showed a floc formation between the ions and nanofibers. The Langmuir isotherm generated from ICP-MS studies indicated a 285.7 mg/g adsorption capacity and over a 90% adsorption efficiency for all lanthanide concentrations, which supersedes current water purification mechanisms such as iron oxide beads (123.6 mg/g adsorption capacity). These results suggest that the agave nitro oxidized carboxycellulose nanofibers are effective for the removal of lanthanide ions for drinking water purification and lanthanide ion industry.

F.SM01.09.02
Tremendously Enhancing Photodegradation Efficiency by Biomorphic Porous Carbon Weizhao Huang and Hui Mei; Northwestern Polytechnical University, China

Traditional lab-based synthesis of photocatalyst are ineligible for urgent demand of exceptional recyclability and stability in industrially large-scale application resulting from the inevitably undergo agglomeration of powder-form catalysts. Immobilizing catalyst is an appealing strategy to obtain enhanced performance for solid support provides chemical, thermal, and mechanical stabilization to the catalytic species besides facilitating catalyst recovery. Carbonaceous materials with unique microstructure obtained by pyrolyzing renewable and environment-friendly nature plants have promising applications in areas such as battery and catalyst support. However, unexpected cracks accompanied by low oxidation resistance retard further development. In this study, a thin SiC coating for strengthening purpose was in-situ deposited on biomorphic porous carbon materials fabricated by pyrolyzing wood while maintaining low density. Continuously ordered microchannel structures from carbonized nature wood with a diameter of ca. 20 μm was completely replicated after depositing SiC coating, resulting in the good anisotropy in mechanical and thermal properties. The thin SiC coating was found to greatly increase compressive strength from 26.4 to 47.4 MPa and thermal conductivity from 0.49 to 14.94 W/m K in the axial direction with improved oxidation resistance of weight loss from 78.5% to 1.51%. In the radial direction, however, the increase of the two properties was lower due to the longitudinal microchannel structure. Feasibility of the biomorphic carbon serving as catalyst support with highly developed continuous channels was evaluated by loading typical molybdenum disulfide (MoS_2). Result shows a significant improvement in both adsorption and photodegradation efficiency against the pure MoS_2, which is because of the enlarged specific surface area of the catalyst.

F.SM01.09.05

Bioinspired Design of Polymers for Protein Binding and Aggregation Modification Sarah E. Morgan[1], Ashleigh N. Bristol[1], Lisa K. Kemp[1], Shahid Karim[2] and Vijay Rangachari[2]; [1]The University of Southern Mississippi, United States; [2]University of Southern Mississippi, United States

Abnormal protein behaviors, such as aggregation or mislabeling as antigens, are involved in a range of disorders including Alzheimer's, Parkinson's, and celiac disease. Water-soluble polymers with functional motifs mimicking those in naturally occurring polymers provide an avenue to interrogate binding and assembly processes and can be designed to modify protein behavior. RAFT polymerization was employed for the synthesis of two different families of polymers, designed for the study of two different protein systems, to produce polymers with desired structures, targeted molecular weight, and low dispersity. Aggregation processes were evaluated with dynamic light scattering, GPC-MALLS, and fluorescence assays. FTIR and NMR were employed to determine hydrogen bonding patterns of the systems. Gliadin, a component of gluten and a known epitope, is implicated in celiac disease (CeD) and results in an inflammatory response in CeD patients when consumed. Stimuli-responsive polyelectrolytes with varying charged groups were employed as models to determine the effect of molecular weight and pendent group on non-covalent interaction modes with gliadin in vitro. The polymers exhibited pH dependent binding and alteration of gliadin secondary structure, providing a platform for therapeutic design of specific structure/binding interactions with food proteins. Glycopolymers with stereospecific pendent groups designed to mimic saccharide clusters in the GM1 ganglioside were prepared to analyze interactions with the amyloid β peptide associated with Alzehiemer's disease. The Aβ42 assembly process was directly impacted by the stereochemistry of the pendent saccharide. Glycopolymer-silicone hydrogels prepared with varying hydrophobic/hydrophilic content and copolymer composition showed structure dependence of diffusion, rheology, and nanomechanical properties. These findings demonstrate the potential for design of selective glycopolymers for targeted molecular interactions for biomedical and personal care applications.

F.SM01.09.06
Living Sorbents for Arsenic-Contaminated Drinking Water Remediation Yidan Bi and Vicki L. Colvin; Brown University, United States

Arsenic is a pervasive contaminant in drinking water, and it has ranked the first on the Substance Priority List of Agency for Toxic Substances and Disease Registry (ATSDR) for more than two decades. Exposure to low-level arsenic in early life impairs children's cognitive development and buries the risk of developing a variety of cancers in young adulthood. To prevent the severe health effect of arsenic ingestion, materials with high arsenic removal capacity and fast treatment speed have been investigated. While these strategies are efficient for As(V), they are rendered ineffective when encountering the less abundant yet more toxic As(III), especially in the presence of competing ions. Solutions such as pretreatment or extensive removal of competing ions along with arsenic dramatically increase the operation cost and unnecessarily eliminate other benign species from water. Thus, there is a need for developing materials that can precisely capture arsenic from drinking water or even more complex beverage matrices and reduce the arsenic level below the EPA regulation (10 ppb) without altering the water chemistry.

In this work, we looked beyond the conventional physicochemical water treatment strategies and acquired insights from natural arsenic detoxification processes. The toxicity of As(III) originates from its high affinity to the cysteine residues in proteins. Natural organisms resolve this issue by expressing cysteine-rich peptides or proteins that can sequester As(III) in the cells. Inspired by this mechanism, we engineered a benign strain of *E. coli* to overexpress fusion proteins containing the binding pockets of two arsenic-binding proteins, ArsR and AfArsR, for improved arsenic scavenging competency. We also applied molecular biology tools to enhance the arsenic sorption capacity and accelerate the removal speed. One gram of these living sorbents can stoichiometrically immobilize milligrams of arsenic within a few hours. The high affinity of the proteins toward the substrate overcomes the selectivity barrier of inorganic sorbents like Bayoxide. For example, the living sorbents can bioaccumulate low levels of arsenic against common interfering species like phosphate, silicate, and natural organic matters, and the trapped As(III) does not leak to the water under these complicated conditions. In addition to remediating intractable matrices such as NSF challenge water, we found these living sorbents are adaptive to beverages including juice and wine, which were reported that are contaminated with arsenic but are not tightly regulated. Moreover, unlike the cumbersome inorganic material transportation, we propose that these living sorbents can be regenerated on-site after shipping the "seed material". We explored freeze-drying the biosorbents for storage and demonstrated that the reconstituted sorbents maintained arsenic-binding ability. To prevent secondary contamination after remediation, we explored tagging the bacterial cells with magnetic nanoparticles and found that the bacteria can be removed with a handhold magnet within a few minutes. This work provides the potential of applying renewable living sorbents for selective drinking water contaminant removal, and it is beneficial for the rural households and small communities who do not have access to the expensive and energy-consuming arsenic treatment technologies.

F.SM01.09.07
Strategic Design of Advanced Bioinspired and Biomimetic Membranes Conjugated with Graphene Oxide for Selective Ion Rejection Sanju Gupta[1,2]; [1]CCNY-CUNY, United States; [2]Western Kentucky University, United States

Recent advances in synthetic membranes allow their use in fields as diverse as food and agriculture, industrial water treatment, potable water production, and bio-separation. Among the newly developed technologies, nanofiltration for liquids and more particularly for desalination of seawater or saline aquifers is the most recent one. However, limitations of current polymeric membranes call for the development of novel formulations that offer both high permeability (water flux) and ion differentiation (selectivity) usually considered antagonist features. We report the fabrication of membranes prepared from track-etched polymeric membranes as supports in which biological ion channels such as Gramicidin A, alpha-hemolysin are confined and ion-selective binding peptide motifs conjugated with graphene oxide as nanoporous hybrids. These bioinspired and biomimetic membranes are attracting widespread attention offering advantages including mechanical robustness, controlled pore dimension, and shape, modifiable surfaces for the desired efficiency. The permeability and selective ion transport are evaluated by ion diffusion kinetics, UV-Visible absorption spectroscopy, and nanofiltration while gaining insights into the role of key parameters including track-etch pore size, surface chemistry, and ion binding through solid-state nanopores or nanochannels. The proposed activity positively impacts the environment by integrating eco-friendly materials design, development, and deployment.

F.SM01.09.09
Biomimetic Musculoskeletal Polymer Nanocomposites for Magnetic Collective Swimming Sukyoung Won, Hee Eun Lee, Young Shik Cho, Seung Jae Yang and Jeong Jae Wie; Inha University, Korea (the Republic of)

In human musculoskeletal system, skeletal muscles attached to spongy bones play an essential role in exerting quick and powerful movement. Herein, we present a musculoskeletal design capable of agile magnetomotility of ternary polymeric nanocomposites. Inspired by protein actin in skeletal muscle, iron particles are attached to surface of helical porous carbon nanotube yarn (CNTY) owing to polydimethylsiloxane (PDMS) elastomer providing a fascia-like connective function. Under rotating 2D quadruple electromagnetic field, soft robots achieved agile rectangular orbital magnetomotility reaching up to 162 body length per second. Upon varying the frequency of the rotating magnetic field, the individual rectangular orbit of multiple soft robots is reconfigured into magnetic-assembled circular orbits. We will discuss magnetic swimming of collectively assembled soft robots that can manipulate vortex chirality of sustaining fluid.

F.SM01.09.10
Construction of Hybrid Soft Nanomaterials Composed of Supramolecular Nanostructures of DNA and Peptide Derivatives Sayuri Higashi[1], Aya Shibata[1], Yoshiaki Kitamura[1], Koichiro M. Hirosawa[1], Kenichi G. Suzuki[1], Kazunori Matsuura[2,2] and Masato Ikeda[1,1,1]; [1]Gifu University, Japan; [2]Tottori University, Japan

Under multi-component molecular conditions such as inside of living cells, fibrous proteins including actin filaments and microtubules are constructed based on orthogonal (self-sorted) self-assembling. Self-sorting enables plural supramolecular nanostructures to retain each property and function as well as their structures even under complex conditions. In artificial systems, construction of complex and discrete soft nanomaterials has received increasing attention in recent years, and only several self-sorting pairs of synthetic self-assembling (small) molecules and peptides have been reported. Meanwhile, the high-fidelity recognition based on Watson-Crick base paring and programmable sequences of DNAs allows a variety of DNA nanostructures with controlled sizes and shapes to be constructed, and hybrid nanomaterials composed of DNA nanostructures have been pursued for a wide range of applications (*e.g.,* nanopores, scaffolds for catalytic reaction and protein assembly). However, much of these hybrid nanomaterials have been constructed based on co-assembly, and the orthogonal coexistence of DNA nanostructures with supramolecular nanostructures obtained by self-sorting with synthetic molecules has yet to be explored in detail.
To develop the hybrid nanomaterials composed of DNA nanostructures based on self-sorting phenomenon, we focused on nucleic acids and peptide derivatives as the component molecular pair. We recently constructed hybrid soft nanomaterials composed of DNA microspheres[1], which can be obtained from three short single-stranded DNAs, and three different supramolecular nanostructures of semi-artificial glycopeptides[2] (helical nanofibers, straight nanoribbons, and flowerlike microaggregates) in single medium by a simple thermal annealing process.[3] Interestingly, both of supramolecular nanostructures exist orthogonally with only marginal impact on their morphology in single medium as a supramolecular hydrogel state. Noteworthily, to observe such self-sorted supramolecular nanostructures by fluorescence imaging, additional fluorochrome-labeled probes are required to synthesize. However, in this research, we have achieved the selective visualization of each supramolecular nanostructure by means of rational staining method focused on each selective

molecular-recognition property of DNAs and glycopeptides (*e.g.,* intercalating agent, lectins, and saccharide-binding DNA aptamer) without additional probe developments. Furthermore, we have demonstrated the sequence-controlled degradation of the individual supramolecular nanostructures in response to distinctive bio-stimuli (*i.e.*, enzyme and ssDNA), rendering these soft nanomaterials active against such stimuli. In this presentation, I would like to discuss the detail of these newly developed hybrid soft nanomaterials and underlying mechanism to form such unique superstructures and functions.

Self-Assembly of Positively Charged Computationally Designed Coiled Coil Peptide 'Bundlemer' Chains with Thiol-Michael Click Chemistry Yao Tang[1], Nairiti Sinha[1], Rui Guo[2], Jeffery G. Saven[2], Christopher Kloxin[1] and Darrin Pochan[1]; [1]University of Delaware, United States; [2]University of Pennsylvania, United States

With the help of computational design, a series of peptides with a length of 29 amino acids were designed to be self-assembled into stable, tetrahelical, anti-parallel coiled coil peptide bundles with net charges ranging from 0 to +32. In this research, +4 charged peptides (leading to +16 charged coiled coil bundles) are synthesized via solid phase peptide synthesis (SPPS) with the N-termini of single peptides modified with cysteine or a non-natural maleimide. These peptides are self-assembled into 4 x 2nm cylindrical peptide bundles by non-covalent interactions and subsequently conjugated via Thiol-Michael 'click' chemistry to form coiled coil peptide bundle chains with extreme rigidity. Transmission electron microscopy (TEM) and circular dichroism (CD) spectroscopy are applied to investigate the effect of temperature, pH and solvent composition on the structure of coiled coil bundle chains. Polarized optical microscopy (POM) is applied to study the liquid crystalline behavior of conjugated peptide bundle chains. Small-angle X-ray scattering (SAXS) and small-angle neutron scattering (SANS) are utilized to characterize the size and structure of formed coiled coil peptide bundle chains. The effect of salt and pH on the solution behavior of the positively charged coiled coil chains will be also discussed. The self-assembled peptide bundles can be further used as building blocks to construct new 1-D and 2-D nanomaterials.

F.SM01.09.13

Dialdehyde Cellulose and Cationic Dialdehyde Cellulose from Bamboo for Dyes Adsorption and Separation Xiangyu Huang, Hongbin Zhuo, Pejman Hadi and Benjamin S. Hsiao; Stony Brook University, United States

In this study, bamboo-achieved cellulose is functionalized and upcycled into efficient, low-cost and environmental-friendly bio-adsorbents for dye adsorption and separation. Dialdehyde cellulose (DAC) was prepared through the chemical oxidation on cellulose surface via sodium periodate oxidation. Then, cationic Girard's reagent T (GT) was covalently crosslinked onto the backbone of cellulose molecules via the Schiff's base reaction between the amino groups of GT and the aldehyde groups on the DAC to form the cationic aldehyde cellulose (cDAC). The chemical structure and morphology of two bio-adsorbents were characterized. The adsorption behaviors of the functionalized DAC and cDAC possessed different available active sites (including aldehyde groups and quaternary ammonium cations) towards various dyes in the aqueous solution were investigated systematically. The effects of dye concentration, contact time and pH environment in the adsorption of the anionic Congo red (CR) and cationic Bismarck brown Y (BBY) were studied. The results showed that DAC could adsorb BBY more effectively while cDAC has a much higher adsorption capacity towards CR, this is due to the adsorption was dominated by both the static electric force and the chemical reaction between dyes and adsorbents. The adsorption process was found to happen promptly (within the first 10 minutes) and follow the pseudo-second-order model. Both DAC and cDAC were proved to exhibit great adsorption behaviors under a wide pH range. Furthermore, the adsorption performance of six different dyes onto DAC and cDAC were studied, separately. Their adsorption capacities varied significantly on CR, BBY, Brilliant cresyl blue (BCB), Acid green 25 (AG25), Acid brown M (ABM) and Alizarin red S (ARS), indicating the DAC and cDAC could adsorb dyes from aqueous system selectively owing to the different reactiveness between dyes and the adsorbents' active sites. Based on the selective adsorption behavior towards different dyes, DAC and cDAC were proved to possess strong abilities for separating dye mixtures, such as: BBY-ARS, AG25-CR and BCB-CR.

F.SM01.09.14

A Composite Superhydrophobic Bio-Membrane from Hydrophilic Biomass for Desalination via Membrane Distillation Ritika Joshi[1], Jackie Zheng[1], Tom Lindstrom[1,2] and Benjamin Hsiao[1]; [1]Stony Brook University, United States; [2]Royal Institute of Technology, Sweden

Over 2 billion people live in countries experiencing high water stress (UN, 2018) and water crisis has become one of the biggest challenges for the world. Current desalination techniques necessitate complex infrastructure and high operating pressures, making them impractical in poor and technologically underdeveloped regions. Membrane distillation (MD) is an emerging water purification technique capable of purifying highly saline or contaminated water, which can help to alleviate water stress especially for the off-grid community. It is a thermally driven separation process employing a porous hydrophobic membrane which allows the passage of vapor molecules only. Currently used polymeric membranes in water filtration techniques have a large carbon footprint which makes it imperative to find an environmental and sustainable solution without compromising performance. In this study, a composite porous nanostructured cellulose based membrane was fabricated using carboxymethylated fibers (obtained from wood and non-wood plants like jute). The top barrier layer in this composite membrane is hydrophobic (mimicking lotus leaf) which prevents liquid penetration followed by a hydrophilic layer. The carboxymethylated cellulose fibers were cross-linked with wet strength additives to improve wet-integrity and water retention properties. The hydrophobic layer was developed by introducing micro-scale roughness using minerals like precipitated calcium carbonate followed by sizing with dimer giving high contact angle exceeding 140° to prevent wetting of the membrane. The porosity of the entire membrane is in the range of 70-80%. Different characterization techniques like infra-red spectroscopy, solid state NMR, scanning electron microscopy, thermo-gravimetric analysis, and contact angle were used to study membrane properties. The performance of composite membrane was evaluated using a laboratory scale direct contact membrane distillation (DCMD) system. Water flux and salt rejection were tested under a set of feed water temperatures ranging between 40-60°C keeping the permeate water temperature same at 20°C. Moreover, the fabricated cellulosic membrane exhibited a comparable performance to that of commercial hydrophobic PTFE membranes.

F.SM01.09.15

Effect of Net Charge on Solution Structurs of Polymerized Peptide Coiled-Coil 'Bundlemers' Yi Shi[1], Rui Guo[2], Jacquelyn Blum[2], Jeffery G. Saven[2], Christopher Kloxin[1] and Darrin Pochan[1]; [1]University of Delaware, United States; [2]University of Pennsylvania, United States

De Novo design of peptides for assembly into targeted nanostructrue is being explored extensively in the self-assembly community with the help of computational methods. Various peptide structures and solution assembly behaviors have been achieved by computational design of the peptide molecule sequences. Previous work of our collaborative group has demonstrated that computationally designed anti-parallel, homotetrameric coiled-coil, or 'bundlemers', with N-terminal modifications can form nanomaterials ranging from 2-D materials with desired inter-bundle symmetry to polymer chain rigid rods via thiol-Michael reaction. In the case of concentrated rod solutions, birefringence was observed in concentrated rigid rod solutions which proved the presence of liquid crystal phases. In this current work, further study into controlling solution behavior of peptide rods was conducted with newly designed peptide sequences. Solution structure of highly net-charged bundlemers (-16 through -24 at pH 7) and bundlemers with parallel packing of constituent peptides were verified experimentally. Preliminary studies on liquid crystal behavior of rigid rods was investigated with these highly charged sequences due to their exterior charge repulsion, which can be controlled by ionic strength of solution and pH. Furthermore, semiflexible chains formed by conjugating coiled-coil and tetra-functional organic linkers as characterized via transmission electron microscopy and cryo-TEM. The semiflexible chains are expected to provide opportunities to achieve structures that resembles biological molecules.

F.SM01.09.16

Interfacial Assembly of Bundlemers Matthew Langenstein[1], Rajkumar Misra[1], Rui Guo[2], Jeffery G. Saven[2], Christopher Kloxin[1] and Darrin Pochan[1]; [1]University of Delaware, United States; [2]University of Pennsylvania, United States

Bundlemers are a series of computationally designed peptides that form monodisperse cylindrical particles through aqueous self-assembly into antiparallel homotetrameric coiled coils. Due to their robust coiled-coil-forming motif these peptidic colloids have extremely tunable surface chemistry mostly independent from their structure. Using this tunability, we have previously developed bundlemers that form predesigned 2D lattices, nanocages, and nanofibers through tailoring their surface chemistry and solution assembly conditions. Recently, we have used bundlemers as macromonomers to create stiff and extremely high aspect ratio supramolecular polymers through covalent chemistry between the neighboring bundlemer ends. As the library of bundlemers continues to grow, it is important to develop applications and processing methods to grow useful, disparate nanostructures out of these versatile building blocks. Drawing inspiration from carbon nanotubes, bundlemer brush nanoforests present an interesting potential nanostructure for the tuning of surface properties and the interaction of designed interfaces. By first templating a surface through the directed self-assembly of bundlemers onto a flat planar substrate, it should be possible to grow thin films of highly aligned supramolecular bundlemers brushes with tunable surface chemistry and packing structure. Ongoing work on the formation of the template layer has shown a dependence between deposition kinetics and electrostatic interactions between bundlemers. This presentation will overview the

characterization of bundlemer monolayers on a flat planar gold substrate as well as the impact of pH, ionic strength, and bundlemer surface charge on deposition kinetics through the use of atomic force microscopy, infrared reflection adsorption spectroscopy (IRRAS) and quartz crystal microgravimetry with dissipation monitoring (QCM-D).

F.SM01.09.17
PEEU Fiber Mesh Elasticity and Its Regulatory Effects on Human Endothelial Cells Xianlei Sun, Wingtai Tung, Weiwei Wang, Yue Liu, Jie Zou, Karl Kratz, Nan Ma and Andreas Lendlein; Institute of Biomaterial Science and Berlin-Brandenburg Centre for Regenerative Therapies, Helmholtz-Zentrum Geesthacht, Germany

Electrospinning technique enables the transformation of polymers into functional fiber/mesh architectures, with the comparable length scales to the native extracellular matrix[1]. Given the significant variation in local elastic properties of micro/nano fibers caused by the highly intersected and suspended architecture[2], here we elucidated the correlation of the local mechanical properties of a fiber meshwork to its microscale network architecture, and investigated the influence of fiber mesh elasticity on the behavior of human umbilical vein endothelial cells (HUVECs).
The multiblock copolymers polyesteretherurethane (PEEU), containing poly(*ε*-caprolactone) (PCL) and poly(*p*-dioxanone) (PPDO) segments with different ratios (40-70wt% PPDO) were used to prepare the fiber meshes via electrospinning technique. The fiber diameter was not remarkably influenced by the copolymer composition, with the diameter below 2 μm in all groups. The E-modulus of the fiber mesh at a dry state increased with the increase of PPDO percentage, according to the tensile tests. The three-point bending tests using an atomic force microscope (AFM) revealed a correlation between the local stiffness of a specific point on a single fiber and its position. HUVECs cultured on stiffer fiber meshes presented elongated F-actin filaments and spindle morphology, in comparison with their softer counterparts. The fiber mesh elasticity did not affect the initial HUVEC attachment, and a faster cell proliferation rate of HUVEC was shown on stiffer fibers. HUVEC pre-cultured on stiffer fiber meshes presented a faster migration velocity and an increased tube formation capacity than those from softer fibers, indicating a higher angiogenesis potential.
In summary, the functionality of HUVEC can be strongly regulated by the elasticity of fiber meshes. Mechanical characterization of the fibers at different scales, e.g. AFM for microscale in combination with tensile test for macroscale, could deepen our understanding on the cellular mechanosensing process and enable more meaningful substrate design towards favorable cell function.

Bioinspired Novel-Tip-Shaped Micropillar Arrays for Selective Liquid Sliding Surfaces Seongmin Kang, Ji Seong Choi and Joon Hyung An; Chungnam National University, Korea (the Republic of)

Recently, superomniphobic (meaning highly water and oil-repellent) surfaces have been extensively studied both theoretically and experimentally in the materials community with several remarkable findings. Considering a notable process towards springtail-inspired omniphobic surfaces, however, a robust liquid repelling surface that is capable of inducing a selective liquid sliding property has been rarely reported, which would have many potential applications in microfluidics, mobile market, electronic devices and precision industry. Here, we present for the first time a selective liquid sliding surface using a springtail-inspired mushroom-like re-entrant structure with a novel geometry of concave tip. By implementing a simple yet sturdy silicon fabrication and lithography method, the fabricated micropillar arrays displayed high structural fidelity. We investigated a design rule for the cap of the proposed structures, which resulted in not only superomniphobicity but also a selective liquid sliding property with DI water and mineral oil. We believe that our study makes a significant contribution to the literature because it proposes a novel springtail-inspired mushroom-like re-entrant structure that can induce a selective liquid sliding property between water and oil, which has not been accomplished before.

F.SM01.09.19
Improving Control of Inverse Opal Surface Chemistry and Interactions with Fluids Natalie Nicolas; Harvard University, United States

Inverse opal photonic crystals are bioinspired structurally colored porous materials that have been utilized in many applications including sensing, catalysis, and microfluidics. By modifying the surface chemistry and geometry of inverse opal pores to improve control over surface-fluid interactions in these materials, we can achieve highly localized effects and

dynamically alter the wetting point of inverse opal films. Several strategies were used to fine-tune the behavior of the inverse opal. The pore size and pore neck angle, which determine the threshold contact angle for fluid infiltration, were adjusted by atomic layer deposition. This technique provides sub-nanometer control of the pore radius and can be used in conjunction with surface chemical modification to change the wetting point of an inverse opal film. The surface chemistry of the pore, which controls the contact angle that a fluid forms with the surface, was patterned with multiple silanes. By taking advantage of the inherent disorder in self-assembled monolayers at features with a small radius of curvature, such as pore necks, controlled local patterns in surface chemistry were produced. For dynamic modulation of the contact angle, photoswitchable spiropyran and azobenzene molecules were attached to the pore surface. These molecules reversibly altered the hydrophobicity of the surface when their conformation was changed by exposure to ultraviolet or visible light. By understanding how pore geometry and surface chemistry contribute to the static and dynamic behavior of inverse opals and their interactions with fluids, we can more effectively utilize these structured materials.

F.SM01.09.24

Late News: Investigation on the Partitioned Multilayers of the Wing Scale of Papilio maackii for Nature-Inspired Structural Coloration Seungmuk Ji[1], Deok-Jin Jeon[1], Jihun Kang[1], Seunghwan Moon[1], Eunok Lee[2], Jinhee Kim[2] and Jong-Souk Yeo[1]; [1]Yonsei University, Korea (the Republic of); [2]National Institute of Ecology, Korea (the Republic of)

Butterflies present a variety of brilliant colors on their wings based on pointillism. Pointillism is well-known drawing technique, however, to express colors, butterflies use very unique and diverse nanostructures such as tree-like multilayered ridges, chitin-air multilayers, photonic crystals, etc. Through investigating these photonic structures, we are able to come up with effective engineering strategies to produce vivid, durable, and eco-friendly colors. *Papilio maackii,* the alpine black swallowtail, is a butterfly that uses air-chitin partitioned multilayers to exhibit a blueish-green like color on its wing. Since it has scales that show various colors between blue to green, it has the advantage of studying how to control structural colors using multilayered structures.
In this work, we investigate the structural coloration of the wing scale of *Papilio maackii* according to its nanoscale multilayered. The color of the wing scales changes from blue to green, depending on the thickness of the chitin and air layer. We demonstrate by using finite difference time domain (FDTD) simulations that the chitin partitions in air-chitin mixed layers regulate the effective refractive index to improve the color contrast with low background intensities. Cross-sectional TEM investigations show that the thickness of the air-chitin mixed layers varies gradually, and when this gradual change is reflected in the simulation, it shows a more similar reflectance spectrum with that of the experimentally measured. We identify the presence of melanin on the colored scales, which is a light-absorbing pigment, by measuring Raman spectroscopy. FDTD simulations show that melanin can contribute to the intensity of the reflectance spectrum in the region of long wavelength. In order to realize the structural colors based on the partitioned multilayers, we use a method to coat polymeric nanoparticles and sol-gel glass thin films repeatedly. By using this method, the effects of inhomogeneity and volume fraction of air voids in the multilayered structure are experimentally examined.
This research was supported by National Research Foundation (NRF) grant funded by the Ministry of Education, under “Basic Science Research Program” (NRF-2017R1D1A1B04033182) and also supported by Research Program through the National Institute of Ecology (NIE-Basic Research-2020-18).

F.SM01.09.20

Magnetic Field Alignment of Chitin Nanocrystals Confined to a Polymer Microgel Sujin Rebecca Lee, Elsa Reichmanis, Jung O Park and Mohan Srinivasarao; Georgia Institute of Technology, United States

It is well documented that twist axis of cellulosic fiber aligns parallel to applied magnetic field. In here, we showed change in orientation of bio-derived cholesteric phase confined to microgel using low magnetic fields (0.5 – 1.2 T). As equilibrated on commercial magnet, droplets of chitin nanocrystal and superparamagnetic nanoparticles mixture possessed homeotropic anchoring and light induced polymerization of the monomer in droplets captured the phase into microgels. The helix orientation directly affected the texture of microgels under polarized optical microscopy. The exhibited structures of microgel were nested cup configuration of lamellar planes or bipolar structure even in the high chirality regime. Moreover, the microgels are responsive to temperature, as we used N-isopropyl acrylamide as a monomer. With temperature change we could observe swelling and de-swelling of nested cup structure which allowed us to understand the structure with more information. These findings give fundamental understanding bio-derived cholesteric materials and their self-assembly under confinement. Methodology for embedding twisted structure in polymer with bottom-up fabrication will give guideline for designing and controlling multifunctional nature-inspired programmable devices or materials with sustainable use of our resources.

F.SM01.09.22
Late News: Biomimetic Moth-Eye Nanostructure with Improved Optical Properties and Facilitated Application to Optical Devices Jiseong Choi, Joon Hyung An, Hyunjung Kim and Seongmin Kang; Chungnam National University, Korea (the Republic of)

Moth-eye inspired structure (MIS) has been regarded as important technology to enhance efficiency of optical device in biomimetic field. Since the nanostructures of the moth-eye surface gradually changed the refractive index from the air to devices, the MIS improved the optical properties of transmittance and reflectance. Despite these developments, film-based structures were difficult to apply and surface coating might damage to the surface of optical device during additional processes. Therefore, we fabricated three different sizes of MIS, 300 nm, 500 nm and 1000 nm, followed by optimizing materials and nanostructure size supported through two theoretical phenomena which are diffraction grating equation and double-slit effect. Then, optical devices were packaged by attaching polymer-based MIS without any treating and processing. As a result, the freestanding MIS composed of PDMS were identified to enhanced optical properties with over 94% transmittance and below 3.5% reflectance, compared to the MIS composed of PUA with substrate of PET film. In addition, PDMS-MIS attached to cell phone and ITO glass, which was used as substrate of optical devices, was proved that optical devices facilitated packaging as well as enhanced optical properties.

F.SM01.09.25
Late News: Silk-Like Structure of Freshwater Mussel Byssus Fabricated via Shear-Induced Alpha to Beta Transition of Intermediate Filament-Like Precursors Miriam Simmons and Matthew J. Harrington; McGill University, Canada

Freshwater invasive mussel species *Dreissena polymorpha* (zebra mussels) adhere themselves in underwater environments with a collection of protein-based fibers known as a byssus. The byssus of the zebra mussel is stronger, stiffer and faster to recover after deformation than those of the well-characterized marine mussels, but very little is known of its structure or composition. Here, we used a combination of Raman, FTIR and wide angle x-ray diffraction to elucidate the secondary structure of fresh and induced byssal fibres. Out data indicates that the secreted fibers are comprised of a mixture of parallel β-crystallites, similar to spider silk. Furthermore, investigation of the byssus biofabrication process indicates that the precursor proteins are stored in an α-helical structure and transition from an α-helix to β-sheet secondary structure during the formation process, similar to other structural proteins like intermediate filaments and keratin. This stress-induced transformation in secondary structure is being attributed to a coiled-coil protein predicted in the mussel transcriptome, and current efforts are aimed at extracting this protein to further understand its shear-induced phase transformation.

Removal of Rare Earth Metal Ions from Contaminated Water by Sustainable Carboxycellulose Nanofibers Derived from Agave Through Nitro Oxidation Process Isha Brahmbhatt[1,2], Sunil Sharma[1], Priyanka Sharma[1], Marc Nolan[1] and Benjamin Hsiao[1]; [1]Stony Brook University, The State University of New York, United States; [2]Ardsley High School, United States

There is a growing need for rare earth metal ions such as lanthanides for use in electronics, fuel cells, and various other applications. These precious ions are currently derived by mining, causing major pollution and contamination in nearby water sources. As cellulose is the most abundant organic material, we derived carboxycellulose nanofibers from raw agave biomass using the simple nitro oxidation process for the removal of lanthanide ions. The nitro oxidation method converts untreated biomass to carboxycellulose nanofibers in a one step process using nitric acid and sodium nitrite. Zeta potential indicates that the fibers are highly electronegative (zeta potential -117.3 mV), and the conductometric titration method reveals that the fibers have a high carboxylate content (0.75 mmol/g). SEM measurements show that the fibers contain clearly visible fibrous

structures. The TEM measurements of the fibers record fiber lengths of 55-690 nm and average fiber widths of 5-6 nm, and AFM data displayed an average thickness of 1.6 nm. The oxidation of the agave nanofibers was confirmed with ^{13}C CPMAS NMR data. The lower crystallinity of the agave nitro oxidized carboxycellulose nanofibers compared to raw agave was determined by WAXD. The nitro oxidation approach also offers beneficial reductions in the consumption of water and electric energy as well as the need for multi-chemicals when compared with conventional multiple-step processes at bench scale (e.g. TEMPO oxidation). Remediation studies on lanthanide ions showed a floc formation between the ions and nanofibers. The Langmuir isotherm generated from ICP-MS studies indicated a 285.7 mg/g adsorption capacity and over a 90% adsorption efficiency for all lanthanide concentrations, which supersedes current water purification mechanisms such as iron oxide beads (123.6 mg/g adsorption capacity). These results suggest that the agave nitro oxidized carboxycellulose nanofibers are effective for the removal of lanthanide ions for drinking water purification and lanthanide ion industry.

F.SM01.09.02

Tremendously Enhancing Photodegradation Efficiency by Biomorphic Porous Carbon Weizhao Huang and Hui Mei; Northwestern Polytechnical University, China

Traditional lab-based synthesis of photocatalyst are ineligible for urgent demand of exceptional recyclability and stability in industrially large-scale application resulting from the inevitably undergo agglomeration of powder-form catalysts. Immobilizing catalyst is an appealing strategy to obtain enhanced performance for solid support provides chemical, thermal, and mechanical stabilization to the catalytic species besides facilitating catalyst recovery. Carbonaceous materials with unique microstructure obtained by pyrolyzing renewable and environment-friendly nature plants have promising applications in areas such as battery and catalyst support. However, unexpected cracks accompanied by low oxidation resistance retard further development. In this study, a thin SiC coating for strengthening purpose was in-situ deposited on biomorphic porous carbon materials fabricated by pyrolyzing wood while maintaining low density. Continuously ordered microchannel structures from carbonized nature wood with a diameter of ca. 20 μm was completely replicated after depositing SiC coating, resulting in the good anisotropy in mechanical and thermal properties. The thin SiC coating was found to greatly increase compressive strength from 26.4 to 47.4 MPa and thermal conductivity from 0.49 to 14.94 W/m K in the axial direction with improved oxidation resistance of weight loss from 78.5% to 1.51%. In the radial direction, however, the increase of the two properties was lower due to the longitudinal microchannel structure. Feasibility of the biomorphic carbon serving as catalyst support with highly developed continuous channels was evaluated by loading typical molybdenum disulfide (MoS_2). Result shows a significant improvement in both adsorption and photodegradation efficiency against the pure MoS_2, which is because of the enlarged specific surface area of the catalyst.

F.SM01.09.05

Bioinspired Design of Polymers for Protein Binding and Aggregation Modification Sarah E. Morgan[1], Ashleigh N. Bristol[1], Lisa K. Kemp[1], Shahid Karim[2] and Vijay Rangachari[2]; [1]The University of Southern Mississippi, United States; [2]University of Southern Mississippi, United States

Abnormal protein behaviors, such as aggregation or mislabeling as antigens, are involved in a range of disorders including Alzheimer's, Parkinson's, and celiac disease. Water-soluble polymers with functional motifs mimicking those in naturally occurring polymers provide an avenue to interrogate binding and assembly processes and can be designed to modify protein behavior. RAFT polymerization was employed for the synthesis of two different families of polymers, designed for the study of two different protein systems, to produce polymers with desired structures, targeted molecular weight, and low dispersity. Aggregation processes were evaluated with dynamic light scattering, GPC-MALLS, and fluorescence assays. FTIR and NMR were employed to determine hydrogen bonding patterns of the systems. Gliadin, a component of gluten and a known epitope, is implicated in celiac disease (CeD) and results in an inflammatory response in CeD patients when consumed. Stimuli-responsive polyelectrolytes with varying charged groups were employed as models to determine the effect of molecular weight and pendent group on non-covalent interaction modes with gliadin in vitro. The polymers exhibited pH dependent binding and alteration of gliadin secondary structure, providing a platform for therapeutic design of specific structure/binding interactions with food proteins. Glycopolymers with stereospecific pendent groups designed to mimic saccharide clusters in the GM1 ganglioside were prepared to analyze interactions with the amyloid β peptide associated with Alzehiemer's disease. The Aβ42 assembly process was directly impacted by the stereochemistry of the pendent saccharide. Glycopolymer-silicone hydrogels prepared with varying hydrophobic/hydrophilic content and copolymer composition showed structure dependence of diffusion, rheology, and nanomechanical properties. These findings demonstrate the potential for design of selective glycopolymers for targeted molecular interactions for biomedical and personal care applications.

Living Sorbents for Arsenic-Contaminated Drinking Water Remediation Yidan Bi and Vicki L. Colvin; Brown University, United States

Arsenic is a pervasive contaminant in drinking water, and it has ranked the first on the Substance Priority List of Agency for Toxic Substances and Disease Registry (ATSDR) for more than two decades. Exposure to low-level arsenic in early life impairs children's cognitive development and buries the risk of developing a variety of cancers in young adulthood. To prevent the severe health effect of arsenic ingestion, materials with high arsenic removal capacity and fast treatment speed have been investigated. While these strategies are efficient for As(V), they are rendered ineffective when encountering the less abundant yet more toxic As(III), especially in the presence of competing ions. Solutions such as pretreatment or extensive removal of competing ions along with arsenic dramatically increase the operation cost and unnecessarily eliminate other benign species from water. Thus, there is a need for developing materials that can precisely capture arsenic from drinking water or even more complex beverage matrices and reduce the arsenic level below the EPA regulation (10 ppb) without altering the water chemistry.

In this work, we looked beyond the conventional physicochemical water treatment strategies and acquired insights from natural arsenic detoxification processes. The toxicity of As(III) originates from its high affinity to the cysteine residues in proteins. Natural organisms resolve this issue by expressing cysteine-rich peptides or proteins that can sequester As(III) in the cells. Inspired by this mechanism, we engineered a benign strain of *E. coli* to overexpress fusion proteins containing the binding pockets of two arsenic-binding proteins, ArsR and AfArsR, for improved arsenic scavenging competency. We also applied molecular biology tools to enhance the arsenic sorption capacity and accelerate the removal speed. One gram of these living sorbents can stoichiometrically immobilize milligrams of arsenic within a few hours. The high affinity of the proteins toward the substrate overcomes the selectivity barrier of inorganic sorbents like Bayoxide. For example, the living sorbents can bioaccumulate low levels of arsenic against common interfering species like phosphate, silicate, and natural organic matters, and the trapped As(III) does not leak to the water under these complicated conditions. In addition to remediating intractable matrices such as NSF challenge water, we found these living sorbents are adaptive to beverages including juice and wine, which were reported that are contaminated with arsenic but are not tightly regulated. Moreover, unlike the cumbersome inorganic material transportation, we propose that these living sorbents can be regenerated on-site after shipping the "seed material". We explored freeze-drying the biosorbents for storage and demonstrated that the reconstituted sorbents maintained arsenic-binding ability. To prevent secondary contamination after remediation, we explored tagging the bacterial cells with magnetic nanoparticles and found that the bacteria can be removed with a handhold magnet within a few minutes. This work provides the potential of applying renewable living sorbents for selective drinking water contaminant removal, and it is beneficial for the rural households and small communities who do not have access to the expensive and energy-consuming arsenic treatment technologies.

F.S7M01.09.0
Strategic Design of Advanced Bioinspired and Biomimetic Membranes Conjugated with Graphene Oxide for Selective Ion Rejection Sanju Gupta[1,2]; [1]CCNY-CUNY, United States; [2]Western Kentucky University, United States

Recent advances in synthetic membranes allow their use in fields as diverse as food and agriculture, industrial water treatment, potable water production, and bio-separation. Among the newly developed technologies, nanofiltration for liquids and more particularly for desalination of seawater or saline aquifers is the most recent one. However, limitations of current polymeric membranes call for the development of novel formulations that offer both high permeability (water flux) and ion differentiation (selectivity) usually considered antagonist features. We report the fabrication of membranes prepared from track-etched polymeric membranes as supports in which biological ion channels such as Gramicidin A, alpha-hemolysin are confined and ion-selective binding peptide motifs conjugated with graphene oxide as nanoporous hybrids. These bioinspired and biomimetic membranes are attracting widespread attention offering advantages including mechanical robustness, controlled pore dimension, and shape, modifiable surfaces for the desired efficiency. The permeability and selective ion transport are evaluated by ion diffusion kinetics, UV-Visible absorption spectroscopy, and nanofiltration while gaining insights into the role of key parameters including track-etch pore size, surface chemistry, and ion binding through solid-state nanopores or nanochannels. The proposed activity positively impacts the environment by integrating eco-friendly materials design, development, and deployment.

Biomimetic Musculoskeletal Polymer Nanocomposites for Magnetic Collective Swimming Sukyoung Won, Hee Eun Lee, Young Shik Cho, Seung Jae Yang and Jeong Jae Wie; Inha University, Korea (the Republic of)

In human musculoskeletal system, skeletal muscles attached to spongy bones play an essential role in exerting quick and

powerful movement. Herein, we present a musculoskeletal design capable of agile magnetomotility of ternary polymeric nanocomposites. Inspired by protein actin in skeletal muscle, iron particles are attached to surface of helical porous carbon nanotube yarn (CNTY) owing to polydimethylsiloxane (PDMS) elastomer providing a fascia-like connective function. Under rotating 2D quadruple electromagnetic field, soft robots achieved agile rectangular orbital magnetomotility reaching up to 162 body length per second. Upon varying the frequency of the rotating magnetic field, the individual rectangular orbit of multiple soft robots is reconfigured into magnetic-assembled circular orbits. We will discuss magnetic swimming of collectively assembled soft robots that can manipulate vortex chirality of sustaining fluid.

F.SM01.09.10

Construction of Hybrid Soft Nanomaterials Composed of Supramolecular Nanostructures of DNA and Peptide Derivatives Sayuri Higashi[1], Aya Shibata[1], Yoshiaki Kitamura[1], Koichiro M. Hirosawa[1], Kenichi G. Suzuki[1], Kazunori Matsuura[2,2] and Masato Ikeda[1,1,1]; [1]Gifu University, Japan; [2]Tottori University, Japan

Under multi-component molecular conditions such as inside of living cells, fibrous proteins including actin filaments and microtubules are constructed based on orthogonal (self-sorted) self-assembling. Self-sorting enables plural supramolecular nanostructures to retain each property and function as well as their structures even under complex conditions. In artificial systems, construction of complex and discrete soft nanomaterials has received increasing attention in recent years, and only several self-sorting pairs of synthetic self-assembling (small) molecules and peptides have been reported. Meanwhile, the high-fidelity recognition based on Watson-Crick base paring and programmable sequences of DNAs allows a variety of DNA nanostructures with controlled sizes and shapes to be constructed, and hybrid nanomaterials composed of DNA nanostructures have been pursued for a wide range of applications (*e.g.,* nanopores, scaffolds for catalytic reaction and protein assembly). However, much of these hybrid nanomaterials have been constructed based on co-assembly, and the orthogonal coexistence of DNA nanostructures with supramolecular nanostructures obtained by self-sorting with synthetic molecules has yet to be explored in detail.
To develop the hybrid nanomaterials composed of DNA nanostructures based on self-sorting phenomenon, we focused on nucleic acids and peptide derivatives as the component molecular pair. We recently constructed hybrid soft nanomaterials composed of DNA microspheres[1], which can be obtained from three short single-stranded DNAs, and three different supramolecular nanostructures of semi-artificial glycopeptides[2] (helical nanofibers, straight nanoribbons, and flowerlike microaggregates) in single medium by a simple thermal annealing process.[3] Interestingly, both of supramolecular nanostructures exist orthogonally with only marginal impact on their morphology in single medium as a supramolecular hydrogel state. Noteworthily, to observe such self-sorted supramolecular nanostructures by fluorescence imaging, additional fluorochrome-labeled probes are required to synthesize. However, in this research, we have achieved the selective visualization of each supramolecular nanostructure by means of rational staining method focused on each selective molecular-recognition property of DNAs and glycopeptides (*e.g.,* intercalating agent, lectins, and saccharide-binding DNA aptamer) without additional probe developments. Furthermore, we have demonstrated the sequence-controlled degradation of the individual supramolecular nanostructures in response to distinctive bio-stimuli (*i.e.*, enzyme and ssDNA), rendering these soft nanomaterials active against such stimuli. In this presentation, I would like to discuss the detail of these newly developed hybrid soft nanomaterials and underlying mechanism to form such unique superstructures and functions.

Self-Assembly of Positively Charged Computationally Designed Coiled Coil Peptide 'Bundlemer' Chains with Thiol-Michael Click Chemistry Yao Tang[1], Nairiti Sinha[1], Rui Guo[2], Jeffery G. Saven[2], Christopher Kloxin[1] and Darrin Pochan[1]; [1]University of Delaware, United States; [2]University of Pennsylvania, United States

With the help of computational design, a series of peptides with a length of 29 amino acids were designed to be self-assembled into stable, tetrahelical, anti-parallel coiled coil peptide bundles with net charges ranging from 0 to +32. In this research, +4 charged peptides (leading to +16 charged coiled coil bundles) are synthesized via solid phase peptide synthesis (SPPS) with the N-termini of single peptides modified with cysteine or a non-natural maleimide. These peptides are self-assembled into 4 x 2nm cylindrical peptide bundles by non-covalent interactions and subsequently conjugated via Thiol-Michael 'click' chemistry to form coiled coil peptide bundle chains with extreme rigidity. Transmission electron microscopy (TEM) and circular dichroism (CD) spectroscopy are applied to investigate the effect of temperature, pH and solvent composition on the structure of coiled coil bundle chains. Polarized optical microscopy (POM) is applied to study the liquid

crystalline behavior of conjugated peptide bundle chains. Small-angle X-ray scattering (SAXS) and small-angle neutron scattering (SANS) are utilized to characterize the size and structure of formed coiled coil peptide bundle chains. The effect of salt and pH on the solution behavior of the positively charged coiled coil chains will be also discussed. The self-assembled peptide bundles can be further used as building blocks to construct new 1-D and 2-D nanomaterials.

F.SM01.09.13
Dialdehyde Cellulose and Cationic Dialdehyde Cellulose from Bamboo for Dyes Adsorption and Separation Xiangyu Huang, Hongbin Zhuo, Pejman Hadi and Benjamin S. Hsiao; Stony Brook University, United States

In this study, bamboo-achieved cellulose is functionalized and upcycled into efficient, low-cost and environmental-friendly bio-adsorbents for dye adsorption and separation. Dialdehyde cellulose (DAC) was prepared through the chemical oxidation on cellulose surface via sodium periodate oxidation. Then, cationic Girard's reagent T (GT) was covalently crosslinked onto the backbone of cellulose molecules via the Schiff's base reaction between the amino groups of GT and the aldehyde groups on the DAC to form the cationic aldehyde cellulose (cDAC). The chemical structure and morphology of two bio-adsorbents were characterized. The adsorption behaviors of the functionalized DAC and cDAC possessed different available active sites (including aldehyde groups and quaternary ammonium cations) towards various dyes in the aqueous solution were investigated systematically. The effects of dye concentration, contact time and pH environment in the adsorption of the anionic Congo red (CR) and cationic Bismarck brown Y (BBY) were studied. The results showed that DAC could adsorb BBY more effectively while cDAC has a much higher adsorption capacity towards CR, this is due to the adsorption was dominated by both the static electric force and the chemical reaction between dyes and adsorbents. The adsorption process was found to happen promptly (within the first 10 minutes) and follow the pseudo-second-order model. Both DAC and cDAC were proved to exhibit great adsorption behaviors under a wide pH range. Furthermore, the adsorption performance of six different dyes onto DAC and cDAC were studied, separately. Their adsorption capacities varied significantly on CR, BBY, Brilliant cresyl blue (BCB), Acid green 25 (AG25), Acid brown M (ABM) and Alizarin red S (ARS), indicating the DAC and cDAC could adsorb dyes from aqueous system selectively owing to the different reactiveness between dyes and the adsorbents' active sites. Based on the selective adsorption behavior towards different dyes, DAC and cDAC were proved to possess strong abilities for separating dye mixtures, such as: BBY-ARS, AG25-CR and BCB-CR.

F.SM01.09.14
A Composite Superhydrophobic Bio-Membrane from Hydrophilic Biomass for Desalination via Membrane Distillation Ritika Joshi[1], Jackie Zheng[1], Tom Lindstrom[1,2] and Benjamin Hsiao[1]; [1]Stony Brook University, United States; [2]Royal Institute of Technology, Sweden

Over 2 billion people live in countries experiencing high water stress (UN, 2018) and water crisis has become one of the biggest challenges for the world. Current desalination techniques necessitate complex infrastructure and high operating pressures, making them impractical in poor and technologically underdeveloped regions. Membrane distillation (MD) is an emerging water purification technique capable of purifying highly saline or contaminated water, which can help to alleviate water stress especially for the off-grid community. It is a thermally driven separation process employing a porous hydrophobic membrane which allows the passage of vapor molecules only. Currently used polymeric membranes in water filtration techniques have a large carbon footprint which makes it imperative to find an environmental and sustainable solution without compromising performance. In this study, a composite porous nanostructured cellulose based membrane was fabricated using carboxymethylated fibers (obtained from wood and non-wood plants like jute). The top barrier layer in this composite membrane is hydrophobic (mimicking lotus leaf) which prevents liquid penetration followed by a hydrophilic layer. The carboxymethylated cellulose fibers were cross-linked with wet strength additives to improve wet-integrity and water retention properties. The hydrophobic layer was developed by introducing micro-scale roughness using minerals like precipitated calcium carbonate followed by sizing with dimer giving high contact angle exceeding 140° to prevent wetting of the membrane. The porosity of the entire membrane is in the range of 70-80%. Different characterization techniques like infra-red spectroscopy, solid state NMR, scanning electron microscopy, thermo-gravimetric analysis, and contact angle were used to study membrane properties. The performance of composite membrane was evaluated using a laboratory scale direct contact membrane distillation (DCMD) system. Water flux and salt rejection were tested under a set of feed water temperatures ranging between 40-60°C keeping the permeate water temperature same at 20°C. Moreover, the fabricated cellulosic membrane exhibited a comparable performance to that of commercial hydrophobic PTFE membranes.

F.SM01.09.15
Effect of Net Charge on Solution Structurs of Polymerized Peptide Coiled-Coil 'Bundlemers' Yi Shi[1], Rui Guo[2], Jacquelyn Blum[2], Jeffery G. Saven[2], Christopher Kloxin[1] and Darrin Pochan[1]; [1]University of Delaware, United States; [2]University of Pennsylvania, United States

De Novo design of peptides for assembly into targeted nanostructrue is being explored extensively in the self-assembly community with the help of computational methods. Various peptide structures and solution assembly behaviors have been achieved by computational design of the peptide molecule sequences. Previous work of our collaborative group has demonstrated that computationally designed anti-parallel, homotetrameric coiled-coil, or 'bundlemers', with N-terminal modifications can form nanomaterials ranging from 2-D materials with desired inter-bundle symmetry to polymer chain rigid rods via thiol-Michael reaction. In the case of concentrated rod solutions, birefringence was observed in concentrated rigid rod solutions which proved the presence of liquid crystal phases. In this current work, further study into controlling solution behavior of peptide rods was conducted with newly designed peptide sequences. Solution structure of highly net-charged bundlemers (-16 through -24 at pH 7) and bundlemers with parallel packing of constituent peptides were verified experimentally. Preliminary studies on liquid crystal behavior of rigid rods was investigated with these highly charged sequences due to their exterior charge repulsion, which can be controlled by ionic strength of solution and pH. Furthermore, semiflexible chains formed by conjugating coiled-coil and tetra-functional organic linkers as characterized via transmission electron microscopy and cryo-TEM. The semiflexible chains are expected to provide opportunities to achieve structures that resembles biological molecules.

F.SM01.09.16

Interfacial Assembly of Bundlemers Matthew Langenstein[1], Rajkumar Misra[1], Rui Guo[2], Jeffery G. Saven[2], Christopher Kloxin[1] and Darrin Pochan[1]; [1]University of Delaware, United States; [2]University of Pennsylvania, United States

Bundlemers are a series of computationally designed peptides that form monodisperse cylindrical particles through aqueous self-assembly into antiparallel homotetrameric coiled coils. Due to their robust coiled-coil-forming motif these peptidic colloids have extremely tunable surface chemistry mostly independent from their structure. Using this tunability, we have previously developed bundlemers that form predesigned 2D lattices, nanocages, and nanofibers through tailoring their surface chemistry and solution assembly conditions. Recently, we have used bundlemers as macromonomers to create stiff and extremely high aspect ratio supramolecular polymers through covalent chemistry between the neighboring bundlemer ends. As the library of bundlemers continues to grow, it is important to develop applications and processing methods to grow useful, disparate nanostructures out of these versatile building blocks. Drawing inspiration from carbon nanotubes, bundlemer brush nanoforests present an interesting potential nanostructure for the tuning of surface properties and the interaction of designed interfaces. By first templating a surface through the directed self-assembly of bundlemers onto a flat planar substrate, it should be possible to grow thin films of highly aligned supramolecular bundlemers brushes with tunable surface chemistry and packing structure. Ongoing work on the formation of the template layer has shown a dependence between deposition kinetics and electrostatic interactions between bundlemers. This presentation will overview the characterization of bundlemer monolayers on a flat planar gold substrate as well as the impact of pH, ionic strength, and bundlemer surface charge on deposition kinetics through the use of atomic force microscopy, infrared reflection adsorption spectroscopy (IRRAS) and quartz crystal microgravimetry with dissipation monitoring (QCM-D).

F.SM01.09.17

PEEU Fiber Mesh Elasticity and Its Regulatory Effects on Human Endothelial Cells Xianlei Sun, Wingtai Tung, Weiwei Wang, Yue Liu, Jie Zou, Karl Kratz, Nan Ma and Andreas Lendlein; Institute of Biomaterial Science and Berlin-Brandenburg Centre for Regenerative Therapies, Helmholtz-Zentrum Geesthacht, Germany

Electrospinning technique enables the transformation of polymers into functional fiber/mesh architectures, with the comparable length scales to the native extracellular matrix[1]. Given the significant variation in local elastic properties of micro/nano fibers caused by the highly intersected and suspended architecture[2], here we elucidated the correlation of the local mechanical properties of a fiber meshwork to its microscale network architecture, and investigated the influence of fiber mesh elasticity on the behavior of human umbilical vein endothelial cells (HUVECs).
The multiblock copolymers polyesteretherurethane (PEEU), containing poly(ε-caprolactone) (PCL) and poly(*p*-dioxanone) (PPDO) segments with different ratios (40-70wt% PPDO) were used to prepare the fiber meshes via electrospinning technique. The fiber diameter was not remarkably influenced by the copolymer composition, with the diameter below 2 μm in all groups. The E-modulus of the fiber mesh at a dry state increased with the increase of PPDO percentage, according to the tensile tests. The three-point bending tests using an atomic force microscope (AFM) revealed a correlation between the local stiffness of a specific point on a single fiber and its position. HUVECs cultured on stiffer fiber meshes presented elongated F-actin filaments and spindle morphology, in comparison with their softer counterparts. The fiber mesh elasticity did not affect the initial HUVEC attachment, and a faster cell proliferation rate of HUVEC was shown on stiffer fibers. HUVEC pre-cultured on stiffer fiber meshes presented a faster migration velocity and an increased tube formation capacity than those from softer fibers, indicating a higher angiogenesis potential.

In summary, the functionality of HUVEC can be strongly regulated by the elasticity of fiber meshes. Mechanical characterization of the fibers at different scales, e.g. AFM for microscale in combination with tensile test for macroscale, could deepen our understanding on the cellular mechanosensing process and enable more meaningful substrate design towards favorable cell function.

Bioinspired Novel-Tip-Shaped Micropillar Arrays for Selective Liquid Sliding Surfaces Seongmin Kang, Ji Seong Choi and Joon Hyung An; Chungnam National University, Korea (the Republic of)

Recently, superomniphobic (meaning highly water and oil-repellent) surfaces have been extensively studied both theoretically and experimentally in the materials community with several remarkable findings. Considering a notable process towards springtail-inspired omniphobic surfaces, however, a robust liquid repelling surface that is capable of inducing a selective liquid sliding property has been rarely reported, which would have many potential applications in microfluidics, mobile market, electronic devices and precision industry. Here, we present for the first time a selective liquid sliding surface using a springtail-inspired mushroom-like re-entrant structure with a novel geometry of concave tip. By implementing a simple yet sturdy silicon fabrication and lithography method, the fabricated micropillar arrays displayed high structural fidelity. We investigated a design rule for the cap of the proposed structures, which resulted in not only superomniphobicity but also a selective liquid sliding property with DI water and mineral oil. We believe that our study makes a significant contribution to the literature because it proposes a novel springtail-inspired mushroom-like re-entrant structure that can induce a selective liquid sliding property between water and oil, which has not been accomplished before.

F.SM01.09.19

Improving Control of Inverse Opal Surface Chemistry and Interactions with Fluids Natalie Nicolas; Harvard University, United States

Inverse opal photonic crystals are bioinspired structurally colored porous materials that have been utilized in many applications including sensing, catalysis, and microfluidics. By modifying the surface chemistry and geometry of inverse opal pores to improve control over surface-fluid interactions in these materials, we can achieve highly localized effects and dynamically alter the wetting point of inverse opal films. Several strategies were used to fine-tune the behavior of the inverse opal. The pore size and pore neck angle, which determine the threshold contact angle for fluid infiltration, were adjusted by atomic layer deposition. This technique provides sub-nanometer control of the pore radius and can be used in conjunction with surface chemical modification to change the wetting point of an inverse opal film. The surface chemistry of the pore, which controls the contact angle that a fluid forms with the surface, was patterned with multiple silanes. By taking advantage of the inherent disorder in self-assembled monolayers at features with a small radius of curvature, such as pore necks, controlled local patterns in surface chemistry were produced. For dynamic modulation of the contact angle, photoswitchable spiropyran and azobenzene molecules were attached to the pore surface. These molecules reversibly altered the hydrophobicity of the surface when their conformation was changed by exposure to ultraviolet or visible light. By understanding how pore geometry and surface chemistry contribute to the static and dynamic behavior of inverse opals and their interactions with fluids, we can more effectively utilize these structured materials.

F.SM01.09.20

Magnetic Field Alignment of Chitin Nanocrystals Confined to a Polymer Microgel Sujin Rebecca Lee, Elsa Reichmanis, Jung O Park and Mohan Srinivasarao; Georgia Institute of Technology, United States

It is well documented that twist axis of cellulosic fiber aligns parallel to applied magnetic field. In here, we showed change in orientation of bio-derived cholesteric phase confined to microgel using low magnetic fields (0.5 – 1.2 T). As equilibrated on commercial magnet, droplets of chitin nanocrystal and superparamagnetic nanoparticles mixture possessed homeotropic anchoring and light induced polymerization of the monomer in droplets captured the phase into microgels. The helix orientation directly affected the texture of microgels under polarized optical microscopy. The exhibited structures of microgel were nested cup configuration of lamellar planes or bipolar structure even in the high chirality regime. Moreover, the microgels are responsive to temperature, as we used N-isopropyl acrylamide as a monomer. With temperature change we

could observe swelling and de-swelling of nested cup structure which allowed us to understand the structure with more information. These findings give fundamental understanding bio-derived cholesteric materials and their self-assembly under confinement. Methodology for embedding twisted structure in polymer with bottom-up fabrication will give guideline for designing and controlling multifunctional nature-inspired programmable devices or materials with sustainable use of our resources.

F.SM01.09.22

Late News: Biomimetic Moth-Eye Nanostructure with Improved Optical Properties and Facilitated Application to Optical Devices Jiseong Choi, Joon Hyung An, Hyunjung Kim and Seongmin Kang; Chungnam National University, Korea (the Republic of)

Moth-eye inspired structure (MIS) has been regarded as important technology to enhance efficiency of optical device in biomimetic field. Since the nanostructures of the moth-eye surface gradually changed the refractive index from the air to devices, the MIS improved the optical properties of transmittance and reflectance. Despite these developments, film-based structures were difficult to apply and surface coating might damage to the surface of optical device during additional processes. Therefore, we fabricated three different sizes of MIS, 300 nm, 500 nm and 1000 nm, followed by optimizing materials and nanostructure size supported through two theoretical phenomena which are diffraction grating equation and double-slit effect. Then, optical devices were packaged by attaching polymer-based MIS without any treating and processing. As a result, the freestanding MIS composed of PDMS were identified to enhanced optical properties with over 94% transmittance and below 3.5% reflectance, compared to the MIS composed of PUA with substrate of PET film. In addition, PDMS-MIS attached to cell phone and ITO glass, which was used as substrate of optical devices, was proved that optical devices facilitated packaging as well as enhanced optical properties.

F.SM01.09.24

Late News: Investigation on the Partitioned Multilayers of the Wing Scale of Papilio maackii for Nature-Inspired Structural Coloration Seungmuk Ji[1], Deok-Jin Jeon[1], Jihun Kang[1], Seunghwan Moon[1], Eunok Lee[2], Jinhee Kim[2] and Jong-Souk Yeo[1]; [1]Yonsei University, Korea (the Republic of); [2]National Institute of Ecology, Korea (the Republic of)

Butterflies present a variety of brilliant colors on their wings based on pointillism. Pointillism is well-known drawing technique, however, to express colors, butterflies use very unique and diverse nanostructures such as tree-like multilayered ridges, chitin-air multilayers, photonic crystals, etc. Through investigating these photonic structures, we are able to come up with effective engineering strategies to produce vivid, durable, and eco-friendly colors. *Papilio maackii,* the alpine black swallowtail, is a butterfly that uses air-chitin partitioned multilayers to exhibit a blueish-green like color on its wing. Since it has scales that show various colors between blue to green, it has the advantage of studying how to control structural colors using multilayered structures.

In this work, we investigate the structural coloration of the wing scale of *Papilio maackii* according to its nanoscale multilayered. The color of the wing scales changes from blue to green, depending on the thickness of the chitin and air layer. We demonstrate by using finite difference time domain (FDTD) simulations that the chitin partitions in air-chitin mixed layers regulate the effective refractive index to improve the color contrast with low background intensities. Cross-sectional TEM investigations show that the thickness of the air-chitin mixed layers varies gradually, and when this gradual change is reflected in the simulation, it shows a more similar reflectance spectrum with that of the experimentally measured. We identify the presence of melanin on the colored scales, which is a light-absorbing pigment, by measuring Raman spectroscopy. FDTD simulations show that melanin can contribute to the intensity of the reflectance spectrum in the region of long wavelength. In order to realize the structural colors based on the partitioned multilayers, we use a method to coat polymeric nanoparticles and sol-gel glass thin films repeatedly. By using this method, the effects of inhomogeneity and volume fraction of air voids in the multilayered structure are experimentally examined.

This research was supported by National Research Foundation (NRF) grant funded by the Ministry of Education, under “Basic Science Research Program” (NRF-2017R1D1A1B04033182) and also supported by Research Program through the National Institute of Ecology (NIE-Basic Research-2020-18).

F.SM01.09.25

Late News: Silk-Like Structure of Freshwater Mussel Byssus Fabricated via Shear-Induced Alpha to Beta Transition of Intermediate Filament-Like Precursors Miriam Simmons and Matthew J. Harrington; McGill University, Canada

Freshwater invasive mussel species *Dreissena polymorpha* (zebra mussels) adhere themselves in underwater environments with a collection of protein-based fibers known as a byssus. The byssus of the zebra mussel is stronger, stiffer and faster to recover after deformation than those of the well-characterized marine mussels, but very little is known of its structure or composition. Here, we used a combination of Raman, FTIR and wide angle x-ray diffraction to elucidate the secondary structure of fresh and induced byssal fibres. Out data indicates that the secreted fibers are comprised of a mixture of parallel β-crystallites, similar to spider silk. Furthermore, investigation of the byssus biofabrication process indicates that the precursor proteins are stored in an α-helical structure and transition from an α-helix to β-sheet secondary structure during the formation process, similar to other structural proteins like intermediate filaments and keratin. This stress-induced transformation in secondary structure is being attributed to a coiled-coil protein predicted in the mussel transcriptome, and current efforts are aimed at extracting this protein to further understand its shear-induced phase transformation.

F.SM02.05.01
Hydrated Poly(ether urethane) Semi-Interpenetrating Network with High Lubricity and Mechanical Properties Under Physiologically Relevant Loading for Cartilage Replacement Applications Shimon Unterman, Mushtaq Al Zuhairi and Iraklis C. Kourtis; Hyalex Orthopaedics, United States

Orthopaedic biomaterials for use as bearings against cartilage in diarthrodial joints face the dual challenges of being able to withstand high multiaxial loads while minimizing coefficient of friction and wear. High lubricity in aqueous conditions has been achieved with hydrogels such as poly(vinyl alcohol) (PVA), but mechanical properties of these hydrated polymeric networks have typically been inferior to native cartilage. Conversely, high mechanical properties can be achieved with other engineered materials but with increased cartilage wear. This study describes a novel biomimetic hydrated semi-interpenetrating network (IPN) based on poly(ether urethane) (PEU) that was previously implanted in a rabbit cartilage repair model[1]. The frictional and mechanical properties compare favorably with native cartilage.

A tunable semi-IPN of PEU and a cross-linked polyelectrolyte network was synthesized. Similar to proteoglycans in hyaline cartilage, the polyelectrolyte caused the semi-IPN to swell in water, imparting the high lubricity of a hydrophilic polymer network, while the PEU imparted high stiffness and strength, resembling the collagen type II of cartilage. Upon completion of synthesis, the semi-IPN was a translucent, highly hydrated, qualitatively slippery material. The semi-IPN passed standard ISO 10993 biocompatibility testing.

The semi-IPN was evaluated for coefficient of friction (COF) using a pin-on-disk friction tester with ~1 MPa normal loading in aqueous conditions against a fused silica counterface, yielding a COF of < 0.05; typical cartilage COFs have been reported as <0.01-0.04[2]. The mechanical properties were measured in tension, compression, tear, and shear in physiologically relevant conditions (simulated body fluid at 37° C) and compared to known properties of articular cartilage and PVA orthopaedic hydrogels. Compressive and tensile moduli at physiologic loads were > 40 MPa, stiffer than PVA orthopaedic hydrogels[4] and considerably closer to the modulus of cartilage[3] than traditional joint replacement materials like ultra-high molecular weight polyethylene (UHMWPE) and cobalt chrome alloys (CoCr). Tensile strength was > 30 MPa (cartilage: 3.75 MPa[5]), tear strength was > 40 N/mm (cartilage: 1.21 N/mm[6]), shear strength was > 20 MPa (cartilage: 7.25 MPa[5]), and the material did not fail in the measured compression range (>180 MPa; cartilage: 35.7 MPa[7]). By design the material strength exceeded that of native cartilage, in order to ensure long term performance without adversely impacting adjacent or opposing cartilage.

Hydrated semi-IPNs based on PEU and a polyelectrolyte network offer an attractive combination of mechanical strength, stiffness, and lubricity under physiologic loads. The semi-IPN properties, which closely mimic or exceed the high strength and low friction of native cartilage, provide a promising and novel platform for cartilage replacement applications.

An Investigation of Timolol Introduction on Three Hydrogel-Based Drug Delivery Devices for Glaucoma Treatment Nicole Mortensen and Jeffrey S. Bates; The University of Utah, United States

Contact lenses can be used as drug delivery systems because they are cross-linked, water-soluble, biocompatible hydrogels. Glaucoma is the second largest cause of blindness worldwide that increases the interocular pressure (IOP) of the eye. Topical eye drops of timolol is a common treatment that lowers IOP. The number of patients who become bilaterally blind every year is high due to the inefficiencies of eye drops and low patient adherence. In this study, three hydrogel-based contact lenses were analyzed on their uptake and release concentrations, reversibility, drug concentration profile over 12 hours, as well as their optical and mechanical properties. Synthesized molecular imprinted and soaked, non-imprinted, hydroxyethyl methacrylate (HEMA) based hydrogels resulted in having an uptake and release concentration dependent on the loading solution concentration it was left to soak in. Soaking Acuvue contact lenses resulted in having an uptake and release concentration independent of the timolol loading solution concentration. It released significantly higher concentrations than a daily dosage of timolol. All three hydrogel-based contact lenses successfully delivered timolol for 12 hours and could be reused up to six times. The synthesized HEMA hydrogels lacked in optical and mechanical properties that were to ensure comfort and prevent vision problems when used as a contact lens. As a result, further optimization is needed. Using contact lenses to deliver glaucoma medication has the potential to become a more efficient method of treatment that will increase patient adherence by eliminating barriers within glaucoma therapy created by eye drop medication.

Versatile 3D Printing of Hydrogels by Pluronic Kusuma Betha Cahaya Imani and Jinhwan Yoon; Pusan National University, Korea (the Republic of)

In recent years, there's an increase of study regarding 3D printing of soft materials, because of its importance for development of new technologies such as wearable electronic devices and artificial human organs, which require both non-rigid property and precise positioning. For 3D printing of soft materials study, it is required to choose a material which has enough viscosity but also can be easily extruded without clogging, and for that, pluronic is one of the most widely used materials. Pluronic is a thermo-responsive triblock copolymers consisting of poly(propylene oxide) (PPO) and poly(ethylene oxide) (PEO), as the hydrophobic center and hydrophilic side blocks respectively. This structure allows pluronic to form spherical micelles above its critical micelle temperature (CMT) within aqueous solution, which is suitable for 3D printing. Upon deposition on a substrate, by controlling the extruder and bath, pluronic can quickly change its phase, preventing the ink from flowing out of the intended position and retaining the desired 3D shape. In this study, pluronic F127 ($(PEO)_{99}$-$(PPO)_{65}$-$(PEO)_{99}$) is synthesized into pluronic F-dimethacrylate (FDMA) to prepare hydrogels for extrusion-based 3D printing. This work can be further developed to have 3D printed hydrogels with conductive property or controllable elastic modulus. The synthesis of FDMA is simple and it has the prospect for applications in various fields.

The Effect of Fibrin on the Osteogenic Differentiation of Human Dental Pulp Stem Cells Kao Li[1], Evan Cheng[2], Tianjian Bai[3], Jake D. Feldman[4], Alyssa Kim[5] and Juyi Li[1]; [1]Stony Brook University, The State University of New York, United States; [2]Syosset High School, United States; [3]Huron High School, United States; [4]Plainview-Old Bethpage John F. Kennedy High School, United States; [5]New Hyde Park Memorial High School, United States

In addition to having non-toxic degradation products, being cytocompatible, and causing the formation of an extracellular matrix, fibrin, a major plasma protein, has been found to be highly suitable in supporting dental tissue formation and improving cell-dentin interactions[1]. This study sought to determine the effects of fibrin on the proliferation and differentiation of dental pulp stem cells, DPSCs, an investigation with potential applications in osteogenic regenerative therapy. Prior studies for in-vitro cultures of DPSCs directly on fibrin clots failed due to rapid fibrinolysis of the substrates prior to differentiation. Here we demonstrate the construction of a gelatin/fibrin scaffold, which is not enzymatically degraded at least during the 28 days required for DPSC differentiation. Furthermore, since gelatin is easily bioprinted it also offers an effective scaffold for fibrinogen, which is then rapidly cross-linked after extrusion, maintaining its shape. Gelatin-fibrinogen hydrogels were created using 9% w/v gelatin and 4 mg/mL bovine fibrinogen cross-linked by 2 different concentration of mTG (microbial transglutaminase) and 2units/ml thrombin, respectively. The gels were media exchanged and cells were cultured in osteogenic media, but without dexamethasone, the standard inducer of osteogenic differentiation. On Days 8 and 28, confocal microscopy indicated that strong tissue formation was occurring on both substrates. RT-PCR was performed at day 8 and 28 to measure the upregulation of genes associated with differentiation; ALP, COL1, and OCN. Even though this set of genes was upregulated on all samples, relative to cells plated on TCP controls, the levels for ALP and OCN for cells plated on the for gelatin-fibrinogen mixture were two and three times higher, respectively, than those for cells plated on pure gelatin confirming the regenerative potential of fibrin clots.

F.SM02.05.08
Dual-Network Hydrogels Reinforced with Field-Responsive Hydroxyapatite Exhibiting High Strength and Stiffness

While Fully Hydrated Morgan Pfaff and Jessica Faust; Northeastern University, United States

Modern medicine is seeking stronger composite materials for artificial bone graft applications that are both osteoconductive and exhibit high strength. Alginate-calcium phosphate (CaP) hydrogels have been studied as a potential material, but lack the strength required for artificial bone grafts. Here, we suggest using an alginate-gelatin dual-network embedded with magnetically-aligned CaP rods to significantly increase the overall strength of the material. CaP rods were prepared through hydrothermal precipitation and functionalized with iron oxide nanoparticles. These rods were incorporated into uncrosslinked dual-network solution and aligned under a magnetic field with constant heat and vibration. After alignment, the gelatin was thermally crosslinked at room temperature and the alginate ionically crosslinked in 10% calcium chloride solution. Tensile samples were analyzed using dynamic mechanical analysis. Preliminary results show superior mechanical strength in the dual network films compared to alginate- and gelatin-only hydrogels. The mechanical strength is further increased with higher concentrations of CaP rods. Alignment orientation also impacts hydrogel mechanics, with parallel alignment providing greatest strength and perpendicular alignment the greatest elasticity. The results of this study indicate that an osteoconductive alginate-gelatin hydrogel with high strength is possible with magnetically-aligned reinforcement and is a promising material for bone graft applications.

F.SM02.05.09
Thermo-Responsive Artificial Perspiration Membrane Jeong Hun Kim[1], Junsoo Kim[1], Solyee Im[1], Sang Moon Kim[2], Jong Pil Im[1], Jiyong Woo[1] and Seung Eon Moon[1]; [1]Electronics and Telecommunications Research Institute, Korea (the Republic of); [2]Incheon National University, Korea (the Republic of)

Thermal management is essential for living organisms and electronic devices to survive and maintain their functions. However, it has been challenging to develop a flexible cooling devices for flexible electronics or biological systems because conventional coolers are bulky and require rigid batteries. In nature, however, the skin helps to maintain the body temperature constantly by dissipating the heat through the perspiration. Inspired by nature, we introduce an artificial perspiration membrane which automatically regulates evaporation rate at water-air interface depending on temperature. This membrane consists of a valve structure and a rigid frame; the valve is made of silicone-coated thermo-responsive hydrogels and the frame is made of plastics. Those two components are stably bonded by copolymerization. By designing the shape of the valve and the mechanical constraint, we were able to control the area where evaporation occurs depending on temperature. As a result, the valves in the membrane open in a hot environment, which facilitates the evaporation of water, and the valves close in a cool environment, which suppresses the evaporation of water, mimicking cooling function of perspiration in a flexible manner. Our work shows the potential value of a bio-inspired, membrane-type, and automatic cooling device that can solve heat problems in artificial skin devices.
The thermo-responsive hydrogel is patterned with pinwheel-like shape and supported by backbone through copolymerizing at the interface to control the evaporation area depending on the temperature. The stretchable rubber is selectively coated to prevent the unintended evaporation through the hydrogel while securing the water path for swelling. Consequently, the water surface at open state is about 6 times greater than that of close state with fast transition rate (~1 s). The evaporation rate is automatically controlled depending on the temperature with 30% of evaporation reduction at lower temperature. Our study on a smart membrane that can automatically regulate cooling power without external power source may solve thermal problems in wearable or artificial skin devices.

F.SM02.05.11
Enhancing Osteogenic Differentiation of Mesenchymal Stem Cells Using Injectable Microporous Hydrogel Seth Edwards and Kyung Jae Jeong; University of New Hampshire, United States

Mesenchymal stem cell (MSC) delivery and subsequent differentiation into bone forming cells has promising implications for the future of bone repair. Use of hydrogel as a delivery vehicle is advantageous in order to enhance cell retention, and provide a scaffold to facilitate new bone growth. Here we describe a microporous injectable hydrogel for encapsulation of MSCs with the intent to improve proliferation and subsequent osteogenic differentiation. Physically crosslinked microgels are formed by thermal crosslinking of gelatin in a water in oil emulsion. Bulk scaffold formation involves chemical crosslinking of gelatin by nontoxic enzymatic reaction. Enzymatic crosslinking of gelatin provides prolonged strengthening of the bulk gel, and provides a covalent mechanism for tissue adhesion. A hydrated suspension of microgels and cells can be injected for noninvasive cell delivery, and the scaffold can crosslink *in situ*, encapsulating delivered cells in the pore space. This hydrogel provides an advantageous environment for MSC growth and differentiation due to the large interstitial space between microgels, which improved cell spreading and proliferation when examined by confocal microscopy, and improved osteogenic differentiation when examined using alizarin red S stain and high resolution micro computed tomography.

F.SM02.05.12

A Smart LEA for Dynamic Adjustments to Brain Aneurysm Embolization and Healing* Juyi Li[1], Robert Wong[1], Aaron Slutsky[2], Daniel Cohn[2], Chandramouli Sadasivan[1], Anya Chabria[3], Jessica Guo[4], Varun Nimmagadda[5], Tyler Shern[6], Stephanie Tarrab[7], Jeffrey Zhang[8], Emily Zhou[9], Jeffrey Huang[10], Ikshu Pandey[11] and Miriam H. Rafailovich[1]; [1]Stony Brook University, The State University of New York, United States; [2]The Hebrew University of Jerusalem, Israel; [3]The Wheatley School, United States; [4]Ward Melville High School, United States; [5]Novi High School, United States; [6]Mission San Jose High School, United States; [7]Yeshivah of Flatbush Joel Braverman High School, United States; [8]Centerville High School, United States; [9]The Harker School, United States; [10]University of Pennsylvania, United States; [11]Johns Hopkins University, United States

Brain aneurysms are focal, pathological dilations that mostly form at branch points of the cerebral vasculature. These weak-wall structures can rupture leading to hemorrhagic stroke with mortality and morbidity rates as high as 40% and 25%, respectively. More than 60% of aneurysms are currently treated with minimally invasive endovascular/interventional methods. Most of these methods involve the permanent implantation of metallic devices such as intrasaccular coils and meshes or endovascular flow diversion. These implants reduce blood flow velocity within the aneurysm and thus promote clot formation within the aneurysmal sac, which is converted to fibrous tissue over a period of several months. However, current devices show unfavorable primary outcomes in 20% to 30% of cases on average and success rates are substantially lower depending on aneurysm type and location. In this project, we discuss the development of an injectable, multi-functional, reverse thermo-responsive, in situ cross-linkable, shape-conforming, intrasaccular porous scaffold. This scaffold changes dynamically to enhance the associated wound healing process which follows obduration. The scaffold is engineered to work with the natural blood flow and promotes vascular remodeling and endothelialization followed by personalized biodegradation, at the end of the process, leaving no residue behind. This research program harnesses the unique behavior of a family of reverse thermo-responsive (RTR) polymers to generate a novel Biodegradable Intrasaccular Polymeric Device, displaying enhanced clinical performance. The aqueous solutions of these polymers display low viscosity at infa-physiological temperatures and are gels at 37 degrees. The device is an easily syringable, low viscosity multi-component aqueous solution comprising: [a] a cross-linkable RTR component that forms a robust and homogenously porous scaffold for controlled intrasaccular thrombosis, [b] a leachable RTR-displaying component acting as the porogen, [c] an iodine-rich radiopaque agent, [d] a polymerizable (RGD)-containing oligopeptide that will *in situ* co-polymerize with the other components, aimed at accelerating the generation of an endothelial cell layer at the aneurysm neck, [e] inclusion of basic Fibroblast Growth Factor (bFGF) in the cross-linked component to promote thrombus organization and intrasaccular fibrosis/remodeling, and [f] a cross-linkable oligopeptide containing the matrix metalloprotease (MMP)- degradable leucine-glycine motif that will be *in situ* co-crosslinked with the RTR components, to impart to the polymer device to degrade in a personalized, patient-specific manner, as a function of the healing process. This process represents a major step in treatment of aneurysms, which shortens optimize brain aneurysm treatment with short procedure times, require no chronic anti-platelet medications, promote endothelialization of the parent-vessel interface, enhance aneurysm 'sac' fibrosis, and degrade in a patient-specific manner to leave no trace of the pathology or the treatment, with lower costs.

Late News: Using Coarse-Grained Molecular Dynamics to Model Hydrogel Viscosity Kyle R. Shi[1], Hannah Even[2], Shoumik Saha[3] and Dilip Gersappe[3]; [1]Dublin High School, United States; [2]Staples High School, United States; [3]Stony Brook University, The State University of New York, United States

Hydrogels are systems of hydrophilic polymers that swell when placed in a solvent to form a gel-like structure. When nanocomposites are added to hydrogels, they can enhance their properties by crosslinking the polymers. Hydrogels have shown promise as an environmentally friendly substitute to cement as soil stabilizers, mechanically improving the strength of the soil. While past studies have found a positive relationship between clay nanocomposite concentration and hydrogel viscosity with a qualitative stress-autocorrelation function, specific mechanical properties and structure formation of these hydrogels remain unknown. Our research aims to learn more about the properties of hydrogels with rigid rod-shaped clay nanocomposites and explore the possibility of determining more quantitative

trends on viscosity by simulating shear stress on the hydrogel system, imitating realistic soil movement on the hydrogels. We performed Molecular Dynamics simulations in order to understand the rheological properties of hydrogels. The concentration of the nanocomposite and the shear rate were varied and different polymer-nanocomposite interaction energies were used in order to determine the effects of these factors on the viscosity of hydrogels. The results show a clear shear thinning behavior in these systems and reflect similar trends to previous studies. Our results can be used to predict an optimum hydrogel composition in different conditions for soil stability.

We gratefully acknowledge support from the Louis Morin Charitable Trust.

Late News: Optically Active Nanoengineered Fibrous Scaffolds for Cardiac Cell Monitoring Stijn Jooken[1], Olivier Deschaume[1], Olga Krylychkina[2], Yovan de Coene[1], Thierry Verbiest[1], Koen Clays[1], Geert Callewaert[3] and Carmen Bartic[1]; [1]KU Leuven, Belgium; [2]imec, Belgium; [3]KU Leuven KULAK, Belgium

In cardiac tissue engineering the incorporation of nanoparticles (NPs) such as plasmonic NPs, carbon nanotubes or magnetic particles was shown to improve the function of in vitro cardiac patches in terms of cell viability, electrical signal coupling, beat synchronicity, etc. [1,2]. Moreover, it has also allowed to locally deliver stimuli to cells and guide cell behavior, for instance, by heating of plasmonic NPs[3].

In this work, we created a smart scaffold capable of optically reporting cardiomyocyte activity *in situ* (electrical and contractile) by incorporating voltage-sensitive semiconductor quantum dots (QDs) in 2D scaffolds and 3D hydrogels.

We have characterized the fluorescence voltage sensitivity of Type I CdSe/ZnS QDs and pseudo-Type II CdSe/CdS rods, investigated in a controlled environment, under single and two photon optical excitation. Then, QDs were incorporated in 2D scaffolds of collagen nanofibers and used two-photon fluorescence microscopy to readout of the activity of cultured primary cardiomyocytes [4]. The method was validated in a pharmacological assay where the drugs epinephrine and blebbistatin were used for their combined chronotropic and inotropic effects. Finally, the concept is extended to 3D by incorporating QD-labeled collagen fibers in 3D hydrogel constructs.

Late News: Gelation-Based Naked-Eye Detection of Glucose via Dual-Enzyme Cascade Reaction Jisoo Lee and Seonki Hong; DGIST, Korea (the Republic of)

Many efforts have been conducted to develop bioassays in point-of-care settings for rapid and convenient biomarker detection. Among them, the colorimetric-based system has been emerging due to the advantages in simple read-out through the naked-eye without requiring any expensive devices. However, it has still been challenging to simplify the labor-intensive multiple steps required to improve the limit of detection and remove the background color which may interfere with the detection signal.
Herein, we report a gelation-based bioassay mediated by a cascade reaction of two enzymes. We reasoned that biomarker-specific gelation can provide a detectable signal through the naked-eye even in the presence of the background color biospecimens such as blood and urine. Gelation is triggered by the quinone tanning reaction of catechol-conjugated polyethylene glycols via horseradish peroxidase (HRP) in the presence of hydrogen peroxide (H_2O_2). Therefore, we coupled another enzyme, glucose oxidase (GOx), that produces the H_2O_2 depending on the concentration of glucose to initiate the HRP-mediated gelation.
In our system, parameters adjusting the gelation time include the concentration of enzymes (HRP and GOx), catechol content conjugated to the polymeric precursor, the concentration of polymeric precursor, and the pH. In the experiment using H_2O_2 as a positive control to glucose/GOx system, the gelation time dramatically decreased down to 1 minute as the HRP concentration increased up to 1 U/mL. In the HRP/GOx dual-enzyme system, 0.25 U/mL of HRP was sufficient to achieve successful gelation within 80 minutes with 10-100 U/mL of GOx in the presence of 10 mM glucose. The best conditions of

other parameters for the fastest gelation were observed at 83% of catechol content, 5wt% of the precursor, and pH 7. Finally, as low as 16 mM of glucose was detectable through the naked-eye within 20 minutes of gelation time.
With the advantage of the cascade reaction of two enzymes, we expect improvement in the detection sensitivity. In addition, single-step glucose detection is allowed without requiring washing steps due to the enzymes' intrinsic specificity.

F.SM02.05.16
Late News: A Clock-Like Hydrogel That Visually Indicates Time So Hyun Ahn, Srinivasa Raghavan and William E. Bentley; University of Maryland, United States

Microcapsules can be used to monitor the local micro-environment *in vivo*, e.g., within the gastro-intestinal (GI) tract. For example, when molecular signals are released into the GI, the payload within the microcapsules could undergo a color change in response to the signal. While the nature of the signal is often the key piece of information in such experiments, the *time* at which the signal is released could be another vital aspect. To obtain information regarding time, there is the need for a gel-like material that could function like a 'clock' – i.e., exhibit systematic changes at regular time intervals.

Here, we report a simple 'clock' construct based on self-destructing structures embedded in an agarose gel. For this, we fabricate capsules of alginate crosslinked by Ca^{2+} and containing the enzyme alginate lyase. This enzyme severs alginate chains, thereby causing the capsule to degrade over a period of time. The higher the enzyme concentration, the lower the degradation time. Capsules with different concentrations of enzyme are embedded in an agarose gel to create our 'clock'. Capsule degradation proceeds in a sequential manner, and visual inspection of the gel (i.e., the capsules that remain intact) reveals the time elapsed from the start of the experiment. To facilitate visual clarity, we embed colored or fluorescent nanoparticles in each of the capsules. Moreover, the degradation rate can be varied using pH, temperature, and other variables that affect the enzymatic activity. Variations of the above simple clock include: (a) one that is activated by an external trigger; and (b) one that locks-in the elapsed time at a particular juncture.

F.SM03.05.01
Beyond Elastic Limit of Piezoelectric Ceramic with 3D Hollow ZnO Nanostructures Hoon Kim, Seokjung Yun, Kisun Kim, Wonsik Kim, Jeongjae Ryu, Hyeon Gyun Nam, Seung Min J. Han, Seokwoo Jeon and Seungbum Hong; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Piezoelectric materials are suitable for haptic technology as they can convert mechanical stimuli into electrical signals and vice-versa. However, owing to their disadvantageous mechanical properties such as brittleness (in ceramics) and a low piezoelectric coefficient (in polymers), it is still a challenge to use them in haptic technology. Here, we present a truss-like 3D hollow zinc oxide (ZnO) nanostructure that shows a drastically improved elastic strain limit while maintaining a piezoelectric coefficient similar to that of single-crystal ZnO. The ZnO hollow nanostructures were fabricated by proximity field nanopatterning (PnP) and atomic layered deposition (ALD) at four different process temperatures from 90 to 300°C. The piezoelectric properties were visualized and analyzed through dual AC resonance tracking piezoresponse force microscopy (PFM). The piezoelectric coefficient was approximately 9.2 pm/V. Furthermore, we measured the measured elastic strain limit of approximately 10% using the nanopillar compression test, which was at least 3 times greater than the prior report. The extended elastic limit of the 3D hollow structure was further supported by finite element simulations. We envision that our ZnO hollow nanostructure can be used in enhanced haptic devices, which mimic the human sense of touch.

F.SM03.05.02
Highly Crystalline PCL Ultrathin Films as Thermally Switchable Biomaterial Coatings Shivam Saretia[1,2], Rainhard Machatschek[1,2] and Andreas Lendlein[1,2]; [1]Helmholtz-Zentrum Geesthacht, Germany; [2]University of Potsdam, Germany

Degradable semi-crystalline polymers are a class of materials that modern regenerative medicine heavily relies on. While their formulation into nanostructured devices can be advantageous to tailor functional properties such as cellular uptake kinetics and degradation behaviour, it is difficult to assess and control the morphology, crystallinity and organization of nanostructured polymer materials by common preparation methods.

The Langmuir technique overcomes most of the drawbacks concerning preparation and investigation of nanostructured polymer materials. Here, ultrathin films at the air-liquid interface serve as model systems for polymer devices and interfaces, which can be manipulated and observed in a straightforward way. In particular, the semi-crystalline morphology, including crystal size, number density, thickness, and melting temperature can be precisely adjusted. By transferring the layers to solid substrates, functional biomaterial interfaces with unique properties can be created. For example, via enzymatic degradation of

the amorphous chains, a semi-crystalline Langmuir film can converted into an almost entirely crystalline film with a thickness of a few nanometers. The preparation and analysis of these highly functional, entirely crystalline thin films based on oligo(ε-caprolactone)s (OCL) with different end-groups is of particular interest. Poly(ε-caprolactone) (PCL) is established in clinical applications with a relatively low melting point point and well documented enzymatic degradability[1]. The melting temperature of PCL or OCL crystals can be adjusted via the crystallization temperature to be very close to physiological conditions, producing a polymer coating that changes a broad variety of its functional properties upon application of a small thermal stimulus.
For example, highly crystalline films of hydroxyl and methacrylate end capped linear OCL are prepared by degrading its amorphous phase by the enzyme *Pseudomonas cepacia* lipase (0.007 $mg{\cdot}mL^{-1}$) at constant surface pressure of ~7 $mN{\cdot}m^{-1}$ on air-water interface at room temperature. The thickness of the OCL crystals in the film can be adjusted in the range of ~ 6 to 8 nm, resulting in a melting temperature between ~30 to 40 °C at the air-water interface. Upon melting, the elastic moduli of the film are drastically altered. Further, functional end groups are expelled from the crystals and therefore accumulated at the crystalline surface. Upon melting, these end-groups are buried in the amorphous phase, resulting in a change of the chemical composition of the material surface. Moreover, the degradability of the thin film increases significantly upon melting, meaning that the lifetime of the material can be adjusted via its thermal history. In addition, the barrier properties of the thin film depend on its crystallinity, with polymer crystals being considered impenetrable for small molecules.

Here, we demonstrate the fabrication and behaviour of these thermally switchable OCL crystals coatings, which are of interest for applications such as barrier layers, substrates modulating stem cell adhesion, or coatings with on-demand acceleration of degradability. Another possible application are friction reducing coatings, for example on sutures. Here, the temperature at the suture-tissue interface does not increase as long as the heat generated by frictional forces is absorbed by the melting enthalpy of the crystals.

Late News: Functionalised Capacitive Microfluidic Force Sensors for Orthopaedic Surgery Liam Ives[1], Qingshen Jing[1], Alizée Pace[1], Anke Husmann[1], Vikas Khanduja[1], Jehangir Cama[2] and Sohini Kar-Narayan[1]; [1]University of Cambridge, United Kingdom; [2]University of Exeter, United Kingdom

The correct balance of forces on the hip joint during total hip arthroplasty (THA) is essential for implant longevity and to prevent the need for revision surgery. This has become increasingly important since the average age of a THA patient is decreasing, hence these implants must survive greater activity levels and correspondingly higher stresses than those typically found in older, less active patients. Currently, the lifetime of an implant positioned purely by a surgeon's judgement is approximately 15 years. Quantitative force feedback during surgery could provide more accurate implant positioning, increasing the average lifetime. However, there are currently no force sensors capable of providing this information within the small and complex geometry of the hip joint.

Here, we solve this unmet clinical need by presenting a thin, conformable and flexible microfluidic capacitive force sensor, which can be incorporated into the surgical process without significant modification to existing implants. The sensor consists of a deformable microfluidic chip bonded to a flexible substrate, on which interdigitated electrodes are incorporated, and that can operate in confined spaces to give accurate force readings from joints. The sensor operates by monitoring the change in capacitance of the electrodes as the fluid in the microfluidic channel is displaced in response to an applied force. Multiple sensors were incorporated into a model hip implant geometry, and a bespoke mechanical testing rig was built to simulate loading of the acetabular cup from the femoral head at different angles. The experimental results were validated using finite element modelling. This was used to optimise the sensor geometry for the production of sensitive devices that can withstand the high forces required for surgery. Our novel microfluidic-based force sensing technology can potentially be adapted for application in joints either for sensor-assisted orthopaedic surgery, or for gathering telemetric data from joints before, during and/or after surgery. Such biocompatible and implantable force sensors will contribute significantly to several clinical drivers, through providing quantitative feedback to the attending clinician, and could also serve to underpin robot-assisted orthopaedic surgery in the future.

Formulating Bioinks and Bioink Processing Methods for Tissue Bioprinting Yu Shrike Zhang; Harvard Medical School, United States

Over the last decade, three-dimensional bioprinting has offered great versatility to fabricate biomimetic volumetric tissues that are both structurally and functionally relevant to their native counterparts. The technology enables precise control over the composition, spatial distribution, and architecture of the bioprinted constructs, facilitating recapitulation of the delicate shapes and structures of targeted organs and tissues. This talk will discuss our recent efforts on developing various cytocompatible and cell-instructive bioink formulations, as well as their processing methods, for the fabrication of engineered tissues towards regenerative medicine and tissue model engineering applications, using a series of established or customized bioprinting strategies.

Chemical and Topological Design of Mussel-Inspired Polymers—A Single-Molecule Adhesion Perspective Yiran Li[1], Peyman Delparastan[2], Jing Cheng[2], Haoqi Wang[1], Kelsey DeFrates[2], Yi Cao[1] and Phillip B. Messersmith[2,3]; [1]Nanjing University, China; [2]University of California, Berkeley, United States; [3]Lawrence Berkeley National Laboratory, United States

In mussels, the adhesive proteins that are instrumental for attachment to wet surfaces are known to contain high levels of 3,4-dihydroxy-L-alanine (DOPA), often located adjacent to amino residues such as lysine (Lys). The special synergistic relationship between catechols and amines is a subject of high interest, not only for understanding native proteins but also for informing the design of bioinspired polymer systems. Other research groups have shown that catechol and amine functional groups act synergistically to enhance adhesion at wet surfaces, however reports of catechol-amine interfacial phenomena on a single molecule level have been limited. In this talk we will describe single molecule force spectroscopy (SMFS) measurements that are providing new insights into interactions between Lys-DOPA peptides and various surfaces. Of particular interest is the impact of chemical composition (DOPA and Lys), peptide length and topology (i.e. distribution of adhesive elements along a polymer) on interfacial adhesion to a wet substrate. The results may inform the future design of novel polymer adhesives, including adhesive hydrogels, pressure sensitive adhesives and high-strength thermoset adhesives.

Smart Material and Adhesive Utilizing Mussel Adhesive Chemistry Bruce Lee; Michigan Technological Univ, United States

Marine mussels secrete adhesive proteins that enable these organism to anchor themselves to various substrate (i.e., ship hull,

rock) in a rough, intertidal zone. These mussel foot proteins contain a unique amino acid, L-3, 4 dihydroxyphenylalanine (DOPA), that is responsible for strong interfacial binding and curing of the proteins. The catechol side chain of DOPA is capable of participating in various stimuli responsive, reversible interactions, dictated by its oxidation state. In this presentation, I will describe our efforts in utilizing these interactions in designing various types of smart biomaterial. We have incorporated catechol-metal ion coordination bond to design hydrogel actuators that can fold into various 3-dimentional shapes. We have also utilized catechol-boronic acid complexation chemistry to design moisture-resistant smart adhesive with tunable adhesive properties. Most recently, we demonstrated the feasibility of using applied electricity to directly deactivate catechol-based adhesive that is bonded to a surface.

Evolution of Self-Oscillating Polymer Gels as Life-Like Softmachines Ryo Yoshida; The University of Tokyo, Japan

In living systems, there are many autonomous and oscillatory phenomena to sustain life such as heart beating. We developed "self-oscillating" polymer gels that undergo spontaneous cyclic swelling–deswelling changes without any on–off switching of external stimuli, as with heart muscle. The self-oscillating gels were designed by utilizing the Belousov-Zhabotinsky (BZ) reaction, an oscillating reaction, as a chemical model of the TCA cycle. We have systematically studied these self-oscillating polymer gels since they were first reported in 1996. Potential applications of the self-oscillating polymers and gels include several kinds of functional material systems such as biomimetic actuators, mass transport systems and functional fluids. For example, it was demonstrated that an object was autonomously transported in the tubular self-oscillating gel by the peristaltic pumping motion similar to an intestine. Further, self-oscillating polymer brush surface like cilia, vesicles or colloidosomes undergoing cell-like autonomous shape oscillations with buckling, was prepared. Besides, autonomous sol-gel oscillation and amoeba-like motion was realized utilizing well-designed block copolymer solution. In this presentation, our recent progress on the self-oscillating polymer gels is summarized.

HASEL Artificial Muscles—Versatile High-Performance Actuators for Bioinspired Robotics Christoph Keplinger; University of Colorado-Boulder, United States

Robots today rely on rigid components and electric motors based on metal and magnets, making them heavy, unsafe near humans, expensive and ill-suited for unpredictable environments. Nature, in contrast, makes extensive use of soft materials and has produced organisms that drastically outperform robots in terms of agility, dexterity, and adaptability. To create a new generation of soft, life-like robots that reproduce the vast capabilities of biological systems, we need to develop actuators that replicate the astonishing all-around actuation performance of biological muscle. Hydraulically Amplified Self-healing ELectrostatic (HASEL) transducers are a new class of self-sensing, high-performance muscle-mimetic actuators, which are electrically driven and harness a mechanism that couples electrostatic and hydraulic forces to achieve a wide variety of actuation modes. Current designs of HASEL artificial muscles exceed actuation stress of 0.3 MPa, linear strain of 100%, specific power of 600W/kg, efficiency of 30% and bandwidth of 100Hz; all these metrics match or exceed the capabilities of biological muscle. This talk gives an overview over the latest developments, including materials systems, modeling, new designs of actuators, fabrication techniques, and creation of untethered soft robotic devices.

3:00 PM *F.SM02.04.03
Non-Equilibrium Signal Integration in Hydrogels Peter Korevaar, Nadir Kaplan and Joanna Aizenberg; Harvard University, United States

Materials that perform complex chemical signal processing are ubiquitous in living systems. Their synthetic analogs would transform developments in biomedicine, catalysis, and many other areas. By drawing inspiration from biological signaling dynamics, we show how simple hydrogels have a previously untapped capacity for non-equilibrium chemical signal processing and integration. Using a common polyacrylic acid hydrogel, with divalent cations and acid as representative stimuli, we demonstrate the emergence of non-monotonic osmosis-driven spikes and waves of expansion/contraction, as well as traveling color waves. These distinct responses emerge from different combinations of rates and sequences of arriving stimuli. A non-equilibrium continuum theory we developed quantitatively captures the nonmonotonic osmosis-driven deformation waves and determines the onset of their emergence in terms of the input parameters. These results suggest that simple hydrogels, already built into numerous systems, have a much larger sensing space than currently employed.

3:15 PM F.SM02.01.02
3D Printing of Jammed Double Network Granular Hydrogels with Superior Mechanical Properties Matteo Hirsch,

Alvaro Charlet and Esther Amstad; EPFL, Switzerland

Hydrogels are among the first biomaterials expressly designed for their use in biomedicine. However, state-of-the-art applications of hydrogels are severely limited because of their mechanical properties. Most hydrogels are either too soft or too brittle to be used for load-bearing applications. To overcome this shortcoming, double network (DN) hydrogels composed of two interpenetrating polymeric networks have been introduced. These DN hydrogels are composed of a highly crosslinked network, the filler, responsible for the stiffness of the hydrogel and a second loosely crosslinked one, the matrix, that regulates the toughness of the material. Despite this great improvement in mechanics, composition and structural complexity found in soft natural tissues remain yet to be matched. Indeed, soft natural materials possess locally varying compositions and structures that are well-defined over many length scales. By contrast, synthetic hydrogels typically have an ill-defined microstructure and their composition is most often homogeneous. To obtain a better structural control, we introduce a novel 3D printing approach to fabricate strong and tough soft materials, namely double network granular hydrogels (DNGHs). This is achieved with an ink composed of microgels that are swollen in a monomer-containing solution. Upon printing and post-curing, the monomers are converted into a percolating network, yielding a solid DNGH. These DNGHs possess mechanical properties that are superior to reported additive manufactured hydrogels. In this work, we demonstrate that this technique enables printing macroscopic strong and tough objects with a high shape fidelity. Because this new technology employs a microgel-based ink, it significantly extends the choice of materials that can be additive manufactured. Moreover, the modularity of the jamming approach allows for the combination of different ink in the same printing process, resulting in mechanically robust stimuli responsive structures.

3:25 PM F.SM02.01.03
Programmable Living Hydrogels for Gut Therapeutics and 3D Printing Anna Duraj-Thatte[1,2], Avinash Manjula Basavanna[1,2] and Neel Joshi[1,2]; [1]Harvard University, United States; [2]Northeastern University, United States

Over the last few decades, living cells have been employed as factories to make organic molecules, polymers, drugs, and fuels. Lately, living cells are being engineered to make materials and/or to modulate its properties, giving rise to an exciting field of Living Materials. Earlier work has shown that engineered living materials (ELMs) can bind to nanoparticles, catalyze reactions, and modulate conductivity amongst others.

Herein, we present a versatile strategy for the fabrication of living hydrogels directly from the bacterial culture by a simple filtration protocol. This hydrogel comprises of *E. coli* embedded in an extracellular matrix of engineered protein fibers. Genetic programming enables the hydrogels to be customized to interact and adhere to different tissues of the gastrointestinal tract. The designed mucoadhesive and anti-inflammatory hydrogels can be sprayed directly in the gut serving as an innovative wound healing strategy for the gut lumen.

By genetic engineering, we have also developed a functional microbial ink for 3D printing of living materials. This microbial ink is produced from engineered bacteria and can also be embedded with desired microbes to enable the printing of complex 3D architectures having various functions like sensing and sequestration.

Thus, we demonstrate the very first examples of microbial ink for 3D printing and the biomedical application of living materials. This unique platform of genetically programmable living hydrogels provides unprecedented opportunities to harvest the characteristics of living systems and thereby enables advanced applications of living materials.

Electrically Conductive Bioadhesive Interface for Bioelectronics Jue Deng[1,2], Hyunwoo Yuk[1], Claudia Varela[1], Jingjing Wu[1,2], Xiaoyu Chen[1], Ellen Roche[1], Chuanfei Guo[2] and Xuanhe Zhao[1]; [1]Massachusetts Institute of Technology, United States; [2]Southern University of Science and Technology, China

Reliable functions of bioelectronic devices require conformal, stable, and conductive interfaces with biological tissues. Integrating bioelectronic devices with native tissues usually relies on physical attachment or surgical suturing. Whilst these conventional methods face challenges such as non-conformal contact, unstable fixation, tissue damage and/or scar formation. Here we present a new class of bioadhesive electronic devices capable of compatibly and robustly integrating with various wet dynamic tissues, offering a promising solution beyond suturing and physical attachment to address the aforementioned challenges. The bioadhesive electronics are enabled by a new nanocomposite interface that can provide rapid (adhesion formation within five seconds), robust (interfacial toughness over 400 J m^{-2}), and on-demand detachable adhesion of bioelectronic devices on diverse wet tissues. The nanocomposite interface is electrically conductive (conductivity over 2.6 S

m^{-1}) to allow bi-directional bioelectronic communications. We demonstrate applicability, mechanical and electrical stability, biocompatibility, and bioelectronic recording and stimulation functionalities of the bioadhesive electronics based on ex vivo porcine and in vivo rat models. This study provides a new powerful platform for diverse bioelectronics to address the long-standing challenges in human-machine interface.

Linking Molecular Behavior to Macroscopic Properties in Ideal Dynamic Covalent Hydrogels Mark W. Tibbitt; ETH Zürich, Switzerland

Dynamic covalent chemistry has emerged as an elegant molecular design strategy to engineer functional polymer networks that combine advantageous properties of both chemically and physically cross-linked materials. Dynamic covalent networks (DCvNs) are increasingly used in advanced materials design with applications ranging from recyclable thermosets to self-healing hydrogels. However, the relationship between the underlying chemistry at the junctions of DCvNs and their macroscopic properties is still not fully understood. In this presentation, we will outline a robust framework to predict how complex network behavior in DCvNs emerges from the chemical landscape of the dynamic chemistry at the junction. We use ideal dynamic covalent boronic ester-based hydrogels as model DCvNs. We will describe physical models that explain how viscoelastic properties, as measured by shear rheometry, are linked to the molecular behavior of the dynamic junction, quantified via fluorescence and NMR spectroscopy and DFT calculations. Additionally, shear rheometry is combined with Eyring Transition State Theory to quantify the kinetics and thermodynamics of network rearrangements, enabling a mechanistic understanding including preferred reaction pathways for dynamic covalent chemistries. We apply this approach to corroborate the 'loose-bolt' postulate for the reaction mechanism in Wulff-type boronic acids. These findings, grounded in molecular principles, advance our understanding and rational design of dynamic polymer networks, improving our ability to predict, design, and leverage their unique properties for future applications. We will also discuss applications of these materials for the thermal stabilization of biologics and as tunable viscoelastic materials.

8:15 AM *F.SM02.03.03
Non-Linear Mechanics and Failure of Composite Fibre Gels Jasper van der Gucht; Wageningen University & Research, Netherlands

Living tissues show an extraordinary adaptiveness to strain, which is crucial for their proper biological functioning. The physical origin of this mechanical behaviour has been widely investigated using reconstituted networks of collagen fibres, the principal load-bearing component of tissues. However, collagen fibres in tissues are embedded in a soft hydrated polysaccharide matrix which generates substantial internal stresses whose effect on tissue mechanics is unknown. Here, by combining mechanical measurements and computer simulations, we show that networks composed of collagen fibres and a hyaluronan matrix exhibit synergistic mechanics characterized by an enhanced stiffness and delayed strain-stiffening. We demonstrate that the polysaccharide matrix has a dual effect on the composite response involving both internal stress and elastic reinforcement. Moreover, the matrix has a pronounced effect on fracture of the networks, leading to enhanced toughness and a transition from brittle to ductile behaviour. Our findings elucidate how tissues can tune their strain-sensitivity over a wide range and provide a novel design principle for synthetic materials with programmable mechanical properties.

Self-Assembly to Build Hydrogels and Insights into Their Morphology Cécile A. Dreiss; King's College London, United Kingdom

Interest in hydrogels over the past couple of decades has exploded for a wide range of biomedical applications, including drug delivery, and tissue engineering.[1] There is a huge interest in building these supramolecular structures from non-covalent interactions, e.g. hydrogen bonds, host-guest interactions, which provide an easy tailoring of dynamic properties, impart shear-thinning and thus injectability and self-healing, making them more amenable to biomedical applications.
Our group focuses on harnessing and understanding simple gelation processes in materials that come from renewable sources or are easily accessible. We exploit hybrid gelation processes to the cross-linking process,[2] spontaneous self-assembly in mixtures of modified polymers and surfactants,[3] formation of pseudopolyrotaxanes with cyclodextrins,[4] and thermally-triggered gelation.[5] In this talk I will present some of our recent work on self-assembled gels and in particular how we use small-angle neutron scattering to elucidate the spatial organisation of the networks that sustain the rheological properties, and ultimately build towards a rationale for hydrogel formulations.

Viscoelastic Properties of Supramolecular Gels and Mixtures Based on Hydrogen Bonding Dimitri Vlassopoulos[1,2]; [1]FORTH, Greece; [2]University of Crete, Greece

Understanding and tailoring the self-assembly of supramolecular moieties is a challenging subject with potential implications in materials engineering and biological function. Here we discuss two problems associated with the viscoelastic properties of (i) hydrogel mixtures due to competitive interactions and (ii) organogels due to the presence of traces of humidity.
Concerning the former, we investigated a class of binary hydrogels made by mixing fibrillar supramolecular polymers that are formed from two compounds: 1,3,5-benzene-tricarboxamide decorated with aliphatic chains terminated by tetra(ethylene glycol) (BTA) and a 20 kg/mol telechelic poly(ethylene glycol) decorated with the same hydrogen bonding BTA motif on both ends (BTA-PEG-BTA). We found that the respective single-compound-based supramolecular systems form very different networks which exhibit drastically different rheology. More strikingly, mixing the compounds results in a non-monotonic dependence of modulus and viscosity on composition, suggesting a competition between interactions of the two compounds, which can then be used to fine-tune the mechanical properties.
The latter problem concerns the self-assembly of supramolecular moieties in organic solvents which is affected by the presence of trace amounts of water in the monomeric state that induce competitive association and change the helicity of the assembled structure. We investigated an organogel in dodecane (biphenyl tricarboxamide, BPTA) and found that water affects the self-assembled structure by changing the persistence length and contour length of the fiber. The content of water in the fiber changed with temperature, bequeathing the linear and nonlinear viscoelastic properties with unusual temperature responsiveness. For instance, as the temperature increased from 15 to 35ºC, the relaxation time of the system varied non-monotonically with temperature. This stems from the fact that the system loses its reversible and dynamic character for temperatures above 35ºC where water does not mediate the association of BPTA units.
These findings are discussed in the context of existing theories of living polymers and of the perspective of designing gels with desired and tunable properties.

Work in collaboration with E. Vereroudakis (Crete), N.J. Van Zee (ESPCI, Paris), E. Del Gado (Georgetown) and E.W. Meijer (T. U. Eindhoven).

9:00 AM *F.SM02.04.04
Polymer Gels for Autonomous Motion and Mesoscale Assembly Alfred J. Crosby; University of Massachusetts Amherst, United States

Nature is masterful at using limited components and basic driving forces to achieve complex tasks, such as high power movement and multi-structure assembly, across a broad range of size scales. The materials that enable these achievements often rely upon the integration of phases that allow for internal transport, elastic energy storage, system protecting dissipation, and tunable sensitivity to interfacial interactions. Accordingly, polymer gels, which combine liquid phases with shear-sustaining macromolecular network structures, offer a robust materials platform for transferring lessons from nature into synthetic engineered devices. Here, we describe two examples from our research group of how to take advantage of

mesoscale structural asymmetry, mechanics, liquid transport, and interfacial interactions to achieve new engineered capabilities. The first example takes inspiration from multiple examples in nature, including mantis shrimp and trap-jaw ants, that use Latch-Mediated Spring Actuation (LaMSA) to achieve high power, impulsive movements. We demonstrate how transient metastable deformations associated with swelling and deswelling of a polymer gel can be exploited to generate mechanical bi-stability, giving rise to multiple, self-repeating, snap-through movements. We introduce models to quantitatively describe these mechanisms and harness them to develop autonomous jumping devices. In a related manner, the second example describes the use of structural asymmetry to mediate swelling/deswelling processes and elastic restoring forces to control the motion and assembly of mesoscale polymer gel ribbons. Collectively, both examples provide new insight into how polymer gel properties, related to elasticity, diffusion, and interfacial forces, can combine with purposeful structural design to yield complex tasks, which can be used in the development of microscale robots and new adaptable composite materials.

9:15 AM F.SM02.03.09
Intrinsic Fracture Energy of Soft Mechanical Metamaterials Dongchang Zheng[1,2], Shaoting Lin[1], Liu Wang[1] and Xuanhe Zhao[1,1]; [1]Massachusetts Institute of Technology, United States; [2]University of Science and Technology of China, China

Diverse soft metamaterials have been developed for energy-absorbing, tunable thermal expansion, soft actuator, etc. Although various functional properties of soft metamaterials have been investigated, their fatigue properties have not been studied yet, which hinders the translation of soft metamaterials into real applications. With 3D printing techniques, we control the geometrical parameters of soft metamaterials. Fracture tests and simulations are conducted to measure the S-N curve of a single printing filament and fatigue threshold of 3D printed soft metamaterials. We show that the fatigue threshold of soft metamaterials is linearly proportional to the fiber's diameter and strain energy density limit, but independent of its length. Constitutive relation of the materials and geometrical shapes determine the prefactor of such proportion relations. The results are intrinsically different from the classical Lake-Thomas theory for polymer networks, leading to a generalized theory for predicting soft metamaterials' fatigue threshold. The capability of the theory correlating the fatigue property of a single filament and entire topological networks is critical for the design of durable soft metamaterials. This theory inspires us to manufacture sinusoidal structure metamaterials, whose fatigue threshold increase dramatically.

9:25 AM F.SM02.04.15
Surface Engineering of Hydrogels for Solar Water Purification Youhong Guo and Guihua Yu; The University of Texas at Austin, United States

Water scarcity has been an increasingly severe threat to our society. Solar vapor generation provides a sustainable means for desalination and water purification technologies. With highly tunable structures, unique polymer-water interactions, and ease of integration with functional materials, hydrogels show great potential for efficient solar water purification. The rational design and engineering of hydrogel surfaces have a substantial impact on the interfacial solar water vaporization process. Here, we will discuss effective ways to tailor the surface topography and wetting states of hydrogel solar evaporators to accelerate the solar vapor generation rate. Specifically, the nanotextured topography of the surface can be fabricated by a liquid-liquid interface-guided gelation process, resulting in an increased heat flux at the sharply dimpled hydrogel-air interface. In addition, hydrogel evaporators with inhomogeneous surface wettability demonstrate an ultrahigh evaporation rate with synergistic contributions from both wetting regions. Molecular dynamics simulation reveals the surface-modulated escaping behavior of water molecules. By applying hydrophilic polymers as building blocks, the hydrogel evaporators have been endowed with multifunctionalities, such as antifouling and complex contaminants removal, to improve both quantity and quality of collected water. Together with an easy-to-employ and portable purification prototype, hydrogels are an emerging materials platform for high-performance yet cost-effective water purification applications.

9:35 AM F.SM02.03.11
Late News: Mesoscale Modeling of Controlled Degradation in Hydrogels Vaibhav A. Palkar, Chandan K. Choudhury and Olga Kuksenok; Clemson University, United States

Hydrogel based soft materials with chemical functionalities that allow controlled degradation of the polymer are utilized as active stimuli responsive platforms for numerous applications. As one example, a hydrogel with multiple degradable functional groups that degrade in response to different wavelengths of light enables sequential release of drugs from the network. Herein, we present Dissipative Particle Dynamics (DPD) based simulations of degradation in tetra-arm polyethylene glycol (tetra-PEG [1]) hydrogels. Controlled degradation can be introduced in these gels via several chemical pathways [2,3].

In our DPD model we use the modified segmental repulsive potential (mSRP [4]) to avoid unphysical polymer chain crossing and we first establish model parameters that mimic the hydrophilicity of PEG. Further, we use our recently developed framework [5] to introduce controlled degradation in these gels and measure the fraction of degradable bonds intact during degradation. Our method allows modeling of first order degradation kinetics in these gels. We track the evolution of mass loss from bulk degrading gels and note the occurrence of a slow mass loss regime due to erosion followed by a fast regime due to reverse gelation of the polymer network. We quantify the reverse gel point of these gels by tracking the size of the second largest cluster during degradation. We focus on the effect of finite size on mass loss and reverse gel point calculations and compare these effects with previously developed scaling [6]. The reverse gel point for tetra-PEG hydrogels measured from our simulations corresponds well with the value obtained from percolation theory on a diamond lattice.

5:35 AM F.SM02.01.05
Late News: Development of the Thermomechanical Properties of the Gelatin/Siloxane Hybrid Material as Bioink Bryan Valenzuela; Universidad Autónoma de Ciudad Juárez, Mexico

Bioinks are hydrogels that have the ability to encapsulate cells and promote their proliferation, there are compound and hybrid bioinks of the following natural materials, synthetic polymers, bioceramics, metallic nanoparticles.
Composite bioinks are materials where their chemical structure and properties are combined in homogeneous way, otherwise, the hybrid bioinks have a chemical structure and properties combined in heterogeneous way, even in some hybrids bioinks, it is possible to observe different phases of this components.
At use gelatin/siloxane hybrid material in a room temperature, is possible to observe the organic (gelatin) and inorganic (siloxane) phase which is a temendous advantage. It is important to remark the presence of these phase offers thermomechanical properties that facilitate its funcionalization as bioink.
Siloxane is a direct derivate of silicon dioxide gel that is biocompatible and non - cytotoxic, properties that allows cell culture deposition and encapsulation, gelatin is a material derived from collagen which consist of a biopolymer of three aminoacids (arginine, glycine and lysine).
The functionalization of siloxane and gelatin by means of magnetic stirring allows the interaction of the amine groups (NH^{+}) of gelatin and the hydroxyl groups (OH^{-}) of the siloxane.
The lost of water through the oxidation of the siloxane allows the modulation of thermomechanical properties of the gelatin/siloxane hybrid material, through physical treatments such as UV radiation and heat treatments in the range of fifty degrees centigrade (50C) to seventy degrees centigrade (70C), forming the siloxane bonds that improve the termomechanical properties of the material such viscosity and mechanical compression.
The gelatin/siloxane hybrid material possesses a viscosity that can be modulated by heat treatments in the range of thirty-two degrees centigrade (32C) to forty-two degrees centigrade (42C).
The viscosity of the gelatin/siloxane hybrid material is related to the concentration of dispersed siloxane particles.

This relationshio permit that at temperature in the range of four degrees centigrade (4C) to fifteen degrees centigrade (15C), the material reticulates by forming fibers that help maintain the fidelity and mechanical properties necessary to use the gelatin/siloxane hybrid material as bioink.
The aforementioned thermomechanical properties of the gelatin/siloxane hybrid material provide the support of being used as bioink. The gelatin/siloxane hybrid material let the cultivation of various cell lines such as: (carotid artery cells, liver, myocytes, cardiomyocytes amog others).
In function on its thermomechanical properties. The degradation of siloxane inhibits certain enzymes in bacterial metabolism that generate antibacterial properties.
3D bioprinting is a technique for biofabrication of three - dimensional structures thtat, through layered printing technology, allows manufacture constructs for the depost or seeding of cell cultures. The BIO X bioprinter (Cellink®) is a bioprinter with a resolution in the range of 10 to 100 μm depending on the bioink used ad the printing syringe nozzle. Is one of the most user - friendly bioprinters on the market, in addition to allow the use of composite and hybrid bioinks depending on the printing paramters (nozzle size, applied pressure, printing speed, head and print bed temperature), however, bioprinters are highly sophisticated and precise equipment, therefore, to determine the printing parameters of a bioink it is imperative to perfom mathematical analysis.
In conclusion, this work deals with the development of a bioprinting process specifically of the gelatin/siloxane hybrid material that, thanks to the matjematical model used, generates a better mechanical perfomance of the printed constructs with the assistance of the BIO X bioprinter (Cellink®) and provides a look to the futures with the first tests of a bioprinter that combines extrusion and injection technology.

Chemical and Topological Design of Mussel-Inspired Polymers—A Single-Molecule Adhesion Perspective Yiran Li[1], Peyman Delparastan[2], Jing Cheng[2], Haoqi Wang[1], Kelsey DeFrates[2], Yi Cao[1] and Phillip B. Messersmith[2,3]; [1]Nanjing University, China; [2]University of California, Berkeley, United States; [3]Lawrence Berkeley National Laboratory, United States

In mussels, the adhesive proteins that are instrumental for attachment to wet surfaces are known to contain high levels of 3,4-dihydroxy-L-alanine (DOPA), often located adjacent to amino residues such as lysine (Lys). The special synergistic relationship between catechols and amines is a subject of high interest, not only for understanding native proteins but also for informing the design of bioinspired polymer systems. Other research groups have shown that catechol and amine functional groups act synergistically to enhance adhesion at wet surfaces, however reports of catechol-amine interfacial phenomena on a single molecule level have been limited. In this talk we will describe single molecule force spectroscopy (SMFS) measurements that are providing new insights into interactions between Lys-DOPA peptides and various surfaces. Of particular interest is the impact of chemical composition (DOPA and Lys), peptide length and topology (i.e. distribution of adhesive elements along a polymer) on interfacial adhesion to a wet substrate. The results may inform the future design of novel polymer adhesives, including adhesive hydrogels, pressure sensitive adhesives and high-strength thermoset adhesives.

Smart Material and Adhesive Utilizing Mussel Adhesive Chemistry Bruce Lee; Michigan Technological Univ, United States

Marine mussels secrete adhesive proteins that enable these organism to anchor themselves to various substrate (i.e., ship hull, rock) in a rough, intertidal zone. These mussel foot proteins contain a unique amino acid, L-3, 4 dihydroxyphenylalanine (DOPA), that is responsible for strong interfacial binding and curing of the proteins. The catechol side chain of DOPA is capable of participating in various stimuli responsive, reversible interactions, dictated by its oxidation state. In this presentation, I will describe our efforts in utilizing these interactions in designing various types of smart biomaterial. We have incorporated catechol-metal ion coordination bond to design hydrogel actuators that can fold into various 3-dimentional shapes. We have also utilized catechol-boronic acid complexation chemistry to design moisture-resistant smart adhesive with tunable adhesive properties. Most recently, we demonstrated the feasibility of using applied electricity to directly deactivate catechol-based adhesive that is bonded to a surface.

Electrically Conductive Bioadhesive Interface for Bioelectronics Jue Deng[1,2], Hyunwoo Yuk[1], Claudia Varela[1], Jingjing Wu[1,2], Xiaoyu Chen[1], Ellen Roche[1], Chuanfei Guo[2] and Xuanhe Zhao[1]; [1]Massachusetts Institute of Technology, United States; [2]Southern University of Science and Technology, China

Reliable functions of bioelectronic devices require conformal, stable, and conductive interfaces with biological tissues. Integrating bioelectronic devices with native tissues usually relies on physical attachment or surgical suturing. Whilst these conventional methods face challenges such as non-conformal contact, unstable fixation, tissue damage and/or scar formation. Here we present a new class of bioadhesive electronic devices capable of compatibly and robustly integrating with various wet dynamic tissues, offering a promising solution beyond suturing and physical attachment to address the aforementioned challenges. The bioadhesive electronics are enabled by a new nanocomposite interface that can provide rapid (adhesion formation within five seconds), robust (interfacial toughness over 400 J m^{-2}), and on-demand detachable adhesion of bioelectronic devices on diverse wet tissues. The nanocomposite interface is electrically conductive (conductivity over 2.6 S m^{-1}) to allow bi-directional bioelectronic communications. We demonstrate applicability, mechanical and electrical stability, biocompatibility, and bioelectronic recording and stimulation functionalities of the bioadhesive electronics based on ex vivo porcine and in vivo rat models. This study provides a new powerful platform for diverse bioelectronics to address the long-standing challenges in human-machine interface.

5:40 AM F.SM02.02.04
Multi-Functional Bioadhesive Platforms for Translational Tissue Adhesive Technologies Hyunwoo Yuk and Xuanhe Zhao; Massachusetts Institute of Technology, United States

Tools to close and repair wounds in our body are the first set of medical devices in human history. Despite the long history even started from the pre-historic use sutures, the standard care to close wounds still mostly rely on the traditional methods such as sutures and surgical staplers. These old standard cares have faced numerous lingering challenges including slow or complex procedure, leakage, and tissue damage with a huge cost to our society: each year, over millions of people suffer and perish due to the leakages of sealed incisions of organs, failures of prompt hemostasis, and chronic open wounds. Considering the fact that how the entire world has been suffered from the less than 1M death toll by the COVID-19, the degree of the clinical and societal burden from the limitations of current tissue closure and repair technologies is startlingly grave.

Tissue adhesives including tissue sealants and hemostatic agents have been the most recent technologies to address these challenges. However, translational benefits of the tissue adhesives in clinical applications have still been in the nascent state due to the long list of limitations of existing tissue adhesive technologies including 1) slow adhesion formation, 2) weak bonding, 3) low biocompatibility, 4) poor mechanical match with tissues, 5) incompatibility to body fluids like blood, 6) lack of triggerable on-demand detachment, 7) lack of programmable modulation of wounded tissues, and/or 8) poor compatibility to emerging surgical techniques such as minimally invasive surgeries (MIS). In this talk, we will introduce our set of recent advances to translational tissue adhesive technologies based on various yet highly synergistic multi-functional bioadhesive platforms to address all of the abovementioned limitations. We will first briefly summarize the unmet clinical demands in existing tissue adhesives with associated scientific backgrounds for the mechanistic source of the challenges. Then, we will introduce our multi-functional bioadhesive platforms to satisfy the unmet clinical demands with corresponding clinical applications that we are exploring with collaboration with leading clinical experts.

5:50 AM F.SM02.02.05
Multifunctional Tissue Sealant for Minimally Invasive Surgery Sarah Wu[1], Hyunwoo Yuk[1], Jingjing Wu[1], Christoph Nabzdyk[2] and Xuanhe Zhao[1]; [1]Massachusetts Institute of Technology, United States; [2]Mayo Clinic, United States

Methods for tissue sealing and repair in minimally invasive surgery (MIS) represent a significant challenge in the shift toward less invasive procedures. Traditional surgical sutures and stapling devices are often difficult to maneuver precisely in MIS, and these pointwise modalities of sealing can cause tissue damage and lead to anastomotic leakage. While tissue adhesives offer the potential to overcome these limitations, existing adhesives have significant drawbacks; for example, they can be easily washed out in dynamic physiological environments, are prone to fouling in the presence of blood and body fluids, exhibit slow and/or weak adhesion to wet tissue, and may induce unfavorable inflammatory responses. Here, we propose a novel multifunctional bioadhesive designed to achieve controllable tissue adhesion in diverse physiological environments. The bioadhesive takes the form of a conformable patch and is realized by a synergistic combination of three

functional layers: *1)* a hydrophobic liquid overlayer for protection against blood and body fluids, *2)* a micro-textured bioadhesive layer for rapid and robust pressure-triggered adhesion, and *3)* a zwitterionic anti-fouling layer for mitigation of foreign-body response and postoperative adhesion formation. The patch can be adapted to integrate with existing MIS tools, giving it the potential to advance a wide range of surgical procedures.

6:00 AM F.SM02.02.06
Strain Programmable Bioadhesive Patch for Accelerated Diabetic Wound Closure and Healing Heejung Roh[1], Hyunwoo Yuk[1], Georgios Theocharidis[2], Aristidis Veves[2] and Xuanhe Zhao[1]; [1]Massachusetts Institute of Technology, United States; [2]Harvard, United States

Impaired wound healing capability and consequent chronic wounds such as diabetic foot ulcers (DFU) are devastating complications in diabetic patients with rapidly growing clinical and economic burdens in aging societies, recording over 750,000 new DFU each year. Furthermore, significant clinical outcomes including lower extremity amputations are readily induced, resulting in the total annual cost of treatment of DFU and amputations at over 11 billion dollars. Given the rapidly growing patients across the world and the deleterious economic costs including a critical reduction in quality of lives, the treatment of diabetic wounds is one of the major current and future clinical challenges in need of effective solutions.

Despite various therapeutic strategies including several skin scaffolds and growth factor-based treatments that have been introduced and clinically tested for treatment of DFU in the last few decades, their benefits are rather limited as more than 50% of treated DFU patients fail to respond. This lack of effective treatment along with the gravity of the problem highlights the critical importance of developing new therapeutic solutions for diabetic wound healing.

Mechanical modulation of wounded or scarred skin has been a promising strategy to repair and remodel healthy skin in both animal models and human clinical trials. Given the previous animal studies indicating the reduced degree of contractibility of the wound as one of the sources of impaired wound healing in diabetes patients, such mechanical modulation is an attractive treatment route for diabetic wounds. However, the potential therapeutic benefits of the mechanical modulation approach have not been well investigated for chronic wounds such as DFU due to several technical limitations. Existing wound dressings and bandages for mechanical reinforcement or stimuli lack capabilities to 1) form rapid and robust adhesion on wet wounded skin and 2) precisely program mechanical contraction, limiting their use only for passive mechanical coverage, uncontrolled contraction, and/or fully closed wounds. These limitations have prevented the use of a mechanical modulation approach for chronic wounds such as DFU, leaving this potential therapeutic strategy untapped.

In this work, we report a strain programmable bioadhesive patch capable of rapid and fully programmable contraction and stress remodeling of wet wounded skins as a promising therapeutic platform for chronic diabetic wounds. The strain programmable bioadhesive patch synergistically combines a novel hydration-based shape-memory mechanism and the dry-crosslinking mechanism to simultaneously achieve rapid, robust, and on-demand detachable adhesion as well as predictable mechanical modulation when on wet wounded skin tissues. The strain programmable bioadhesive patch takes the form of a thin flexible film consisting of non-adhesive elastomer backing in the rubbery state (Young's modulus ~ 1 MPa) and a dry bioadhesive in the glassy state (Young's modulus ~ 5 GPa) with the programmed strain. Once hydrated by the native physiological fluids or moisture from the wounded tissue, the patch rapidly and robustly adheres to the underlying tissue by the bioadhesive while releasing its programmed strain to provide mechanical contraction to the wound.

To validate the proposed strain programmable bioadhesive patch and its efficacy on diabetic wound contraction and healing, we have performed systematic mechanical analysis (mechanical properties, adhesion performance, theoretical and FEM-based framework for predictable strain programming and mechanical modulation of a wound), in vitro and in vivo biocompatibility, and in vivo diabetic wound healing based on ex vivo porcine and in vivo diabetic mice models. The current study not only provides a promising solution for the treatment of chronic wounds but also offers insights into the development of technologies for programmable mechanical modulation of biological tissues.

6:10 AM F.SM02.02.07
Late News: Biocompatible Hydrogel Ostomy Adhesive William Pan[1], Beverly Matsuda[1] and Hyunwoo Yuk[2]; [1]Northwood High School, United States; [2]Massachusetts Institute of Technology, United States

Ostomies are digestive and excretory surgeries where waste is redirected to the outside of the abdomen, requiring a bag to catch excretion. Current methods use adhesives to create adhesion for 24-hour usage of the ostomy bag. However, current adhesives are weak and unstable, and often lead to leakages of ostomy effluents resulting various clinical complications including irritant dermatitis and infection. Despite these challenges, no commercially-available product can provide strong

enough adhesion nor mechanical softness to prevent skin damage from ostomy leaks. In this work, we introduce a hydrogel ostomy adhesive (HOA) made from a tough double-network hydrogel based on polyacrylamide and sodium alginate that can be strongly adhered onto the skin for over 24 hours and prevent leaks by maintaining fluid-tight sealing against regular bodily movements. The adhesion of HOA to abdominal skin is achieved by the topological adhesion formed by a biopolymer chitosan solution. The HOA's capability to form robust adhesion of ostomy bag is demonstrated based on *ex vivo* porcine skin and *in vivo* human skin in comparison with existing commercially-available ostomy bag adhesives.

6:20 AM F.SM02.02.08
Late News: Electrically Induced Adhesion of Polyelectrolyte Hydrogels to Animal and Plant Tissues Leah K. Borden, Uma J. Kokilepersaud and Srinivasa Raghavan; University of Maryland, United States

This talk will present studies from our lab on the electrically induced adhesion of hydrogels to various soft matter. The basic phenomenon involves crosslinked acrylate hydrogels made with either anionic or cationic co-monomers. When a rectangular strip of a cationic gel (connected to an anode) is contacted for just a few seconds with a strip of anionic gel (connected to a cathode) within an electric field of ~ 2-4 V/ mm, the two gel strips form a strong adhesive bond. When the polarity of the electrodes is reversed, the phenomenon is reversed, i.e., the gels can be easily detached.

While the above phenomenon of 'electro-adhesion' has been reported before for hydrogels, we show that it is much more general and widespread. Specifically, we can substitute either of the above gel strips with gels of various geometrical structures made using charged biopolymers such as chitosan or alginate. The same electro-adhesion works in resealing punctures in gel tubes thereby preventing gas and liquids from leaking out of these punctured structures. As an extreme case, two severed pieces of a tube can be stuck back together using a gel strip that spans both cut segments. In turn, electro-adhesion can also be applied for the pick-up and drop-off of soft cargo, and for the sorting of small cargo. Most interestingly, the same phenomenon also works with certain animal and plant tissues – that is, we show that cationic gels can be electro-adhered to these tissues. We thereby demonstrate that cuts or tears in tissues can be electro-sealed using gel strips.

Linking Molecular Behavior to Macroscopic Properties in Ideal Dynamic Covalent Hydrogels Mark W. Tibbitt; ETH Zürich, Switzerland

Dynamic covalent chemistry has emerged as an elegant molecular design strategy to engineer functional polymer networks that combine advantageous properties of both chemically and physically cross-linked materials. Dynamic covalent networks (DCvNs) are increasingly used in advanced materials design with applications ranging from recyclable thermosets to self-healing hydrogels. However, the relationship between the underlying chemistry at the junctions of DCvNs and their macroscopic properties is still not fully understood. In this presentation, we will outline a robust framework to predict how complex network behavior in DCvNs emerges from the chemical landscape of the dynamic chemistry at the junction. We use ideal dynamic covalent boronic ester-based hydrogels as model DCvNs. We will describe physical models that explain how viscoelastic properties, as measured by shear rheometry, are linked to the molecular behavior of the dynamic junction, quantified via fluorescence and NMR spectroscopy and DFT calculations. Additionally, shear rheometry is combined with Eyring Transition State Theory to quantify the kinetics and thermodynamics of network rearrangements, enabling a mechanistic understanding including preferred reaction pathways for dynamic covalent chemistries. We apply this approach to corroborate the 'loose-bolt' postulate for the reaction mechanism in Wulff-type boronic acids. These findings, grounded in molecular principles, advance our understanding and rational design of dynamic polymer networks, improving our ability to predict, design, and leverage their unique properties for future applications. We will also discuss applications of these materials for the thermal stabilization of biologics and as tunable viscoelastic materials.

Non-Linear Mechanics and Failure of Composite Fibre Gels Jasper van der Gucht; Wageningen University & Research,

Netherlands

Living tissues show an extraordinary adaptiveness to strain, which is crucial for their proper biological functioning. The physical origin of this mechanical behaviour has been widely investigated using reconstituted networks of collagen fibres, the principal load-bearing component of tissues. However, collagen fibres in tissues are embedded in a soft hydrated polysaccharide matrix which generates substantial internal stresses whose effect on tissue mechanics is unknown. Here, by combining mechanical measurements and computer simulations, we show that networks composed of collagen fibres and a hyaluronan matrix exhibit synergistic mechanics characterized by an enhanced stiffness and delayed strain-stiffening. We demonstrate that the polysaccharide matrix has a dual effect on the composite response involving both internal stress and elastic reinforcement. Moreover, the matrix has a pronounced effect on fracture of the networks, leading to enhanced toughness and a transition from brittle to ductile behaviour. Our findings elucidate how tissues can tune their strain-sensitivity over a wide range and provide a novel design principle for synthetic materials with programmable mechanical properties.

Self-Assembly to Build Hydrogels and Insights into Their Morphology Cécile A. Dreiss; King's College London, United Kingdom

Interest in hydrogels over the past couple of decades has exploded for a wide range of biomedical applications, including drug delivery, and tissue engineering.[1] There is a huge interest in building these supramolecular structures from non-covalent interactions, e.g. hydrogen bonds, host-guest interactions, which provide an easy tailoring of dynamic properties, impart shear-thinning and thus injectability and self-healing, making them more amenable to biomedical applications.
Our group focuses on harnessing and understanding simple gelation processes in materials that come from renewable sources or are easily accessible. We exploit hybrid gelation processes to the cross-linking process,[2] spontaneous self-assembly in mixtures of modified polymers and surfactants,[3] formation of pseudopolyrotaxanes with cyclodextrins,[4] and thermally-triggered gelation.[5] In this talk I will present some of our recent work on self-assembled gels and in particular how we use small-angle neutron scattering to elucidate the spatial organisation of the networks that sustain the rheological properties, and ultimately build towards a rationale for hydrogel formulations.

Viscoelastic Properties of Supramolecular Gels and Mixtures Based on Hydrogen Bonding Dimitri Vlassopoulos[1,2]; [1]FORTH, Greece; [2]University of Crete, Greece

Understanding and tailoring the self-assembly of supramolecular moieties is a challenging subject with potential implications in materials engineering and biological function. Here we discuss two problems associated with the viscoelastic properties of (i) hydrogel mixtures due to competitive interactions and (ii) organogels due to the presence of traces of humidity.
Concerning the former, we investigated a class of binary hydrogels made by mixing fibrillar supramolecular polymers that are formed from two compounds: 1,3,5-benzene-tricarboxamide decorated with aliphatic chains terminated by tetra(ethylene glycol) (BTA) and a 20 kg/mol telechelic poly(ethylene glycol) decorated with the same hydrogen bonding BTA motif on both ends (BTA-PEG-BTA). We found that the respective single-compound-based supramolecular systems form very different networks which exhibit drastically different rheology. More strikingly, mixing the compounds results in a non-monotonic dependence of modulus and viscosity on composition, suggesting a competition between interactions of the two compounds, which can then be used to fine-tune the mechanical properties.
The latter problem concerns the self-assembly of supramolecular moieties in organic solvents which is affected by the presence of trace amounts of water in the monomeric state that induce competitive association and change the helicity of the

assembled structure. We investigated an organogel in dodecane (biphenyl tricarboxamide, BPTA) and found that water affects the self-assembled structure by changing the persistence length and contour length of the fiber. The content of water in the fiber changed with temperature, bequeathing the linear and nonlinear viscoelastic properties with unusual temperature responsiveness. For instance, as the temperature increased from 15 to 35ºC, the relaxation time of the system varied non-monotonically with temperature. This stems from the fact that the system loses its reversible and dynamic character for temperatures above 35ºC where water does not mediate the association of BPTA units.
These findings are discussed in the context of existing theories of living polymers and of the perspective of designing gels with desired and tunable properties.

Work in collaboration with E. Vereroudakis (Crete), N.J. Van Zee (ESPCI, Paris), E. Del Gado (Georgetown) and E.W. Meijer (T. U. Eindhoven).

6:00 AM F.SM02.03.06
Amphiphilic Interfacial Hydrogel Films for Biocompatible Emulsion Stabilization Joerg G. Werner[1,2], Brendan Deveney[2], John Heyman[2], Julie Brouchon[2] and David Weitz[2]; [1]Boston University, United States; [2]Harvard University, United States

Aqueous droplets dispersed in fluorinated oils have found a wide variety of applications as biomimetic compartments for the isolation and analysis of cells and biomolecules. Advances in microfluidic manipulation of emulsion drops has enabled biological assays and diagnostics on the single cell and single molecule level at high throughput. Despite the significant advancements in the field of droplet microfluidics, some challenges remain. The stability of especially large drops over 50 microns in diameter is a key issue for applications involving long incubation periods necessary for cell proliferation or organoid growth, as well as thermal stresses experienced in thermocyling for polymerase chain reaction (PCR). Here we report our recently developed approach for stabilizing water-in-fluorocarbon emulsion drops with biocompatible interfacial films that contain a water-facing hydrogel and an oil-facing fluoropolymer that are cross-linked with dynamic covalent bonds. We combine fluorocarbon-soluble random copolymers that contain boronic acid moieties with biocompatible and hydrophilic polymers dispersed in microfluidics-derived water-in-fluorocarbon emulsion droplets. The dynamic covalent chemistry of boronic acids enables the formation of an amphiphilic interfacial thin film around the drop without the use of charged species that often inhibit or interfere with biologic functionalities such as enzyme activity. The amphiphilic interfacial film contains an inert polyol hydrogel facing the water drop and a highly fluorinated outer layer, providing armor to coalescence even in surfactant-free environments. We demonstrate the successful application of our armored droplets for in-drop (RT-)PCR with repeated thermocycling to 96 °C without drop coalescence or inter-drop diffusion even for drops as large as 200 microns, as well as the expansion of cells in 375 micron-sized drops incubated for 96 hours. The strength of the interfacial film is tunable by the choice of complexing polymer and copolymer composition. Our strategy of oil-soluble, boronic acid-containing copolymers for interfacial film formation and droplet stabilization is transferrable to water-hydrocarbon emulsions. Furthermore, tunable adhesive strength between the armored drops enables additive drop assemblies, producing filaments of aqueous microdroplets that are of interest to the hierarchically shape-guided growth of organoids and other cell colonies.

Anisotropic Double Network Hydrogels Based on Semi-Rigid Polyelectrolyte Physical Networks Daniel R. King, Riku Takahashi, Takuma Ikai, Kazuki Fukao, Takayuki Kurokawa and Jian Ping Gong; Hokkaido University, Japan

Many biomaterials possess unique structures that result in anisotropic mechanical properties, along with high strength, toughness, and water content. Applying the double network principle to develop tough hydrogels that possess these features with different polymer chemistries is important for the potential application of hydrogel materials. Synthesis of the two interpenetrating networks with contrasting structure and physical properties required for double networks usually involves a two-step polymerization process. First, the sacrificial network is fabricated, followed by the stretchable, weak network. In this work, we present a new method to synthesize tough double network hydrogels by post-physical crosslinking of linear, semi-rigid polyelectrolytes entrapped in a chemically crosslinked neutral network. This has been achieved through a one-pot polymerization method. Owing to their semi-rigid structure, poly(2,2'-disulfonyl-4,4'-benzidine terephthalamide) (PBDT) can form a brittle physical network above their overlap concentration in multi-valent $ZrCl_2O$ ion solutions without macroscopic phase separation, within the flexible neutral network. The double network hydrogels thus prepared exhibit high modulus (~1.7 MPa), strength (~1.3 MPa), fracture strain (~7.3), and strain energy density (~5.9 MJ/m^3), while containing over 80% water. These materials also exhibit modest self-healing ability (~51% after 30 minutes), demonstrating an additional benefit of a physical sacrificial network. Furthermore, applying pre-stretch prior to physical crosslinking allows for the fabrication of an oriented sacrificial network. The anisotropic hydrogels demonstrate a Young's modulus anisotropy ratio

of close to 3. The method presented here is simpler than the conventional two-step polymerization of traditional double network hydrogels and could be applied to develop tough hydrogels from rigid polyelectrolytes, including biopolymers such as DNA, HA, and chondroitin sulfate.

6:20 AM F.SM02.03.08
Coformulation with Water to Improve the Properties of Gelatin-Supported Deep Eutectic Solvent Gel Electrolytes Rachel E. Owyeung, Sameer Sonkusale and Matthew Panzer; Tufts University, United States

Ionic skin devices aim to mimic their biological counterparts for wearable devices and soft robotic applications by sensing touch due to a capacitive change upon deformation. Commonly, salts are added to hydrogels to create ionic conductors that are supported by mechanically compliant polymer networks for these devices. However, hydrogel systems are often unstable with respect to liquid evaporation and can require additional chemical crosslinks to improve gel mechanical stiffness and toughness.
Our group recently demonstrated gelatin-supported deep eutectic solvent (DES) gels using a 1:2 molar ratio of choline chloride (ChCl) and ethylene glycol (EG) as nonvolatile gel electrolyte alternatives. Compared to a hydrogel with the same gelatin content (22 wt.%), the DES gel demonstrated remarkably improved stretchability (fracture strain improved from 40% to 320%) and toughness (improved from 2.1 to 133 kJ/m^3). As these gels were supported only by noncovalent cross-links formed via gelatin self-assembly (*e.g.* triple helices), there was a clear synergistic effect of both ChCl and EG on the gelatin scaffold to improve DES gel mechanical properties relevant to ionic skin applications. However, there is still a need to better understand how the solvent dictates *in situ* gelation.
In this work, we probe the inherent interactions between the solid and liquid components within these gels by exploring the effects of the organic hydrogen bond donor (HBD) of the DES as well as coformulation with 25 mol% water on the resulting gelatin self-assembly. These gel electrolytes were characterized to determine their tensile properties, ionic conductivities, and thermal transitions in order to probe interactions between ChCl, HBD, and water and the gelatin scaffold.
We have observed that varying the HBD identity within DES/water mixture gels enables tuning of the Young's modulus by up to a six-fold increase: from 7 kPa (1,2-propanediol) to 42 kPa (glycerol) for a fixed gelatin content (20 wt.%). Additionally, DES/water mixture gels exhibit notable improvements in toughness and ionic conductivity versus their "dry" DES gel counterparts. Toughness was increased from 23 to 68 kJ/m^3 for ethylene glycol-based gels and ionic conductivity increased from 3.3 to 5.2 mS/cm. Similar improvements to toughness and conductivity were found for glycerol-based DES gels, with water addition increasing gel toughness from 46 to 198 kJ/m^3 and ionic conductivity from 0.9 to 1.2 mS/cm.
The results of this work demonstrate that water-in-DES mixtures can synergistically improve ion transport and mechanical properties within DES/water mixture gel electrolytes, and that proper materials selection of the liquid electrolyte and polymer scaffold system can lead to greater tunability of gel properties relevant to ionic skin device applications.

6:30 AM F.SM02.03.09
Intrinsic Fracture Energy of Soft Mechanical Metamaterials Dongchang Zheng[1,2], Shaoting Lin[1], Liu Wang[1] and Xuanhe Zhao[1,1]; [1]Massachusetts Institute of Technology, United States; [2]University of Science and Technology of China, China

Diverse soft metamaterials have been developed for energy-absorbing, tunable thermal expansion, soft actuator, etc. Although various functional properties of soft metamaterials have been investigated, their fatigue properties have not been studied yet, which hinders the translation of soft metamaterials into real applications. With 3D printing techniques, we control the geometrical parameters of soft metamaterials. Fracture tests and simulations are conducted to measure the S-N curve of a single printing filament and fatigue threshold of 3D printed soft metamaterials. We show that the fatigue threshold of soft metamaterials is linearly proportional to the fiber's diameter and strain energy density limit, but independent of its length. Constitutive relation of the materials and geometrical shapes determine the prefactor of such proportion relations. The results are intrinsically different from the classical Lake-Thomas theory for polymer networks, leading to a generalized theory for predicting soft metamaterials' fatigue threshold. The capability of the theory correlating the fatigue property of a single filament and entire topological networks is critical for the design of durable soft metamaterials. This theory inspires us to manufacture sinusoidal structure metamaterials, whose fatigue threshold increase dramatically.

6:40 AM F.SM02.03.10
Noninvasive Study of Hydrogel Re-Swelling Inside Soft Tissues Michael Shur, Kangling Wu, Outman Akouissi and Stephanie P. Lacour; Ecole Polytechnique Federale de Lausanne, Switzerland

Neural tissues are extremely soft with kPa-range modulus. Hydrogels offer a unique opportunity to design neural interfaces

with biomimetic mechanical properties. Some designs which utilize hydrogels either as coating or bulk material, such as penetrating intracortical probes, require de-hydration of the hydrogel before the time of implantation to prevent any buckling during insertion and to minimize the hydrogel delamination due to shear forces. Once inserted into the brain the hydrogel absorbs moisture from the tissue, swells and provides a tissue-like interface.

We report on the re-swelling process and assess the mechanical properties of the hydrogel in as-prepared and post re-swelling conditions, comparing thermal and freeze drying as de-hydration methods. We studied polyacrylamide (PAAm) hydrogel with increasing monomer concentrations (3 to 6% AAm), which correspond to shear storage moduli (G') in the 120 to 750 Pa range. We found that the recovery of G' and of the swelling capacity depends on the initial composition of the hydrogel. Following either thermal or freeze-drying process, the softest hydrogel (3% AAm) displays only 40% swelling capacity recovery and a 3.5 times increase in storage modulus, compared to its initial properties. Stiffer hydrogels were found to be less sensitive to the de-hydration process with a 2 to 2.8 G' increase factor.

Next we studied the re-swelling kinetics and normal forces associated to the process, both in free and constrained swelling scenario (mimicking the implant-tissue interface). Finite element simulation extended the analysis to help quantify the mechanical stresses that are being exerted on the neural tissue during the re-swelling stage. Preliminary results indicate that these stresses may reach up to several tens of kPa for a 100μm thick hydrogel coating, being applied on the surrounding during a constrained re-swelling process of a 300 Pa hydrogel.

These preliminary results indicate hydrogel dynamics should be taken into account when designing in vivo probes and suggest that the soft material in vivo may display stiffer properties than those in vitro. We believe this work provides important insights on hydrogel-tissue interface and inherent limitations associated with the use of ultra-soft hydrogels for implantable neural interfaces.

6:50 AM F.SM02.03.11
Late News: Mesoscale Modeling of Controlled Degradation in Hydrogels Vaibhav A. Palkar, Chandan K. Choudhury and Olga Kuksenok; Clemson University, United States

Hydrogel based soft materials with chemical functionalities that allow controlled degradation of the polymer are utilized as active stimuli responsive platforms for numerous applications. As one example, a hydrogel with multiple degradable functional groups that degrade in response to different wavelengths of light enables sequential release of drugs from the network. Herein, we present Dissipative Particle Dynamics (DPD) based simulations of degradation in tetra-arm polyethylene glycol (tetra-PEG [1]) hydrogels. Controlled degradation can be introduced in these gels via several chemical pathways [2,3]. In our DPD model we use the modified segmental repulsive potential (mSRP [4]) to avoid unphysical polymer chain crossing and we first establish model parameters that mimic the hydrophilicity of PEG. Further, we use our recently developed framework [5] to introduce controlled degradation in these gels and measure the fraction of degradable bonds intact during degradation. Our method allows modeling of first order degradation kinetics in these gels. We track the evolution of mass loss from bulk degrading gels and note the occurrence of a slow mass loss regime due to erosion followed by a fast regime due to reverse gelation of the polymer network. We quantify the reverse gel point of these gels by tracking the size of the second largest cluster during degradation. We focus on the effect of finite size on mass loss and reverse gel point calculations and compare these effects with previously developed scaling [6]. The reverse gel point for tetra-PEG hydrogels measured from our simulations corresponds well with the value obtained from percolation theory on a diamond lattice.

Evolution of Self-Oscillating Polymer Gels as Life-Like Softmachines Ryo Yoshida; The University of Tokyo, Japan

In living systems, there are many autonomous and oscillatory phenomena to sustain life such as heart beating. We developed "self-oscillating" polymer gels that undergo spontaneous cyclic swelling–deswelling changes without any on–off switching of external stimuli, as with heart muscle. The self-oscillating gels were designed by utilizing the Belousov-Zhabotinsky (BZ) reaction, an oscillating reaction, as a chemical model of the TCA cycle. We have systematically studied these self-oscillating polymer gels since they were first reported in 1996. Potential applications of the self-oscillating polymers and gels include several kinds of functional material systems such as biomimetic actuators, mass transport systems and functional fluids. For example, it was demonstrated that an object was autonomously transported in the tubular self-oscillating gel by the peristaltic pumping motion similar to an intestine. Further, self-oscillating polymer brush surface like cilia, vesicles or colloidosomes undergoing cell-like autonomous shape oscillations with buckling, was prepared. Besides, autonomous sol-gel oscillation and amoeba-like motion was realized utilizing well-designed block copolymer solution. In this presentation, our recent progress on the self-oscillating polymer gels is summarized.

HASEL Artificial Muscles—Versatile High-Performance Actuators for Bioinspired Robotics Christoph Keplinger; University of Colorado-Boulder, United States

Robots today rely on rigid components and electric motors based on metal and magnets, making them heavy, unsafe near humans, expensive and ill-suited for unpredictable environments. Nature, in contrast, makes extensive use of soft materials and has produced organisms that drastically outperform robots in terms of agility, dexterity, and adaptability. To create a new generation of soft, life-like robots that reproduce the vast capabilities of biological systems, we need to develop actuators that replicate the astonishing all-around actuation performance of biological muscle. Hydraulically Amplified Self-healing ELectrostatic (HASEL) transducers are a new class of self-sensing, high-performance muscle-mimetic actuators, which are electrically driven and harness a mechanism that couples electrostatic and hydraulic forces to achieve a wide variety of actuation modes. Current designs of HASEL artificial muscles exceed actuation stress of 0.3 MPa, linear strain of 100%, specific power of 600W/kg, efficiency of 30% and bandwidth of 100Hz; all these metrics match or exceed the capabilities of biological muscle. This talk gives an overview over the latest developments, including materials systems, modeling, new designs of actuators, fabrication techniques, and creation of untethered soft robotic devices.

5:30 AM *F.SM02.04.03
Non-Equilibrium Signal Integration in Hydrogels Peter Korevaar, Nadir Kaplan and Joanna Aizenberg; Harvard University, United States

Materials that perform complex chemical signal processing are ubiquitous in living systems. Their synthetic analogs would transform developments in biomedicine, catalysis, and many other areas. By drawing inspiration from biological signaling dynamics, we show how simple hydrogels have a previously untapped capacity for non-equilibrium chemical signal processing and integration. Using a common polyacrylic acid hydrogel, with divalent cations and acid as representative stimuli, we demonstrate the emergence of non-monotonic osmosis-driven spikes and waves of expansion/contraction, as well as traveling color waves. These distinct responses emerge from different combinations of rates and sequences of arriving stimuli. A non-equilibrium continuum theory we developed quantitatively captures the nonmonotonic osmosis-driven deformation waves and determines the onset of their emergence in terms of the input parameters. These results suggest that simple hydrogels, already built into numerous systems, have a much larger sensing space than currently employed.

5:45 AM *F.SM02.04.04
Polymer Gels for Autonomous Motion and Mesoscale Assembly Alfred J. Crosby; University of Massachusetts Amherst, United States

Nature is masterful at using limited components and basic driving forces to achieve complex tasks, such as high power movement and multi-structure assembly, across a broad range of size scales. The materials that enable these achievements often rely upon the integration of phases that allow for internal transport, elastic energy storage, system protecting dissipation, and tunable sensitivity to interfacial interactions. Accordingly, polymer gels, which combine liquid phases with shear-sustaining macromolecular network structures, offer a robust materials platform for transferring lessons from nature into synthetic engineered devices. Here, we describe two examples from our research group of how to take advantage of mesoscale structural asymmetry, mechanics, liquid transport, and interfacial interactions to achieve new engineered capabilities. The first example takes inspiration from multiple examples in nature, including mantis shrimp and trap-jaw ants, that use Latch-Mediated Spring Actuation (LaMSA) to achieve high power, impulsive movements. We demonstrate how transient metastable deformations associated with swelling and deswelling of a polymer gel can be exploited to generate mechanical bi-stability, giving rise to multiple, self-repeating, snap-through movements. We introduce models to quantitatively describe these mechanisms and harness them to develop autonomous jumping devices. In a related manner, the second example describes the use of structural asymmetry to mediate swelling/deswelling processes and elastic restoring forces to control the motion and assembly of mesoscale polymer gel ribbons. Collectively, both examples provide new insight into how polymer gel properties, related to elasticity, diffusion, and interfacial forces, can combine with purposeful structural design to yield complex tasks, which can be used in the development of microscale robots and new adaptable composite materials.

6:00 AM F.SM02.04.05
Bioinspired Self-Healing Protein Hydrogels for Soft Machines Abdon Pena-Francesch[1,2], Melik C. Demirel[3] and Metin Sitti[1]; [1]Max Planck Institute for Intelligent Systems, Germany; [2]University of Michigan, United States; [3]The Pennsylvania State University, United States

Recent research efforts have focused on developing soft, flexible, compliant materials for robotics, biointerfacing, and biosensing applications. Because of their intrinsic softness, these materials are susceptible to cut, puncture, scratch, and/or tear damage that compromise their physical integrity, and therefore self-healing properties are indispensable for soft machines and devices operating in dynamic environments. However, current self-healing materials have shortcomings that limit their practical application, such as low healing strength (below MPa) and long healing times (hours).
Here, we introduce high-strength bioinspired synthetic proteins that self-heal micro- and macro-scale mechanical damage within a second by local heating. These protein hydrogels are systematically optimized to improve their hydrogen-bonded nanostructure and network morphology, with programmable healing properties (23 MPa strength after 1 second of healing) surpassing those found in other natural and synthetic soft materials by several orders of magnitude. Such healing performance opens new opportunities for bioinspired materials design, and addresses current limitations in self-healing materials for soft robotics and wearable technology.

6:10 AM F.SM02.04.06
Coiled pH-Responsive and Athermal Polymer Artificial Muscles Sevketcan Sarikaya[1], Frank Gardea[2] and Mohammad Naraghi[1]; [1]Texas A&M University, United States; [2]U.S. Army Combat Capabilities Development Command Army Research Laboratory South, United States

The interest in artificial muscles has been expanding due to the shortcomings of traditional motors and actuators, such as piezoelectric actuators and shape memory alloys. Stiffness incompatibility with human bodies and IR-detectable actuation mechanisms are among the limitations of the traditional actuators. Soft matter and polymers, including hydrogels, as artificial muscles offer great potential to enhance robotic applications where lightweight and flexible structures are desired. Upon application of an external stimulus, polymer artificial muscles can expand or contract, similar to a mammalian muscle, replicating comparable stroke and stiffness, which enables safe interactions with humans. pH is one of the stimuli which provides a silent and athermal motion to artificial muscles. pH-driven polymer gels can lead to significant swelling and deswelling behaviors when exposed to acid and basic environments and provide muscle-like actuation when in a fiber form. In this work, we investigated the actuation behaviors of polyacrylonitrile (PAN) gel fibers by exploiting structural adjustments in which a simple but efficient method, twisting and coiling approach was applied. In this manner, the material response –dimensional change with change in pH- was enhanced with the peculiar structural design of a coil, leading to drastically augmented strokes. Here, we first characterized electrospun PAN nanofibers and commercially available PAN microfibers in terms of fabrication conditions. In this step, the variables of thermal stabilization and hydrolysis, resulting in a PAN pH-responsive gel, were tested in order to obtain optimum actuation conditions. Aligned micro and electrospun nanofibers prepared with different fabrication conditions were actuated at various levels of mechanical loading. A maximum of ~54% actuation was achieved under no stress and it was found that higher thermal stabilization results in lower actuation. Radius and overall volume change of pH-responsive single PAN microfiber were measured. Next, as-received PAN

microfibers were highly twisted and coiled to produce volume-change induced actuation. Coiled PAN fibers yielded a promising actuation performance compared to their linear and aligned counterparts. Analytical models relating material response to structural responses were studied. This work shows that pH-responsive PAN gel fibers can be further enhanced in terms of actuation performance through structural design.

6:20 AM F.SM02.04.07

Development of a Bilayered Hydrogel with Cartilage-Mimicking Mechanical and Lubrication Properties Lorenzo Vannozzi[1,2], Diego Trucco[1,2,3], Eti Teblum[4], Madina Telkhozhayeva[4], Saverio Affatato[3], Gina Lisignoli[3], Gilbert D. Nessim[4] and Leonardo Ricotti[1,2]; [1]Scuola Superiore Sant'Anna, Italy; [2]Scuola Superiore Sant'Anna, Italy; [3]IRCCS Istituto Ortopedico Rizzoli, Italy; [4]Bar Ilan Institute for Nanotechnology and Advanced Materials, Israel

Recently, new tissue engineering approaches are being developed as an alternative to traditional treatments for articular cartilage (AC) repair. Being an avascular tissue, AC has a limited ability to heal from defects caused by traumas and/or degenerative diseases. Materials in the form of hydrogels are particularly attractive as owing to their biocompatibility, degradability, and ability to homogeneously mix with cells and smart nanomaterials. Hydrogels can be injectable, thus to easily fill defects with different shapes, thus repairing the articular cartilage in a minimally invasive way.
Several tissue engineering approaches have been proposed to restore the AC native properties [1]. This specialized tissue provides a low-friction surface for articulation, guaranteeing shock-absorption and wear-resistance [2]. Despite the noticeable efforts spent in the recent years, there is still a high difficulty to reproduce *in vitro* the mechanical and lubrication properties of AC.
We developed a bilayered hydrogel made of blends of Gellan Gum (GG) and Polyethylene glycol diacrylate (PEGDA), able to mimic the mechanical and lubrication features of AC. Graphene Oxide (GO) was used as an effective lubricant agent [3]. GG (1.5 % wt. in deionized water) was mixed with PEGDA (Mn: 575) at different concentration (10 and 15 % wt. for top and bottom layer, respectively). The photocrosslinking was enabled by the addition of Irgacure 2959 (0.1 % wt.) and different UV light exposure time (5 and 10 min) have been tested. Then, samples were immersed in magnesium chloride ($MgCl_2$, 1 % wt. in deionized water) for 10 min and/or culture medium (DMEM) for 24 h to enable the ionic crosslinking. Mechanical compression tests allowed to determine the optimal crosslinking parameters. We found two combination of crosslinking able to match the compression Young's modulus of the human AC, which ranges from 0.28 ± 0.16 MPa to 0.73 ± 0.26 MPa, respectively for its superficial and deep layer [4]. We achieved the targeted range of Young's modulus values for the top (0.18 ± 0.06 MPa) and bottom (0.80 ± 0.15 MPa) layers of AC by combining photo (5 min) and ionic crosslinking with $MgCl_2$. The contribution of ionic crosslinking with $MgCl_2$ was also more effective than the UV exposure time for the improvement of the toughness and fracture stress/strain of the hydrogels, important features of AC. GO nanosheets were synthesized as described in [5] and added to the top layer solution (0.01 % wt.). The hydrogels with and without GO were analyzed with a custom setup (flat-on-flat geometry) made of using a MCR 102 rheometer equipped with the Tribocell T-PTD200 and a Peltier temperature control. Tribological analyses demonstrated that the non-doped formulation possessed a smaller friction factor (~0.03) in the static regime than the doped formulation (~0.04), while the presence of GO led the friction factor to smaller values in the kinetic regime, as opposed to the bare hydrogel in which that value progressively increased.
In summary, we demonstrated the achievement of the target compressive Young's modulus of AC layers and the improved lubricant behavior provided by the presence of GO in the kinetic regime of compression, which is important for guaranteeing low friction in the articulation during daily life activities. These results are extremely promising in view of the fabrication of a multi-layered synthetic implant for restoring AC defects.

Fabrication of Hydrogel Objects and Devices in Liquids with Focused Electron Beams Andrei A. Kolmakov; National Institute of Standards and Technology, United States

Electron/X-ray focused beams fabrication of hydrogels with submicron resolution and rate inside liquid precursor solutions

would be highly demanded development which, however, is hard to realize due to the vacuum incompatibility of liquid samples. In this contribution, we resolve this impediment and demonstrate a technique for in-liquid focused beam induced crosslinking of hydrogels using fluidic enclosures equipped with electron/x-ray transparent windows. Being inspired by continuous liquid interface production 3D printing technology (CLIP)[1], we developed an alternative method of controllable delamination of the e-beam printed layer from the supporting membrane. Our approach is based on electrochemical quenching of the crosslinking process at the electrified membrane-solution interface. The potential of this technique for sensorics, bioelectronics, interfacing, and drug delivery is demonstrated via in situ addressable immobilization of live-cell, synthesis of nanocomposite hydrogels, and microfabrication of photonic sensors[2].

Fatigue Resistant Hydrogel Fiber for Light Delivery Xinyue Liu, Siyuan Rao and Xuanhe Zhao; Massachusetts Institute of Technology, United States

Light technologies have enabled numerous biomedical devices to assess health and treat disease, among which optical fibers permit light transmission between the external world and human nervous system. The peripheral nervous system flexes with the human body during movement, while silica-based optical fibers with limited deformability constrain the natural movement of the nerves, impeding light delivery in freely moving animals. On the other side, the high compliance, high water content, and biocompatibility make hydrogels an ideal material candidate for optic devices, especially for those in close contact with biological organisms. However, existing hydrogel optical fibers suffer from low mechanical stability, poor coupling with external optics, and severe light leakage. Here, we present a fatigue-resistant hydrogel-based optically stimulating technology (FAR-HOST) that utilizes nanocrystalline hydrogels as optical fibers for optogenetic control in the peripheral nervous system. The hydrogel optical fibers are soft and stretchable to conform to the flexible substrates, and meanwhile the formation of polymeric nanocrystals in hydrogels confers fatigue-resistance to these hydrogel materials against repeated movements. In addition, hydrogels with polymeric nanocrystals exhibit a relatively high refractive index that minimizes interfacial light leakage, and high transparency that reduces light absorption or scattering, synergistically contributing to efficient light transmission. In vitro and in vivo results demonstrate that using FAR-HOST to exert optogenetic control over the sciatic nerve, revealing its potentials diagnostic imaging, health monitoring, and neuromodulation.

6:50 AM F.SM02.04.10
Hydrogel Embedded Quantum Dot-Transcription Factor Sensor for Quantitative Progesterone Detection Mingfu Chen[1], Chloe Grazon[1], Prerana Sensharma[1], Thuy Nguyen[1], Yunpeng Feng[1], Margaret Chern[1], R Baer[1], Nitinun Varongchayakul[1], Katherine Cook[1], Sébastien Lecommandoux[2], Catherine Klapperich[1], James Galagan[1], Allison M. Dennis[1] and Mark Grinstaff[1]; [1]Boston University, United States; [2]Univ. Bordeaux, France

Immobilization of biosensors in or on a functional material is critical for subsequent device development and translation to wearable technology. Here we present the development and assessment of an immobilized quantum dot - transcription factor - nucleic acid complex for progesterone detection as a first step toward such device integration. The sensor is composed of a polyhistidine-tagged transcription factor linked to a quantum dot and a fluorophore-modified cognate DNA, and embedded within a hydrogel as an immobilization matrix. The hydrogel is optically transparent, soft, and flexible as well as traps the quantum dot - transcription factor DNA assembly but allows free passage of the analyte, progesterone. Upon progesterone exposure, DNA dissociates from the quantum dot - transcription factor DNA assembly resulting in an attenuated ratiometric fluorescent output via Förster resonance energy transfer. The sensor performs in a dose-dependent manner with a limit of detection of 55 nM. Repeat analyte measurements are also similarly successful. Our approach combines a systematically characterized hydrogel as an immobilization matrix and a transcription factor – DNA binding as a recognition/ transduction element, offering a promising framework for future biosensor devices based upon allosteric transcription factor.

7:00 AM F.SM02.04.11
Interference-Assisted Wide-Range Plasmonic Coloration of Single Gold Nanoparticles and Its Dynamic Control Bokusui Nakayama, Keiko Esashika, Yuki Hiruta and Toshiharu Saiki; Keio University, Japan

The main challenges in conventional color printing involve protecting ink from fading and enabling it to be rewritable. As for color displays, a liquid crystal display, for example, suffers from high power consumption and small viewing angle. Alternatively, as seen in stained glass and peacock feathers, some of the historical artifacts and natural livings exhibit rich colors, whose principle include localized surface plasmon resonance (LSPR) and/or interference effects. Recently novel color printing and displays based on these effects have been widely demonstrated.
Towards plasmonic color display at video frame rate, dynamic modulation of plasmonic coloration by using volume phase transition of responsive polymer gels has been proposed [1,2]. In these studies, a hydrogel with drastic volume responsibility to an external field was employed for fine tuning of gap distance of neighboring metal nanostructures to control of LSPR. The color modulation range, however, is still unsatisfied and far behind from practical use.
In this study, we propose a new method to widen the wavelength range of plasmonic coloration by exploiting interference between illuminating white light and LSPR scattering light. The sample consists of gold nanoparticles (AuNP; $\Phi = 80$ nm) dispersed in Poly(N-isopropylacrylamide) (PNIPAM) hydrogel, which was sandwiched between two coverslips (Fig. 1 inset). Under bright-field microscope observation, back-scattered light from AuNP interferes with white light reflected back from the bottom coverslip. Depending on the distance between AuNP and the bottom coverslip, the relative phase of interfering lights differs for individual AuNPs and they appear in different colors in a wide-range (Fig. 1). In addition, we can control the AuNP-coverslip distance via volume phase transition of PNIPAM induced by temperature control (Fig. 2 inset). Figure 2 demonstrates continuous color tuning of a single AuNP, broadly covering the chromatic diagram, upon heating and cooling of PNIPAM.

Novel Integration of Fabric-Based Hydrogel Electrodes and Pressure Sensors in Smart Eyewear S. Zohreh Homayounfar, Soha Rostaminia, Ali Kiaghadi, Deepak Ganesan and Trisha Andrew; University of Massachusetts, Amherst, United States

There is a significant interest in measuring biopotential signals (such as ECG and EOG) unobtrusively via novel textile-based electronics. Herein, electrodes are the interface who receives the charges in the ionic form from the body and injects them as electrons through wires. A fundamental challenge to be addressed to reliably measure biopotential parameters with fabric-based electrodes is whether we can design an electrode that has the signal quality of traditional wet electrodes and the comfort of dry electrodes. The crucial role of a hydrogel in an electrode, specifically in reducing the motion artifact, is undeniable. However, fabricating a hydrogel which can be stably grafted to the underneath plate and, more importantly, can be fully recovered after being dried out is still a great challenge among scientists. In this study, we developed a mechanically stable hydrogel as the electrolyte on our bioelectrode by taking advantage of initiated Chemical Vapor Deposition (iCVD). Our first-of-its-kind hydrogel electrodes successfully address all known drawbacks of conventional “wet” electrodes, in addition to affording high signal to noise ratio during long-term data acquisition, displaying wash-stability, breathability, no skin irritation, and being capable of further miniaturization for embedding into any wearable platforms. The functionality of these electrodes has been successfully approved by being incorporated into an eye-mask to detect eye movement (EOG). To capture additional physiological measures that are complementary to eye movement information captured by the electrodes, we embedded a fabric-based pressure sensor for pulse detection along the strap of the eyewear which let the wearer’s pulse to be imperceptibly measured, simultaneously with any eye movement. We anticipate that the ability to track pulse along with eye movement in a single device will enable a host of cutting-edge biomedical, psychological and psycho-social studies, in addition to improving the accuracy and usability of gaming and virtual reality headsets.

7:20 AM F.SM02.04.13
PEDOT:PSS/pNIPAAm Hydrogel-Based Electrodes for the Monitoring of the Capture and Release of Label-Free Biomarkers Janire Saez[1], Maite Garcia-Hernandez[2], Achilleas Savva[1], Lourdes Basabe-Desmonts[2,3], Fernando Benito-Lopez[2] and Roisin Owens[1]; [1]University of Cambridge, United Kingdom; [2]University of the Basque Country, Spain; [3]IKERBASQUE, Spain

Circulating Tumor Cells (CTCs) are responsible for inducing metastasis when they exit from a primary tumor, they travel through blood and invade another healthy tissue. They are considered as crucial biomarkers of the prognosis of cancer patients, but they are normally found in low concentrations in the first stages of the disease and their detection and is still a challenge. Therefore, the development of biosensors capable of not only detecting, but also collecting pure CTCs is of great interest for the scientific community and society in general. Stimuli responsive materials are gaining interest for cell capture and release, specifically, poly(*N*-isopropylacrylamide) (pNIPAAm), which changes its configuration in response to variations in temperature above and below 32 °C in a range able to preserve cell viability. In parallel, the extensive use of conducting polymers (CPs) in the bioengineering field is enabling important advances in cell applications. This is thanks to their properties such as optical transparency, amenability to surface functionalization, high biocompatibility and chemical stability,

high conductivity/weight ratio, high porosity and very good electrical and physical properties. The additional ability of CPs to be turned into mechanically soft hydrogels opened exciting new possibilities to integrate electrically conducting materials within thermoresponsive polymers and create biosensors. Here, we report a hybrid functional, conductive and thermoresponsive copolymer, based on poly(3,4-ethylenedioxythiophene) / poly(styrene sulfonate) (PEDOT:PSS) blended with pNIPAAm. The material is capable of performing label free, non-invasive cell capture, release, and simultaneous electrical monitoring of the process of cell capture and release. This technology opens a new possibility for detecting and collecting CTC biomarkers in early stage cancers for further analysis to improve patient prognosis.

Keywords: living materials, synthetic biology, genetic logic

Qualities exhibited by living systems, including self-regulation, self-healing, morphology control, and environmental responsiveness, are highly attractive from a material design perspective. Collectively, these capabilities all arise from the ability of living systems to perform computation. However, traditional biological materials, such as biofilms and tissues, are generally less robust and more difficult to engineer than synthetic materials. Next-generation materials must bridge the computational abilities of natural systems with the precision of synthetic systems. These designs will require programming of genetic and transcriptional responses whose outputs can control non-biological material properties. Towards these goals, living materials are a class of materials defined by their incorporation of autonomous cells that use biological functions to control material properties. Our group recently demonstrated that leveraging extracellular electron transfer (EET) from the organism *Shewanella oneidensis* enables control over the redox equilibrium of metal catalysts to polymerize and cross-link syntheic materials via atom-transfer radical polymerization[1,2]. Using this method, we report the production of hydrogel living materials in which *S. oneidensis* controls the cross-linking of methacrylated hyaluronic acid[3]. Cross-linking by genetic knockouts demonstrated that hydrogel formation was closely coupled to the expression of specific EET proteins, as gelation kinetics and stiffness correlated to the number of removed EET genes. Furthermore, strains complemented with an inducible EET gene showed inducer-dependent cross-linking activity and hydrogel mechanics, including both gel microstructure and bulk properties. Modeling gene expression using an activating Hill Function yielded quantitative prediction of hydrogel storage modulus, demonstrating control over material properties using design principles from synthetic biology. Genetic circuits controlling different EET genes also yielded networks with tunable properties depending on the choice of gene, demonstrating traditional buffer gate logic. By coupling EET activity to cross-link density, we have engineered a platform that utilizes autonomous bacterial metabolism to design computational materials that cross-link in response to environmental cues using genetic logic. Next, we will further demonstrate the general applicability of EET-controlled catalysis for computational material synthesis, cross-linking fully synthetic polymer networks using thiol-ene and CuAAC click chemistries. Genetic control over these chemistries will significantly expand the synthetic capability of microorganisms. Finally, more sophisticated Boolean logic, such as NOT, AND, and OR gates will enable more advanced living material computation for applications in biosensing, tissue engineering, and additive manufacturing.

Surface Engineering of Hydrogels for Solar Water Purification Youhong Guo and Guihua Yu; The University of Texas at Austin, United States

Water scarcity has been an increasingly severe threat to our society. Solar vapor generation provides a sustainable means for desalination and water purification technologies. With highly tunable structures, unique polymer-water interactions, and ease of integration with functional materials, hydrogels show great potential for efficient solar water purification. The rational design and engineering of hydrogel surfaces have a substantial impact on the interfacial solar water vaporization process. Here, we will discuss effective ways to tailor the surface topography and wetting states of hydrogel solar evaporators to accelerate the solar vapor generation rate. Specifically, the nanotextured topography of the surface can be fabricated by a liquid-liquid interface-guided gelation process, resulting in an increased heat flux at the sharply dimpled hydrogel-air interface. In addition, hydrogel evaporators with inhomogeneous surface wettability demonstrate an ultrahigh evaporation rate with synergistic contributions from both wetting regions. Molecular dynamics simulation reveals the surface-modulated escaping behavior of water molecules. By applying hydrophilic polymers as building blocks, the hydrogel evaporators have been endowed with multifunctionalities, such as antifouling and complex contaminants removal, to improve both quantity and quality of collected water. Together with an easy-to-employ and portable purification prototype, hydrogels are an emerging materials platform for high-performance yet cost-effective water purification applications.

7:50 AM F.SM02.04.16
Tough Hydrogel-Based Biocontainment of Engineered Organisms for Continuous, Self-Powered Sensing and Computation Tzu-Chieh Tang[1], Eleonore Tham[1], Xinyue Liu[1], Kevin Yehl[1], Alexis Rovner[2], Hyunwoo Yuk[1], Farren Isaacs[3], Xuanhe Zhao[1] and Timothy Lu[1]; [1]Massachusetts Institute of Technology, United States; [2]Harvard University, United States; [3]Yale University, United States

Genetically modified microorganisms (GMMs) can enable a wide range of important applications, including environmental sensing, precision therapeutics, and responsive materials. However, the containment of GMMs to prevent environmental escape and satisfy regulatory requirements is a bottleneck for real-world use. While biochemical strategies have been developed to restrict unwanted growth and replication of GMMs in the environment, there is a need for deployable physical containment technologies to achieve redundant, multi-layered, and robust containment. In addition, form factors that enable easy retrieval would be useful for environmental sensing. To address this challenge, we developed a hydrogel-based encapsulation system for GMMs that incorporates a biocompatible multilayer tough shell and an alginate-based core. This DEployable Physical COntainment Strategy (DEPCOS) allows no detectable GMM escape, bacteria to be protected against environmental insults including antibiotics and low pH, controllable lifespan, and easy retrieval of genetically recoded bacteria. To highlight the versatility of a DEPCOS, we demonstrate that robustly encapsulated cells can execute useful functions, including performing cell-cell communication with other encapsulated bacteria and sensing heavy metals in water samples from the Charles River. We envision that our multilayered physical and chemical containment strategy will facilitate the realization of a wide range of real-world applications for 'living' biosensors.

Late News: Robust and Flexible Gel-Sheet That Can Rapidly Absorb Water and Blood Hema Choudhary, Srinivasa Raghavan and Matthew Dowling; University of Maryland, College Park, United States

Superabsorbent polymer gels that can absorb a significant amount of water are widely used in materials such as diapers and for keeping soil moist. These gels are typically in the form of microscale beads. The same gels can also be made as macroscopic solids (e.g., a sheet or cube), but these solids take a long time (~ 24 h) to swell in water. For a large, solid gel to swell rapidly, it is necessary to make it porous, but porous gels tend to be fragile.

Here, we present a simple and low-cost approach to create solid gels that are both porous and highly robust. Our approach involves the polymerization of a foamed monomer solution, with the bubbles of the foam being stabilized by novel polymers. The final dried material is typically in the form of a sheet (thickness ~ 1 mm, length and width from 1 to 100 cm). The sheet is flexible and robust; it can be rolled up like a paper towel and cut into patches of desired size. When added to water, the gel-sheet absorbs 150 times its weight in water within 30 s, and the swollen sheet can be lifted up by hand.

We expect this type of superabsorbent material to have many applications, one of which is in stopping bleeding from severe wounds. In that regard, our gel-sheet is able to rapidly absorb whole blood – up to 60 times its weight within a minute. Moreover, due to the presence of the polymer stabilizers, the blood tends to remain immobilized in the swollen gel. Data from experiments with bleeding models in animals will be presented.

Late News: 2D Material-Integrated Hydrogels as Multifunctional Protective Skins for Soft Robots Lin Jing and Po-Yen

Chen; National University of Singapore, Singapore

The deployment of soft robotic technologies for rescue and navigation missions are expected to provide safe object-machine interactions and substantially reduce the risks associated with operation staff. Yet, most of the reported soft robots were made of soft matter with insufficient material stability to support normal robotic operations in extreme environments. Installation of conventional protective modules/exoskeletons onto soft robots inevitably compromises their compliant/complex actuations and increases their energy consumption rates. Herein, we developed a set of soft robotic skins composed of two-dimensional materials (2DM) and gelatin hydrogels, featuring with skin-like multifunctionality (including stretchability, thermoregulation, threat protection, strain sensation). The 2DM-integrated hydrogel skins (2DM/H) enabled the protected soft robots to execute designated missions upon exposure to various environmental threats. All 2DM/H robotic skins demonstrated autonomic perspiration behaviors and maintained mild machine temperatures under high heat. By adopting different 2DM units (including graphene oxide (GO), montmorillonite (MMT), titanium carbide (MXene)), the 2DM/H-protected grippers performed soft grasping missions in organic liquids (GO/H), open fire (MMT/H), electromagnetic radiation and biocontamination (MXene/H). Furthermore, through blending MXene into the hydrogel layer, the MXene-blended hydrogel skin (M-H) was strain sensitive and capable of providing piezoresistive signals in real-time. We next applied conformal GO/M-H skin onto a soft gripper, which demonstrated the ultimate integration of skin-mimicking capabilities to handle irregular objects in hot organic liquids. Two demonstrations were finally presented: a dual-bellows walker robot with MMT/H skin performed a vision-guided search mission in an open fire, and a GO/H-protected batoid robot conducted autonomous underwater locomotion/navigation upon serious DCM spills.

8:20 AM F.SM02.04.20
Late News: A Smart Skin for Hydrogels That Regulates the Entry and Exit of Solutes Sai Nikhil Subraveti and Srinivasa Raghavan; University of Maryland, United States

Many applications of hydrogels rely on their ability to deliver encapsulated solutes such as drugs or dyes to an external medium. However, a problem in many such applications is that, the moment the gel is placed in contact with water, the solutes rapidly leak out by diffusion. Ideally, there should be a way to regulate the release of solutes – i.e., to ensure zero release until a desired time, and thereafter, for the release to be 'switched on'. Moreover, it would be even better if this was a repeatable switch, i.e., if the gel could be cycled many times between the on and off states. Such a perfect, cyclical on-off release of contents from hydrogels has never been achieved to our knowledge.

We address this challenge by taking inspiration from structures found in nature such as fruits and vegetables, which have a hydrophobic skin that envelops and protects their water-rich core. We have found a way to synthesize a soft hydrophobic skin around any gel. The initial skin completely prevents hydrophilic solutes from leaking out of the gel into the external solution. The skin is also equipped with redox-responsive properties. That is, in the presence of oxidants, the skin becomes hydrophilic, thereby 'turning on' the release of solutes out of the gel. Conversely, solute release can be 'turned off' at any time by adding a reducing agent that reverts the skin to its hydrophobic state. Thus, our smart skin enables regulated (on-off) release of solutes out of a gel, and this concept is likely to be useful in many applications.

Hydrated Poly(ether urethane) Semi-Interpenetrating Network with High Lubricity and Mechanical Properties Under Physiologically Relevant Loading for Cartilage Replacement Applications Shimon Unterman, Mushtaq Al Zuhairi and Iraklis C. Kourtis; Hyalex Orthopaedics, United States

Orthopaedic biomaterials for use as bearings against cartilage in diarthrodial joints face the dual challenges of being able to withstand high multiaxial loads while minimizing coefficient of friction and wear. High lubricity in aqueous conditions has been achieved with hydrogels such as poly(vinyl alcohol) (PVA), but mechanical properties of these hydrated polymeric networks have typically been inferior to native cartilage. Conversely, high mechanical properties can be achieved with other engineered materials but with increased cartilage wear. This study describes a novel biomimetic hydrated semi-

interpenetrating network (IPN) based on poly(ether urethane) (PEU) that was previously implanted in a rabbit cartilage repair model[1]. The frictional and mechanical properties compare favorably with native cartilage.

A tunable semi-IPN of PEU and a cross-linked polyelectrolyte network was synthesized. Similar to proteoglycans in hyaline cartilage, the polyelectrolyte caused the semi-IPN to swell in water, imparting the high lubricity of a hydrophilic polymer network, while the PEU imparted high stiffness and strength, resembling the collagen type II of cartilage. Upon completion of synthesis, the semi-IPN was a translucent, highly hydrated, qualitatively slippery material. The semi-IPN passed standard ISO 10993 biocompatibility testing.

The semi-IPN was evaluated for coefficient of friction (COF) using a pin-on-disk friction tester with ~1 MPa normal loading in aqueous conditions against a fused silica counterface, yielding a COF of < 0.05; typical cartilage COFs have been reported as <0.01-0.04[2]. The mechanical properties were measured in tension, compression, tear, and shear in physiologically relevant conditions (simulated body fluid at 37° C) and compared to known properties of articular cartilage and PVA orthopaedic hydrogels. Compressive and tensile moduli at physiologic loads were > 40 MPa, stiffer than PVA orthopaedic hydrogels[4] and considerably closer to the modulus of cartilage[3] than traditional joint replacement materials like ultra-high molecular weight polyethylene (UHMWPE) and cobalt chrome alloys (CoCr). Tensile strength was > 30 MPa (cartilage: 3.75 MPa[5]), tear strength was > 40 N/mm (cartilage: 1.21 N/mm[6]), shear strength was > 20 MPa (cartilage: 7.25 MPa[5]), and the material did not fail in the measured compression range (>180 MPa; cartilage: 35.7 MPa[7]). By design the material strength exceeded that of native cartilage, in order to ensure long term performance without adversely impacting adjacent or opposing cartilage.

Hydrated semi-IPNs based on PEU and a polyelectrolyte network offer an attractive combination of mechanical strength, stiffness, and lubricity under physiologic loads. The semi-IPN properties, which closely mimic or exceed the high strength and low friction of native cartilage, provide a promising and novel platform for cartilage replacement applications.

An Investigation of Timolol Introduction on Three Hydrogel-Based Drug Delivery Devices for Glaucoma Treatment Nicole Mortensen and Jeffrey S. Bates; The University of Utah, United States

Contact lenses can be used as drug delivery systems because they are cross-linked, water-soluble, biocompatible hydrogels. Glaucoma is the second largest cause of blindness worldwide that increases the interocular pressure (IOP) of the eye. Topical eye drops of timolol is a common treatment that lowers IOP. The number of patients who become bilaterally blind every year is high due to the inefficiencies of eye drops and low patient adherence. In this study, three hydrogel-based contact lenses were analyzed on their uptake and release concentrations, reversibility, drug concentration profile over 12 hours, as well as their optical and mechanical properties. Synthesized molecular imprinted and soaked, non-imprinted, hydroxyethyl methacrylate (HEMA) based hydrogels resulted in having an uptake and release concentration dependent on the loading solution concentration it was left to soak in. Soaking Acuvue contact lenses resulted in having an uptake and release concentration independent of the timolol loading solution concentration. It released significantly higher concentrations than a daily dosage of timolol. All three hydrogel-based contact lenses successfully delivered timolol for 12 hours and could be reused up to six times. The synthesized HEMA hydrogels lacked in optical and mechanical properties that were to ensure comfort and prevent vision problems when used as a contact lens. As a result, further optimization is needed. Using contact lenses to deliver glaucoma medication has the potential to become a more efficient method of treatment that will increase patient adherence by eliminating barriers within glaucoma therapy created by eye drop medication.

Versatile 3D Printing of Hydrogels by Pluronic Kusuma Betha Cahaya Imani and Jinhwan Yoon; Pusan National University, Korea (the Republic of)

In recent years, there's an increase of study regarding 3D printing of soft materials, because of its importance for development of new technologies such as wearable electronic devices and artificial human organs, which require both non-

rigid property and precise positioning. For 3D printing of soft materials study, it is required to choose a material which has enough viscosity but also can be easily extruded without clogging, and for that, pluronic is one of the most widely used materials. Pluronic is a thermo-responsive triblock copolymers consisting of poly(propylene oxide) (PPO) and poly(ethylene oxide) (PEO), as the hydrophobic center and hydrophilic side blocks respectively. This structure allows pluronic to form spherical micelles above its critical micelle temperature (CMT) within aqueous solution, which is suitable for 3D printing. Upon deposition on a substrate, by controlling the extruder and bath, pluronic can quickly change its phase, preventing the ink from flowing out of the intended position and retaining the desired 3D shape. In this study, pluronic F127 ($(PEO)_{99}$-$(PPO)_{65}$-$(PEO)_{99}$) is synthesized into pluronic F-dimethacrylate (FDMA) to prepare hydrogels for extrusion-based 3D printing. This work can be further developed to have 3D printed hydrogels with conductive property or controllable elastic modulus. The synthesis of FDMA is simple and it has the prospect for applications in various fields.

F.SM02.05.07

The Effect of Fibrin on the Osteogenic Differentiation of Human Dental Pulp Stem Cells Kao Li[1], Evan Cheng[2], Tianjian Bai[3], Jake D. Feldman[4], Alyssa Kim[5] and Juyi Li[1]; [1]Stony Brook University, The State University of New York, United States; [2]Syosset High School, United States; [3]Huron High School, United States; [4]Plainview-Old Bethpage John F. Kennedy High School, United States; [5]New Hyde Park Memorial High School, United States

In addition to having non-toxic degradation products, being cytocompatible, and causing the formation of an extracellular matrix, fibrin, a major plasma protein, has been found to be highly suitable in supporting dental tissue formation and improving cell-dentin interactions[1]. This study sought to determine the effects of fibrin on the proliferation and differentiation of dental pulp stem cells, DPSCs, an investigation with potential applications in osteogenic regenerative therapy. Prior studies for in-vitro cultures of DPSCs directly on fibrin clots failed due to rapid fibrinolysis of the substrates prior to differentiation. Here we demonstrate the construction of a gelatin/fibrin scaffold, which is not enzymatically degraded at least during the 28 days required for DPSC differentiation. Furthermore, since gelatin is easily bioprinted it also offers an effective scaffold for fibrinogen, which is then rapidly cross-linked after extrusion, maintaining its shape. Gelatin-fibrinogen hydrogels were created using 9% w/v gelatin and 4 mg/mL bovine fibrinogen cross-linked by 2 different concentration of mTG (microbial transglutaminase) and 2units/ml thrombin, respectively. The gels were media exchanged and cells were cultured in osteogenic media, but without dexamethasone, the standard inducer of osteogenic differentiation. On Days 8 and 28, confocal microscopy indicated that strong tissue formation was occurring on both substrates. RT-PCR was performed at day 8 and 28 to measure the upregulation of genes associated with differentiation; ALP, COL1, and OCN. Even though this set of genes was upregulated on all samples, relative to cells plated on TCP controls, the levels for ALP and OCN for cells plated on the for gelatin-fibrinogen mixture were two and three times higher, respectively, than those for cells plated on pure gelatin confirming the regenerative potential of fibrin clots.

Dual-Network Hydrogels Reinforced with Field-Responsive Hydroxyapatite Exhibiting High Strength and Stiffness While Fully Hydrated Morgan Pfaff and Jessica Faust; Northeastern University, United States

Modern medicine is seeking stronger composite materials for artificial bone graft applications that are both osteoconductive and exhibit high strength. Alginate-calcium phosphate (CaP) hydrogels have been studied as a potential material, but lack the strength required for artificial bone grafts. Here, we suggest using an alginate-gelatin dual-network embedded with magnetically-aligned CaP rods to significantly increase the overall strength of the material. CaP rods were prepared through hydrothermal precipitation and functionalized with iron oxide nanoparticles. These rods were incorporated into uncrosslinked dual-network solution and aligned under a magnetic field with constant heat and vibration. After alignment, the gelatin was thermally crosslinked at room temperature and the alginate ionically crosslinked in 10% calcium chloride solution. Tensile samples were analyzed using dynamic mechanical analysis. Preliminary results show superior mechanical strength in the dual network films compared to alginate- and gelatin-only hydrogels. The mechanical strength is further increased with higher concentrations of CaP rods. Alignment orientation also impacts hydrogel mechanics, with parallel alignment providing greatest strength and perpendicular alignment the greatest elasticity. The results of this study indicate that an osteoconductive alginate-gelatin hydrogel with high strength is possible with magnetically-aligned reinforcement and is a promising material for bone graft applications.

Thermo-Responsive Artificial Perspiration Membrane Jeong Hun Kim[1], Junsoo Kim[1], Solyee Im[1], Sang Moon Kim[2], Jong Pil Im[1], Jiyong Woo[1] and Seung Eon Moon[1]; [1]Electronics and Telecommunications Research Institute, Korea (the Republic of); [2]Incheon National University, Korea (the Republic of)

Thermal management is essential for living organisms and electronic devices to survive and maintain their functions. However, it has been challenging to develop a flexible cooling devices for flexible electronics or biological systems because conventional coolers are bulky and require rigid batteries. In nature, however, the skin helps to maintain the body temperature constantly by dissipating the heat through the perspiration. Inspired by nature, we introduce an artificial perspiration membrane which automatically regulates evaporation rate at water-air interface depending on temperature. This membrane consists of a valve structure and a rigid frame; the valve is made of silicone-coated thermo-responsive hydrogels and the frame is made of plastics. Those two components are stably bonded by copolymerization. By designing the shape of the valve and the mechanical constraint, we were able to control the area where evaporation occurs depending on temperature. As a result, the valves in the membrane open in a hot environment, which facilitates the evaporation of water, and the valves close in a cool environment, which suppresses the evaporation of water, mimicking cooling function of perspiration in a flexible manner. Our work shows the potential value of a bio-inspired, membrane-type, and automatic cooling device that can solve heat problems in artificial skin devices.
The thermo-responsive hydrogel is patterned with pinwheel-like shape and supported by backbone through copolymerizing at the interface to control the evaporation area depending on the temperature. The stretchable rubber is selectively coated to prevent the unintended evaporation through the hydrogel while securing the water path for swelling. Consequently, the water surface at open state is about 6 times greater than that of close state with fast transition rate (~1 s). The evaporation rate is automatically controlled depending on the temperature with 30% of evaporation reduction at lower temperature. Our study on a smart membrane that can automatically regulate cooling power without external power source may solve thermal problems in wearable or artificial skin devices.

Enhancing Osteogenic Differentiation of Mesenchymal Stem Cells Using Injectable Microporous Hydrogel Seth Edwards and Kyung Jae Jeong; University of New Hampshire, United States

Mesenchymal stem cell (MSC) delivery and subsequent differentiation into bone forming cells has promising implications for the future of bone repair. Use of hydrogel as a delivery vehicle is advantageous in order to enhance cell retention, and provide a scaffold to facilitate new bone growth. Here we describe a microporous injectable hydrogel for encapsulation of MSCs with the intent to improve proliferation and subsequent osteogenic differentiation. Physically crosslinked microgels are formed by thermal crosslinking of gelatin in a water in oil emulsion. Bulk scaffold formation involves chemical crosslinking of gelatin by nontoxic enzymatic reaction. Enzymatic crosslinking of gelatin provides prolonged strengthening of the bulk gel, and provides a covalent mechanism for tissue adhesion. A hydrated suspension of microgels and cells can be injected for noninvasive cell delivery, and the scaffold can crosslink *in situ*, encapsulating delivered cells in the pore space. This hydrogel provides an advantageous environment for MSC growth and differentiation due to the large interstitial space between microgels, which improved cell spreading and proliferation when examined by confocal microscopy, and improved osteogenic differentiation when examined using alizarin red S stain and high resolution micro computed tomography.

F.SM02.05.12
A Smart LEA for Dynamic Adjustments to Brain Aneurysm Embolization and Healing* Juyi Li[1], Robert Wong[1], Aaron Slutsky[2], Daniel Cohn[2], Chandramouli Sadasivan[1], Anya Chabria[3], Jessica Guo[4], Varun Nimmagadda[5], Tyler Shern[6], Stephanie Tarrab[7], Jeffrey Zhang[8], Emily Zhou[9], Jeffrey Huang[10], Ikshu Pandey[11] and Miriam H. Rafailovich[1]; [1]Stony Brook University, The State University of New York, United States; [2]The Hebrew University of Jerusalem, Israel; [3]The Wheatley School, United States; [4]Ward Melville High School, United States; [5]Novi High School, United States; [6]Mission San Jose High School, United States; [7]Yeshivah of Flatbush Joel Braverman High School, United States; [8]Centerville High School, United States; [9]The Harker School, United States; [10]University of Pennsylvania, United States; [11]Johns Hopkins University, United States

Brain aneurysms are focal, pathological dilations that mostly form at branch points of the cerebral vasculature. These weak-wall structures can rupture leading to hemorrhagic stroke with mortality and morbidity rates as high as 40% and 25%, respectively. More than 60% of aneurysms are currently treated with minimally invasive endovascular/interventional methods. Most of these methods involve the permanent implantation of metallic devices such as intrasaccular coils and meshes or endovascular flow diversion. These implants reduce blood flow velocity within the aneurysm and thus promote clot formation within the aneurysmal sac, which is converted to fibrous tissue over a period of several months. However, current devices show unfavorable primary outcomes in 20% to 30% of cases on average and success rates are substantially lower depending on aneurysm type and location. In this project, we discuss the development of an injectable, multi-functional, reverse thermo-responsive, in situ cross-linkable, shape-conforming, intrasaccular porous scaffold. This scaffold changes dynamically to enhance the associated wound healing process which follows obduration. The scaffold is engineered to work with the natural blood flow and promotes vascular remodeling and endothelialization followed by personalized

biodegradation, at the end of the process, leaving no residue behind. This research program harnesses the unique behavior of a family of reverse thermo-responsive (RTR) polymers to generate a novel Biodegradable Intrasaccular Polymeric Device, displaying enhanced clinical performance. The aqueous solutions of these polymers display low viscosity at infa-physiological temperatures and are gels at 37 degrees. The device is an easily syringable, low viscosity multi-component aqueous solution comprising: [a] a cross-linkable RTR component that forms a robust and homogenously porous scaffold for controlled intrasaccular thrombosis, [b] a leachable RTR-displaying component acting as the porogen, [c] an iodine-rich radiopaque agent, [d] a polymerizable (RGD)-containing oligopeptide that will *in situ* co-polymerize with the other components, aimed at accelerating the generation of an endothelial cell layer at the aneurysm neck, [e] inclusion of basic Fibroblast Growth Factor (bFGF) in the cross-linked component to promote thrombus organization and intrasaccular fibrosis/remodeling, and [f] a cross-linkable oligopeptide containing the matrix metalloprotease (MMP)- degradable leucine-glycine motif that will be *in situ* co-crosslinked with the RTR components, to impart to the polymer device to degrade in a personalized, patient-specific manner, as a function of the healing process. This process represents a major step in treatment of aneurysms, which shortens optimize brain aneurysm treatment with short procedure times, require no chronic anti-platelet medications, promote endothelialization of the parent-vessel interface, enhance aneurysm 'sac' fibrosis, and degrade in a patient-specific manner to leave no trace of the pathology or the treatment, with lower costs.

Late News: Using Coarse-Grained Molecular Dynamics to Model Hydrogel Viscosity Kyle R. Shi[1], Hannah Even[2], Shoumik Saha[3] and Dilip Gersappe[3]; [1]Dublin High School, United States; [2]Staples High School, United States; [3]Stony Brook University, The State University of New York, United States

Hydrogels are systems of hydrophilic polymers that swell when placed in a solvent to form a gel-like structure. When nanocomposites are added to hydrogels, they can enhance their properties by crosslinking the polymers. Hydrogels have shown promise as an environmentally friendly substitute to cement as soil stabilizers, mechanically improving the strength of the soil. While past studies have found a positive relationship between clay nanocomposite concentration and hydrogel viscosity with a qualitative stress-autocorrelation function, specific mechanical properties and structure formation of these hydrogels remain unknown. Our research aims to learn more about the properties of hydrogels with rigid rod-shaped clay nanocomposites and explore the possibility of determining more quantitative trends on viscosity by simulating shear stress on the hydrogel system, imitating realistic soil movement on the hydrogels. We performed Molecular Dynamics simulations in order to understand the rheological properties of hydrogels. The concentration of the nanocomposite and the shear rate were varied and different polymer-nanocomposite interaction energies were used in order to determine the effects of these factors on the viscosity of hydrogels. The results show a clear shear thinning behavior in these systems and reflect similar trends to previous studies. Our results can be used to predict an optimum hydrogel composition in different conditions for soil stability.

We gratefully acknowledge support from the Louis Morin Charitable Trust.

Late News: Optically Active Nanoengineered Fibrous Scaffolds for Cardiac Cell Monitoring Stijn Jooken[1], Olivier Deschaume[1], Olga Krylychkina[2], Yovan de Coene[1], Thierry Verbiest[1], Koen Clays[1], Geert Callewaert[3] and Carmen Bartic[1]; [1]KU Leuven, Belgium; [2]imec, Belgium; [3]KU Leuven KULAK, Belgium

In cardiac tissue engineering the incorporation of nanoparticles (NPs) such as plasmonic NPs, carbon nanotubes or magnetic particles was shown to improve the function of in vitro cardiac patches in terms of cell viability, electrical signal coupling, beat synchronicity, etc. [1,2]. Moreover, it has also allowed to locally deliver stimuli to cells and guide cell behavior, for instance, by heating of plasmonic NPs[3].

In this work, we created a smart scaffold capable of optically reporting cardiomyocyte activity *in situ* (electrical and contractile) by incorporating voltage-sensitive semiconductor quantum dots (QDs) in 2D scaffolds and 3D hydrogels.

We have characterized the fluorescence voltage sensitivity of Type I CdSe/ZnS QDs and pseudo-Type II CdSe/CdS rods, investigated in a controlled environment, under single and two photon optical excitation. Then, QDs were incorporated in 2D scaffolds of collagen nanofibers and used two-photon fluorescence microscopy to readout of the activity of cultured primary cardiomyocytes [4]. The method was validated in a pharmacological assay where the drugs epinephrine and blebbistatin were used for their combined chronotropic and inotropic effects. Finally, the concept is extended to 3D by incorporating QD-labeled collagen fibers in 3D hydrogel constructs.

Late News: Gelation-Based Naked-Eye Detection of Glucose via Dual-Enzyme Cascade Reaction Jisoo Lee and Seonki Hong; DGIST, Korea (the Republic of)

Many efforts have been conducted to develop bioassays in point-of-care settings for rapid and convenient biomarker detection. Among them, the colorimetric-based system has been emerging due to the advantages in simple read-out through the naked-eye without requiring any expensive devices. However, it has still been challenging to simplify the labor-intensive multiple steps required to improve the limit of detection and remove the background color which may interfere with the detection signal.
Herein, we report a gelation-based bioassay mediated by a cascade reaction of two enzymes. We reasoned that biomarker-specific gelation can provide a detectable signal through the naked-eye even in the presence of the background color biospecimens such as blood and urine. Gelation is triggered by the quinone tanning reaction of catechol-conjugated polyethylene glycols via horseradish peroxidase (HRP) in the presence of hydrogen peroxide (H_2O_2). Therefore, we coupled another enzyme, glucose oxidase (GOx), that produces the H_2O_2 depending on the concentration of glucose to initiate the HRP-mediated gelation.
In our system, parameters adjusting the gelation time include the concentration of enzymes (HRP and GOx), catechol content conjugated to the polymeric precursor, the concentration of polymeric precursor, and the pH. In the experiment using H_2O_2 as a positive control to glucose/GOx system, the gelation time dramatically decreased down to 1 minute as the HRP concentration increased up to 1 U/mL. In the HRP/GOx dual-enzyme system, 0.25 U/mL of HRP was sufficient to achieve successful gelation within 80 minutes with 10-100 U/mL of GOx in the presence of 10 mM glucose. The best conditions of other parameters for the fastest gelation were observed at 83% of catechol content, 5wt% of the precursor, and pH 7. Finally, as low as 16 mM of glucose was detectable through the naked-eye within 20 minutes of gelation time.
With the advantage of the cascade reaction of two enzymes, we expect improvement in the detection sensitivity. In addition, single-step glucose detection is allowed without requiring washing steps due to the enzymes' intrinsic specificity.

F.SM02.05.16
Late News: A Clock-Like Hydrogel That Visually Indicates Time So Hyun Ahn, Srinivasa Raghavan and William E. Bentley; University of Maryland, United States

Microcapsules can be used to monitor the local micro-environment *in vivo*, e.g., within the gastro-intestinal (GI) tract. For example, when molecular signals are released into the GI, the payload within the microcapsules could undergo a color change in response to the signal. While the nature of the signal is often the key piece of information in such experiments, the *time* at which the signal is released could be another vital aspect. To obtain information regarding time, there is the need for a gel-like material that could function like a 'clock' – i.e., exhibit systematic changes at regular time intervals.

Here, we report a simple 'clock' construct based on self-destructing structures embedded in an agarose gel. For this, we fabricate capsules of alginate crosslinked by Ca^{2+} and containing the enzyme alginate lyase. This enzyme severs alginate chains, thereby causing the capsule to degrade over a period of time. The higher the enzyme concentration, the lower the degradation time. Capsules with different concentrations of enzyme are embedded in an agarose gel to create our 'clock'. Capsule degradation proceeds in a sequential manner, and visual inspection of the gel (i.e., the capsules that remain intact) reveals the time elapsed from the start of the experiment. To facilitate visual clarity, we embed colored or fluorescent

nanoparticles in each of the capsules. Moreover, the degradation rate can be varied using pH, temperature, and other variables that affect the enzymatic activity. Variations of the above simple clock include: (a) one that is activated by an external trigger; and (b) one that locks-in the elapsed time at a particular juncture.

5:00 AM *F.SM03.01.01
Soft Electrically-Driven Actuators for Wearable Haptics Herbert R. Shea; Ecole Polytechnique Federale de Lausanne, Switzerland, Switzerland

For virtual reality (VR) to be truly immersive, the sense of touch must be stimulated: a tennis ball should feel light and rubbery, a wall must be impenetrable, a lightswitch must click when pressed. Why don't we have haptic suits with thousands of individual actuators (taxels) when every smartphone display has millions of individually addressed pixels? Generating localized forces on the human body in a comfortable and safe way is a major challenge for soft actuation: both fast motion and high forces are needed, yet the device must conform to the human body, and consume low power.
I will present some approaches developed in my lab for flexible actuators combining high strain and high force, operating at high speed, and that do not rely on external compressed air or vacuum supplies. Due to its high energy density, we have focused on electrostatic actuation, using high electric fields to deform elastomers or textile structures.
For kinesthetic feedback, which can be described as controlling the motion of joint, we have focused on textile-based brakes, only 1 mm thick, that can block the motion of two sliding strips in a few milliseconds[1]. By coating conductive textile strips with high permittivity dielectrics, we developed a clutch that blocks up to 20 N pulling force per square centimeter of active region, for a power consumption of under 2 mW. We integrated these clutches into thin gloves. Users wearing them are much more accurate when manipulating virtual objects and feel deeper immersion. We will report a new fabrication method allowing for even higher forces for use in full-body kinesthetic haptics, blocking shoulder and elbow motion to allow feeling virtual objects as being heavy, and virtual tables as blocking hand motion.
Cutaneous feedback requires dense arrays of actuators to locally stimulate to skin to provide the illusion of touching an

object. We use our fingers to identify objects by sliding our fingertips over them, and we know if a glass is about to slip out of our hand by sensing shear forces. Simulate this in VR requires being able to generate normal and shear forces with high spatial resolution. We have developed arrays of sub-mm thick flexible actuators that generate over 60% strain and operate at over 300 Hz. A 6 mm diameter actuator generates 300 mN normal force and 500 µm displacement. This is achieved using fluidically coupled electrostatic zipping and a combination of flexible polymers with high breakdown field and silicone elastomers that allow for high displacement[2]. We have made 5x5 arrays, mounted them directly on the arm and on consumer products, and report on user feedback for notification, control and navigation.
By use of thin dielectrics, high permittivity films, and low stiffness electrodes, we have reduced the drive voltage of Dielectric Elastomer Actuators (DEAs) to 400 V, a level at which we can use SMD components for compact control electronics[3]. We report "feel-through" untethered cutaneous haptics, with DEA actuators only 18 µm thick, so thin the user does not feel them mounted on his or her fingertip when they are off. However, when the 3 mm diameter devices are turned on, the user feels localized pulsation that allows receiving rich haptic information.
I will close by going over the challenge of integrating these technologies in a glove or suit, and the promise of this field.

5:30 AM F.SM03.01.02
Scaling of Hydraulically Amplified Electrostatic Zipping Actuators (HAXELs) Edouard Leroy and Herbert R. Shea; École Polytechnique Fédérale de Lausanne, Switzerland

Haptic interfaces for virtual reality (VR) or augmented reality (AR) require dense arrays of actuators to provide realistic feedback to the user. These actuators must be fast (<20 ms), generate large static forces (>100 mN) and displacements (>300 µm) while being easy to integrate in lightweight, comfortable interfaces. The actuator mechanical compliance should be close to that of skin. Conventional actuation technologies such as electromagnetic, piezoelectric or pneumatic either provide only vibratory feedback or are difficult to integrate in low-profile interfaces. Flexible electrostatic actuators such as our HAXEL devices offer effective solutions to these challenges.
HAXELs are hydraulically amplified zipping electrostatic actuators, less than one millimeter in thickness, designed for integration into textile-based haptic interfaces for VR or AR scenarios. In previous work [1], we reported 6 mm x 6 mm HAXEL actuators that can produce up to 300 mN force and 500 µm displacement (i.e. 60% strain). We report here the modeling and experimental results on scaling HAXELS down to 3 mm and up to 50 mm diameter, for applications in wearable haptics and in soft robotics.
Each HAXEL consists of a fluid-filled cavity whose shell is made of a non-stretchable polymer in the outer regions and of a stretchable elastomer for the central region. Electrodes are patterned in both top and bottom polymer shells. When a voltage is applied to the annular electrodes, they are pulled together by Maxwell pressure, starting to zip at the outer regions where the electric field is highest. As the top and bottom polymer regions are pulled together, the fluid is rapidly forced into the stretchable region, forming a raised bump. To obtain high power density (>100 W/kg), we use high permittivity layers based on PVDF terpolymers.
These actuators can easily be felt by users and provide both normal force and shear force by using segmented electrodes to drive the fluid in-plane. Using a flexible 5x5 matrix of HAXELs, users can obtain information about the location and texture of a virtual object. HAXELs could lead to lightweight and comfortable gloves, sleeves or full-body suits delivering realistic haptic feedback.
Different locations on our bodies have different sensitivity thresholds for feeling force and displacement, and different pitch discrimination. On fingertips we can feel pins 0.8 mm apart, while on our back the distance is roughly 5 mm. It is necessary to adapt the size of the taxels to body location and to the targeted VR application.
The force and displacement characteristics of HAXELs from 3 mm x 3 mm up to 50 mm x 50 mm are discussed and compared to a finite element model that accounts for coupled electrostatics and mechanics using nonlinear material models. Both static and dynamic characteristics are studied as they are equally important for haptic feedback. The measured static displacements range from 100 µm to several mm while the forces range from tens of mN to over 1 N. Good agreement between the model and the experiment is shown, validating the finite element model as a tool for future designs. Optimized electrode shape, cavity shape and effect of materials choice on actuation voltage and generated force, displacement and device dynamics are presented.
Although HAXEL actuators were initially designed for haptics, they can find applications in other areas such as microfluidics

as dense arrays of valves or to rapidly reconfigure channels, and for soft robotic as matrices of high force actuators for locomotion or grasping.

5:45 AM F.SM03.01.04
A Dynamic Electrically-Driven Soft Valve for the Control of Mesoscale Fluidic Flows Siyi Xu[1], Yufeng Chen[2], Nak-Seung Patrick Hyun[1] and Robert Wood[1]; [1]Harvard University, United States; [2]Massachusetts Institute of Technology, United States

Soft valves for hydraulic actuators that based on meso-scale channels have been designed in various forms, primarily fluid-driven or electrically-driven, with promise for the control of soft robots. Fluid-driven valves are often tethered to external pressure sources that limit, for example, robot locomotion. Electrically-driven valves based on electrostatic forces exhibit a large hysteresis and slow response times. In our work, we present a dynamic electrically-driven soft valve made of ultra high power density dielectric elastomer actuators (DEAs). These dynamic DEAs are actuated at 200Hz or above, with low damping ($\tan(\delta) < 0.34$ at 100Hz) and a short response time (in less than 10 milliseconds). Dynamic actuation produces 300% greater blocked force compared to quasi-static operation with the same DEAs due to higher driving voltages and greater than five times increase in free displacement at the actuator resonance. The channel, on the contrary, is cast with a dissipative material. The viscoelasticity difference between the actuator and the channel materials makes it possible to achieve both pressure and flow control with the dynamic DEAs. The valve performance can be tuned by the input voltage, the driving frequency, and the active area of the DEAs. This dynamic electrically-driven soft valve, as a component of a soft fluidic robot, enables effective control of 1.5psi flow pressure in soft channels. The novel dynamic design represents a substantial performance improvement over existing quasi-steady DEA valves, and will enable effective control of future meso-scale hydraulic robots.

6:00 AM *F.SM03.01.05
fMRI-Compatible Force Controlled Robots and Their Application in Motor Neuroscience Fabrizio Sergi; University of Delaware, United States

Can we use robots to help humans learn a new motor skill, or to improve performance of a motor task? If so, what are the neural substrates that enable humans to improve motor skill learning or execution when they interact physically with external agents? These are fundamental motor neuroscience questions, which have or will have special relevance in multiple domains, such as human augmentation, surgical training, athletics, and neurorehabilitation. In this talk, I will present the development of methods that can help address these questions, which combine MRI-compatible robotics with functional neuroimaging and advanced biosignal processing, and will present two applications of these methods in fundamental motor neuroscience research.

Over the past years, my lab has developed a new class of MRI-compatible robots that can be used in conjunction with functional Magnetic Resonance Imaging to study the neural substrates involved in the neural control of movements during physical interaction with external agents. Specifically, I will present two systems, the MR-SoftWrist, a 2 DOF wrist exoskeleton capable of force feedback designed to study neural substrates involved in the control of wrist movements during externally imposed forces, and the MR-StretchWrist, a 1DOF wrist robot designed to apply velocity-controlled perturbations to the wrist to condition stretch reflexes and study their neural correlates using fMRI.

The development of these robots is complicated by the magnetic fields of MRI, which pose challenges from the standpoint of materials selection for robot components, electrodes for measuring biosignals associated with motor tasks, as well as biosignal processing. To achieve MRI-compatibility, our current solution is to include piezoelectric ultrasonic motors for actuators, shielding and filtering of sensor signals, and use non-magnetic metal for all robot parts. However, because piezoelectric motors are intrinsically high-impedance actuators, we have developed custom solutions based on series elastic actuation and nonlinear passivity-based force control for reducing actuator impedance. Moreover, we have recently developed a novel method for measuring artifact-free electromyographic signals during MRI which enables for the first time collection of biosignals during arm movements under fMRI using a novel set of electrodes and nonlinear interference estimation algorithms. Validation experiments demonstrate that the biosignals measured during MRI are not significantly different than those measured in normal lab conditions.

In this talk, I will also present the application of MRI-compatible robots to establish the neural correlates involved in the neural control of movements. In one experiment, we exposed 30 healthy individuals to lateral force perturbations during

point-to-point wrist movements to elicit adaptation to this condition. By analyzing resting state fMRI data measured before and after motor execution and before and after adaptation, we were able to identify areas involved in creating and processing the memory related to movement execution under force perturbations. In a second experiment, we used the MR-StretchWrist to apply perturbations to the wrist along the flexion/extension axes and condition long-latency responses. Long-latency responses are interesting components of motor control because they gracefully blend fast reaction times of spinal reflexes with sophisticated modulation capabilities of voluntary control. In our first experiment with the MR-StretchWrist, we were able to determine the somatotopic organization of long-latency responses of flexor and extensor muscles in the brainstem for the first time in-vivo in humans. The observed organization is partially consistent with animal models, with activity primarily in the ipsilateral medulla for flexors and in the contralateral pons for extensors, but also include other areas, such as the midbrain and bilateral pontomedullary contributions.

6:30 AM F.SM03.01.06
Electroactive Artificial Muscles Actuators for Human-Machine Interaction and Soft Robotics Maduran Palaniswamy, Shardul Panwar, Ty Ebling, Max Herzog, Erin Rutledge and Michael P. Rowe; Toyota Research Institute of North America, United States

Electroactive artificial muscles have been a scientific novelty soft actuator for many years, but of little practical use because they lack substantial force output or large-enough displacement. Significant advancements in constituent materials, actuator design and assembly of component artificial muscles for devices have now allowed the transition of this interesting technology into actual consideration for real-world applications in haptics, human-machine interactions and soft robotics. The electroactive artificial muscles discussed here are, fundamentally, flexible capacitors that give a mechanical response when an electrical potential is applied to them. As with any capacitor, greater force is expressed with an inverse squared relationship to the thickness of the electrical insulation used to space the positive and negative electrodes. As insulation thickness is reduced, output force from the artificial muscle is increased. We have determined that particular acrylic polymer blends exhibit an impressively high resistance to electrical breakdown per-micron-thickness of material in these systems, when compared to other polymers including: polypropylenes, polyesters, polyimides and silicone polymers. Electrical insulation polymer optimization was found to be able to reduce electrode spacing by x4, which can manifest in up to a x16 increase in force. It was found that this increased force is lost if the artificial muscle stiffness is not tuned correctly. Too much stiffness immobilizes the muscle whereas a lower value would result in the muscle not able to transfer the elevated force being generated. This optimization was accomplished through specific layering of biaxially oriented polypropylene (BOPP). With these marked material improvements, forces of nearly 7N were generated for 0.5mm of displacement from an artificial muscle that is only ~350 microns thick in a resting state are achieved. A single stack of artificial muscles is rarely capable of generating the necessary force for real-world applications. The exceptional artificial muscles discussed here are uniquely capable of functioning by arranging the individual artificial muscles are arranged in an overlapping closest-packed tessellated pattern. This original system-level optimization still further improves artificial muscle force output by an additional x4; setting these original ensembles of artificial muscles apart from related technology in the field of soft robotics research. These flexible actuators hold the promise to proliferate the automotive industry and beyond for haptics in general because they are light weight, quiet, compliant, thin, simple to implement and new.

F-SM03

5:00 AM *F.SM03.02.01
Liquid Metal Architectures for Wearable Energy Harvesting and Storage Carmel Majidi; Carnegie Mellon University, United States

Wearable technologies for human-machine interaction (HMI) require on-board sources of energy to power sensors for tactile or physiological monitoring, actuators for haptic feedback, and electronics for signal processing and communication. For many emerging haptic/HMI applications, miniature battery technologies (e.g. coin cells, LiPo) are inadequate – operation over sustained durations instead depends on larger batteries or methods of harvesting energy from the body or environment. However, in order to be compatible with the human body, such energy storage and harvesting systems should be soft and stretchable so that they can deform with the surrounding tissue and not impair natural motion.

In this talk, I will highlight progress in creating soft, highly stretchable batteries and energy harvesting devices using liquid metal (LM) alloys. Eutectic gallium indium (EGaIn) is selected as the LM alloy due to its enabling combination of high electrical conductivity and fluidic deformability. In particular, I will focus on the following LM architectures: (i) soft-matter batteries composed of EGaIn and ionic gel that can be stretched to >300% strain; (ii) LM-polymer composites for thermoelectric and triboelectric energy harvesting; and (iii) dielectric elastomer generators composed of an LM-polymer dielectric and thin-film EGaIn coating. To demonstrate their potential role in future haptics/HMI, I will present examples of how these LM-based technologies are used for powering wearable sensors and electronics.

5:30 AM F.SM03.02.02
Liquid Metal-Based Strain-Insensitive Conductors for Stretchable Electronic Circuits Shanliangzi Liu[1,2], Dylan Shah[2] and Rebecca Kramer-Bottiglio[2]; [1]Purdue University, United States; [2]Yale University, United States

Gallium-based liquid metals have shown great potential in applications such as soft and stretchable electronics due to their high conductivity and intrinsic softness. However, liquid metal-based bulk conductors are typically sensitive to strain and therefore not be suitable for stretchable interconnects. Additionally, reliably interfacing liquid metal with conventional, rigid electronics often requires cumbersome fabrication processes. In this work, we present a liquid metal-based biphasic conductor with high conductivity, extreme stretchability (>1000%), negligible resistance change when strained, cyclic stability, and a reliable interface with rigid electronics. The biphasic material is a mixture of liquid metal and crystalline solids, which are produced by thermally processing liquid metal particles. We use a scalable transfer-printing process to create various multilayer circuit board assemblies that maintain their performance when stretched. This technique enables facile and direct conversion of existing PCB designs into soft and stretchable forms for applications in soft robotics and wearable devices.

5:45 AM *F.SM03.02.03
Conductive Polymers as Electro-Active Materials for Haptics Laure V. Kayser; University of Delaware, United States

Conductive polymers have been extensively used as flexible and transparent alternatives to inorganic conductors in transistors, light-emitting diodes, and solar cells. These “classic” applications, however, do not take advantage of some of the unique features of conductive polymers such as their ionic conductivity and our ability to tune their physical and mechanical properties via chemical modification. These features really shine in the developing area of bioelectronics: the interface between electronic materials and devices, and biological systems. In particular, I will highlight in this talk our efforts in using conductive polymers for haptics, to study or stimulate the human sense of touch.
The most widely-used conductive polymer is doped poly(3,4-ethylenedioxythiophene) (PEDOT), commercially available in water as a polyelectrolyte complex with poly(styrene sulfonate) (PSS). PEDOT:PSS, however, often requires the use of additives to modify its electronic and mechanical properties leading to potentially unstable and unsafe materials. Instead, we are using PSS copolymers to modify the intrinsic properties of PEDOT:PSS without additives. In particular, we have synthesized stretchable conductive polymers which served as electro-tactile materials to simulate rough and smooth surfaces in virtual reality. I will also share our preliminary research in the development of PEDOT:PSS conductive copolymers that can dynamically change their mechanical properties under applied voltages: electro-active actuators.

6:15 AM F.SM03.02.04
Designing Magnetorheological Fluids with 2D Materials for Soft Robotics Abigail L. Rendos[1], Kevin McDonald[1], Ran Li[1], Stephanie Woodman[1,2], Xi Ling[1], Tommaso Ranzani[1] and Keith A. Brown[1]; [1]Boston University, United States; [2]Yale, United States

Smart fluids are suspensions of functional particles in which an applied field drastically changes the fluid’s properties. For example, magnetic microparticles in solution can form magnetorheological fluids (MRFs) that solidify upon the application of a magnetic field because of the formation of rigid particle chains. By virtue of being a fluid, these materials could provide an empowering path to realizing tunable actuators in soft robotic systems for human interactions. To test this idea, we successfully use an MRF as the active fluid in a soft actuator and gripper. Despite this success, the efficacy of MRF is inversely proportional to its density, which is commonly high on account of containing a high volume fraction of iron. As a path to realizing more efficient MRFs, we hypothesized that the inclusion of ultra-high aspect ratio 2D materials could provide the needed increase in yield stress without requiring a high volume fraction of dense iron particles. Thus, we explored 2D material sheets as additives in an MRF and tested its response to magnetic fields in shear mode, where the fluid is sheared between two plates, and in valve mode, where a pressure gradient pushes the fluid through a tube. While the addition of the 2D material did not affect performance in shear mode, its presence increased the pressure difference seen in

valve mode at low flow rates. To explain these seemingly contradictory results, we propose a model based on the 2D material improving the yield stress by averaging out the shear stress over length scales commensurate with the particle size. This discovery can be used to rationally design MRFs for valve mode operation, which is important to their successful incorporation into soft robotics. These advances motivate further exploration of MRFs in soft robotics and reveal the influence of highly anisotropic additives on MRF performance.

6:30 AM *F.SM03.02.05
Sustainable, Bioderived and Degradable Soft Materials for Human Machine Interfaces Martin Kaltenbrunner; Johannes Kepler University, Austria

Nature inspires a wide range of bio-mimetic systems ranging from soft robotic actuators to perceptive electronic skins that enhance and support our life. The growing demand on assistive, medical and bioelectronic technologies however raises concerns on the ecological footprint of this emerging platforms, as they are often designed for a defined, limited operational lifetime. Introducing a key feature essential to nature - biodegradability - will enable soft electronic and robotic devices that reduce (electronic) waste and are paramount for a sustainable future.
We here introduce materials and methods such as tough yet biodegradable biogels for soft systems that facilitate a broad range of applications, from transient wearable electronics to metabolizable soft robots. These embodiments are highly stretchable, are able to heal and are resistant to dehydration with unchanged mechanical properties for more than one year on the shelf. Our forms of soft electronics and robots are built from resilient gelatin-based gels with tunable, extreme mechanical properties that uniquely combine performance and durability with degradability. They are engineered for long-term operation in ambient conditions without fatigue, sustaining more than 350 000 actuation cycles and even operate under water for extended periods of time, but fully degrade after use through biological triggers. Electronic skins that measure pressure, strain, temperature and humidity serve as human-friendly on-skin interfaces or equip robotic systems with sensory feedback. Such advances in the synthesis of biodegradable, mechanically tough and stable gels that do not compromise in performance when compared to their non-degradable counterparts may bring bionic soft systems a step closer to nature and enable human-friendly technologies with reduced ecological footprint.

M. Baumgartner, F. Hartmann, M. Drack, D. Preninger, D. Wirthl, R. Gerstmayr, L. Lehner, G. Mao, R. Pruckner, S. Demchyshyn, L. Reiter, M. Strobel, T. Stockinger, D. Schiller, S. Kimeswenger, F. Greibich, G. Buchberger, E. Bradt, S. Hild, S. Bauer, M. Kaltenbrunner, “Resilient yet entirely degradable gelatin-based biogels for soft robots and electronics”, *Nature Materials* (2020)

7:00 AM *F.SM03.02.06
Materials Control of Tactile Sensations Charles Dhong; University of Delaware, United States

For the sense of sight, we can purchase high definition screens to recreate nearly any image. There is no equivalent technology for the sense of touch. However, the accurate and rich recreation of tactile sensations could have broad implications in human machine interfaces, virtual reality, and health.

Touch is a complex event. As a finger and object make contact, a rich variety of mechanical vibrations are produced, which contributes to the subtlety and object identification behind every day tactile experiences. In this talk, we will discuss how we can use materials control at interfaces to create new tactile sensations by controlling friction and adhesion. We will share our work on screening and characterizing tactile materials, demonstrating that tactile perception cannot be predicted from material properties alone. We also share our complementary work on building a fundamental basis for tactile perception, enabled by materials control over tactile stimuli. Establishing a fundamental basis for touch could help unify our understanding of touch and help recreate arbitrary tactile sensations through a combination of more basic units.

7:15 AM F.SM03.02.07
Development of Soft Robotic Morphing Nanocomposite PVDF/SWCNT and PVDF/BNNT Ji Eun Lee[1], Ryan Nam[1], Michael Jakubinek[2], Behnam Ashrafi[2] and H.E. Naguib[1]; [1]University of Toronto, Canada; [2]National Research Council, Canada

Stimuli responsive polymers and composites have garnered attention in the development of novel actuators due to their ability to respond to various stimuli such as light, heat, electric field, magnetic field, and more. Compared to traditional electric motors, these actuators offer advantages such as conformability, better biomimicking ability, lower cost, and higher power-to-weight ratio. These advantages also are ideal for the field of soft robotics, creating flexible morphing structures that

is able to move with more degrees of freedom then conventional stiff robotics. Piezoelectric materials, with external stimuli of electric field, the morphing device in use can respond with great speed and accuracy.
The current study investigates the development of a nanocomposite with 1D nanofillers single-walled carbon nanotubes (SWCNT) and boron nitride nanotubes (BNNT) in a piezoelectric polymer Polyvinylidene Fluoride (PVDF) matrix. The addition of nanotubes will: (i) increase piezoelectric property for enhanced actuation with its alignment, (ii) lower applied power due to conductive nanofiller percolation, and (iii) enhance mechanical property to withstand the environmental conditions of various actuation applications. Due to its high aspect ratio and conductivity, PVDF/SWCNT samples after stretching had high polar β crystal content of 80% and high conductivity (>10-6 S/cm). This resulted in high deflection magnitude at low applied electric field. At 0.5 wt.% PVDF/SWCNT stretched resulted in a maximum deflection of 570μm at 5.88 V/mm. With PVDF/BNNT, the samples after electric poling whilst lower in β crystal content, had higher deflection magnitude due to the higher overall dipole moment. PVDF/BNNT stretched and poled had β crystal content 12% lower than that of only stretched but 520% increase in deflection magnitude (from 50μm to 260μm) With an increase in conductivity and piezoelectric property, the material's actuation can be performed with greater displacement and lower power.
With the addition of nanotube which provided constraints for alignment, percolation, and enhancement of mechanical properties, flexible morphing devices were developed. The choice of nanotube is important to optimize specific properties (i.e., electrical) but both nanofillers exhibited great morphing magnitude to various electric fields applied. This study provides insight to future research utilizing piezoelectric materials for actuation application in soft robotics.

7:25 AM F.SM03.02.08
Hard-Magnetic Elastica Liu Wang, Yoonho Kim and Xuanhe Zhao; Massachusetts Institute of Technology, United States

Recently, *ferromagnetic soft continuum robots* – a type of slender, thread-like robots that can be steered magnetically – have demonstrated the capability to navigate through the brain's narrow and winding vasculature, offering a range of captivating applications such as robotic endovascular neurosurgery. Composed of soft polymers with embedded hard-magnetic particles as distributed actuation sources, ferromagnetic soft continuum robots produce large-scale elastic deflections through magnetic torques and/or forces generated from the intrinsic magnetic dipoles under the influence of external magnetic fields. This unique actuation mechanism based on distributed intrinsic dipoles yields better steering and navigational capabilities at much smaller scales, which differentiate them from previously developed continuum robots. To account for the presence of intrinsic magnetic polarities, this emerging class of magnetic continuum robots provides a new type of active structure – *hard-magnetic elastica* – which means a thin, elastic strip or rod with hard-magnetic properties. In this work, we present a nonlinear theory for hard-magnetic elastica, which allows accurate prediction of large deflections induced by the magnetic body torque and force in the presence of an external magnetic field. From our model, explicit analytical solutions can be readily obtained when the applied magnetic field is spatially uniform. Our model is validated by comparing the obtained solutions with both experimental results and finite element simulations. The validated model is then used to calculate required magnetic fields for the robot's end tip to reach a target point in space, which essentially is an inverse problem challenging to solve with a linear theory or finite-element simulation. Providing facile routes to analyze nonlinear behavior of hard-magnetic elastica, the presented theory can be used to guide the design and control of the emerging class of magnetically steerable soft continuum robots.

7:35 AM F.SM03.02.09
Mixed-Conducting Particulate Composites for High Resolution Human-Machine Interfaces Patricia Jastrzebska-Perfect[1,2], Han Yu[1], Jennifer Gelinas[1] and Dion Khodagholy[1]; [1]Columbia University, United States; [2]Massachusetts Institute of Technology, United States

Human-machine interfaces require soft, biocompatible materials that can provide high spatiotemporal resolution-coupling with bioelectronic devices. Here, we introduce an organic mixed-conducting particulate composite material (MCP) that enables highly-resolvable coupling by varying particle size and density. MCP-based high performance anisotropic films are pattern-free, scalable, and biocompatible. MCP enabled facile and effective electronic bonding between soft and rigid electronics, permitting recording of neurophysiological data at the resolution of individual neurons from freely moving rodents and from the surface of the human brain through a small opening in the skull. We also acquired high spatiotemporal resolution electrophysiological signals non-invasively by directly interfacing MCP with human skin. MCP provides a single material solution to facilitate development of bioelectronic devices that can safely acquire, transmit, and process complex biological signals.

7:45 AM *F.SM03.02.10
High-Sensitivity and Wide-Range Capacitive Pressure Sensors Enabled by the Hybrid Response of Conductive Foams Kyoung-Ho Ha[1], Weiyi Zhang[2], Seungmin Kang[1] and Nanshu Lu[1]; [1]The University of Texas at Austin, United

States; [2]Tianjin University, China

Soft pressure sensors with high sensitivity over a wide pressure range are required for various applications such as electronic skins for human-mimetic robotics and electronic tattoos for digitizing human body. In the last decade, most research aiming at increasing the sensitivity of capacitive pressure sensors focused on developing dielectric materials with added air gaps and/or higher dielectric constants. After extensive research, sensitivity has been significantly improved at low pressure range, e.g. 1 kPa, but drops drastically as the pressure increases. To overcome this challenge, we present a novel soft capacitive pressure sensor employing an electrically conductive foam capable of both piezoresistive and piezocapacitive responses. The foam is made out of functionalized carbon nanotubes and Ecoflex and can be inexpensively fabricated without MEMS technology. The foam is 600-μm thick, 85% porous, and open cell with tubular ligaments. An ultrathin dielectric layer was added between the conductive foam and the electrode to ensure the whole device is still capacitive. The sensor has a modulus of 2 kPa and an initial impedance of 47 MΩ with a phase angle of -86°. This capacitive sensor exhibits a sensitivity of 1.95 kPa^{-1} within 0-1 kPa, 1.06 kPa^{-1} within 1-5 kPa, 0.88 kPa^{-1} within 5-10 kPa, 0.52 kPa^{-1} within 10-30 kPa, and 0.35 kPa^{-1} within 30-50 kPa of pressure ranges. The hybrid response is fully understood through a simplified circuit model, which has been validated by the experimental measurements. We have successfully applied this sensor to measure subtle mechanophysiology on human body, including the pulse waves on the neck and the seismocardiogram on the chest.

8:00 AM F.SM03.02.11
Mechanics Guided Designs of Stretchable Nanowire Conductors Shuang Wu, Yuxuan Liu, Shanshan Yao and Yong Zhu; North Carolina State University, United States

There are two main strategies to develop stretchable conductors based on the materials used – nanocomposites with synthesized nanomaterials dispersed into a polymer matrix and deposited thin films exploiting mechanics guided structural design. Both strategies have seen remarkable progresses in developing highly conductive and stretchable conductors. However, so far the mechanical design strategy has been mainly applied to the deposited thin films. It would be interesting to exploit this strategy for the nanocomposites. Here we present two mechanical designs – delaminated buckle and horseshoe – for developing highly conductive and stretchable silver nanowire conductors. In the first design, a polymer composite film (with a thin layer of silver nanowires encased) was bonded to a pre-stretched elastomer substrate. Upon releasing the prestrain, a partially delaminated wavy geometry of the composite film is created. During the evolution of the buckle delamination, the blisters pop up randomly but self-adjust into a uniform distribution, which effectively reduces the local strain in the silver nanowires. The resistance change of the conductor is less than 3% with the applied strain up to 100%. In the second design, the polymer film was patterned into a horseshoe shape and bonded to an elastomer substrate. We found that the substrate thickness and bonding strength can dictate the deformation modes of the polymer film. For thin substrate and weak bonding, the resistance change of the conductor is less than 1% with the applied strain up to 100%.

SESSION F.SM03.03: Haptics in Virtual and Augmented Reality

5:00 AM *F.SM03.03.01
Toward the Haptic Display of Texture James E. Colgate; Northwestern University, United States

An important problem in the field of haptics is the recording and playback (or similarly, composition and display) of *texture*. This problem is by no means unique to haptics: texture is a vital component of computer-generated graphics and it has been studied in the auditory domain as well (think of crickets chirping or wind blowing through leaves). Haptics, however, presents unique challenges.

Consider the problem of recording: what signals should be measured? While an argument can be made for measuring material and geometric properties of the textured surface, very little progress has been made toward realistic playback on the basis of such information. One reason is that the perception of texture requires contact and, typically, relative movement. This interaction causes the skin to deform whereupon various specialized mechanoreceptors capture aspects of that deformation including localized strain, skin stretch, and vibration. Arguably, the right signals to record are the same ones that the mechanoreceptors respond to. Indeed, measurements of normal and lateral force, movement speed, and skin vibration, have generally proved more useful than measurements of surface properties when it comes to playback. Playback, however,

is limited in two additional respects: one, the ability of the haptic display to physically create spatiotemporal patterns of skin deformation similar to those caused by real world interaction; two, the ability of the display to control those patterns as a function of state variables such as finger pressure and speed.

In this talk, I'll discuss the issues of recording and playback in the context of electroadhesive variable friction haptic displays. The talk will necessarily begin with a discussion of fingertip mechanics, including the roles of moisture and stratum corneum plasticization, in regulating friction; and then go on to a discussion of electroadhesion in which the material properties of both the skin and the countersurface are highly significant.

Electroadhesion is a technology that provides very good temporal control (bandwidth from DC up to several tens of kHz … well beyond the tactile range), but limited spatial resolution (the touch surface remains flat at all times and actuation is typically synchronous across the full fingerpad). This puts rather stringent limitations on playback, the perceptual consequences of which are sometimes surprising. I'll review a number of studies we have performed to explore and expand the gamut of variable friction textures.

Ultimately, the gamut of an electroadhesive display, especially one built on a rigid surface, is limited. Properties such as hardness/softness, warmth/coolness, as well as coarseness (i.e., 2.5D shape), are unlikely to be realized without advances in the underlying display technology. While it is certainly possible that electroadhesion could be combined with other existing actuation methods (e.g., vibrotactile, pin arrays, thermoelectric, etc.) to expand the range of stimuli, the pathway toward an elegant, robust, and cost-effective solution is not evident. Instead, a pathway rooted in the development of novel "haptic materials" is more appealing. I will close this talk by discussing some of the characteristics such materials should possess.

5:30 AM *F.SM03.03.02
Wireless Sensing for Medical Continuum Robots Tania Morimoto; University of California, San Diego, United States

Continuum robots are promising for medical interventions due to their ability to traverse around obstacles in confined spaces and conform to highly curved paths. In addition, their inherent structural compliance offers improved safety and adaptability, which is critical for interactions with sensitive structures inside the body. Real-time information about robot shape and applied forces is important for enabling more advanced control methods, ensuring safety, and creating new human-machine interfaces with haptic feedback. Yet the small size, and in particular, the highly limited space for routing wires through these robots, introduces a number of challenges for sensing and makes the integration of standard sensors difficult, especially if measurements along the entire robot length are required. To begin addressing these challenges, we are developing both wireless localization and force sensing methods compatible with continuum robots. This talk will first focus on a permanent-magnet based method for the localization of the tip of a growing robot (also known as a vine robot). The approach combines analytical and machine learning techniques to localize the robot tip in 5 degrees of freedom without requiring any significant modifications of the robot. The second part of the talk will focus on a new wireless force sensor based on backscatter tags. When a force is applied, the sensor deforms, creating contact between two conductive traces, which results in the reflection of electromagnetic waves on the edges of this contact area. The reflected waves will have a phase change that is dependent on the amount of contact between the traces, and can be used to determine the magnitude and location of the applied force. The development of these sensors is important to enable user interfaces with improved control and haptic feedback.

6:00 AM F.SM03.03.03
Visualizing Strain of the Body Movement with Highly Responsible Hierarchical Thermochromism Byeonghak Park and Tae-il Kim; Sungkyunkwan University, Korea (the Republic of)

As eidetic signal recognition has become important, displaying mechanical signals visually has imposed huge demands for simple readability and without complex signal processing. Such visualization of mechanical signals has been used in delicate urgent medical or safety-related industries. Accordingly, chromic materials have been considered to facilitate the visualization with multiple colors and simple process, yet the response and recovery time is very long, so that rapid regular signals are unable to be detected, i.e., physiological signals, such as respiration. Here, we suggest the simple visualization of low strain ~2 %, with ultrasensitive crack-based strain sensors with a hierarchical thermochromic layer. The sensor shows a gradient color change from red to white color in each strain, which is attributed to the hierarchical property, and the thermal response (recovery) time is dramatically minimized within < 0.3 s, as the hierarchical membrane was inspired by termite mounds for efficient thermal management. The fast recovery property can be taken advantage of in medical fields, such as monitoring regular respiration, and the color changes can be delicately monitored with high accuracy by software on a mobile phone.

SESSION F.SM03.04: Wearable Haptic Devices

F-SM03

5:00 AM F.SM03.04.01
Soft Magnetic Actuators for Wearable Tactile Feedback Alex J. Mazursky and Pedro Lopes; University of Chicago, United States

Recent developments in wearable devices brought technology much closer to the user's skin in the form of interactive fabrics, electronic skins, interactive tattoos, and more. However, these devices are typically only used for user input and do not provide haptic feedback in response to interactions. In fact, while we have seen many advances in the materials that make up wearable devices, the haptic feedback included in most wearables is, typically, based on off-the-shelf actuators such as linear resonant actuators that, due to their rigidity, cannot conform to the soft, flexible, and dynamic human body. To tackle this, we created a haptic device based on stretchable magnets. Our haptic device has two components: (1) a silicone skin doped with permanent magnetic micro powder (NdFeB) allowing it to display tunable magnetic polarity, and (2) a fingernail-worn device that includes an electromagnetic coil, 9-DOF IMU, and microcontroller. Users interact with our wearable haptic device by touching or dragging their finger over the magnetic silicone skin. Our device senses the proximity to the magnetic layer (via its IMU) and actuates the coil, causing the magnetic skin to oscillate—creating haptic vibrations on the user's skin. Using this mechanism, we can render a wide range of haptic sensations such as detents, button presses, or textures.
We believe our device is especially suited for on-body gestures, such as thumb-to-index pinching (popularized by Google's Soli or Microsoft's HoloLens, to cite a few) or to expand haptic output to different areas of the body where rigid devices are uncomfortable. Lastly, we studied our device's dynamic performance via modal analysis and users' perception of tactile feedback by means of psychophysical studies.

5:15 AM *F.SM03.04.02
Wireless Multimodal E-Tattoos Capable of Long-Term Operation Nanshu Lu; The University of Texas at Austin, United States

Merging human body with electronics and machines can enable internet of health (IoH), human-machine interface (HMI), as well as augmented human capabilities. However, bio-tissues are soft, curvilinear and dynamic whereas wafer-based electronics are hard, planar, and rigid. Over the past decade, stretchable electronics have emerged as a result of new materials development, structural design and manufacturing processes. In particular, epidermal electronics, a.k.a. electronic tattoos (e-tattoos), represent a class of stretchable circuits, sensors, and stimulators that are ultrathin, ultrasoft and skin-conformable. This talk will introduce a dry and freeform (subtractive) "cut-solder-paste" process for the rapid prototyping of modular and reconfigurable e-tattoos. This method is applicable for thin film metals, polymers, ceramics, as well as 2D materials and can easily incorporate integrated circuits to the stretchable e-tattoos. Electrically conductive open cell foams with hybrid piezoresistive and piezocapacitive responses has been applied as high-sensitivity mechanical transducer. The e-tattoos can laminate at different locations of the human skin for the synchronous and continuous tracking of electrophysiology (ECG, EEG, EMG, EOG), mechanophysiology (respiration, seismocardiogram, blood pressure, etc.), as well as thermophysiology etc.. In addition to sensing, the e-tattoos can also be used as personalized treatment and therapeutic devices. For wireless operation, we leverage near field communication (NFC) for wireless and Bluetooth low energy (BLE) for wireless data transfer. A wireless charging-on-the-go strategy enables the long-term (e.g., 3 days) operation of the e-tattoo.

5:45 AM *F.SM03.04.04
Wearable Haptics—Device Design Opportunities and Challenges Marcia K. O'Malley; William Marsh Rice University, United States

Wearable haptics refers to systems worn on the body or integrated into clothing that can provide haptic feedback to the wearer in a wide range of forms, such as vibrotactile, cutaneous, skin stretch, pressure, and kinesthetic feedback. The potential for wearable haptics is supported by technological advancements in sensing and actuation that allow for the design and deployment of flexible materials, fabrics, and small-footprint actuators that can augment and enhance human performance. While rigid and grounded haptic feedback devices have been explored as a means to train new motor skills, rehabilitate movement coordination after neurological injury, and even augment human force output capabilities in tasks such

as lifting or running, the application space is limited due to the weight and scale of such devices. Wearable haptic devices seek to overcome the limitations of rigid and grounded haptic devices.

Vibrotactile haptic feedback is ubiquitous for notifications and alerts in portable devices such as phones, smart watches, and fitness trackers, but the set of possible notifications is limited by the nature of the eccentric motors so often used to deliver such cues. In recent years, my group has been shifting to wearable haptic systems that provide multiple haptic modalities of feedback to the user, including vibration, skin stretch, pressure, and kinesthetic feedback, all packaged in bands that can be worn on the arm, or in hybrid rigid-soft exosuits that can apply forces directly to the limbs. We are particularly interested in applications where the provision of such feedback has a measurable impact on human performance.

In this talk, I will present some of our wearable haptic systems, describe our target applications, and highlight the distinguishing features our hardware while identifying opportunities for improvement. Two systems that I will discuss leverage multi-sensory haptic cues that are displayed directly on the user's arm. Tasbi is a wearable haptic device that provides squeeze and vibration feedback for haptically enhanced augmented and virtual reality interactions. MISSIVE incorporates skin stretch, squeeze and vibration cues presented simultaneously to the user in distinct patterns. The use of multisensory cues allows us to design large discrete cue sets while maintaining a small and wearable form factor. With MISSIVE, we demonstrated language transmission via haptic phonemes, or units of sound encoded as haptic cues consisting of vibration, radial squeeze, and lateral skin stretch components. I will also present two wearable exosuit systems for upper limb movement assistance and rehabilitation, a glove, and an upper limb garment. Using cable-based actuation systems that enable remote placement of actuators, rigid spines precisely located for load transfer and cable management, and soft goods for compliant human-machine interfacing, these devices offer the potential for improved wearability compared to their rigid robotic counterparts, and feasible integration into the performance of everyday functional tasks.

6:15 AM *F.SM03.04.05
Minimizing Haptic Hardware in Wearable Devices Heather Culbertson; University of Southern California, United States

Wearable haptic devices present many challenges in actuator selection and design. In addition to providing a sufficiently strong signal to be easily felt by the user, the actuators must also not encumber the user's motion. Ideally the actuators should be small, thin, lightweight, flexible, low power, and provide multiple degrees of actuation. An actuator with all these properties is not currently available commercially, forcing haptic designers to make decisions regarding trade-offs between magnitude, resolution, degrees of freedom, and workspace among many others. These limitations motivate our research towards providing complex haptic signals using minimal hardware. We approach this problem from two directions by using haptic illusions and by creating novel actuators that can provide multiple haptic sensations simultaneously.

Haptic illusions seek to fool our sense of touch into thinking we are feeling something different than what is being displayed by taking advantage of the inexactness of our perception. In our research, we employ haptic illusions to allow small, lightweight actuators to create sensations that would normally require actuators that are impractical for a wearable device. I will discuss two haptic illusions and their uses: asymmetric vibrations for generating ungrounded forces and sequential indentation for creating lateral motions.

I will also present our work in creating multi-modal hardware, which allows for complex haptic sensations using minimal actuator size and weight. Our PATCH (Pump-Actuated Thermal Compression Haptic) device presents simultaneous thermal and pressure cues. The PATCH system is actuated by using pumps to fill fabric actuators with water of varying temperature. The actuators are lightweight, flexible, and provide a wide range of haptic cues.

6:45 AM F.SM03.04.06
High-Resolution Liquid Metal Patterning for Stretchable and Ultra-Transparent Electronic Interfaces Haotian Chen, Laurent Dejace and Stephanie P. Lacour; École Polytechnique Fédérale de Lausanne, Switzerland

Integrated wearable electronics capable of providing biophysical information on complex and dynamic systems have attracted interests in diverse fields such as healthcare and robotics. Gallium and gallium-based liquid metals stand out for their excellent combination of electrical conductivity and mechanical deformability. However, liquid metals feature complex physical and chemical properties that pose challenges to the fabrication of miniaturized soft and stretchable circuits. Herein, we present a manufacturing approach to form ultrathin (1.5 μm) and high-resolution (2.2 μm) liquid metal features with high surface density over large surface areas (wafer scale). Based on a combination of soft lithography, selective wetting, Ion Beam Etching and thermal evaporation of gallium, the process enables a range of channel designs and geometries with unprecedented aspect ratios (> 10'000) that can be used to form liquid metal based stretchable electronic conductors with

unrivaled transparency.
We demonstrate conducting grids of w = 2.2 μm width and variable pitch (p = 100.2, 50.2, 29.2, 15.2 μm) that can reversibly stretch to 100 %. Adjusting the density of the narrow lines across the PDMS substrate offer tunability in the patterned metallic grid. In the relaxed state, the liquid metal grids display optical transmittances at 550 nm wavelength of 69.3 %, 80.2 %, 86.9 %, and 89.6 % for p = 15.2 μm, 29.2 μm, 50.2 μm, 100.2 μm with sheet resistance of 4.8 Ohm/sq., 6.4 Ohm/sq., 8.8 Ohm/sq., 12.5 Ohm/sq. respectively. The accuracy and the robustness of the patterning technique are demonstrated by stretching the most transparent structure (p = 100.2 μm) to 100 % deformation. The combination of high electrical conductivity (12.5 Ohm/sq.), optical transparency (89.6 %) and mechanical deformability (100 %) ranks these soft and stretchable liquid metal grids amongst the best performing transparent conductors reported to date.

SESSION F.SM03.05: Poster Session: Materials for Haptics

F.SM03.05.01
Beyond Elastic Limit of Piezoelectric Ceramic with 3D Hollow ZnO Nanostructures Hoon Kim, Seokjung Yun, Kisun Kim, Wonsik Kim, Jeongjae Ryu, Hyeon Gyun Nam, Seung Min J. Han, Seokwoo Jeon and Seungbum Hong; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Piezoelectric materials are suitable for haptic technology as they can convert mechanical stimuli into electrical signals and vice-versa. However, owing to their disadvantageous mechanical properties such as brittleness (in ceramics) and a low piezoelectric coefficient (in polymers), it is still a challenge to use them in haptic technology. Here, we present a truss-like 3D hollow zinc oxide (ZnO) nanostructure that shows a drastically improved elastic strain limit while maintaining a piezoelectric coefficient similar to that of single-crystal ZnO. The ZnO hollow nanostructures were fabricated by proximity field nanopatterning (PnP) and atomic layered deposition (ALD) at four different process temperatures from 90 to 300°C. The piezoelectric properties were visualized and analyzed through dual AC resonance tracking piezoresponse force microscopy (PFM). The piezoelectric coefficient was approximately 9.2 pm/V. Furthermore, we measured the measured elastic strain limit of approximately 10% using the nanopillar compression test, which was at least 3 times greater than the prior report. The extended elastic limit of the 3D hollow structure was further supported by finite element simulations. We envision that our ZnO hollow nanostructure can be used in enhanced haptic devices, which mimic the human sense of touch.

F.SM03.05.02
Highly Crystalline PCL Ultrathin Films as Thermally Switchable Biomaterial Coatings Shivam Saretia[1,2], Rainhard Machatschek[1,2] and Andreas Lendlein[1,2]; [1]Helmholtz-Zentrum Geesthacht, Germany; [2]University of Potsdam, Germany

Degradable semi-crystalline polymers are a class of materials that modern regenerative medicine heavily relies on. While their formulation into nanostructured devices can be advantageous to tailor functional properties such as cellular uptake kinetics and degradation behaviour, it is difficult to assess and control the morphology, crystallinity and organization of nanostructured polymer materials by common preparation methods.

The Langmuir technique overcomes most of the drawbacks concerning preparation and investigation of nanostructured polymer materials. Here, ultrathin films at the air-liquid interface serve as model systems for polymer devices and interfaces, which can be manipulated and observed in a straightforward way. In particular, the semi-crystalline morphology, including crystal size, number density, thickness, and melting temperature can be precisely adjusted. By transferring the layers to solid substrates, functional biomaterial interfaces with unique properties can be created. For example, via enzymatic degradation of the amorphous chains, a semi-crystalline Langmuir film can converted into an almost entirely crystalline film with a thickness of a few nanometers. The preparation and analysis of these highly functional, entirely crystalline thin films based on oligo(ε-caprolactone)s (OCL) with different end-groups is of particular interest. Poly(ε-caprolactone) (PCL) is established in clinical applications with a relatively low melting point point and well documented enzymatic degradability[1]. The melting temperature of PCL or OCL crystals can be adjusted via the crystallization temperature to be very close to physiological conditions, producing a polymer coating that changes a broad variety of its functional properties upon application of a small thermal stimulus.

For example, highly crystalline films of hydroxyl and methacrylate end capped linear OCL are prepared by degrading its amorphous phase by the enzyme *Pseudomonas cepacia* lipase (0.007 $mg{\cdot}mL^{-1}$) at constant surface pressure of ~7 $mN{\cdot}m^{-1}$ on air-water interface at room temperature. The thickness of the OCL crystals in the film can be adjusted in the range of ~ 6 to 8 nm, resulting in a melting temperature between ~30 to 40 °C at the air-water interface. Upon melting, the elastic moduli of the film are drastically altered. Further, functional end groups are expelled from the crystals and therefore accumulated at the crystalline surface. Upon melting, these end-groups are buried in the amorphous phase, resulting in a change of the chemical composition of the material surface. Moreover, the degradability of the thin film increases significantly upon melting, meaning that the lifetime of the material can be adjusted via its thermal history. In addition, the barrier properties of the thin film depend on its crystallinity, with polymer crystals being considered impenetrable for small molecules.

Here, we demonstrate the fabrication and behaviour of these thermally switchable OCL crystals coatings, which are of interest for applications such as barrier layers, substrates modulating stem cell adhesion, or coatings with on-demand acceleration of degradability. Another possible application are friction reducing coatings, for example on sutures. Here, the temperature at the suture-tissue interface does not increase as long as the heat generated by frictional forces is absorbed by the melting enthalpy of the crystals.

F.SM03.05.03
Late News: Functionalised Capacitive Microfluidic Force Sensors for Orthopaedic Surgery Liam Ives[1], Qingshen Jing[1], Alizée Pace[1], Anke Husmann[1], Vikas Khanduja[1], Jehangir Cama[2] and Sohini Kar-Narayan[1]; [1]University of Cambridge, United Kingdom; [2]University of Exeter, United Kingdom

The correct balance of forces on the hip joint during total hip arthroplasty (THA) is essential for implant longevity and to prevent the need for revision surgery. This has become increasingly important since the average age of a THA patient is decreasing, hence these implants must survive greater activity levels and correspondingly higher stresses than those typically found in older, less active patients. Currently, the lifetime of an implant positioned purely by a surgeon's judgement is approximately 15 years. Quantitative force feedback during surgery could provide more accurate implant positioning, increasing the average lifetime. However, there are currently no force sensors capable of providing this information within the small and complex geometry of the hip joint.

Here, we solve this unmet clinical need by presenting a thin, conformable and flexible microfluidic capacitive force sensor, which can be incorporated into the surgical process without significant modification to existing implants. The sensor consists of a deformable microfluidic chip bonded to a flexible substrate, on which interdigitated electrodes are incorporated, and that can operate in confined spaces to give accurate force readings from joints. The sensor operates by monitoring the change in capacitance of the electrodes as the fluid in the microfluidic channel is displaced in response to an applied force. Multiple sensors were incorporated into a model hip implant geometry, and a bespoke mechanical testing rig was built to simulate loading of the acetabular cup from the femoral head at different angles. The experimental results were validated using finite element modelling. This was used to optimise the sensor geometry for the production of sensitive devices that can withstand the high forces required for surgery. Our novel microfluidic-based force sensing technology can potentially be adapted for application in joints either for sensor-assisted orthopaedic surgery, or for gathering telemetric data from joints before, during and/or after surgery. Such biocompatible and implantable force sensors will contribute significantly to several clinical drivers, through providing quantitative feedback to the attending clinician, and could also serve to underpin robot-assisted orthopaedic surgery in the future.

How Can We Approach *In Vivo* Bioelectronics Challenges with Stretchable Electronics? János Vörös; ETH Zurich, Switzerland

A new class of electronic devices based on stretchable materials can interact with the soft human body in an unprecedented manner. They are highly suitable for epidermal electronics because they can be designed to conform closely to and with the irregular shape of the skin, providing an improved functional interface even during motion, while being imperceptible to the user.[1,2]
But does the stretchability also provide benefits for *in vivo* applications? This lecture will systematically discuss the challenges and possibilities for *in vivo* bioelectronics[3]:
The first part will discuss our progress on using metal nanowires embedded in PDMS that can be processed using regular photolithography or filtration to realize stretchable conductive leads down to 10 micrometer resolution. Stretchable and biocompatible transparent microelectrode arrays can thus be realized that enable stimulation and recording of brain activity directly from the cortex both electronically and optically. [4,5]
The technology also allows for creating strain sensors with up to 500% stretchability and Gauge factors of over 100 that can be used as smart and passive RFID tags to measure the filing level of the bladder in handicapped users, or to record the volume of the heart during operation.[6,7] Here, advanced imaging with coherent X-rays in combination with machine learning based data evaluation helped to provide a full theoretical understanding of the strain-response and to build a model with predictive value.[8]
The biggest challenge of in vivo bioelectronics remains the lack of understanding of the brain. Stretchable electronics can be used to create well-defined, in vitro neuron networks of human iPSC-derived neurons that can be stimulated and recorded in a closed-loop fashion enabling a new approach, i.e. bottom-up neuroscience.[9]

12:30 PM *F.SM04.04.01
Large-Area Printable and Flexible Electronic Biosensors for Label-Free Single-Molecule Detection Luisa Torsi[1,2]; [1]University of Bari A. Moro, Italy; [2]Åbo Akademi University, Finland

Detecting a marker or a pathogen at the physical limit is the new frontier in medical analysis as it endows the clinicians with the attacker's advantage over life-threatening diseases such as tumours and pandemics. It is also received that label-free and electronic transductions can be conveniently fast and wieldy. Within this field different transducing approaches are pursued. They involve a transducing interface functionalized with biological recognition elements, such as antibodies or DNA probes, that endow the device with recognition properties by selectively capturing the analyte e.g. an antigen or a genomic marker, respectively. One recently proposed approach involves a large interface hosting trillions of highly-packed bio-recognition elements. The challenge is indeed that of measuring one single molecule in a large volume such as for instance 100 ml. This means being able to deploy a technology that can detect 10 - 20 10^{-21} mole l^{-1} (zeptomolar).
Mimicking cell's behaviour, ecently proposed approach involves a large interface hosting trillions of highly-packed bio-recognition elements. This is called, the "**Si**ngle **Mo**lecule with a large **T**ransistor (SiMoT)" technology that was proposed to sense a solution with markers present at extremely low concentrations. It is based on an Electrolyte Gated Organic filed-effect transistor operated in deionized water, with a gate that has an area of ca. 0.5 cm^2, hosting 10^{12} antibodies or genomic probes. The SiMoT platform has been proven to perform label-free and selective detection at the physical limit in real biofluids of protein biomarkers such as: human Immunoglobulin G, Immunoglobulin M, C-reactive protein, MUC1 and HIV1 p24 antigen as well as genomic markers such as miR-182-5p and KRAS. Indeed, the widely applicable method used to conjugate the recognition elements to the gate electrode, makes the SiMoT platform suitable for the detection of different classes of markers and pathogens reaching world record detections limits for label-free protein detection.

1:00 PM *F.SM04.03.02
Self-Assembled Bioinspired Nanostructures for Green Electronics Nurit Ashkenasy; Ben Gurion University of the Negev, Israel

Self-assembling peptides that are inherently biodegradable and biocompatible are extremely suitable for use in devices that adhere on, or even implanted into, the human body in order to monitor and regulate biological functions. The challenge for incorporating these materials in bioelectronic devices is the optimization of their electronic properties for the desired application. In this talk I will present peptide design rules that can be used to prepare electron and/ or proton conducting peptide based materials. Specifically, I will discuss the influence of aromatic side chains (both natural and non-natural) on electron conductivity.[1,2] I will further present enhancement of proton conduction in these films by the incorporation of protonating side chains, which can lead to extremely high proton conductivity values in these materials.[3,4] I will finally discuss the control of conductivity, thermal stability and biodegradability of self-assembling peptide nanostructures by peptide backbone motifs. These studies demonstrate the great potential of using peptide building blocks for the fabrication of green electronic materials.

Multifunctional Fibers as Bioelectronic Interfaces Polina Anikeeva; Massachusetts Institute of Technology, United States

The ability to seamlessly integrate a diversity of electronic and optical materials within the flexible thermally-drawn fibers has recently enabled their applications as biocompatible and multifunctional tools for neural recording, modulation, and tissue repair. In this talk, I will highlight the advances in multimaterial fiber-based interfaces with neural tissue and illustrate how integration of active electronics and elastomers may allow for expanding the application domain of these devices toward probing physiology of other electroactive organs deep within the body. Furthermore, this talk will discuss the materials innovation to permit combinatorial thermal drawing and lithographic patterning within fibers that will further expand the geometries of fiber-based bioelectronic interfaces.

Optimizing Synergy Between Materials and Cell Microenvironments Using Functional Polyesters Milica Radisic; University of Toronto, Canada

Material based technologies play an integral role in many medical treatment strategies, including joint replacements, vascular stents, drug delivery methods, contact lenses and medical sutures. The application of successful technologies continues to grow, with an estimated market size of $130 billion USD by 2020. Although successes are notable, a number of biomaterial-based devices are limited in application by non-specific material properties to tissue type and undesired inflammation at the device interface. In application, polyester materials have traditionally been an effective polymer strategy, with successes in tissue engineering scaffolds and a variety of biomedical devices. Leveraging advantageous polyester degradability and well understood chemical synthesis, these materials serve as a strong functional platform to further optimize material-cell microenvironments. In this talk, I will describe the development of polyesters that (a) exhibit controllable mechanical properties to mimic the elastic properties of cardiac tissue extracellular matrix (ECM) and (b) incorporate a biomimetic moiety of mammalian immunity to recapitulate mechanistic inflammation regulation at the material surface. Development of engineered cardiac tissue requires material scaffolds that match the elastic behavior of cardiac ECM. Using polycondensation techniques to incorporate unsaturated carbonyl groups into elastic polyester material gels, we generated materials that can be molded into intricate designs with secondary crosslinking to generate constructs with highly tunable elasticity. By adapting material synthesis conditions (i.e. monomer ratios, reaction time), elastic mechanical behavior was highly tunable across a range of soft biomaterial applications. Material applicability was highlighted in a number of micro-designed elastomeric scaffold supports for engineered tissue, both for *in vitro* organ-on-a-chip and *in vivo* cardiac patch technologies, wherein the two-step synthesis process allowed for micro molding into intricate shapes prior to gelation. With biomaterial application *in vivo*, inflammation at the biomaterial surface limits device application. To tackle this, we looked to itaconate, a powerful small molecule metabolite of innate immunity that has recently emerged as a regulator of innate immune inflammation. This molecule has been previously limited therapeutically by short circulation times. To circumvent this, itaconate was incorporated directly into material backbones to impart biomimetic small molecule modulation, with quantified hydrolytic degradation release from polyester chains. Harnessing hydrolytic degradation release from polyester backbones, itaconate polymers resulted in the mechanism specific immunoregulatory properties on macrophage polarization in vitro. In a functional assay, the polymer-released itaconate inhibited bacterial growth on acetate. Translation to an *in vivo* model of biomaterial associated inflammation, intraperitoneal injection of ITA polymers demonstrated a rapid resolution of inflammation in comparison to a control polymer silicone, demonstrating the value of sustained biomimetic presentation of itaconate. Using scalable polyester synthesis techniques, we have demonstrated the power of instructive biomaterial technologies as functional modulators of the cell microenvironment.

Pushing the Limits of Elasticity in Soft-Matter Electronics Carmel Majidi; Carnegie Mellon University, United States

In order for machines and electronics to interface with biological tissue, they should be soft and elastic – i.e. remain functional when stretched and then return to their natural length when unloaded. In recent years, there has been tremendous progress in creating conductive elastomers and gels that are capable of extreme stretchability and which have been successfully utilized as bioelectronic interfaces. These include material architectures that are self-healing and can restore electrical and/or mechanical functionality when torn or punctured.

In this talk, I will review recent efforts to create mechanically robust, stretchable electronics using a variety of soft material architectures. In particular, I will focus on the following approaches: (i) silver-hydrogel composites that exhibit an unprecedented combination of mechanical compliance and electrical conductivity; (ii) biphasic compositions of silver nanoparticles and eutectic gallium-indium (EGaIn) liquid metal alloy for ultrathin “epidermal" electronics; and (iii) EGaIn-polymer composites capable of high electrical conductivity, extreme stretchability, negligible electromechanical coupling, and a variety of self-healing properties. To demonstrate their potential role in future bioelectronic applications, I will present

examples of how these soft material architectures are used as electrodes for physiological monitoring (e.g. EMG, ECG) and as electrical interconnects for highly stretchable digital circuits.

Fabrication of 3D Monolithic Architecture Electrodes Based on Conducting Polymer Microstructures Youngseok Kim and Myung-Han Yoon; Gwangju Institute of Science and Technology, Korea (the Republic of)

The conventional bioelectronic interfaces have been based on either 2-D thin films or 1-D fibers/wires which limit 3-D scalability as well as volume-/mass-dependent performance. Moreover, biological tissues and organs typically exhibit 3D arbitrary curvatures with wet surface, which impeded the close physical contact between the target tissue/organ and bioelectronic interfaces, leading to the low efficiency in bioelectric signal recording and/or stimulation. In this research, we report on 3D monolithic architectures with arbitrary shapes by employing conducting polymer microstructures as building blocks. Such arbitrary 3D structures were constructed by performing the seamless fusion of separate conducting polymer microstructures without using binder or adhesive. The resultant 3D structures exhibited decent mechanical robustness, high water stability, and outstanding biocompatibility, while the sheet resistance was reduced below 1 Ohm/square and the gravimetric capacitance was increased up to 79 F/g by taking advantage of cumulative mass loading and structural fusion. Finally, we demonstrated that 3D conductive mesh electrodes could be attached to the wet surface of biological organs/tissues such as heart and sciatic nerves without glue or clamp and efficiently record/stimulate bioelectrical signals *in vivo*.

How Can We Approach *In Vivo* Bioelectronics Challenges with Stretchable Electronics? János Vörös; ETH Zurich, Switzerland

A new class of electronic devices based on stretchable materials can interact with the soft human body in an unprecedented manner. They are highly suitable for epidermal electronics because they can be designed to conform closely to and with the irregular shape of the skin, providing an improved functional interface even during motion, while being imperceptible to the user.[1,2]
But does the stretchability also provide benefits for *in vivo* applications? This lecture will systematically discuss the challenges and possibilities for *in vivo* bioelectronics[3]:
The first part will discuss our progress on using metal nanowires embedded in PDMS that can be processed using regular photolithography or filtration to realize stretchable conductive leads down to 10 micrometer resolution. Stretchable and biocompatible transparent microelectrode arrays can thus be realized that enable stimulation and recording of brain activity directly from the cortex both electronically and optically. [4,5]
The technology also allows for creating strain sensors with up to 500% stretchability and Gauge factors of over 100 that can be used as smart and passive RFID tags to measure the filing level of the bladder in handicapped users, or to record the volume of the heart during operation.[6,7] Here, advanced imaging with coherent X-rays in combination with machine learning based data evaluation helped to provide a full theoretical understanding of the strain-response and to build a model with predictive value.[8]
The biggest challenge of in vivo bioelectronics remains the lack of understanding of the brain. Stretchable electronics can be used to create well-defined, in vitro neuron networks of human iPSC-derived neurons that can be stimulated and recorded in a closed-loop fashion enabling a new approach, i.e. bottom-up neuroscience.[9]

Biocompatible and Biodegradable Solid-State Electrolyte Based Organic Transistors and Their Integrated Circuits Young Jin Jo and Tae-il Kim; Sungkyunkwan University, Korea (the Republic of)

Organic Electronics are essential components of bio-integrated electronics for wearable electronics, electronic skins and soft robotics. However, there are a variety of obstacles like mechanical properties similar to biological surface (skin, tissues and organs), reliability of electrical characteristics under deformations, biocompatibility, biodegradability and low-voltage operation of electronics to apply organic electronics to biomedical devices. One of the candidates to reduce the operating voltage is using electrolyte as dielectrics in organic transistors as known as electrolyte-gated transistors (EGTs). Electrolytes can dramatically reduce operating voltage of organic electronics due to high capacitance from the electrical double layers, but liquid electrolyte requires harsh passivation layer to prevent it from escaping from the devices in the biological environment. Also, ion gel based on synthetic organic compound and polymers has not been proved as being biocompatible and biodegradable. Here, we suggest solid-state electrolytes based on natural compound such as gelatin, levan polysaccharide for organic electronics. Gelatin is a semi-solid electrolyte and a sort of natural, protein-based hydrogel with great biocompatibility and biodegradability. Moreover, thermo-responsive behavior of gelatin hydrogels can realize fabrication of organic electronics with printing method by solution process. We fabricated organic electrochemical transistors (OECT) and simple logic circuits by all printing-process with gelatin hydrogels. We also utilized choline as the biocompatible and biodegradable ionic compound to cast solid electrolyte by coupling with levan polysaccharide (Levan-based Solid-state Electrolyte, LSE). This electrolyte is flexible and highly transparent, also can be served as substrate for organic electronics. Therefore, we fabricated organic transistor on free-standing LSE films directly and we also utilized LSE based organic transistors for biomedical device due to their flexibility, biocompatibility and biodegradability, especially recording electrocardiogram by attaching on biological surface.

Biodegradable Device with Energy Harvesting Operation Abdulilah M. Mayet; King Khalid University, Saudi Arabia

Low power consumption devices and hygienic material are the heist concern in biomedical devices. Our innovative material amorphous tungsten nitride (WNx) is one of the optimal solutions for both demand characteristics. Fabricating amorphous WNx based nanoelectromechanical (NEM) switches that can be used to obtain power by reusing the stored potential energy in a bent NEM switch to power the next logic operation could solve the power consummation issue. we exhibit the power dissipated in silicon CMOS adiabatic circuit and compare it with the power dissipated in an energy reversible adiabatic NEM switch fabricated with amorphous metal. Besides, amorphous WNx can provide an effective solution to nano-scaled devices and systems, as the absence of significantly larger grains and associated boundaries during subtractive etching provides more uniform architecture. Therefore, we are reporting dissolution characteristics and biocompatibility of an amorphous WNx – which has a grain-less molecular structure. Tungsten nitride's structure contributes to corrosion resistance, high endurance, smooth surface, low contact wear, and exacerbation resistance. Here, we report its dissolution characteristics and mechanism in groundwater (GW), deionized (DI) water, and saline. Complete dissolution times were analyzed for different size features, between the nanoscale and macroscale. As an example, we have fabricated an amorphous WNx based nanoelectromechanical (NEMS) switch to demonstrate nanoscale structures. We also fabricated an accelerometer to show a microscale device and a temperature sensor to display a large surface area macroscopic dimensions. The dissolution rate for all devices is approximately 20-60 nm/hour, at room temperature, in groundwater. The successful and complete dissolution of WNx based devices highlights the versatile nature and simple chemistry of amorphous WNx film and its utility in transient electronic applications. Besides, we reported the material amorphous WNx based devices could be used in sub-dermal implants for biodegradable function. We aim to insulate transdermal wires connected to an externally mounted miniaturized wireless potentiostat for data transmission. This biodegradable function will prevent bacteria from forming biofilms along transdermal

wires, or seeding haematogenously, with the potential to migrate within the body and to provoke immune-mediated pathological tissue reactions. Another application is to use the amorphous WNx as a stent or tubular support placed temporarily inside a blood vessel, canal, or duct to aid healing or relieve an obstruction which degrades gradually by the time with no need for extraction surgery.

Protein-Based Multifunctional Bio-Nanocomposite—A Conformal Coating for Perishable Fruits Yufei Cui, Seohui Jung, Pulickel Ajayan and Muhammad Rahman; Rice University, United States

Hunger and chronic undernourishment impact over 800 million people, which equals 10.7% of the world population. While countries are increasingly making efforts to reduce poverty and hunger by pursuing sustainable energy and agricultural practices, a third of the food produced around the globe still never consumed and thus wasted. Reducing food shortages is vital in this effort and is often addressed by the development of genetically modified produce or chemical additives and inedible coatings to extend freshness, which creates additional health and environmental concerns. Hence, a novel material needed to be developed that is both protective of fresh produce, biocompatible, and biodegradable while at the same time brings economical and environmental sustainability. Herein, a multifunctional bio-nanocomposite comprised largely of egg-derived polymers and cellulose nanomaterials as a conformal coating onto fresh produce that slows down food decay by retarding ripening, dehydration, and microbial invasion is reported. Chemical composition and morphology of the composite were characterized by Infrared Spectra, TEM, and AFM. Affinity to multiple fruit surfaces and hydrophilicity of the coating was measured by the sessile droplet test. The composite forms a uniform coating of approximately 18 μm thick on fruits, as measured through confocal microscopy. The coating's effectiveness against fruit ripening was tested on representative climacteric and non-climacteric fruits: strawberries, bananas, avocados, and papayas. Through time-elapse photos, fruit stiffness measurement, and weight loss measurement of bare and coated fruits over time, the coating showed an extension of fruit freshness by more than a week. The dried coating film showed comparably low water vapor transmission rate and oxygen permeability rate among common packaging materials, and thus these distinct barrier properties likely contributed to the retarding of fruit ripening. Moreover, the coating film eliminated the bacteria on top within 24 hrs, displaying excellent antimicrobial property and thus prevent the microbial attack on fruit surfaces. Additionally, the coating is edible, washable, and made from readily available inexpensive or waste materials, making it a promising economic alternative to commercially available fruit coatings. This green coating composite also provides a potential solution to combat food wastage that is rampant in the world.

Polydopamine Interfaces for Integration of Photosynthetic Enzymes on Electrodes Gianluca M. Farinola[1], Gabriella Buscemi[1], Roberta Ragni[1], Francesco Milano[2], Danilo Vona[1] and Massimo Trotta[3]; [1]University degli Studi-Bari Aldo Moro, Italy; [2]CNR-ISPA, Italy; [3]CNR-IPCF, Italy

The reaction center (RC) photoenzymefrom *Rhodobacter sphaeroides*photosynthetic bacterium is a membranespanning proteincapable to convert solar energy intocharge separated states with efficiency close to 100%.The photogenerated electron-hole pairs can beexploited to produce photocurrents and the suitability of RC for photoconversioonin electronic and

electrochemical devices is well estabilished [1,2].
However, the electronic interface of RC with electrodes and the photoenzyme stability after integration in devices still require optimization to improve theefficiency of thephotocurrent production [3]. Enzyme stability can be improved by encapsulationin soft structures, such as vescicles [4] and polymersomes [5].Electron transfer between RC and electrode surface can occur either directly or through electrochemical mediators. In the first case a suitable immobilization strategy is required [6]. Although in the second case the RC can be dispersed in solution, higher photocurrents are produced if it is immobilized onto the electrode. To this aim,variousprotocols are reported in literature,and we have recently demonstrated thatmodification under mild temperature and pH condititons of RC with biomimetic and adhesive polymers, such as polydopamine,is a very promising method to improve the electrode/protein interface without altering the enzyme photoactivity [7].

Cephalopod-Inspired Optical Engineering of Human Cells Alon Gorodetsky, Atrouli Chatterjee, Aleeza Farrukh and Georgii Bogdanov; University of California, Irvine, United States

Although many animals have evolved intrinsic transparency for the purpose of concealment, the development of dynamic, that is, controllable and reversible, transparency for living human cells and tissues has remained elusive to date. By drawing inspiration from the structures and functionalities of adaptive cephalopod skin cells, we have designed and engineer human cells that contain reconfigurable protein-based photonic architectures and, as a result, possess tunable transparency-changing and light-scattering capabilities. Our findings may lead to the development of unique biophotonic and bioelectronic tools for applications in materials science and bioengineering, as well as ultimately facilitate an improved understanding of various biological systems.

5:35 AM F.SM04.02.04
Protein-Based Conductive Biopolymers Nadav Amdursky; Technion-Israel Institute of Technology, Israel

Biological charge transfer processes are based on the controlled transport of charges (electrons, protons, ions) across specific pathways within proteins from the nm-scale up to the μm scale. With this biological inspiration, we report here on a new family of conductive and free-standing biological materials. We are using different types of proteins as building blocks to form various types of materials, which were later functionalized in a bioinspired fashion to exhibit efficient electron transport on the centimeter length scales. With this in mind, we focus only on proteins that can be produced in bulk quantities and in low cost from raw materials, in which most of our work to date has been focused on the bovine serum albumin protein. Following the formation of the biopolymer, we show that it can be functionalized in different ways for the formation of efficient ionomers with measured ionic conduction of >10 mS/cm at room temperature or for the formation of light responsive materials. Due to the protein-based nature of our materials, it enables us to explore the governing factors and mechanisms of long-range biological charge transport. Nonetheless, our new protein-based biopolymers have several attractive properties for their possible integration in various applications. Our materials are environmentally friendly, they possess inherent biodegradability and their formation obeys to most principals of green chemistry. In terms of their mechanical properties, they have high elastic modulus of ~160 MPa, but at the same time, they are highly stretchable, capable of stretching more than 4 times their length. They have high resistance to harsh organic solvents and acids, they are very easy to form, and have a very low price tag with materials cost of around $1/cm^2. Currently, our main targeted application for our new family of materials is for biological interfaces, while other lines of applications include the use of our biopolymers for biomedical application (tissue engineering) and for energy applications such as membranes for fuel cells.
